Fig. 8 Accurate absolute value of peak of sleep apnea-triggered nocturnal blood pressure surge measured by simultaneous blood pressure monitoring using both trigger nocturnal blood pressure monitoring (TNP) and beat-by-beat tonometry-type wrist surge pressure monitoring-1 (WSP-1) system (both of which monitoring are jointly developed by Omron Healthcare Co., Ltd. and Jichi Medical University School of Medicine*). Data are obtained from 53 year-old men with obstructive sleep apnea. *This research is partially supported by the Research and development of supportive device technology for medicine using ICT from Japan Agency for Medical Research and development, AMED.

sleep-onset cardiovascular events in OSAS patients. Using this TNP device, we could specifically identify the SAS patients at high-risk for sleep-onset cardiovascular events.

Finally, we have recently developed an IT-based nocturnal BP monitoring system (ITNP) with oxygen and heat-rate triggers and a 3G Web cloud computing system (Omron Healthcare Co., Ltd., Kyoto, Japan) (Kario, 2015a, 2016). The ITNP system is a cloud computing-based composite management and analysis system for the data sent from the BP device in the patient's home. This system can detect repeated and day-to-day variability in nocturnal and morning BP, and the nighttime BP surges associated with sleep apnea episodes, the degree of which can be affected by daily environmental changes. A single day PSG in the hospital under an alcohol-prohibited condition may underestimate the severity of OSAS and miss subjects with moderate OSAS. However, repeated assessment of OSAS using ITNP in a real-life setting would increase the sensitivity of the diagnosis of OSAS and related nighttime BP surge. ITNP could be used to evaluate the efficacy of continuous positive airway pressure (CPAP). ITNP is thus expected to contribute to the detection of high-risk OSAS with nocturnal hypertension and/or nighttime BP surge, and to the assessment of the quality of BP control during CPAP and/or antihypertensive treatment in OSAS patients. Simultaneous blood pressure monitoring using trigger nocturnal blood pressure monitoring (TNP) and beat-by-beat tonometry-type wrist surge pressure monitoring-1 (WSP-1) system accurately measured the highest absolute value of the peak blood pressure triggered by sleep apnea episode (Fig. 8).

Sleep Hygiene and Medication

Strict BP control over a 24-h period, including nighttime BP and hypoxia-induced peak, would effectively suppress the development of organ damage and cardiovascular events (Kario, 2015a, 2016). CPAP treatment with good adherence is effective for reducing BP, almost eliminating nighttime BP surge in patients with OSAS (Huang et al., 2015). However, in many patients with OSAS, adherence to the CPAP regimen is relatively poor over the long term. For OSAS patients with poor adherence to CPAP treatment, or those who decline to use CPAP, bedtime dosing of sympatholytic agents (Kario et al., 2014b), renal denervation (Kario et al., 2015b, 2016b,c), or vasodilators is effective to reduce nocturnal BP and hypoxia-induced nocturnal BP surge. In non-SAS patients with insomnia, hypnotics such as the GABAergic-agonist zolpidem, the melatonin MT1/MT2 receptor-selective-agonist ramelteon (Viera et al., 2012), or the orexin receptor-antagonist suvorexant have potential to reduce nocturnal BP, especially in those with drug-resistant nocturnal hypertension. However, randomized placebo-controlled clinical trials will be needed to confirm the efficacy of these and other hypnotics.

In clinical practice, the assessment of sleep disturbances, such as sleep deprivation, insomnia, and sleep apnea, and the promotion of sleep hygiene to maintain a sleep duration of >6 h and good sleep quality are essential components in the reduction of BP and cardiovascular risk.

Introduction

Every day over 2200 Americans die of cardiovascular disease (Mozaffarian et al., 2016). It has been estimated that up to 287,000 annual deaths may be attributable to heart failure (HF) (Mozaffarian et al., 2016). Sleep-disordered breathing (SDB), a term that denotes all respiratory disorders of sleep, is broadly categorized into obstructive sleep apnea (OSA) and central sleep apnea (CSA). SDB is independently associated with increased mortality and morbidity in HF patients (Khayat et al., 2012, 2015). The prevalence of SDB is estimated to exceed 60% in patients with systolic HF (heart failure with reduced left ventricular ejection fraction) (Khayat et al., 2009; Oldenburg et al., 2007). The association between SDB and increased mortality and readmission in HF patients supports the need for surveillance and expedited treatment of SDB cases in patients with known HF.

Definitions

SDB is defined by the presence of five or more abnormal respiratory events per 1 h of sleep. These respiratory events are generally divided into apneas and hypopneas (Berry et al., 2017). Apneas indicate absence of airflow defined as a period >10 s with >90% drop in oronasal thermal sensor flow (Berry et al., 2017). The oronasal sensor is placed over the mouth during a polysomnogram (PSG) or sleep study. Apneas are further differentiated into obstructive and central apneas (CA). Obstructive apneas (OA) are associated with persistent effort to breathe as measured by chest and abdomen effort belts that are ineffective in overcoming the upper airway collapse. In CA, there are absent inspiratory efforts caused by a temporary failure of the pontomedullary pacemaker (Javaheri and Dempsey, 2013). In hypopneas, there is a drop of >30% of the nasal pressure signal for that lasts longer than 10 s and there is a $\geq$4% desaturation from baseline (Berry et al., 2017).

Pathophysiology—Cause and Effect

There are multiple mechanisms of abnormal physiology in SDB that are deleterious to the HF patient including intermittent hypoxia, sympathetic overdrive, and endothelial dysfunction accompanied by oxidative stress. HF patients have instability in their respiratory control centers that can cause both obstructive and CSA (Dempsey, 2005). During both central and OA, there are periods of hypoxemia and hypercapnia that cause sympathetic activation. Particularly at the end of these apneic events, there are arousals where there are surges in the systolic and diastolic blood pressure of approximately systolic 20 mmHg and diastolic 15 mmHg (Morgan et al., 1985) accompanied by a rebound in oxygenation as patients frequently desaturate during these events. Not only are these sympathetic activations greater at night when the apneas are occurring, but also the elevated sympathetic tone persists into the waking hours (Somers et al., 1995). Stimuli from these hypoxemic and hypercapnic events change the sensitization of peripheral and central chemoreceptors triggering changes in how the body responds with sympathetic tone and ventilation (Smith and Muenter, 2000; Peng et al., 2003). Aside from considerations of oxygenation, OSA is correlated with oxidant-mediated vascular endothelial dysfunction (Varadharaj et al., 2015). This endothelial dysfunction has been linked to atherosclerosis and also felt to play a role in stroke (Varadharaj et al., 2015).

Although CSA and OSA present differently, they are both associated with a similar pattern of recurrent respiratory events and intermittent hypoxia during the night. Sympathetic activation and blood pressure surges occur similarly in these two types of SDB (Morgan et al., 1993).

Presentation and Risk Factors of Sleep-Disordered Breathing

Patient with SDB may or may not be symptomatic upon presentation. However, symptoms may include excessive daytime sleepiness due to poor sleep quality from respiratory events interrupting sleep. Patients may also present with insomnia as the patient has frequent awakenings from respiratory events and is unable to go to sleep. Querying the bedpartner is relevant as the patient may have been witnessed to have apneas which support the presence of SDB. Snoring is an important symptom that is often reported by bedpartners. known risk factors for OSA include obesity, neck circumference >17 in. (43 cm) in men or >15 in. (38 cm) in women, narrowed airway, male gender, age, family history, alcohol use, tobacco use, and nasal congestion. Further, there are risk stratification tools that can help predict the patient's risk of OSA, such as the Flemmons score. This simple tool uses three risk factors: neck circumference in centimeter, presence of hypertension (four points), and witnessed apneas/gasping most nights (three points) (Flemons, 2002). If the cumulative score is >48, then the patient is high probability for sleep apnea, or 20 times as likely as a low risk patient (<43 cm) to have sleep apnea (Flemons, 2002). CSA, on the other hand, does not have defining symptoms but patients are typically older, have worse cardiac function, and tend to be predominantly males (Oldenburg et al., 2007).

Diagnostic Testing

The diagnosis of SDB is best performed by an attended or in-lab PSG. In the sleep laboratory, electroencephalogram, limb movements, electrocardiogram, and several respiratory parameters are simultaneously recorded during sleep for one night. The main advantage is being able to tell when the patient is definitively asleep and have a technologist available in the lab monitoring data acquisition to be able to fix any issues that arise overnight as well as treat the patient with positive airway pressure if their respiratory events are significant. However, the field is continually moving to more inexpensive and convenient portable home sleep studies, often referred to as unattended studies. Depending on the manufacturer, these can collect any number of variables but often have a chest best, and abdominal belt, as well as a nasal pressure sensor and a continuous pulse oximeter. The unattended sleep study is best reserved for those patients that are considered by risk factors to be high risk for OSA. As well, since the test does not have good negative predictive value, it is recommended that those at high risk for OSA and a negative unattended study have an attended PSG if their home study is negative.

Treatment of SDB Including OSA

Treatment of SDB improves a range of parameters related to HF including a reduction in sympathetic outflow, improvement in blood pressure control, decrease in morbidity from CAD, and is also associated with the nocturnal timing of sudden cardiac death. Regarding hypertension, in a trial of 194 patients receiving continuous positive airway pressure (CPAP) or no CPAP with a mean AHI of 40 on a mean of 3.8 antihypertensive drugs/patient, CPAP treatment for 12 weeks achieved a greater decrease in 24-h mean blood pressure (3.1 mmHg [95% CI, 0.6–5.6]; $P=0.02$) and 24-h diastolic blood pressure (3.2 mmHg [95% CI, 1.0–5.4]; $P=0.005$). However, 24-h systolic blood pressure was not significantly changed (3.1 mmHg [95% CI, −0.6 to 6.7]; $P=0.10$) compared with the control group (Martinez-Garcia et al., 2013). From an arrhythmia perspective, the prevalence of atrial fibrillation is three times higher in patients with OSA than in normal controls (Guilleminault et al., 1983). In a meta-analysis, treatment with CPAP resulted in 42% decreased risk of atrial fibrillation (Qureshi et al., 2015). There is also a beneficial effect on the treatment of SDB on CAD. The treatment of SDB has also been shown to reduce to improve the morbidity of patients with coronary artery disease. The incidence of CAD is higher in patients with OSA, and in one study this was a fivefold increase in risk even when controlling for other variables (Peker et al., 2006). Men in the Sleep Heart Health Study from 40 to 70 years of age with an AHI of ≥30 were 68% more likely to develop CAD than those without OSA (Gottlieb et al., 2010). Further, in patients with OSA treated with CPAP, their risk of developing CAD was reduced (Peker et al., 2006). (Ongoing studies for this NCT01335087, NCT00519597.) There is also a relationship between SDB and sudden cardiac death. In a retrospective review of patients with prior PSG that had suffered sudden cardiac death, it was observed that patients with OSA have peak deaths during the early morning hours between midnight and 6 a.m., whereas otherwise these sudden cardiac deaths occur around 6 a.m. in patients without OSA (Gami et al., 2005).

Treatment of OSA and CSA Including Controversies in Treatment of CSA

The treatments of OSA differ based on the severity of the OSA. For mild OSA, behavioral modifications like weight loss and positional therapy may be effective. In positional therapy, patients are kept out of the supine position in which most of their respiratory events occur. CPAP maintains the patency of the airway during sleep eliminating most of the apneas and hypopneas of OSA. CPAP is the treatment of choice for patients with more moderate to severe OSA (those who have more than 15 events per hour of sleep). Also, patients with milder cases (<15 events per hour) but who have sleepiness can benefit from CPAP. Sleepiness is often

quantified using questionnaires like the Epworth Sleepiness Scale. Also, for symptomatic patients with less severe cases (<15 events per hour), non-CPAP therapies like mandibular advancement using oral appliances can be considered (Epstein et al., 2009).

The treatment of CSA is slightly different from that of OSA. First, the prevalence of CSA is less than that of OSA in the general population. However, in a HF population, there is up to 40% prevalence of CSA (Oldenburg et al., 2007). Cheyne–Stokes breathing is a crescendo–decrescendo breathing style which is seen in patients with HF during sleep. There are CA between these periods of crescendo–decrescendo breathing. It can also be seen while the patient is awake and during periods of exercise (Poletti et al., 2009). Cheyne–Stokes breathing has been associated with higher levels of serum cathecholamines as well as correlates with worse NHYA functional status, and NT-proBNP levels (Poletti et al., 2009). The treatment of choice for OSA in HF patients is CPAP. However, in patients with CSA, CPAP partially treats the abnormality (Javaheri, 2000). It has previously been shown that by adding ASV (adaptive servo ventilation) to patients with HF and CSA incompletely treated with CPAP that both the AHI was improved as well as there were lower amounts of urinary cathecholamines (Kasai et al., 2013). Further, the group that received ASV had an improvement in ejection fraction compared to patients treated with CPAP alone (Kasai et al., 2013). Treatment of CSA in HF is based on CANPAP—The Canadian Continuous Positive Airway Pressure Trial for Congestive Heart Failure (Bradley et al., 2005). CANPAP showed that although CPAP decreased the severity of CSA, increased ejection fraction, improved nocturnal oxygenation, and increased 6 min walk distance, it did not affect the survival of patients enrolled (Bradley et al., 2005). ASV then came in vogue as being the treatment of choice for those with CSA and Cheyne–stokes respirations based on a small study of 25 patients with stable congestive HF that were treated with CPAP or ASV (Philippe et al., 2006). ASV was observed in this study to more fully eradicate SDB events and was the only intervention able to get the AHI to $<10\ h^{-1}$. ASV also showed a significant increase in LVEF and an improvement in quality of life (Philippe et al., 2006).

Recently, a study evaluated 2717 patients with moderate to severe OSA with known coronary or cerebrovascular disease to receive both standard care or CPAP treatment and standard care. Treatment with CPAP for a mean follow-up of 3.7 years did not prevent cardiovascular or cerebrovascular events compared with standard therapy (McEvoy et al., 2016). Recently, the results of this study were overturned by the much larger SERVE-HF study which evaluated 1325 patients with systolic HF and mild and moderate sleep apnea. This trial showed that the use of ASV in HF not only did not improve LVEF, also was associated with increased cardiovascular and all-cause mortality (Cowie et al., 2015).

SDB and Cardiac Surgery

Sleep apnea evaluation prior to cardiac surgery has also been recognized as being increasingly important as recent studies that those with OSA are independently associated with longer postoperative recovery, higher use of postoperative pacemaker use, and higher rate of respiratory insufficiency based on recent data (Ding et al., 2016). The dataset used for this most recent investigation consisted of 290 patients in a single Chinese center, which overturned the suggestion in smaller prior studies that there were not adverse outcomes in those receiving cardiac surgery with SDB, showed a prevalence of OSA in 16.2% of patients and CSA in 22.7% of patients (Ding et al., 2013). Interestingly, those with predominantly CSA had a higher first dose of dobutamine and a higher rate of pacemaker use postoperatively. It remains unclear if intervening by treating the SDB can improve the outcomes in this population.

Summary

SDB is highly prevalent comorbidity in patients with cardiovascular disease. In particular, HF patients have the highest prevalence of SDB. Identification and treatment of SDB cases in these patients can be associated with improved outcome. Treatment of SDB using CPAP is highly effective and well tolerated. Treatment of SDB is associated with significant functional improvement, including resolution of sleepiness and improved alertness.

Introduction

There are numerous studies that have examined the relationship between socioeconomic status (SES) and cardiovascular mortality. Strong associations between low SES and poor health have been observed in many studies (Kaplan and Keil, 1993; Albert et al., 2006; Havranek et al., 2015; Danaei et al., 2010; Lynch et al., 1996). The term "socioeconomic status" includes various measures such as education, income, occupation, and living conditions. The Whitehall study clarified that the lower the job status, the higher the prevalence of coronary heart disease (Marmot et al., 1978). Furthermore, the difference in ischemic heart disease (IHD) prevalence was threefold between the lowest and highest levels of SESs (Gonzalez et al., 1998). Other studies also clarified the inverse relationship between SES and IHD, especially among men in the Western world (Andersen et al., 2003). The main reasons for this phenomenon are differences in lifestyles and exposure to hazardous environments among the social classes (Kaplan and Keil, 1993). Previous studies have shown that health-related behaviors are strongly shaped by social factors such as income, education, and employment (Boniface et al., 2001; Wardle et al., 2002; Laaksonen et al., 2005; Hanson and Chen, 2007). Jemal et al. studied the 2001 US death data and concluded that "potentially avoidable factors associated with lower educational status account for almost half of all deaths among working-age adults in the U.S." (Jemal et al., 2001).

Causal pathways that link SES to cardiovascular diseases (CVS) have been studied extensively (**Fig. 1**). The high prevalence of CVD associated with low SES can be explained by conventional risk factors such as high blood pressure, diabetes, or poor cholesterol profiles through unhealthy lifestyles (e.g., smoking, low physical inactivity, excessive alcohol, etc.). Furthermore, socioeconomic disadvantages may adversely affect cardiovascular risk through its impact on mental health. A vast body of literature has documented associations between emotional states and CVD risk. In particular, depression and elevated depressive symptoms are associated with an increased risk of morbidity, adverse cardiovascular outcomes, and mortality among patients with CVD, even after controlling the other risk factors (Lynch et al., 1996; Owen et al., 2003; Petersen et al., 2008; Jousilahti et al., 2003).

Recently, in addition to the behavioral and psychological pathways, particular attention has been given to the pathophysiological conditions that link stress from the SES to the cardiovascular system. Psychological stress elicits measurable changes in the sympathetic-parasympathetic balance and the tone of the hypothalamic-pituitary-adrenal axis and may negatively affect the cardiovascular system both acutely (by precipitating myocardial infarction, left-ventricular dysfunction, or severe arrhythmia) and chronically (by accelerating the atherosclerotic process) (Brotman et al., 2007). In addition to these processes, inflammation also plays a crucial role in the pathogenesis of atherosclerotic heart disease. We will review two commonly proposed pathways of SES's effect on CVD development: the pathway through lifestyle-related diseases (which includes behavioral and environmental issues) and the pathway via pathophysiological factors (a fairly direct pathway to CVD development from SES as the stressor).

SES and CVD via Lifestyle-Related Diseases (Conventional Risk Factors)

Socioeconomically disadvantaged populations suffer from a variety of Framingham risk factors (Daviglus et al., 2012; Safford et al., 2012; Yusuf et al., 2004). Individuals with a low SES are more likely to be exposed to hazardous environments and tend to engage in unhealthy personal behaviors. Smoking, poor diet, inactivity, obesity, and poor adherence to medication tend to be more prevalent among individuals of low SES, which is observed in many studies such as in the Whitehall study where obesity was more prevalent among individuals with low-status jobs (Havranek et al., 2015; Marmot et al., 1978; Mullie et al., 2010; Giskes et al., 2010; Gilman et al., 2003). In addition, low neighborhood SES was related to a higher incidence of myocardial infarction and heart disease mortality (Chaix et al., 2007). This data implies that socially disadvantaged individuals face environmental stressors, such as poor working conditions or neighborhoods, which, coupled with the lack of knowledge and limited resources, drive these individuals to low-cost, high-calorie fast-food options, resulting in obesity, metabolic syndromes, and hypertension, which are CVD risk factors (Roux, 2001; Chow et al., 2009). Furthermore, smoking was the risk factor that varied the most among the job categories for increased morbidity and mortality, and the prevalence of smoking was also high among the disadvantaged groups compared to the high income and education groups (Laaksonen et al., 2005; Hiscock et al., 2012). However, effective interventions for the lower socioeconomic groups are sparse, while discrepancies in smoking and diabetes worsened in these 30 years in the United States

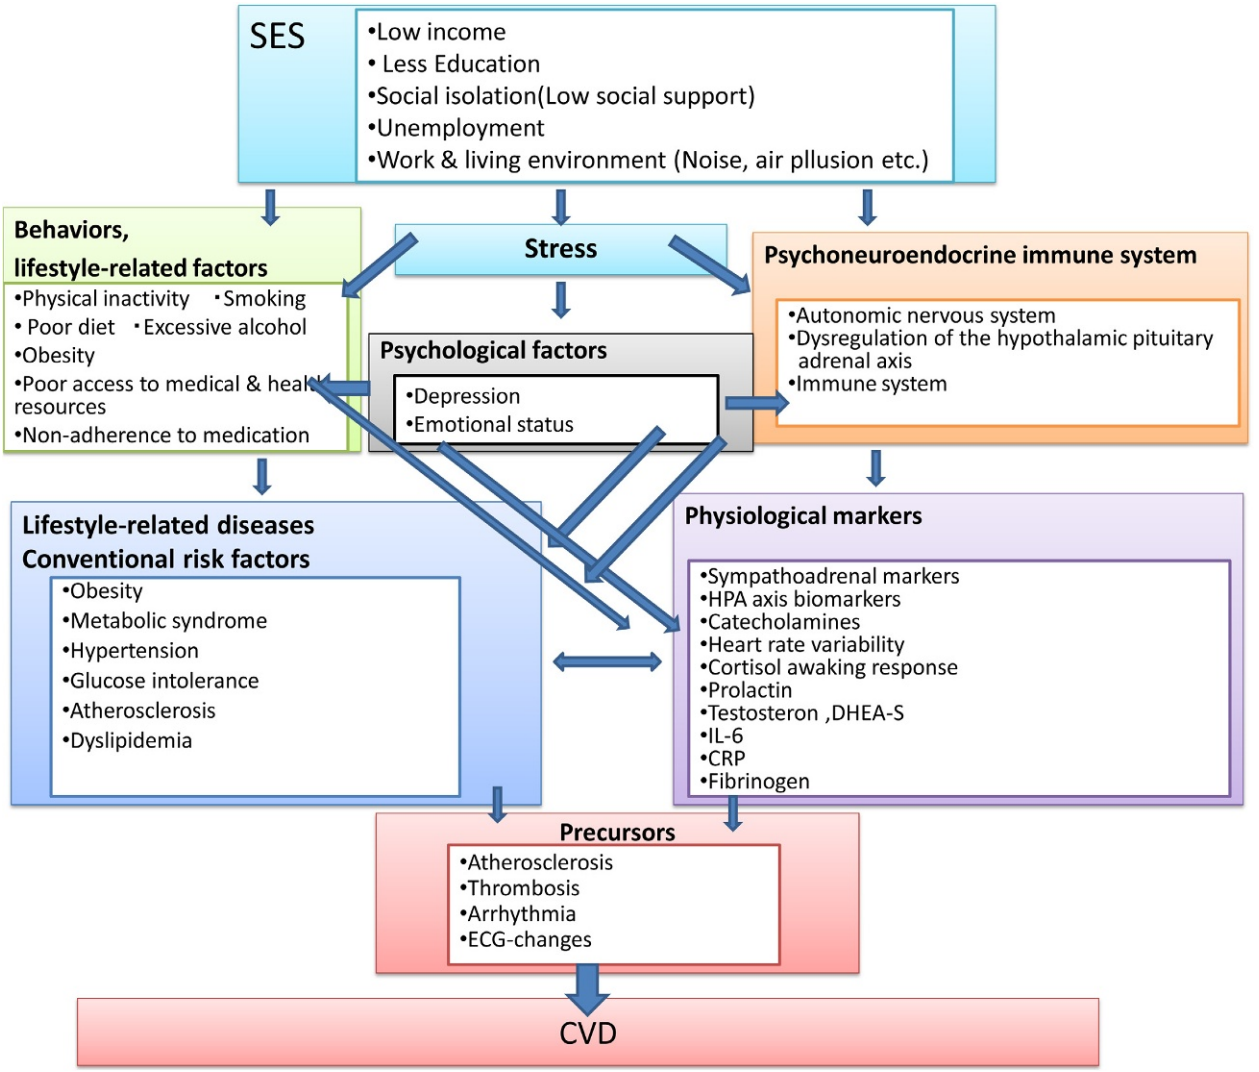

Fig. 1 Pathways to CVD from SES.

(Hiscock et al., 2012; Kanjilal et al., 2006). For individuals with a low SES, the incidence of smoking is twice as high, and the attempts to quit are less likely to be successful. Studies have suggested that this may be the result of reduced social support for quitting, low motivation to quit, stronger addiction to tobacco, increased likelihood of not completing courses in pharmacotherapy or behavioral support sessions, psychological differences, such as lack of self-efficacy, and marketing influences from the tobacco industry (Hiscock et al., 2012).

SES and CVD via the Pathophysiological Pathway From Stress

Based on previous studies, differences in smoking status, obesity, physical activity, blood pressure, and plasma cholesterol level can only partly explain differences in mortality rates due to CVD and imply that there are other aspects beyond the established CVD risk factors (Braveman and Gottlieb, 2014). SES influences psychological and physical experiences and is linked to the function of the limbic system and stress response. A substantial amount of literature has documented the relationship between adverse social position, life stress, low rank in social hierarchies, racism, and disadvantaged living and working conditions and the function of the limbic system and stress response. Exposure to these stressors may directly cause the disease (Brotman et al., 2007; Maria Glymour et al., 2014). Several studies have investigated the relationship among biomarkers, SES, and CVD. For example, the study in Finland clarified the relationship among SES, CRP, serum amyloid A, and fibrinogen levels, where mean levels of these inflammatory markers decreased significantly with increasing SES (Jousilahti et al., 2003). It was also evaluated in the Whitehall II cohort participants, which found high CRP levels were associated with low SES (Owen et al., 2003). Petersen et al. (2008) found that the midlife adults living in less advantaged neighborhoods exhibit higher levels of circulating proinflammatory markers, both IL-6

and CRP, than residents of more affluent areas. The sympathetic nervous system and hypothalamic-pituitary-adrenal (HPA) axis activation are associated with platelet activation, endothelial dysfunction, hypertension, suppression of the immune system, inflammation, and changes in cardiac cellular electrophysiology. Repeated exposure to stressors associated with socioeconomically disadvantageous factors has been hypothesized to eventually overwhelm the body's ability to recover from threatening episodes and lead to the accumulation of an "allostatic load" that increases CVD risk. An allostatic load is a multicomponent construct that reflects the physiological changes across different biological regulatory systems in response to chronic social and environmental stress (Seeman et al., 2010; McEwen and Seeman, 1999; McEwen, 2004). Examples include the induction of proinflammatory responses, such as the production of IL-6 and CRP, due to stress, and the effects of lower income and educational achievements that lead to the direct or the eventual contribution (i.e., through hypertension and poor cholesterol profiles) to CVD.

Perspectives and Recommendations for Preventing CVD by SES

Despite considerable evidence indicating the significant effects of socioeconomic factors on the development of CVD, not every individual exposed to low SES develops the disease. Protective social factors, such as social support, self-esteem, and self-efficacy, may mitigate the deleterious effects of adverse social conditions (Matthews et al., 2010). Income may have less of a health impact when there is less social stigma associated with having limited economic means. Health behaviors may also mediate the link between adverse social environments and cardiovascular risk. Social capital factors, such as social support and cohesion, are associated with health behaviors and CVD risk (e.g., obesity and hypertension) and vary across the socioeconomic spectrum (Havranek et al., 2015; Sundquist et al., 2006; Gallo et al., 2009). In recent years, income disparities are increasing in Japan as well, and there have been concerns regarding the widening health inequalities due to socioeconomic conditions (Kagamimori et al., 2009). Moreover, there is evidence that regardless of the individual's income, living in an area with considerable income disparities raises health risks. To improve these disparities, the Ministry of Health, Labour and Welfare in Japan is promoting "The second term of the National Health Promotion Movement in the twenty-first century (Health Japan 21 (the second term))" from the 2013 to the 2022 fiscal year (Japan, 2011). The goals in implementing the National Health Promotion are to "extend the healthy life expectancy and to reduce health disparities." Furthermore, the development of social capitals in the community has been recommended to reduce health inequalities and extend the healthy life expectancy (Japan, 2011; Kabayama et al., 2014).

Approaches to narrow these disparities should be promoted and implemented in the regional health plans of local governments as well as in the occupational safety, education, and health activities of all ages. Medical and health professionals are expected to cooperate in and support these initiatives from their professional standpoints. Future studies are required to further investigate the associations among neighborhood characteristics, health behaviors, and CVD risk to establish a population-based prevention strategy for the lower SES groups.

Conclusion

We systematically reviewed the literature that highlighted the importance of socioeconomic factors on the development of CVD as well as plausible pathways and mechanisms that may explain their effects. Numerous studies have shown the crucial relationship between socioeconomic factors and CVD. Furthermore, due to the involvement of multiple mechanisms, some may only manifest decades after exposure (Braveman and Gottlieb, 2014). Studies have also indicated that medical care is not enough to prevent CVD, suggesting the importance of individual's SES improvement and narrowing the health disparities. These results highlight the need for strategic approaches to prevent CVD, which focus on the equity of social and physical environments, including psychosocial and physical stress, and social isolation, with population- wide and high-risk interventions (Bell et al., 2012; Clark et al., 2009).

Since social conditions are difficult to change and may take months, years, or decades to modify substantially, public health practitioners can be key resources for local and national policy makers to resolve the crucial issue of health equity (Braveman and Gottlieb, 2014). Through clinical and public health interventions, we need to advance these understandings and overcome challenges to prevent CVD.

Introduction

Heart failure (HF) is an important and growing public health problem with a prevalence in the United States that is expected to increase from 6.5 million adults currently to 8 million by 2030 (Benjamin et al., 2017). Indeed, HF affects the health of many individuals; approximately one in five persons will develop HF during their lifetime (Lloyd-Jones et al., 2002), and HF is listed as a cause of death on one in eight death certificates (Benjamin et al., 2017). The cost to the US health-care system is similarly staggering with an estimated annual cost of ~30 billion dollars (Benjamin et al., 2017). Recognizing the substantial population, individual, and financial burden of HF, recent US (Yancy et al., 2013; Schocken et al., 2008) and international (Ponikowski et al., 2016) HF guidelines have emphasized the importance of disease prevention.

HF is a progressive condition in which risk factors lead to adverse cardiac structural and functional remodeling and eventually to overt congestive HF (Fig. 1). This sequence of events is represented by the American College of Cardiology (ACC)/American Heart Association (AHA) HF stages (Hunt et al., 2001), which were designed to emphasize the progressive nature of HF development. Stage A represents individuals who are at "high risk" for HF but do not have structural heart disease or symptoms of HF, stage B characterizes individuals with structural heart disease but without signs or symptoms of HF, stage C denotes individuals with structural heart disease and current or prior HF symptoms, and stage D is refractory HF (Hunt et al., 2001). This schematic of HF progression highlights the importance of disease prevention as two of the four ACC/AHA HF stages consist of individuals free of symptomatic HF. Hence, the ACC/AHA HF stages highlight that prevention of HF must occur both when risk factors are identified (stage A) and after these risk factors have led to adverse cardiac changes (stage B) in order to prevent overt congestive HF (stage C).

In the following article, we will review the risk factors that comprise stage A HF, summarize the evidence linking these risk factors with incident HF, and evaluate the available data supporting the treatment of these risk factors to prevent new-onset HF.

Prevalence of Stage A HF

Stage A HF is defined by the presence of HF risk factors, several of which are extremely common in the general population. Estimates of the prevalence of stage A HF vary according to the population studied but range from ~33% in a sample from National Health

 https://doi.org/10.1016/B978-0-12-809657-4.64288-6

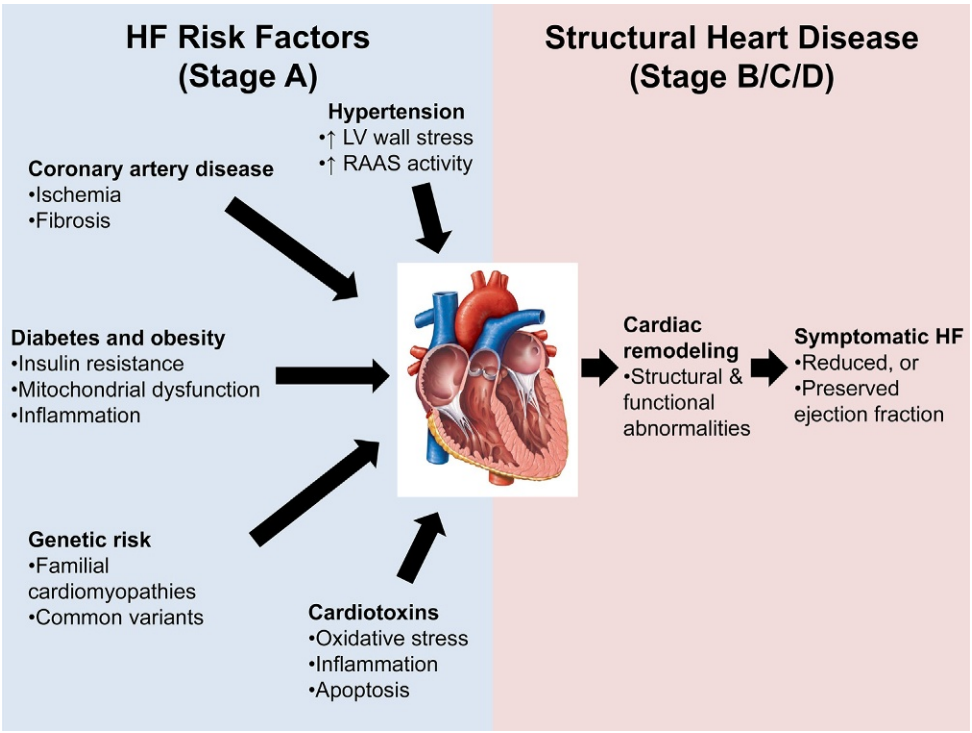

Fig. 1 Schematic representation of heart failure progression.

and Nutritional Examination Survey (NHANES) with a mean age of 47 years (Kovell et al., 2015) to 52% in a sample of older adults ranging in age from 67 to 91 years from the Atherosclerosis Risk in Communities Study (Shah et al., 2017).

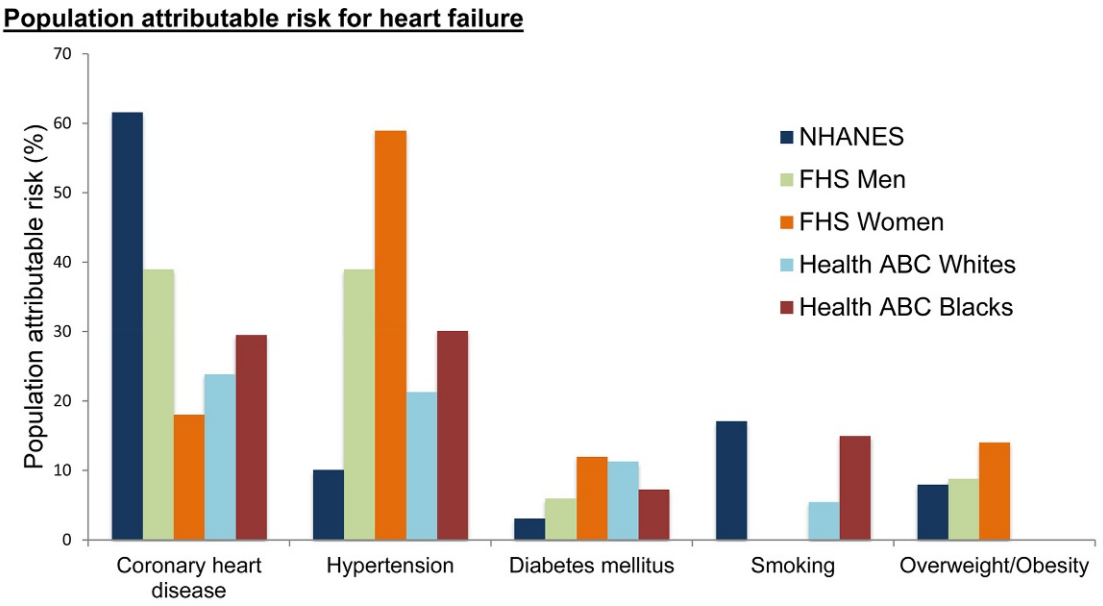
The population attributable risk for HF risk factors has been evaluated in several community-based samples (Dunlay et al., 2009; He et al., 2001; Levy et al., 1996; Kalogeropoulos et al., 2009). While the specific attributable risk estimates vary by sex, race, and cohort characteristics, coronary heart disease (CHD), hypertension, obesity, diabetes, and smoking are consistently demonstrated to be responsible for a majority of incident HF cases (Fig. 2).

Hypertension

Hypertension is a key modifiable risk factor for developing HF. In the Framingham Heart Study (FHS), 91% of individuals with HF had antecedent hypertension (Levy et al., 1996). Indeed, the lifetime risk of HF is largely driven by the burden of hypertension; across age groups, the risk of HF is approximately twofold for individuals with systolic blood pressure $\geq$160 mmHg or diastolic blood pressure $\geq$100 mmHg versus those with blood pressures of $<$140/$<$90 mmHg (Lloyd-Jones et al., 2002). The robust association of hypertension with new-onset HF is consistent across racial and ethnic groups (He et al., 2001; Huffman et al., 2013). In fact, the impact of hypertension may be especially pronounced in African Americans (Bahrami et al., 2008) in whom hypertension is more prevalent, and achievement of treatment targets is less common (Bibbins-Domingo et al., 2009). Hypertension is responsible for a higher population attributable risk in women versus men (Fig. 2; Levy et al., 1996). Investigations of lifetime hypertension exposures suggest that the chronicity (Lee et al., 2007) and severity (Levy et al., 1996) of hypertension are important considerations in estimating future HF risk.

The results from a number of clinical trials have proved that medical therapy for hypertension reduces the risk of developing HF. In a meta-analysis of several trials, treatment of hypertension was observed to reduce the relative risk of HF (40%–46%) more than other cardiovascular outcomes (Psaty et al., 2003). In the recent systolic blood pressure intervention trial (SPRINT), individuals at high risk for cardiovascular disease experienced a 38% relative risk reduction for incident HF with intensive (target systolic blood pressure $<$120 mmHg) versus standard (target systolic blood pressure $<$140 mmHg) antihypertensive treatment (The SPRINT Research Group, 2015). Again, the relative risk reduction for HF was higher than that observed for other cardiovascular outcomes including myocardial infarction and stroke.

The choice of medication to achieve blood pressure lowering does appear to impact the effectiveness of drug treatment. In the antihypertensive and lipid-lowering treatment to prevent heart attack trial (ALLHAT), blood pressure lowering with doxazosin was associated with an increased risk of HF, while amlodipine, lisinopril, and chlorthalidone were associated with similar reductions in risk (ALLHAT Collaborative Research Group, 2000). One potential explanation for the pronounced effect of antihypertensive treatment on HF risk is that diuretics were used as antihypertensives in many of these studies (including SPRINT) (Psaty et al., 2003;



Multivariable-adjusted relative risk of heart failure

Risk Factor	NHANES	FHS Men	FHS Women	Health ABC Whites	Health ABC Blacks
Coronary heart disease	8.11 (6.95-9.46)			2.72 (1.89-3.90)	3.31 (2.26-4.85)
Myocardial infarction		6.34 (4.61-8.72)	6.01 (4.37-8.28)		
Hypertension	1.40 (1.24-1.59)	2.07 (1.34-3.20)	3.35 (1.67-6.73)	1.80 (1.27-2.55)	1.95 (1.33-2.84)
Diabetes mellitus	1.85 (1.51-2.28)	1.82 (1.28-2.58)	3.73 (2.71-5.15)	2.08 (1.35-3.22)	1.37 (0.88-2.14)
Smoking	1.59 (1.39-1.83)			2.04 (1.15-3.64)	2.08 (1.37-3.16)
Overweight	1.30 (1.12-1.52)	1.68 (1.25-2.27)	1.17 (0.86-1.61)		

Fig. 2 Population attributable and relative risks of select heart failure risk factors. (Adapted from Shenoy, M., Chapman, C., Nawaz, Z. and Sweitzer, K. (2006). Diagnosis and management of stage A heart failure. *Congestive Heart Failure* **12** (3), 146–152.) Population attributable risks for heart failure are displayed for individuals from National Health and Nutrition Examination Survey (NHANES; data collection 1982–92), Framingham Heart Study (FHS; data collection 1970–91); Health, Aging, and Body Composition Study (Health ABC Study; data collection from 1997 to approximately 2005). Information included from the following sources: He, J., Ogden, L. G., Bazzano, L. A., et al. (2001). Risk factors for congestive heart failure in US men and women: NHANES I epidemiologic follow-up study. *Archives of Internal Medicine*, **161** (7), 996–1002; Levy, D., Larson, M. G., Vasan, R. S., et al. (1996). The progression from hypertension to congestive heart failure. *JAMA* **275** (20), 1557–1562; Kalogeropoulos, A., Georgiopoulou, V., Kritchevsky, S. B., et al. (2009). Epidemiology of incident heart failure in a contemporary elderly cohort: the health, aging, and body composition study. *Archives of Internal Medicine* **169** (7), 708–715.

The SPRINT Research Group, 2015). Instead of preventing the development of HF, diuretics may simply delay the diagnosis of HF by preventing fluid retention. Diuretics may thus serve to delay phenotype detection without altering the disease course (Kjeldsen et al., 2016). Nevertheless, there is robust evidence to support the treatment of hypertension to prevent the development of symptomatic HF, while the optimal medications and blood pressure targets continue to be debated.

Atherosclerotic Vascular Disease

Atherosclerotic vascular disease contributes to a significant proportion of HF cases and is responsible for the largest population attributable risk among the different risk factors in several studies (Fig. 2). In NHANES, CHD accounted for 61.6% of HF cases (He et al., 2001). The population attributable risk estimates are somewhat lower in other cohorts, such as the FHS, where CHD accounted for 39% of HF cases in men and 18% in women (Lloyd-Jones et al., 2002). The observation that CHD accounts for a higher proportion of HF cases among men versus women is consistent across cohorts (He et al., 2001; Levy et al., 1996; Dunlay et al., 2009). Furthermore, the risk of HF in individuals with CHD is quite high with ~36% of individuals in Rochester Minnesota with CHD from 1979 to 1994 eventually developing HF (Hellermann et al., 2003). While the incidence of future HF in individuals with CHD is likely to be lower in more contemporary populations with higher rates of early revascularization, CHD and myocardial infarction continue to be among the dominant causes of new-onset HF in cohorts with more recent exposures (Kalogeropoulos et al., 2009). CHD causes myocardial damage and cell death, which leads to scar formation, ventricular remodeling, and eventually overt HF. However, atherosclerotic vascular diseases that do not directly affect the heart, such as peripheral arterial disease, have also

been associated with future HF risk (Gupta et al., 2014). While the mechanisms for this association are less direct, vascular dysfunctions, such as increased vascular stiffness and altered ventricular–arterial coupling, are likely to partially explain these relations.

Evidence from clinical trials suggests that treatment of individuals with CHD can prevent the future development of HF. In the Scandinavian Simvastatin Survival Study (4S), individuals with established CHD were randomized to treatment with simvastatin versus placebo. Over a mean follow-up of 5 years, a 21% reduction in incident HF was observed for individuals randomized to simvastatin treatment (Kjekshus et al., 1997). Similarly, in the treating to new targets trial, there was lower incidence of HF hospitalization with high-dose versus low-dose atorvastatin (LaRosa et al., 2005). Significant reductions in HF hospitalizations were also observed with the combination of clopidogrel and aspirin versus aspirin alone after non-ST elevation myocardial infarction in the clopidogrel in unstable angina to prevent recurrent events trial (Yusuf et al., 2001). Hence, secondary prevention of CHD with lipid-lowering therapy or intensification of antiplatelet therapy results in reduced incident HF events. In the setting of an acute myocardial infarction, early revascularization, which has become the standard of care over the last decades, results in less myocardial injury and a lower risk of developing HF (Lystash et al., 1995). Further improvements in primary and secondary prevention of atherosclerotic vascular disease would therefore also be expected to reduce the burden of HF.

Diabetes Mellitus

Diabetes mellitus (Kannel et al., 1974; He et al., 2001; Chen et al., 1999) and insulin resistance (Ingelsson et al., 2005) have long been known to increase the risk of HF. The presence of diabetes is estimated to increase the risk of developing new-onset HF fourfold (Nichols et al., 2004). A linear association between glycemic control and HF risk has been described (Iribarren et al., 2001), and the association of diabetes and incident HF persists after accounting for CHD (Kannel et al., 1974). Dysglycemia is theorized to lead to overt HF through its detrimental effects on cardiac structure and function (Devereux et al., 2000; Rutter et al., 2003; Battiprolu et al., 2013) and through decrements in endothelial and vascular function.

The interaction between medical treatment of diabetes and HF risk has proved complicated. Observational data do support enhanced cardiac structure and function with improvement of cardiometabolic traits (von Bibra, 2004). However, better glycemic control has not consistently resulted in lower HF risk. Indeed, most randomized clinical trials have failed to demonstrate improved cardiovascular outcomes with tighter glycemic control in type 2 diabetes mellitus (Patel et al., 2008; Duckworth et al., 2009; Action to Control Cardiovascular Risk in Diabetes Study Group, 2008). Furthermore, different drug classes appear to have differential effects on HF risk in diabetics (Hippisley-Cox and Coupland, 2016). This observation has become increasingly relevant as a number of recently developed glucose-lowering agents, such as the thiazolidinediones (Komajda et al., 2010; Fitchett et al., 2016b) and dipeptidyl peptidase-4 inhibitors (Fitchett et al., 2016b; Scirica et al., 2014), have been found to increase this risk of HF. On the other hand, in the EMPA-REG OUTCOME trial, empagliflozin (an inhibitor of sodium–glucose cotransporter 2) led to a 35% relative risk reduction in HF hospitalizations in individuals at high cardiovascular risk, regardless of the presence of HF at baseline (Fitchett et al., 2016a; Zinman et al., 2015). The diuretic effect of empagliflozin, via glycosuria, is theorized to be one of the primary mechanisms for the robust effect on HF outcomes with empagliflozin. Whether this reduction in HF events is a class effect observed for other inhibitors of the sodium–glucose cotransporter 2 will be determined after the publication of two ongoing trials (Fitchett et al., 2016b).

In addition to treating hyperglycemia, addressing comorbidities is an important component of cardiovascular risk reduction in type 2 diabetes mellitus. In particular, the use of angiotensin receptor blockers in patients with proteinuria resulted in a 32% relative risk reduction for first HF hospitalizations in the RENAAL and losartan intervention for endpoint reduction studies (Brenner et al., 2001; Lindholm et al., 2002). Angiotensin converting enzyme inhibitors or angiotensin receptor blockers should therefore be considered in all patients with type 2 diabetes and proteinuria to reduce the risk of developing HF.

Obesity

Obesity is directly and robustly related to HF risk. In the FHS, each one-point higher BMI was associated with 5% and 7% higher risk for HF in men and women, respectively (Kenchaiah et al., 2002). Obesity is also known to be associated with adverse cardiac structural and functional remodeling (Bello et al., 2016; Cheng et al., 2010). Despite the strong evidence that obesity is associated with incident HF and potentially causes it (Hagg et al., 2015), the effect of weight-loss interventions on HF risk remains uncertain. As weight loss in patients with established (stage C) HF has been reported to paradoxically lead to worse outcomes (Zamora et al., 2016), the impact of weight loss on the development and progression of HF requires further study.

Dyslipidemia

Individuals with suboptimal lipid profiles are at increased risk of developing HF (Dhingra et al., 2008). In the FHS, lower high-density lipoprotein (HDL) and higher non-HDL cholesterol were associated with incident HF independent of myocardial infarction (Velagaleti et al., 2009), but these data have not been replicated in other cohorts. Higher triglycerides have also been suggested to be

associated with increased HF risk in diabetics (Ebong et al., 2013). The association of dyslipidemia and HF is theorized to be primarily attributable to the contribution of dyslipidemia to epicardial coronary artery disease and microvascular dysfunction. As discussed earlier in section "Atherosclerotic Vascular Disease," lipid-lowering treatment with statins leads to a reduced risk of HF (Kjekshus et al., 1997; LaRosa et al., 2005). Dyslipidemia should therefore be treated according to clinical practice guidelines in order to prevent adverse cardiovascular outcomes including HF.

Smoking

Smoking (both past and current) has been associated with incident HF after adjustment for interim coronary events (Gopal et al., 2012). Although data supporting a reduction in HF risk following smoking cessation are lacking, abstinence from cigarette smoking is a vital component of cardiovascular health promotion and should therefore be routinely emphasized.

Cardiotoxins

Chemotherapy

A number of chemotherapy drugs—including both novel targeted therapeutics and traditional cytotoxic agents—increase the risk of developing HF. The classic example is anthracyclines, which were first described to cause HF symptoms 40 years ago (Von Hoff et al., 1977). HF risk from anthracycline agents is dose-dependent, occurring in 8.8% of patients receiving a cumulative doxorubicin exposure of 250 mg/m^2 and 53.9% of individuals treated with 500 mg/m^2 (Swain et al., 2003). Anthracyclines cause cardiomyocyte damage via the increased production of reactive oxygen species and mitochondrial dysfunction (Zhang et al., 2012). This toxicity usually results in irreversible left ventricular systolic dysfunction. Although anthracycline cardiotoxicity is most commonly seen within the first year of treatment, it can present up to 20 years post treatment (Larsen and Mulvagh, 2017). Trastuzumab, a monoclonal antibody against the human epidermal growth factor receptor 2, which is used in select patients with breast cancer, has been reported to further potentiate the risk of HF in individuals receiving anthracyclines (Chen et al., 2012). A number of other established agents such as cyclophosphamide, 5-fluorouracil, and sunitinib have been linked with increased HF risk (Finet, 2017). The field of targeted cancer therapies is progressing rapidly with many new agents under development. One such class is immune checkpoint inhibitors. These drugs have shown tremendous potential in a number of cancers, but fulminant myocarditis resulting in cardiogenic shock has also been reported as a rare toxicity (Johnson et al., 2016). As new agents are developed, the list of chemotherapies with potential cardiotoxicities is likely to grow.

Several strategies are routinely employed to minimize HF risk in individuals receiving cardiotoxic chemotherapy, particularly anthracyclines. Preventive principles include using the lowest necessary doses and considering alternative agents in patients with cardiovascular risk factors. Several small studies have evaluated the benefit of prophylactic administration of standard HF therapies such as beta-blockers, angiotensin converting enzyme inhibitors, or angiotensin receptor blockers in patients receiving cardiotoxic chemotherapy and showing an attenuation of left ventricular systolic dysfunction (Bosch et al., 2013; Gulati et al., 2016). Larger trials with longer follow-up are needed to determine if these interventions might reduce the risk of incident HF.

Chest Radiation

Precise estimates of the risk of future HF in individuals receiving chest radiation are limited by the long delay between the radiation exposure and the development of HF. Nevertheless, the risk of HF is estimated to be increased fivefold after 30 years in individuals receiving chest radiation (Aleman et al., 2007). Radiation can contribute to the development of HF by promoting coronary artery disease, pericardial disease, interstitial fibrosis and diastolic dysfunction, and complex valvular lesions (Finet, 2017). Careful surveillance of individuals who received chest radiation is therefore necessary to identify individuals at high risk for developing HF (Groarke et al., 2014).

Alcohol

While the precise dose relationships have not been elucidated, the association between alcohol consumption and HF risk is theorized to constitute a J-curve relationship. Modest alcohol consumption (generally defined as 1–2 drinks per day) has been associated with a reduced risk of new-onset HF in the FHS and Atherosclerosis Risk in Communities cohorts (Walsh et al., 2002; Gonçalves et al., 2015). By contrast, heavy alcohol consumption (defined as 100 g (~7 drinks) per day for men or 80 g (~5–6 drinks) per day for women) increases the risk of developing HF (Fernández-Solà, 2015). Heavy alcohol use frequently causes a dilated cardiomyopathy, which is often reversible with decreasing or ceasing alcohol consumption (Nicolás et al., 2002).

Other Cardiotoxins

A number of other drugs—both medications and drugs of abuse—have been linked with cardiotoxicities. In particular, amphetamines and cocaine are reported to lead to left ventricular dysfunction and overt HF (Subzposh et al., 2014; Neeki et al., 2016).

A careful medication and drug history should therefore be collected on all patients, and counseling to avoid potential cardiotoxins should be routinely performed.

Family History and Genetic Risk

HF is theorized to be a heritable condition, with approximately 18% of the HF burden in the FHS attributable to a parental history of HF (Lee et al., 2006). Furthermore, a parental history of HF resulted in a 70% higher individual risk of developing HF.

Family history of HF likely influences HF risk through both direct and indirect mechanisms. Shared genetic risk for associated conditions, such as hypertension, coronary artery disease, and obesity, might explain some of the observed heritability (Lloyd-Jones et al., 2004; Murabito et al., 2005).

While many single-gene mutations have been discovered that lead to specific (familial) cardiomyopathies, such as hypertrophic cardiomyopathy and dilated cardiomyopathy, the genetic architecture of common HF risk remains mostly unknown (Tayal et al., 2017). One example of a genetic variant that has been associated with incident HF is the transthyretin variant valine-to-isoleucine substitution at position 122 (V122I), which is found in 4% of African Americans and is involved in transthyretin cardiac amyloidosis. Recently, carriers of these mutations were found to have a 47% higher risk of incident HF (Quarta et al., 2015). Therefore, this variant may represent a risk factor for HF in African Americans and warrants further study (Alexander and Falk, 2016).

Recognizing the importance of heritability in HF pathogenesis, the US HF guidelines recommend gathering a three-generation family history of HF to assess HF risk (Yancy et al., 2013). First-degree relatives of patients with familial cardiomyopathies should undergo surveillance echocardiography, genetic counseling, and potentially genetic testing (Yancy et al., 2013).

Other Conditions

A number of other conditions have been reported to predispose to HF but have not yet been included in HF guidelines as conditions that define stage A HF (Table 1). While accounting for less population attributable risk for HF, addressing these conditions may be an important component of HF risk reduction strategies for individual patients.

Table 1 Conditions comprising stage A heart failure

	Conditions
Risk factors included in US heart failure guidelines	Hypertension
	Coronary artery disease
	Diabetes
	Cardiotoxins
	Family history of cardiomyopathy
	History of rheumatic fever
	Thyroid dysfunction
	Smoking
	Metabolic syndrome
	Atherosclerotic vascular disease
Additional risk factors (*established*)	Obesity
	Dyslipidemia
	Kidney dysfunction
	Physical inactivity
	Obstructive sleep apnea
	Chronic right ventricular pacing
	Human immunodeficiency virus
Additional risk factors (*potential*)	Genetic risk
	Novel biomarkers
	Risk scores

Information included from the following sources: Hunt, S. A., Baker, D. W., Chin, M. H., et al. (2001). ACC/AHA guidelines for the evaluation and management of chronic heart failure in the adult: executive summary a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines. *Circulation* **104** (24), 2996–3007; Yancy, C. W., Jessup, M., Bozkurt, B., et al. Chronic Kidney Disease

Several measures of chronic kidney disease (CKD) including kidney dysfunction (low estimated glomerular filtration rate) and kidney injury (albuminuria) are associated with new-onset HF in the community (Köttgen et al., 2007; Lam et al., 2011; Dhingra et al., 2011; Fried et al., 2003; Chae et al., 2003; Ingelsson et al., 2007; Blecker et al., 2011; Nayor et al., 2017). Additionally, albuminuria and reduced eGFR have been associated with decrements in cardiac structure and function (Matsushita et al., 2015; Lieb, 2006; Park et al., 2012; Patel et al., 2009), which may underlie these associations.

Prevention of CKD may therefore represent an important consideration for reducing the burden of HF.

Physical Inactivity

Greater physical activity (Djoussé et al., 2009; Agha et al., 2014; Pandey et al., 2015) and less inactivity (He et al., 2001) are associated with lower risks of incident HF in community-based cohorts. In fact, higher physical activity and lower sedentary time have independent and complementary associations with a lower risk of new-onset HF (Young et al., 2014). In a longitudinal analysis from the FHS, reductions in physical activity over time were also associated with elevated HF risk (Kraigher-Krainer et al., 2013). Specific cut points for optimal physical activity or sedentary time to prevent HF have not been agreed upon, but the data do support recommendations to encourage regular physical activity to reduce HF risk.

Chronic Right Ventricular Pacing

Chronic right ventricular pacing results in dyssynchronous cardiac contraction, which can lead to adverse cardiac remodeling and, eventually, to overt HF (Sweeney, 2003; Thambo, 2004; O'Keefe et al., 2005). In one study of 177 patients randomized to right ventricular versus biventricular pacing, right ventricular pacing was associated with a 7% reduction in ejection fraction over the course of the study (Yu et al., 2009). Biventricular pacemakers, in comparison, attenuated ventricular remodeling. Similar benefits would be expected from other interventions to minimize right ventricular pacing such as using lower pacing backup rates and optimization of atrial pacing (Gillis, 2014). Hence, efforts should be made to identify and minimize a high burden of right ventricular pacing in order to mitigate HF risk.

Human Immunodeficiency Virus

Individuals with human immunodeficiency virus (HIV) infection are known to be at increased risk for HF, but the dynamics of this association are changing in the era of widespread use of antiretroviral therapy (Barnes et al., 2017). Previous reports of an HIV-associated cardiomyopathy in 10%–40% of HIV-positive individuals predated the routine use of antiretroviral therapy (Cerrato et al., 2013). Although the risk is certainly lower now, contemporary reports suggest that even on effective antiretroviral treatment, HIV-infected individuals have a higher risk of developing HF than the general population (Al-Kindi et al., 2016; Butt et al., 2011). While mechanisms underlying these observations are being investigated (Remick et al., 2014), increased surveillance and treatment of associated risk factors is important in this population.

Sleep Apnea

Obstructive sleep apnea is associated with an approximately twofold higher risk of developing HF (Shahar et al., 2001). A number of potential mechanisms to explain the association have been posited, including intermittent hypoxia, oxidative stress, systemic inflammation, exaggerated negative intrathoracic pressure, sympathetic overactivation, and hypertension (Kasai and Bradley, 2011). While treatment of sleep apnea with positive-pressure ventilation may improve daytime somnolence and quality of life, trials have generally failed to show that positive-pressure ventilation reduces cardiovascular risk in individuals with sleep apnea (Barbe et al., 2012; McEvoy et al., 2016).

Cardiovascular Health Score

Risk scores combining the assessments of numerous HF risk factors may also prove useful in evaluating and treating stage A HF. A cardiovascular health score can be derived from the presence or absence of optimal values for the seven behaviors and risk factors outlined in the American Heart Association's 2010 strategic planning statement outlining goals for 2020 (Life's Simple 7™) (Lloyd-Jones et al., 2010). Although no trial has been performed in testing this hypothesis, multiple observational studies have demonstrated that an ideal cardiovascular health score is directly associated with a lower risk of developing HF (Nayor et al., 2016; Shah et al., 2015). By combining multiple HF risk factors into one easily calculated metric, this (and similar approaches) might enable patients and clinicians to better gauge HF risk and prioritize lifestyle modifications or treatment goals.

Future Considerations for Stage A HF

The ACC/AHA HF stages were introduced to highlight the progressive nature of HF. While this scheme is a useful construct within which to view the stepwise development of HF, there are several features of stage A HF, as currently defined, that might warrant reevaluation in future HF guidelines.

First, stage A HF is defined by the presence of risk factors without "structural heart disease." However, "structural heart disease" does not have a uniform definition. With further proliferation of advanced cardiac imaging modalities, such as cardiac magnetic resonance and strain imaging (Carerj et al., 2010), this definition will be challenged. For example, would we consider a patient with hypertension and abnormal longitudinal strain imaging (which is associated with incident HF (Cheng et al., 2015)) to have stage A HF if the traditional echocardiographic measures are all within normal limits? Furthermore, it is probable that many individuals currently considered to have stage A HF at rest would have cardiac functional abnormalities with exercise, which might unmask occult organ dysfunction. As cardiovascular diagnostic modalities advance, therefore, the boundaries between stage A and stage B HF are likely to become blurred. For now, we would suggest that patients be characterized as having stage A HF if they have HF risk factors in the absence of cardiac structural or functional abnormalities that are readily available to the clinician.

Second, the ACC/AHA HF stages depict HF as a single condition with various risk factors. However, accumulating data suggest that HF is a heterogenous condition with different subtypes representing distinct pathophysiological pathways and treatment responses (Borlaug and Redfield, 2011). These are currently represented by HF with reduced versus preserved ejection fractions, but it is likely that further subphenotyping will allow for more personalized treatment plans and preventive measures. Therefore, we could envision a novel formulation of stage A HF in the future that considers risk factors within the context of HF subphenotypes.

Summary

Stage A HF is characterized by the presence of conditions and risk factors that are associated with an increased risk for HF in the absence of overt cardiac abnormalities. The conditions comprising stage A HF include traditional cardiovascular risk factors that are highly prevalent in the general population. CHD, hypertension, obesity, smoking, and diabetes are responsible for the highest population attributable risk of HF, while an increasing number of other conditions have been identified to be associated with the development of HF. Early identification and treatment of HF risk factors both at the population and individual level is necessary to reduce the considerable burden of HF.

Introduction

Around 5.7 million Americans suffer from heart failure (HF), and nearly half of those diagnosed will die within 5 years (Mozaffarian et al., 2015). The economic weight of treating HF is as high as $30.7 billion annually (Heidenreich et al., 2011). Given the monumental health care burden, management and treatment of HF is an active area of clinical research. The American College of Cardiology and the American Heart Association (ACCF/AHA), to better manage the disease, have identified four stages to HF: stages A, B, C, and D. Briefly, stage A defines patients at risk for HF, such as those with hypertension or family history of cardiomyopathies, but have yet to develop cardiac structural changes. In stage B, patients have structural heart diseases associated with HF but have not developed symptoms, whereas in stage C patients developed HF symptoms such as dyspnea or fatigue. Lastly, patients with stage

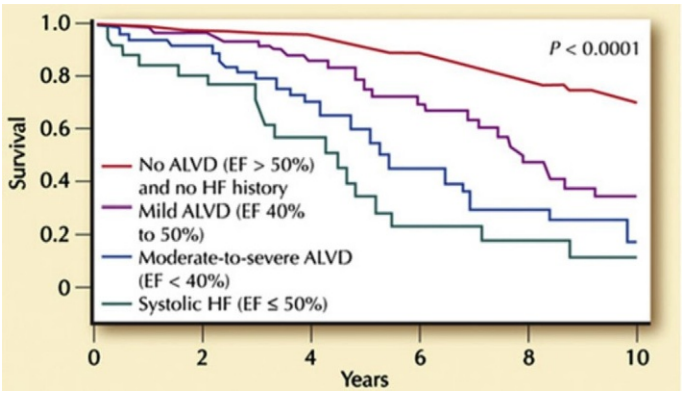

Fig. 1 Kaplan–Meier curves for survival. Referent group consists of subjects with normal left ventricular systolic function (EF >50%) and no history of congestive heart failure. Mild ALVD indicates mild asymptomatic left ventricular systolic dysfunction (EF 40%–50%); moderate-to-severe AVLD (EV <40%); systolic HF indicates congestive heart failure with EF ≤50%. From Wang, T. J., Evans, J. C., Benjamin, E. J., et al. (2003). Natural history of asymptomatic left ventricular systolic dysfunction in the community. *Circulation* **108** (8), 977–182; with permission.

D HF still demonstrate structural heart disease despite optimal medical treatment and are indicated for advanced intervention such as cardiac transplantation. Stage B HF is the culmination of a progressive disease and is a useful designation for patients at high-risk for HF. Developing measures to identify this subset of patient population, before the manifestation of signs or symptoms of HF, can dramatically improve patient outcomes. Understanding the structural basis of stage B HF, its etiology and progression, and the available clinical tools to track its clinical course will prove vital in providing the best care to HF patients.

The characteristic and functional abnormalities that fall into the category of stage B HF are diverse. In many cases of HF, cardiac risk factors that compromise the vascular endothelium and/or hemodynamics are present. Moreover, they contribute to structural changes in cardiomyocytes and the interstitium that lead to gross cardiac remodeling indicative of progressive HF. There are several etiologies that promote cardiac remodeling in progressive HF. Neurohormonal alterations of the renin–angiotensin–aldosterone axis and the adrenergic nervous system are compensatory mechanisms that exacerbate myocyte dysfunction in the long term. Additionally, pathologic states of chronic inflammation and ischemia mediated by cardiotoxins or cardiac structural diseases further play a role in ventricular hypertrophy and advancement to later stages of HF. Understanding of these disease processes and risk factors is crucial in determining the optimal treatment course and screening procedures for patients at jeopardy for HF.

Prevalence of stage B HF is rising because of an aging population and an increase in a number of patients with comorbidities. More patients are developing diabetes, left ventricular (LV) hypertrophy from hypertension, and coronary artery disease (CAD) that can result in myocardial infarction (MI) that impairs heart function. Angiotensin-converting enzyme (ACE) inhibitors and beta blockers in the case of post-MI are proven therapies that can improve survival and even reduce cardiac remodeling and prevent HF stage progression. Consequently, it is crucial to identify patients with stage B HF, as these patients have a fivefold increase in developing overt HF and manage accordingly (**Fig. 1**; Wang et al., 2003). Thus waiting for asymptomatic patients to develop symptomatic HF is a missed opportunity to positively influence the clinical course of the disease. Unfortunately, clinicians tend to focus on stage C and D HF due their symptomatic nature and ease in identification (Ditewig et al., 2010). Identifying and managing patients at earlier stages in HF can prevent progression to overt HF and improve mortality.

Pathogenesis

Cardiac Remodeling Leading to Stage B HF

Cardiac remodeling is a major feature of HF and when not present with clinical symptoms is pathognomonic for stage B HF (Savinova and Gerdes, 2012). Changes in venous return and vascular tone are the primary drivers of gross structural remodeling. Cardiomyocytes can adapt to environmental changes by altering their morphology in a myriad of pathologic states. This is accomplished through the unique positioning of cardiac cells within the heart wall. Here, cardiac cell length and diameter contribute to the heart's chamber circumference and wall thickness, respectively. How the cardiomyocyte's shape alters will determine the nature of cardiac remodeling.

Myocytes are striated cells measuring 25 μm in diameter and 100 μm in length. Each cell contains segments of sarcomeres, termed myofibrils, and the extent to which the myosin and actin filaments of the sarcomere overlap determines the force of muscle contraction. It has been widely accepted that hypertrophy (increase in cell size) rather than hyperplasia (increase in cell number) largely defines cardiac remodeling. Cardiomyocyte shape can strongly influence ventricular wall stress, a major determinant of myocardial oxygen demand. Laplace's Law reveals that wall stress (T) is proportional to chamber or vessel radius (R) and internal pressure (P) and inversely proportional to wall thickness (H):

$$T = PR/2H$$

This equation will be useful in understanding how the different etiologies of cardiac remodeling affect cardiomyocyte changes and risk for HF.

Pressure overload is one of many forms of stress that can lead to cardiac remodeling and is caused by states that increase the pressure gradient that the ventricle must overcome, such as hypertension and valvular stenosis. In addition, mechanical stress can be exacerbated by neurohormonal influences. As mentioned above, wall stress is directly proportional to internal pressure and inversely proportional to wall thickness. To normalize wall stress, the ventricle hypertrophies and increases wall thickness. Pressure overload leads to concentric hypertrophy, where there is an increase in muscle mass with either no change or a small change in chamber volume. In concentric hypertrophy, sarcomeres are added in parallel to increase the cell diameter. These changes ultimately lead to better-adapted muscle. Although left ventricular hypertrophy (LVH) at stage B HF is thought to be beneficial, it has long been found to be an independent risk factor for HF and other cardiovascular diseases (CVD) (Frohlich et al., 2011). The structural and functional changes in cardiomyocytes during hypertrophy, although beneficial at first, confer some increased risk for several cardiovascular disorders.

Volume overload also is another form of stress that can lead to cardiac remodeling. Structural cardiac volume overload has multiple etiologies and different effects on loading conditions for the four different heart chambers. For example, aortic insufficiency leads to volume overload when there is an abnormal regurgitation of blood from the aorta into the left ventricle during diastole. As with pressure overload, remodeling leads to both adaptive and maladaptive consequences. Volume overload causes eccentric hypertrophy, where increased muscle mass develops along with chamber dilation. In certain disease states both volume and pressure overload may be present, which are predisposing factors to stage B HF.

In addition, chronic ischemia of cardiomyocytes may result in remodeling. HF is a common complication of MI (Minicucci et al., 2011). The cardiac dysfunction that follows MI, such as systolic dysfunction or restrictive mitral filling patterns, can lead to compensatory cardiac remodeling. The degree of ventricular remodeling post-MI depends on infarct size and time to reperfusion. Though reperfusion has benefits, it can also cause reperfusion damage and further cardiac remodeling and ventricular dysfunction (Bolognese et al., 2002). Therefore, patients who experienced an MI or have recurrent ischemic issues should be screened for early stages of HF to improve clinical outcome.

Beyond cardiomyocytes, cardiac remodeling also occurs in myocardial interstitium, which consists of fibrillar collagen, non-collagen matrix proteins, proteoglycans, matrix metalloproteinases (MMPs), and a complex milieu of bioactive molecules. The myocardial interstitium is indispensable to cardiac function and orchestrates cardiomyocyte arrangement and contraction (Burlew and Weber, 2000). The myocardial interstitium is altered in disease states such as pressure and volume overload, valvular stenosis, and MI. These alterations are implicated in HF progression and include tissue inhibitors of MMPs (TIMPs), which leave MMPs unencumbered in their myocardial remodeling function. There are also changes in matrix composition such as an increase in galactin-3, which has been shown to be a marker in increased hospitalizations post-MI (Shah et al., 2010). Thus, understanding changes in the myocardial interstitium can offer insights to clinical outcomes and future therapeutic outlets.

Contributors to Heart Failure Progression

In response to abnormal conditions, such as pressure or volume overload, the heart can compensate by altering cardiomyocyte morphology. However, cardiac remodeling is not the only major contributor to HF progression. Studies have shown that neurohormonal stimulation, oxidative stress, inflammation, changes in arterial elasticity, and age-related cardiovascular factors all underwrite the development of HF.

Neurohormonal activation is a cornerstone to the compensatory mechanism during the development of HF. The sympathetic nervous system and renin–angiotensin–aldosterone system (RAAS) coordinate to preserve cardiac output and function. Falls in cardiac output during HF are sensed by baroreceptors in the aortic arch and carotid sinus. As blood pressure falls so does the firing rate of the glossopharyngeal and vagus nerves to the cardiovascular center in the medulla. This leads to an increase in sympathetic nervous activity to the heart and peripheral vascular system causing an increase in heart contractility, heart rate, and vasoconstriction. During HF, decreased renal perfusion, secondary to a lower cardiac output, results in the stimulation of RAAS. This promotes the release of renin, an enzyme that cleaves angiotensinogen to angiotensin I, from juxtaglomerular cells in the afferent renal arterioles. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme (ACE) in the lung and kidney to from angiotensin II. Angiotensin II is a potent vasoconstrictor that helps raise the blood pressure by increasing total peripheral resistance and leads to increases in intravascular volume by stimulating thirst in the hypothalamus. Angiotensin II also acts on the adrenal cortex to stimulate the release of aldosterone, a mineralocorticoid that promotes sodium reabsorption to augment blood volume. Though these changes are adaptive, they also lead to complications such as peripheral edema and pulmonary congestion, making neurohormonal mediators targets for therapy.

Oxidative stress is an imbalance between the generation of reactive oxygen species (ROS) and neutralizing antioxidants. During homeostasis, ROS play an important role in regulating numerous physiological processes by acting as a growth factor and cytokine. However, excess ROS can lead to tissue damage and has been implicated in countless diseases such as diabetes, atherosclerosis, hypertension, and even HF (Kojda and Harrison, 1999). Most studies have investigated the link between ROS and symptomatic HF and evidence shows that ROS play a role in pathogenesis in stage B HF (Bhimaraj and Tang, 2012). In ischemic states, secondary to structural heart disease, ROS are generated due to lack of aerobic respiration and result in a myriad of downstream consequences such as cardio-inhibition and MMP activation. Moreover, diseases that increase the risk for HF, including valvular disease, type 2 diabetes mellitus, or hypertensive disease, also lead to the generation of excess ROS in cardiomyocytes. The role of ROS in dysregulating normal cardiomyocyte function is just being appreciated, and manipulating oxidative stress in the heart could prove beneficial in the treatment of HF.

The inflammatory system is an integral to maintaining homeostasis but pathophysiological inflammatory states can alter myocardial function (Cieslik et al., 2011). Increased levels of proinflammatory medications such as C-reactive protein (CRP) and interleukin-6 (IL-6) have been linked to increased risk for symptomatic HF (Kalogeropoulos et al., 2010). Recent research has also elucidated the link between inflammation and progression from stage A to stage B HF (Kalogeropoulos et al., 2012). A proinflammatory milieu can lead to several mechanisms that compromise cardiac function such as decreasing myocardial contractility, promoting cardiac remodeling, and negatively impacting vasculature. Modulating proinflammatory factors at earlier stages of HF may prevent precipitation of symptoms and improve clinical outcome.

Arterial stiffness, or loss of arterial plasticity, is another marker with utility in identifying those at risk for HF. Reduction in arterial elasticity can impair cardiac output and put patients at increased risk for developing HF. Arterial elasticity determines the buffering capacity of arteries and pulse wave velocity coming from the heart (Laskey and Kussmaul, 1987; Mitchell, 2009). The Windkessel effect is a function of arterial elasticity and helps diminish the fluctuation in blood pressure during the cardiac cycle such that organ perfusion can be maintained during diastole. Assessment of atrial stiffness, along with other risk factors, may offer prognostic clues to the development of HF, especially in older patients who lose arterial elasticity over time.

As the population in developed countries grow older so does the prevalence of HF. This is because as more patients are successfully treated for symptomatic heart disease, the prevalence of individuals with early stages of HF increases (Mozaffarian et al., 2015). With age comes cardiovascular structural and functional changes such as arterial stiffening, increased LV wall thickness, and decreased myocyte contractility that contributes to systolic dysfunction. Additionally, the cardioprotective and repair processes are impaired and can lead to maladaptive remodeling. This leads to a higher incidence of cardiovascular diseases such as coronary artery disease and diabetic cardiomyopathy that can predicate HF. As such, it is imperative to consider aging a risk factor and screening of older patients can prevent the advent of HF.

Diagnosis and Monitoring of Stage B HF

Stage B HF is difficult to diagnose since symptoms have yet to manifest, but advanced imaging techniques and identification of biomarkers have made it possible. Patients in stage B HF stand to greatly benefit from early interventions. Advancements in no imaging modalities such as echocardiography and cardiac magnetic resonance imaging (CMR) have made it possible to detect structural changes in stage B HF. Moreover, radionuclide imaging can offer unique prognostic insights that other imaging techniques cannot. Beyond imaging, assessing biomarkers can provide information on both etiology of HF and risk of progression. In examining patients, it is advantageous to understand some of the limitations of each method and integrate the information offered by these illuminating techniques.

Echocardiography and Stage B Heart Failure

Echocardiography is relatively inexpensive and has a spectrum of applications making it a powerful tool to diagnose stage B HF. Transthoracic echocardiography is regularly used to assess measures of structure and function indicative of stage B HF. The best-studied measure is a reduction in left ventricular ejection fraction (LVEF) (Atherton, 2010). Asymptomatic left ventricular dysfunction (LVD) is typically detected by echocardiography and can be assessed in both diastole and systole to estimate the severity of stage B HF. Normally, LVEF should be between 55% and 70%. Patients with an LVEF less than 50% were found to be at an increased risk for developing symptomatic HF (Wang, 2003). In fact, the lower a patient's LVEF, the higher the risk of overt HF.

Since stage B HF is a detectable structural disease with no symptoms, LVSD, previous MI, LVD, and valve disease can all be designated as stage B HF. An advantage of echocardiography is that it can also be used to dissect structural changes by differentiating concentric and eccentric hypertrophy, valvular disease, and pericardial disease. Additionally, echocardiography can parse systolic and diastolic function by several parameters to offer greater depth of stage B HF severity. It is important to detect diastolic dysfunction since half of the patients presenting with symptomatic HF have preserved ejection fraction (Owan et al., 2006).

The echocardiogram features many settings used to screening for stage B HF (Boyd et al., 2015). In the 2-dimensional setting (2D) and M-mode, echocardiography can be used to measure LV wall thickness and chamber dimensions. Tissue Doppler echocardiography can assess both diastolic and systolic function with high temporal resolution by calculating the contractile velocity of cardiomyocytes. For example, in terms of diastolic function, echocardiography can measure useful parameters to assessing stage B HF severity such as isovolumetric relaxation time and ventricular filling pressure. Stress echocardiography can also be used in asymptomatic patients to illustrate diastolic function. Three-dimensional (3D) echocardiography offers, even more, information about cardiac structure but is diminished by poor spatial resolution. The spectrum of applications for echocardiography makes it an attractive tool for diagnosing and assessing stage B HF.

Cardiac Magnetic Resonance Imaging and Stage B Heart Failure

Cardiac magnetic resonance (CMR) is another imaging tool that can elicit both diagnostic and prognostic information for stage B HF (Partington et al., 2012). To date, this method remains the best noninvasive imaging modality for assessing heart function because it offers superior spatial and visual resolution to echocardiography. CMR, like echocardiography, can assess systolic and diastolic function while providing comprehensive myocardial tissue characterization. Moreover, it can detect inflammation, fibrosis, ischemia, and viability of cardiomyocytes. Distinguishing the cause of asymptomatic cardiac remodeling has significant

implications on risk stratification, prognosis, and treatment of the disease. Unlike echocardiography, CMR can measure cardiac structure, function, and tissue characterization in a single study. These advantages allow for more precise readings of LVED and make CMR the ideal tool for diagnosing and monitoring HF patients. There are some limitations including contraindication in patients who are at risk for radiocontrast-induced nephrotoxicity and those with pacemakers or implantable cardioverter defibrillator (ICD). Even with its limitations, this method of imaging remains a powerful tool for stage B HF.

Radionuclide Imaging

Radionuclide imaging is another tool that has proven valuable in diagnosing and monitoring stage B HF (Janardhanan and Beller, 2012). Equilibrium radionuclide angiography (ERNA) is widely used to assess left ventricular dysfunction. In ERNA, red blood cells (RBCs) are labeled with a radioactive material, namely Technetium-99 m. These RBCs can be seen flowing through the heart chambers and be used to measure systolic and diastolic function. ERNA, like CMR, has the advantage of high precision making it suitable for serial measurements of LVEF.

ERNA can be complimented with single-photon emission computed tomography (SPECT) to assess myocardial perfusion. Myocardial perfusion imaging (MPI) can be used to diagnose CAD in patients with HF and assess myocardial viability, adding another advantage to using radionuclide imaging. But unlike CMR, ERNA cannot accurately distinguish ischemic from nonischemic heart disease. Another radionuclide technique called positron emission tomography (PET) can offer insight to myocardial metabolism. In this modality, biologically active molecules, such as fludeoxyglucose, are labeled and tracked to assess tissue metabolism. This offers another degree to the characterizations of myocardial tissue.

Radionuclide imaging has great utility in investigating HF. Its precision and in-depth myocardial tissue characterization makes it ideal for detecting asymptomatic HF. It can delineate myocardial perfusion, viability, metabolism, interstitial abnormalities, and even neurohormonal receptor function. SPECT imaging can sense sympathetic stimulation, a compensatory mechanism in HF, and identify patients in early stages of HF who can benefit from intervention. Nuclear cardiology yields promising techniques to the detection and management of HF.

Biomarkers in Stage B Heart Failure

Biomarkers are measurable biological substances that indicate a disease process or risks for disease. Biomarkers in the context of HF are used to illuminate the etiology of HF, the presence of HF, and the severity of HF and risks for disease progression (Eleuteri and Di Stefano, 2012). Biomarkers for HF indicate neurohormonal activation, myocyte injury, inflammation, interstitial dysregulation, renal dysfunction, oxidative stress, and other parameters. Biomarkers have been useful in confirming or excluding HF and assessing long-term risks of disease progression.

Perhaps the most useful biomarker in inspecting for HF is the brain natriuretic peptide (BNP) and its cometabolite NT-proBNP, a prohormone. BNP is secreted by the ventricles of the heart in the response to excessive stretching (as would be seen in volume overload in stage B HF). BNP is secreted attached to NT-proBNP. BNP counteracts some of the maladaptive consequences from compensatory changes during HF by lowering systemic vascular resistance and central venous pressure, increasing natriuresis, and suppresses RAAS. The long half-life of NT-proBNP makes it a strong biomarker. In stage A and B HF, elevated NT-proBNP was associated with increased risk for MI, HF progression, and death (Luchner et al., 2000).

Biomarkers of myocyte injury and interstitial remodeling are also useful in assessing risk of HF. Troponins are proteins involved in muscle contraction and are leaked during myocyte injury. Many disease processes can elicit troponin release including HF. The release of troponin during HF may be due to a culmination oxidative stress, inflammation, wall stress, neurohormonal activation, and less perfusion due to an increase in myocardial oxygen demand (Logeart et al., 2001). The efficacy of measuring troponin levels in patients with any stage of HF has yet to be established. Volume and pressure-overload causes changes in the extracellular matrix that can be tracked by detecting changes in MMPs and TIMPs composition. For example, elevated levels of MMP-9 are associated with left ventricular remodeling and TIMP-1 with reduced systolic function (Sundström et al., 2004; Kelly et al., 2007). Despite the insights TIMP and MMP configuration have on cardiac remodeling and function, more proteomic studies need to be conducted before they can be used as reliable biomarkers for HF.

Inflammation and oxidative stress are contributors to HF progression and can be measured using biomarkers. Several proinflammatory cytokines such as IL-1, IL-6, CRP, and TNF-α are elevated in patients with HF (Anker and Von Haehling, 2004). Higher levels of these proinflammatory cytokines have been associated with HF progression and could be predictive of clinical outcome (Levine et al., 1990; Deswal et al., 2001). CRP has been shown to complement BNP screening for HF but even though that inflammatory mediators are contributors are HF, measurements are not typically made to inform therapy (Ng et al., 2006).

Similarly, ROS is observed in HF (Hafstad et al., 2013). A proinflammatory state, myocardial apoptosis, and diminished antioxidative activity are thought to be behind oxidative stress in HF. Several biomarkers have been implicated in presence of HF and HF severity. Higher plasma levels of myeloperoxidase (MPO) and isoprostane, an inflammatory mediator and marker of oxidative stress, correlate with severity of HF, degree of left ventricular remodeling, and mortality (Tang et al., 2006; Kameda et al., 2003). Oxidative stress also correlates with markers of neurohormonal activation and inflammation (Wykretowicz et al., 2004; Nonaka-Sarukawa et al., 2003). Despite the role ROS in advancing HF and these strong correlations, antioxidant therapy has had mixed clinical success in treating HF (Pacher et al., 2005; Hafstad et al., 2013). As with inflammatory markers, biomarkers of oxidative stress are not routinely used to inform therapeutic decisions for HF but are still useful in describing presence and severity of disease.

New biomarkers are emerging as the pathophysiology of HF becomes clearer. Osteoprotegerin is a glycoprotein that regulates bone resorption, inflammation, and other cellular processes and is correlated with heart diseases (Venuraju et al., 2010). Interestingly, osteoprotegerin is involved in asymptomatic left ventricular remodeling (stage B HF) (Omland et al., 2007). Other proteins have been implicated in the early stages of HF as well. Galectin-3, a protein secreted by macrophages, promotes cardiac remodeling and has amplified myocardial expression in stages A and B of HF (Sharma et al., 2004; Shah et al., 2010). As proteomics continues to evolve so will the practice of biomarkers in identifying and characterizing patients with stage B HF.

Prevention

Though the mechanism behind progression of stage A to stage B HF remains largely misunderstood some measures can still be taken to prevent advancement to stage B HF. Several antecedents to symptomatic HF have been identified such as obesity, chronic kidney disease, anemia, atrial fibrillation, smoking, diabetes, sedentary lifestyle, less education, and others. Reduction of these risk factors is the mainstay of prevention of progressing from stage A to stage B HF. Lifestyle changes such as exercising regularly, adapting healthier eating habits and lowering blood cholesterol, avoiding alcohol, and managing stress are all practical strategies for reducing risk for stage B HF. Treating hypertension, dyslipidemia, and diabetes is also beneficial in preventing progression to stage B HF. A summary of risk factors and clinical course of HF is illustrated in **Fig. 2**.

Prevention of HF progression also includes addressing dysfunction of noncardiac organs. Renal, pulmonary and hematopoietic impairment have all been associated with a 30% increased risk of overall HF, with an additive effect if more organs are involved (Lam et al., 2011). The interaction between chronic HF, chronic kidney disease, and anemia, known as cardio-renal-anemia syndrome, serves as a vicious cycle that deteriorates all three organ systems (Von Haehling and Anker, 2011). Additionally, debilitated lung function effects both systolic and diastolic cardiac performance (Barr et al., 2010; Guazzi, 2008). Therefore, improving prevention of HF progression must include attention to both cardiac risk factors and noncardiac organ impairment.

Despite knowledge of risk factors associated with HF, community-based studies suggest little progress has been made in prevention (Owan et al., 2006; Gomez-Soto et al., 2011; Levy et al., 2002). Diagnostic testing has no direct effect on clinical outcome but can improve outcome through initiating and optimizing therapeutic intervention during a critical period of the natural history of HF. Analysis from the SOLVD-Prevention and Survival and Ventricular Enlargement trials provide strong support for ACE inhibitor and β-blocker therapy during stage B HF (Vantrimpont et al., 1997; Exner et al., 1999). Although there is a clear benefit to screening patients for stage B HF and starting therapy, there is no decisive method to identify patients with stage B HF (though the use of biomarkers is promising). The following research designs will help in formulating strategies to screen and best treat patients with stage B HF (Box 1).

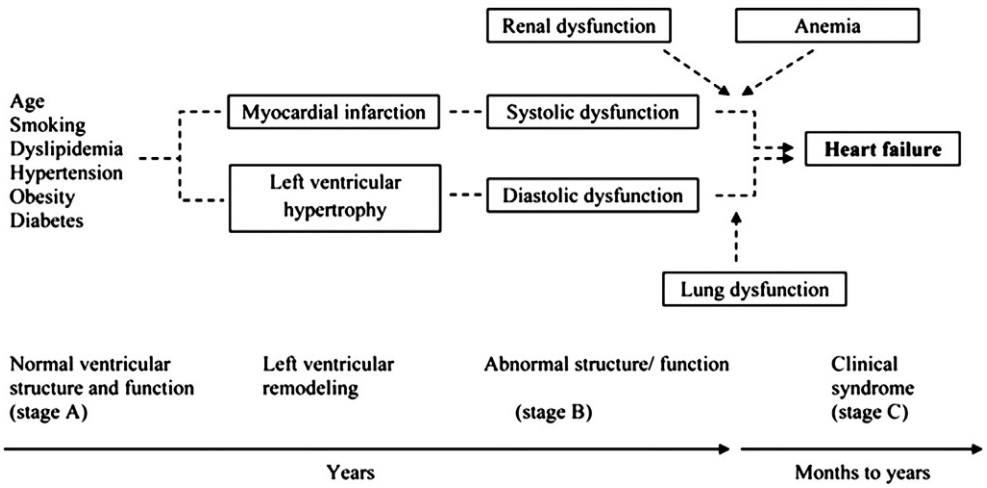

Fig. 2 Interaction of cardiac risk factors along with cardiac and noncardiac dysfunctions that contribute to heart failure progression. From Klein, L. (2011). Omnes Viae Romam Ducunt: Asymptomatic cardiac and noncardiac organ system dysfunction leads to heart failure. *Circulation* **124**, 4–6; with permission.

Box 1 Summary of proposed research designs

1. Determine the incidence of asymptomatic LVSD in community-based cohorts.
2. Characterize the natural history of asymptomatic LVSD in the community:
   a. Natural history in individuals with different degrees of LVSD
   b. Natural history in individuals with LVSD without previous MI
3. Examine the natural history of subclinical left ventricular diastolic dysfunction.
4. Examine the cost-effectiveness of various screening strategies for identifying left ventricular dysfunction and develop better screening tools.
5. Address the role of medications other than ACE inhibitors in managing patients with asymptomatic LVSD.

(*Continued*)

Box 1 (Continued)

6. Increase representation of the following types of patients in clinical trials: patients with mild LVSD, those with LVSD and no history of MI, and those with isolated left ventricular diastolic dysfunction.

ACE, angiotensin-converting enzyme; *LVSD*, left ventricular systolic dysfunction; *MI*, myocardial infarction.

Treatment

For patients with stage B HF, the goal of treatment is to prevent overt disease. Pharmacologic intervention has been proven to alter the natural history of HF. Currents drugs can address the underlying pathophysiology HF and target left ventricular remodeling, the RAAS, neurohormonal activation, and heart arrhythmias. This section describes asymptomatic HF interventions in detail and is summarized by Fig. 3.

Renin–Angiotensin–Aldosterone System Intervention and Stage B Heart Failure

RAAS is critical to cardiac hormonal signaling and is activated as a compensatory mechanism early on in HF to maintain adequate cardiac output and hemodynamic balance. Though adaptive at first, excessive RAAS activation can perpetuate disease mechanisms underlying HF. Pharmacologic manipulation of RAAS has proven beneficial for treating patients with a variety of cardiomyopathies, previous MIs, and LVH. Stage B HF encompasses a spectrum of pathologies exacerbated by RAAS, making RAAS a potent target for therapy.

As discussed, excess angiotensin activity during compensation ultimately leads to complications that aggravate HF. Targeting angiotensin is a pillar to the treatment of stage B HF and other cardiac disorders. ACE inhibitors can prevent the conversion of

angiotensin I to angiotensin II and lower both plasma and tissue levels of angiotensin II. ACE inhibitors facilitate vasodilation by counteracting angiotensin's vasoconstrictor effects and limiting degradation of the vasodilator bradykinin. Preservation of bradykinin levels is known to stimulate nitric oxide production and perhaps explain the antihypertensive, antifibrotic, and antithrombic effects of ACE inhibitors (Hornig et al., 1997; Pretorius et al., 2003). The preservation of bradykinin also precipitates cough, which may contraindicate the use of ACE inhibitors. ACE inhibitors are also contraindicated in patients with edema and hypersensitivity and should be used with caution in patients with renal dysfunction and cardiac outflow obstruction. For patients who are intolerable to ACE inhibitors, angiotensin receptor blockers (ARBs) also can block angiotensin activity and are an alternative. ACE inhibitors are cardioprotective in stage B postinfarct patients and reduce progression to severe HF (Pfeffer et al., 1992; Torp-Pedersen and Køber, 1999). ARB therapy has shown similar efficacy in the same clinical setting (Pfeffer et al., 2003). RAAS therapy is very effective at modulating natural history of asymptomatic heart dysfunction and can alter the natural history of HF.

β-Blocker Utility in Stage B Heart Failure

Another cause to HF as a progressive clinical syndrome is over activity of the neurohormonal system. The sympathetic nervous system modulates heart rate and activity via β1-receptors through the release of catecholamines. Overstimulation of the sympathetic nervous system is thought to contribute to progressive HF and blocking β-adrenergic has proven therapeutically beneficial. β-adrenergic blockers, or β-blockers, also have potent antiremodeling properties, though the reasons why remain unclear. Overall, β-blockers share similar efficacy and safety to RAAS inhibitors and are even associated with the most consistent improvements in LVEF (Campen et al., 1998). These properties make β-blockers an indispensable treatment for stage B HF patients.

LV dysfunction is a hallmark of HF and activates RAAS, increases catecholamine release (namely norepinephrine), and may lead to structural remodeling. Increased levels of norepinephrine (NE) exhibit cardiotoxic effects and paradoxically impair sympathetic stimulation over time (Keys and Koch, 2004). In a protective measure, the heart downregulates β1-receptor expression to reduce the deleterious effects of chronic adrenergic stimulation and counteract the cardiotoxicity of excess NE. β-blockers block NE binding and mitigate its cardiotoxic effects. Also by improving LVEF and systolic function, β-blockers can decrease adrenergic activity. β-blockers such as metoprolol succinate and metoprolol tartrate have been found helpful in treating stage B HF patients by reducing remodeling, improving systolic function, and curtailing mortality (Colucci et al., 2007). β-blockers can be contraindicated in patients with symptoms of HF, such as hypotension, but are favorable in treating stage B HF patients. Regardless of the etiology of stage B HF, patients who suffered from a previous MI should be treated with both RAAS inhibitors and β-blockers.

Implantable Cardioverter Defibrillators for Stage B Heart Failure

Implantable cardioverter defibrillators (ICDs) are devices capable of performing cardioversion, defibrillation, and in some models heart pacing. ICDs are commonly used in patients who are at risk of dying from abnormal heart rhythms and sudden cardiac death. When an abnormal heart rhythm is detected, the ICD delivers a shock to reestablish a normal rhythm. Patients with HF and/or previous MIs are at risk for sudden cardiac death and can benefit greatly from an ICD. For this reason, patients with stage B HF precipitated by an MI are often outfitted with an ICD.

Stage B Heart Failure Management with Comorbidities

Stage B HF is often present with other comorbidities. Stage B HF patients with hypertension, chronic kidney disease (CKD), or diabetes need special management. Since ACE-inhibitors are efficacious in controlling blood pressure, patients with concomitant hypertension can benefit from RAAS inhibitor treatment. Use of ACE-inhibitors and ARBs should be monitored closely in patients with CKD. While the antihypertensive effects of these have renal protective effects, they can cause hyperkalemia and other complications in CKD patients. The renal protective effects of RAAS inhibitors confer a benefit to diabetes patients. Attention should be given to what β-blockers to prescribe to diabetic patients. Carvedilol has been shown to be less detrimental to glucose control in diabetic patients than other β-blockers(Fardoun, 2006; DiNicolantonio et al., 2015). Patients who are hyperkalemic or pregnant should not be prescribed ACE-inhibitors or ARBs.

Introduction

ST-segment elevation myocardial infarction (STEMI) (O'Gara et al., 2013) and non-ST-segment elevation myocardial infarction (NSTEMI) (Roffi et al., 2016) are the most frequent among acute coronary syndromes (ACS) whereas unstable angina (referred to in the past as intermediate coronary syndrome (Anon., 1979)) is a less severe condition. Based on (1) chest pain presentation with typical characteristics, (2) standard electrocardiogram (ECG) with adequate modifications in time, and (3) biomarkers' evolutions, it is now highly probable to correctly diagnose to which clinical form a given patient behaves, which has immediate therapeutic and outcome-related consequences to the extent that diagnosis is a gating for short- and long-term survival which is obtained by speeding up the salvage of myocardium at risk, the real limiting factor of medical, and surgical procedures developed in recent years (Reed et al., 2017; Anderson and Morrow, 2017).

The universal definition of myocardial infarction (MI) recognizes acute myocardial ischemia as the pathophysiological mechanisms whereby cardiomyocytes undergo irreversible damage leading to necrosis in a clinical setting (Reed et al., 2017; Anderson and Morrow, 2017). However, to meet the diagnosis of MI, a combination of criteria is needed. It is, in fact, crucial the presence in the circulating blood of a biomarker normally present in intact cardiac cells only: troponin (T) (Twerenbold et al., 2012; Reiter et al., 2012; Thygesen et al., 2012a). The values of this biomarker are expected to be higher above the 99th percentile of the upper reference limit, which introduces sometimes an element of uncertainty if gender-, age-, and detection-related methods were not tested (and known) in the concerned laboratory hospital. Apart from this golden reference, the most frequently related to the high-sensitivity T-troponin (hs-TnT) (Twerenbold et al., 2012) although hs-I troponin (hs-TnI) (Shah et al., 2015) may also serve as a standard for signaling an irreversible intracellular damage due to acute ischemia, it is necessary that at least one of the following elements is present: (1) symptoms of myocardial ischemia either as chest pain or as systodiastolic dysfunctions of cardiac performance; (2) new or presumably new significant ST-T wave changes (with evolution toward Q waves) or the development of left bundle branch block (LBBB) on 12-lead ECG; (3) imaging evidence of new or presumably new loss of viability at the level of contracting myocardium, which is evidenced by regional wall motion abnormality including loss of systolic increment of wall thickness; and (4) detection of intracoronary thrombi either at selective coronary angiography or autopsy.

When ST-T wave changes persist (in obliged conjunction with critical changes of hs-TnT) more than 20 min and chest pain is typical, the patient is facing an ACS of the STEMI type which later will present with significant (>40 ms in duration: pathological) Q waves at ECG. The most probable cause of STEMI is an acute total coronary occlusion, the occurrence of which might follow to either intraluminal dislocation of a parietal subocclusive coronary atheroma due to intraplaque hemorrhage or to luminal occlusion due to thrombus formation after plaque rupture, erosion or fissuration (Falk et al., 2013; Ylä-Herttuala et al., 2013). Recent studies using optical coherence tomography (OCT) have shown that plaque rupture represents the most common cause of thrombotic coronary occlusions accounting for over 65% plaque morphologies in STEMI. Plaque erosion is recognized in at least 25%–27% of patients with STEMI. Thrombosis of a calcified stenotic lesion is recognized in the reaming 8% of STEMI patients (Higuma et al., 2015; Guagliumi et al., 2014; Burke et al., 1997; Prati et al., 2013; Manfrini et al., 2006). As a consequence of total coronary occlusion, coronary flow ceases and the dependent tissue, so frequently not irrigated by collaterals, may not survive unless reperfused by mechanical restitution of orthogonal coronary flow which is obtained by fibrinolytic dissolution of coronary thrombi and/or coronary dilation by primary (since in the acute context) coronary angioplasty and potential position of a stent to assure maintenance of adequate coronary caliper after intracoronary balloon inflation.

If atherosclerotic involvement is diffuse and all three main coronary vessels (or their major branches) are involved, it might be difficult to detect the culprit lesion actually responsible for the MI and how coronary flow reserve behaves might be useful to

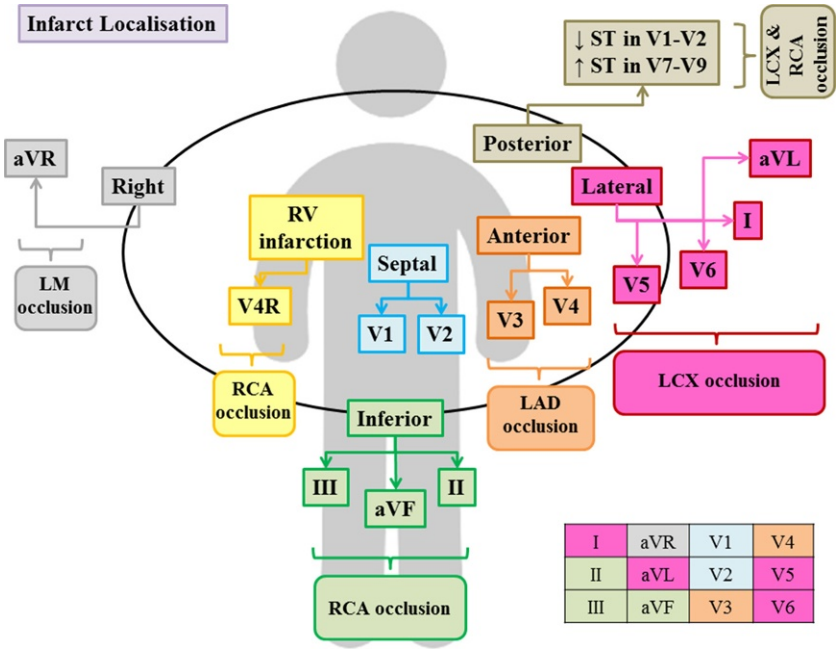

Fig. 1 Overview of ECG leads and criteria for the diagnosis of MI. For STEMI diagnosis ST-segment elevation measured at the level of the J point, should be detected in at least two adjacent leads and be of $\geq$0.20 mV in man and $\geq$0.15 mV in women in leads V_2–V_3 or $\geq$0.10 mV in the remaining leads. These cut-off values have also an age dependency and thus in younger than 40-year men, the criterion is slightly higher ($\geq$0.25 mV). Presence of ST-segment elevation alone indicates myocardial injury and impending infarction; the presence of Q-waves indicates progression to infarction. For NSTEMI, ST-segment depression and/or T-wave inversion indicate ischemic changes and might not be specific to a given coronary artery distribution. There is a certain level of colocalization between ECG exploring leads and the distribution of coronary circulation: right (RCA), left anterior descending (LAD), circumflex (LCX) of left main (LM) coronary arteries (Reed et al., 2017). Therefore, the localized diagnosis of STEMI might be performed based on ECG leads involvement and grouping: lateral (might see reciprocal changes in aVR); inferior, septal (if anteroseptal, might extend to V_3, V_4), anterior (might also see changes in V_2, V_5), right (might see reciprocal ST-depressions laterally; obtain dedicated right-sided electrocardiogram), true posterior that might see ST-depressions in V_1–V_4 (obtain dedicated posterior electrocardiogram) and the risky LM occlusion.

provide functional elements to increase the probability of detecting the actual cause of MI (Pijls et al., 1996). Nevertheless, a certain relation exists between coronary arteries' distribution and ECG leads involvement in detecting ST segment shifts, to the extent that standard 12-lead ECG might be used to localize the potentially culprit artery acting on which may prove of importance when the evolution is toward recovery of localized electromechanical viability (Fig. 1).

Clinical Presentation of STEMI

Patients stacked by STEMI present with an unremarkable physical examination although they refer quite always symptoms that may include chest pain or discomfort, shortness of breath dizziness or light-headedness, nausea or vomiting, diaphoresis unexplained by ambient temperature, palpitations, and anxiety or a feeling of impending doom. Signs of heart failure, hemodynamic or electrical instability mandate quick diagnosis to form the secure base for prompt appropriate treatments. Whereas diagnosis is based on chest pain, ECG and cardiac biomarkers, the recommendations for initial diagnosis, based on the classes and levels of evidence, point to a few actions that should be provided to all patients.

STEMI: A Clinical Overview

Coronary heart disease (CHD) is the single most frequent cause of death worldwide, both in developing than developed countries, accounting for over seven million deaths each year and >12.5% of all deaths (Ezzati et al., 2006; Puddu et al., 2011; Menotti and Puddu, 2013). Although STEMI incidence has continuously declined in the last 25 years and death rate has dramatically decreased (from 30% to << 5%) after coronary care units developed in late 1960s and very effective treatments were introduced such as acute reperfusion following thrombolysis or primary percutaneous interventions along with secondary prevention treatments, both prehospital mortality and long-term mortality following STEMI still remain substantial, leaving room to primary prevention as the most effective means of reducing the global burden of CHD. In fact, when acute myocardial ischemia develops, a particularly threatening consequence is represented by arrhythmias occurring at the border of the jeopardized zone where coronary flow stops and oxygen supply is profoundly compromised. Sudden death (SD) may occur in less than 60 min from the onset of symptoms so

that only prompt hospitalization may be life-saving. In-hospital recognition (by continuous monitoring or telemetry during transport (Puddu et al., 2013)) of the potential deterioration of apparently innocent premature ventricular contractions into serious arrhythmias such as ventricular tachycardia or, after repetitive R on T phenomena, into ventricular fibrillation, may prompt electric defibrillation as the sole treatment capable to restore the heart essential pumping function.

Initial Evaluation

The prehospital phase of STEMI has been repeatedly underlined as a particularly critical issue and might be sketched as a double-edged condition: (1) efforts to increase the probability of life-saving maneuvers by bystanders (Rea et al., 2003), pointing to the need of increasing in the public the capabilities for life support and cardiac massage before delivering heart defibrillation by appropriate electric shocks, provided these defibrillators are at hand or might be rapidly put in action from ambulances; (2) need to convince patients to seek immediate medical advice thus reducing to a minimum the delay-phase from symptoms' onset, so frequently related to negation or disease' fear. Both issues might be resumed by the quote "*time is muscle*" and underline the concept whereby "the sooner the better." As orthogonal coronary circulation is terminal and irrigates a myocardial area that, in general, does not receive transverse or parallel coronary flow from collaterals, myocytes undergo irreversible damage after approximately 20 min of ischemia (Kalogeris et al., 2012). Then the irreversibly damaged area expands (from the center to the periphery in three dimensions) and having symptoms start as time zero, different time lags have been defined (from <60 to <120 min) (Reimer et al., 1977) whereby therapeutic procedures have or have not the probability of obtaining an acceptable recovery of contractile function and might be therefore considered successful. In recent years, the American Heart Association has encouraged a new quality measure called "first medical contact-to-balloon." The goal is to have the procedure completed within 90 min of emergency medical staff (EMS) arriving at the patient's side.

The 12-lead ECG is the most important diagnostic test that is used to screen patients who present with signs and symptoms of a possible STEMI (Voci et al., 2002; Manfrini et al., 2016a). In many health care systems, the ECG will be transmitted to the hospital so that physicians can read the ECG while the patient is still out of the hospital. Regionalized systems of care for STEMI have been developing all over the United States and Europe. Organizations such as the American College of Cardiology's "Door-to-Balloon Alliance" and the American Heart Association's "Mission: Lifeline" have been helping to promote best practices in STEMI care which have resulted in improved outcomes for patients experiencing this life-threatening clinical condition.

Chest Pain

A certain interindividual degree of variability may exist between the beginning of acute myocardial ischemia and symptoms onset. Animal experiments of acute coronary artery ligature induce ST segments shifts (**Fig. 2A**) in a time window of 5 sec to 5 min (Jouve et al., 1986). The clinical presentation of STEMI might be equated with the development of typical symptoms (**Fig. 2B**). All clinical complications (including SD) and delays should refer to chest pain onset as time zero (**Fig. 3**). One of the quality measures for STEMI care is the "door-to-balloon" (D2B) time or the amount of time it takes to successfully reopen the culprit artery. The clock starts when the patient arrives at the hospital and stops when the balloon is inflated in the coronary arteries. There are certain categories of patients (**Fig. 4**), like women, elderly and diabetics in whom the precise time zero might be defined with larger uncertainty (Ricci et al., 2016; Puddu et al., 2016; Bugiardini et al., 2015; Menotti and Puddu, 2016; Mehta et al., 2016). Some of these patients experience denial and dismiss their symptoms as heartburn or indigestion. When this happens they may delay seeking care for hours and angioplasty and stenting may be unsuccessful. Other conditions presenting with ST-segment elevation should be considered for differential diagnosis versus STEMI (**Fig. 5**).

Typical chest pain as disclosed after the interview is said to be characterized by a retrosternal sensation of pressure or heaviness radiating the most frequently to the left arm (more rarely to both arms or the right arm), neck and jaw, which may be intermittent with duration of several minutes and apparent disappearance or persistent. It may have developed independently of any efforts and may be related to some oxygen-increasing demand such as excitement, passion, arousal, or fear, which, in turn, may be accompanied by signs of enhanced sympathetic activation including cold sweating and higher systolic blood pressure due to increased peripheral resistances. Sometimes chest pain may be accompanied by signs of vagal activation including nausea and vomiting or sinus bradycardia. Sympathetic activation is more probable in patients with anterior STEMI whereas vagal activation accompanies more frequently patients with infero-posterior STEMI, which may imply a difference in outcome (Pocock et al., 2015).

Relief of pain by titrated intravenous opioids is recommended (Class I, Level C) once the diagnosis of STEMI is done which will be based on ECG and cardiac biomarkers abnormalities. This may also help relieving anxiety. If pain is accompanied by breathlessness, signs of hypoxemia ($SaO_2 < 95\%$) or of acute heart failure, oxygen administration is indicated (Class I, Level C).

ECG Signs

ECG should be initiated as soon as possible in all patients with suspected STEMI, as early as within 10 min of first medical contact. Although ECG may be normal, characteristic abnormalities include ST segment elevation, but sometimes patient at first presentation may show ST segment depression, and T wave changes. It is wise in these conditions to keep leads on the patient in order to repeat the 12-lead ECG at very short delay since evolution is particularly important to be documented whereas some electrical diagnostic criteria should be met in conjunction with the occurrence of typical chest pain. Code "STEMI" is an expression used in

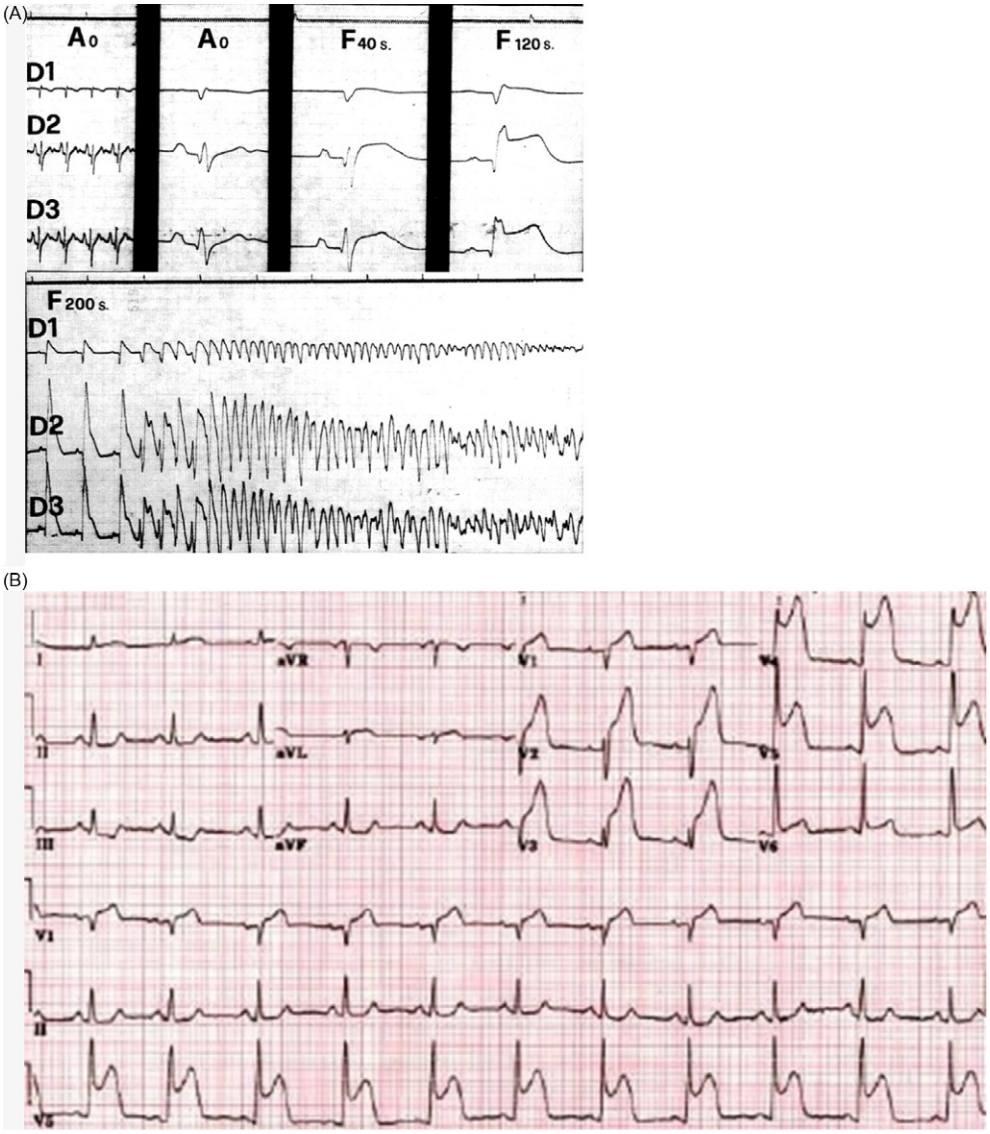

Fig. 2 ECG in experimental and clinical STEMI. Standard ECG may show immediate (earlier than 200 s) ST-segment elevation in latero-inferior leads after left circumflex coronary artery occlusion (due to ligation) in dogs (*panel A*), a critical risk factor for early postischemic ventricular fibrillation and sudden death (Jouve et al., 1986). In human, STEMI may have a similar evolution (*panel B*: here antero-septal localization) although the timing might request a longer evolution (see **Fig. 3**).

many EMS systems and emergency departments that essentially implies that physicians on first medical contact are formally requesting that a life-saving team be assembled immediately. This often means calling in the interventional cardiologist and cath-lab personnel in from home or more simply bypassing the closest hospital for the percutaneous coronary intervention (PCI)-capable hospital.

Localization of STEMI

Localization of STEMI, based on diagnostic ECG leads is important to drive the search of the potentially culprit coronary lesion (**Fig. 1**), which may give also a rough estimation of short- and long-term risks. These latter are related to the extent of the myocardial muscle loss and, thus, in part to the type of coronary artery involved. Indeed, the site of occlusion of the left anterior descending coronary artery is important in acute anterior MI because proximal occlusion is associated with less favorable outcome and prognosis. Of course, left main involvement is important as well. In that case, both left anterior descending and left circumflex coronary arteries are compromised and three quarters of the left ventricular muscle mass is at risk of acute ischemia.

Typically, ST-segment elevation in acute MI, measured at the level of the J point, should be detected in at least two adjacent leads and be of ≥ 0.20 mV in man and ≥ 0.15 mV in women in leads V_2–V_3 or ≥ 0.10 mV in the remaining leads. These cut-off values have

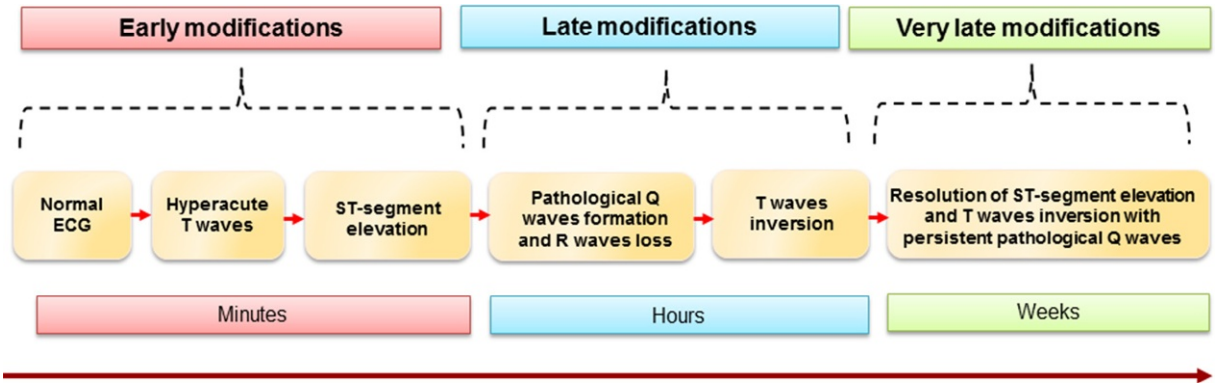

Fig. 3 Evolution of ECG in STEMI. Early to very late modifications might take weeks to occur in clinical acute myocardial infarction and are slower that what occurs after experimental coronary ligation (Goldman, 1986; Nable and Brady, 2009; Morris et al., 2008).

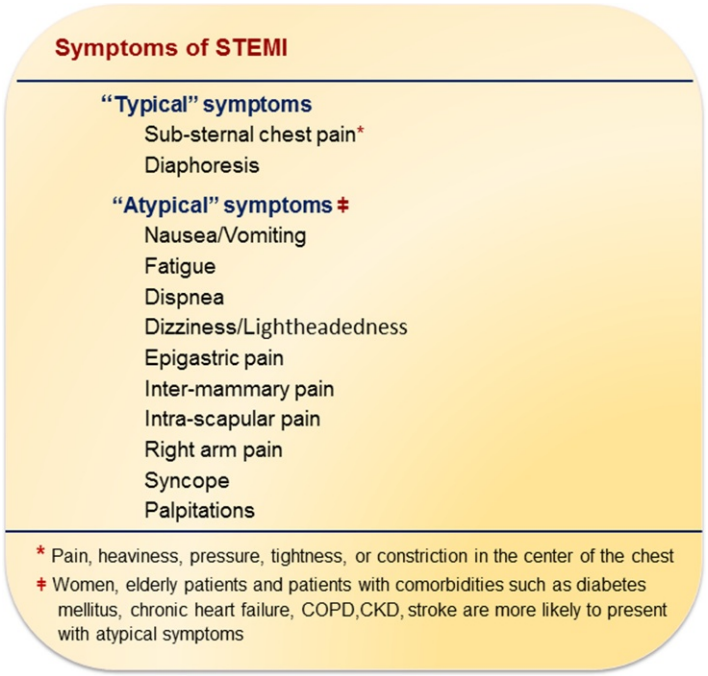

Fig. 4 Symptoms of STEMI. Typical versus atypical symptoms should be recognized in STEMI patients and might help to make the correct diagnosis in peculiar patients' groups (Vaccarino et al., 2013; Ricci et al., 2016; Milner et al., 2004; Manfrini et al.,2016b).

also an age dependency and, thus, in men younger than 40 years, the criterion is slightly higher (≥ 0.25 mV). In peculiar localizations, such as isolated right ventricular infarction with the nondominant right coronary artery, specific criteria were developed (Iannetta et al., 2013). In general, additional recording of nonstandard leads such as V_7–V_8 or V_{2R}–V_{3R} may be helpful to make the diagnosis in selected cases of infero-basal infarction where the circumflex coronary occlusion might be implicated. A quite large literature exists on standard ECG of STEMI (Nable and Brady, 2009; Ayer and Terkelsen, 2014; Deshpande and Birnbaum, 2014). Electrical abnormalities that occur at the onset of acute ischemia are easily recognized by successive ECG records where the classic evolution may be discovered, first at the level of the lesion (or Pardee's) wave consisting of the ST-T shifts and later in the development of the pathological (>40 ms in duration) Q wave. ST segment elevation in lead aVR, ST segment depression in lead V_5 and ST segment elevation in $V_1 > 2.5$ mm may strongly predict left anterior descending occlusion proximal to first septal, whereas abnormal Q wave in V_4–V_6 is often associated with occlusion distal to first septal.

Left bundle branch block

The diagnosis of STEMI in the presence of LBBB has been problematic for years. Until recently, the guidelines for management of acute MI recommended cath lab activation for patients with chest pain and new LBBB. The 2013 guidelines recommended the use of the Sgarbossa criteria, which are well known to be specific, but not sensitive enough. Still, the majority of physicians believe that

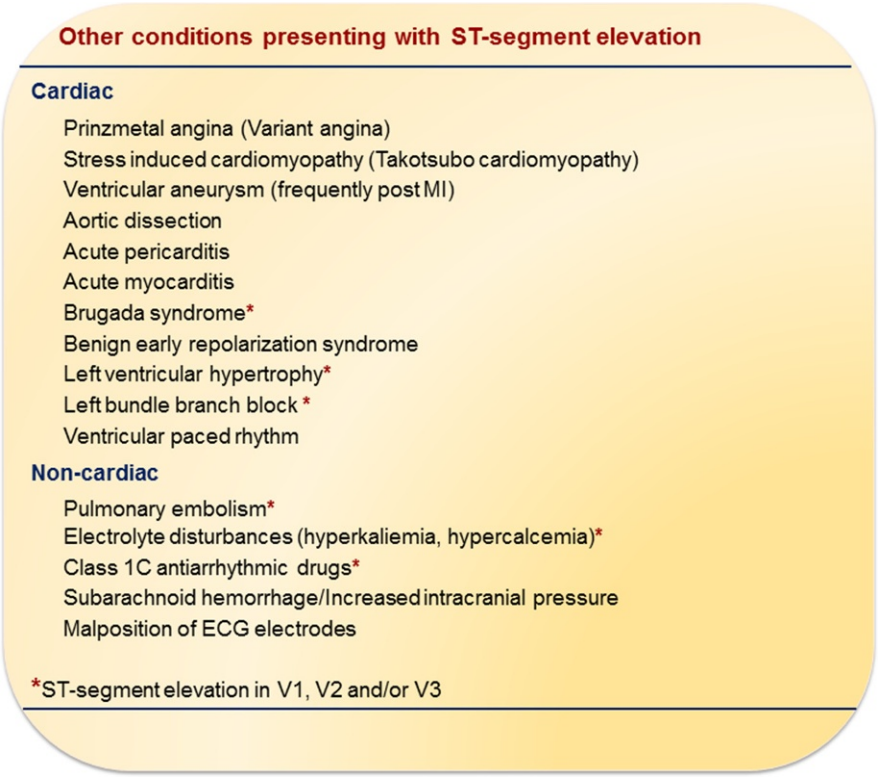

Fig. 5 Other conditions presenting with ST-segment elevation. Differential diagnosis of cardiac and noncardiac conditions should be frequently exercised and considered (Morris et al., 2008; Bonow et al., 2012; Thygesen et al., 2012b).

STEMI cannot be diagnosed in the setting of LBBB. A particularly difficult diagnosis of STEMI is that occurring in the presence of LBBB. In the presence of LBBB and typical symptoms, it is mandatory to repeat blood samples for serum marker determinations without waiting for the results before initiating reperfusion therapy (Class I, Level C).

Atypical ECG presentations

There are conditions such as ventricular paced rhythms, no ST-segment elevation but with persistent ischemic symptoms such as pain or dyspnea, isolated posterior MI, or ST-segment elevation in lead aVR that deserve prompt management and for whom appropriate differential diagnosis should be developed or the evolution of STEMI confirmed. Also among these patients, an essential target is represented by minimizing delays, not only as an objective means of indexing the quality of care but also as a practical tool for improving outcomes.

Prior myocardial infarction

STEMI resulting from total coronary occlusion leads to more homogeneous tissue damage and are usually reflected by a Q-wave MI pattern on the ECG. Pathologic Q waves are not an early sign of MI, but generally, take several hours to days to develop. If STEMI is reperfused early (e.g., as a result of PCI) stunned myocardial tissue can recover and pathologic Q waves may disappear. Definition of a pathologic Q wave can be summarized as follows: any Q-wave in leads V_2–$V_3 \geq 0.02$ s or QS complex in leads V_2 and V_3; Q-wave ≥ 0.03 s and >0.1 mV deep or QS complex in leads I, II, aVL, aVF, or V_4–V_6 in any two leads of a contiguous lead grouping (I, aVL, V_6; V_4–V_6; II, III, and aVF); R-wave ≥ 0.04 s in V_1–V_2 and $R/S \geq 1$ with a concordant positive T-wave in the absence of a conduction defect. It should be noted that the absence of pathologic Q waves does not exclude a MI.

Cardiac Biomarkers

Cardiac markers are used in the diagnosis and risk stratification of patients with chest pain and suspected STEMI (Reed et al., 2017; Anderson and Morrow, 2017). The cardiac troponins, in particular, have become the cardiac markers of choice (cardiac troponin I or T (Twerenbold et al., 2012; Reiter et al., 2012; Thygesen et al., 2012a; Shah et al., 2015)).

In 2012, the Nucleus of the Working Group of the European Society of Cardiology on Acute Cardiac Care prepared a document summarizing the use of high-sensitivity cardiac troponin in clinical routine whereby six points were defined (Thygesen et al., 2012a): (1) There is a need to use the 99th percentile concentration of the reference population as the specific cardiac troponin upper reference limit. (2) A significant change with serial testing is required for diagnosing MI. At low cardiac troponin baseline

concentrations (around the 99th percentile), the change in serial testing in order to be clinically significant requires to be marked, in case of markedly elevated baseline, a minimum change of 20% in follow-up testing is required. (3) An additional testing of other early markers of acute myocardial necrosis, such as myoglobin or creatine kinase-MB (CK-MB) is no longer needed. (4) Blood sampling in patients with suspicion of MI should be performed on admission and 3 h later. Measurement of high-sensitivity cardiac troponin should be repeated 6 h after admission in patients of whom the 3 h values are unchanged but in whom the clinical suspicion of MI is still high. (5) Cardiac troponin is a marker of myocardial necrosis and not a specific marker of MI. The latter may be only diagnosed with a rise and/or fall of cardiac troponin together with characteristic symptoms, and/or ECG changes indicative of ischemia and/or imaging evidence of acute myocardial ischemia, as stated above. In the presence of abnormal changes of cardiac troponin, therefore, also other causes of myocardial necrosis (e.g., acute heart failure or myocarditis) should be considered differentially. (6) Stable or inconsistently variable cardiac troponin values without significant dynamic changes are likely the markers of chronic structural heart disease. Thus, although elevations in the serum levels of TnI, TnT, and CK-MB indicate the presence of injury-associated necrosis of myocardial cells, such elevations do not point to the underlying mechanism of the necrosis.

There are several critical clinical concepts regarding the analytical characteristics of hs-cTn assays (Thygesen et al., 2012a). The most important criticism is that the hs-cTn assays have high precision at lower concentration ranges with an analytical coefficient of variation <10% at the 99th percentile concentration of the reference population. Thus, most TnI assays are imprecise at the 99th percentile reference limit. However, the advantage of ultrasensitive troponins is based on the premise that lower cutoff levels achieve a higher sensitivity that will allow earlier diagnosis, often within 90 min of presentation. hs-cTn is now used for confirming of ruling out MI based on an absolute value of 14 pg/mL (or 0.014 μg/L) (**Fig. 6**) as a differentiating cut-off value (Twerenbold et al., 2012).

Recently, Shah and colleagues (Shah et al., 2015; Cullen et al., 2015) reported results of a prospective observational cohort study of 6304 patients presenting at emergency departments with suspected MI. They identified a threshold for a high-sensitivity cardiac troponin I assay below which patients were at low risk of MI and potentially suitable for early discharge from the hospital. The investigators derived 5 pg/mL as the optimum cutoff for cardiac troponin I concentration, using a predefined negative predictive value of 99.5% as an acceptable threshold of safety. This threshold enabled a large proportion of the total patients presenting to emergency departments (2311 [47%] of 4870) to be identified on presentation as at low risk for events at presentation and at 30 days follow-up. This investigation represents a huge advance in the assessment of patients with possible MI in emergency departments and prompts further collaboration between clinicians and their laboratory colleagues to identify optimum assessment strategies on troponin assay.

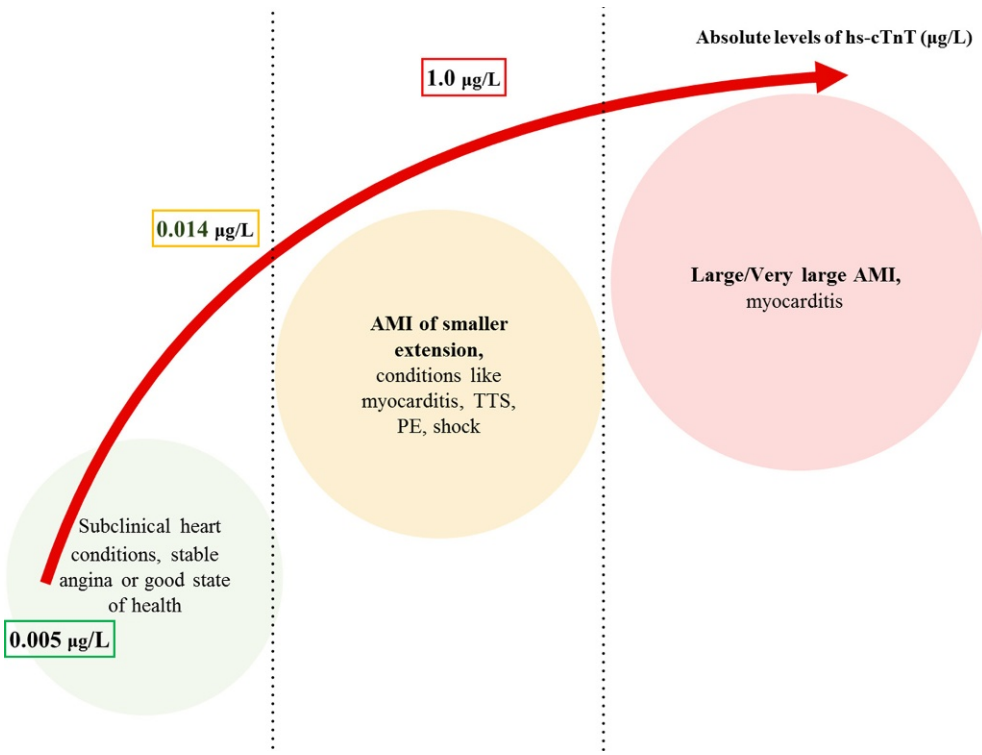

Fig. 6 Differential diagnosis based on high-sensitive troponin T. Absolute levels of hs-cTnT are directly related to the STEMI condition with a cut-off value (14 pg/mL) that might be defined with great accuracy (Twerenbold et al., 2012; Thygesen et al., 2012a).

Introduction

In 1971, Doctor Eugene Braunwald stated that in the setting of acute myocardial infarction "time is muscle" (Maroko et al., 1971). Subsequent numerous studies demonstrated that early reperfusion of the occluded coronary artery significantly improves in-hospital and long-term outcome, and also that benefits of reperfusion therapy are the greatest when it is performed as soon as possible from the onset of symptoms.

Consequently, the key point for a successful management of ST-elevation myocardial infarction (STEMI) patients is the timely diagnosis and the optimal revascularization of the ischemic myocardial tissue; physicians should be able to rapidly identify and treat the majority of STEMI patients, which is the most important advancement in the treatment of these patients and may positively impact morbidity and mortality (Anderson and Morrow, 2017).

 https://doi.org/10.1016/B978-0-12-809657-4.99744-8

The objectives of STEMI management are:

1. Minimizing delay to reperfusion.
2. Reducing area of myocardial ongoing necrosis by selecting the timely suitable reperfusion.
3. Preventing and treating possible complications of the acute phase.
4. Preventing major adverse cardiovascular events during long-term follow-up.

Delay to Reperfusion

Definitions of Time Delays

The first medical contact (FMC) is the moment at which the patient is either initially assessed by a paramedic or a physician in the prehospital (i.e., emergency medical service (EMS)) or hospital setting (Steg et al., 2012).

The ideal time from "*FMC to diagnosis*" should be equal or inferior to 10 min. Therefore, at the point of FMC, a 12-lead electrocardiogram (ECG) should be obtained immediately with an acceptable delay $\leq$10 min.

The time between FMC and reperfusion therapy is called "*system delay*." It is an indicator of the quality of care and a predictor of outcomes. If patients undergo primary percutaneous coronary intervention (PCI), the time lag between FMC and wire passage/balloon inflation through the culprit lesion is called "*time to balloon*" and should be $\leq$120 min (preferably $\leq$90 min), whereas if the reperfusion choice is fibrinolysis (because primary PCI cannot be performed within 120 min), the time lag between FMC and starting of thrombolysis infusion is called "*time to needle*" and should be $\leq$30 min (Steg et al., 2012).

The overall time from symptom onset to reperfusion is called "*time to reperfusion therapy*" (Steg et al., 2012). It is the sum of "*system delay*" and "*patient delay*" (that is the time interval from symptom onset to FMC).

The ability of patients to recognize symptoms possibly related to myocardial ischemia and seek for medical attention is an important aspect of a successful early management of STEMI. To minimize *patient delay*, the public should be made aware of how to recognize possible symptoms of acute myocardial ischemia and about the relevance of calling immediately the EMS.

Role of the EMS

The ambulance service has a critical role in the management of STEMI because it is not only a mode of transport but also a place for initial diagnosis, triage, and treatment.

The goals of the EMS are (1) to make a working diagnosis of STEMI within 10 min, (2) to deploy emergency cardiac care, and (3) to transport the patient, in an acceptable time period, to hospital capable of advanced coronary care for reperfusion therapy (primary PCI or fibrinolysis). The availability of an EMS (i.e., ambulance), capable of recording, interpreting and/or transmitting ECGs to the emergency department (ED) or cardiac catheterization laboratory is the other fundamental factor for a successful early management of STEMI patients. The quality of the care given by EMS depends on the training of the staff. All ambulance personnel should be trained to recognize the symptoms of an acute coronary syndrome, administer oxygen, relieve pain, and provide *basic life support*. All emergency ambulances should be equipped with defibrillators and at least one person on board trained in *advanced life support*.

The initial medications to be given are aspirin (162–325 mg, chewed), sublingual nitroglycerin (0.3–0.4 mg, two times at 5 min interval) for the relief of pain, and oxygen supplementation in the case of hypoxia ($SaO_2 < 90\%–95\%$) or respiratory distress.

Candidates for primary PCI should be transferred by the EMS straight to the catheterization laboratory, bypassing the ED and intensive coronary care unit, while patient candidates for fibrinolysis can be treated in the ED, in the coronary care unit or directly in the prehospital setting (Ting et al., 2008; Amit et al., 2007). Indeed, the delay from symptom onset to treatment can be safely shortened by administration of prehospital fibrinolytic and other antithrombotic therapy, by a trained EMS unit either with a physician on board or with a hospital-based physician in direct contact, when transit time to PCI-capable hospital is longer than 120 min (O'Gara et al., 2013).

In case of cardiac arrest, advanced cardiac life support, which includes a prompt cardiopulmonary resuscitation and early defibrillation, is indicated. Therapeutic hypothermia is indicated in patients who are comatose after resuscitation, at hospital arrival, whereas infusion of cold liquid in the prehospital setting does not provide beneficial effects on outcome. Moreover, immediate angiography with a view to primary PCI is recommended in patients with resuscitated cardiac arrest whose ECG shows STEMI (Steg et al., 2012).

Early Hospital Assessment

The initial evaluation and management of patients with STEMI involves several steps which can be categorized by the following interventions, without any gender, race, and age differences.

1. Put patients at bed rest with the availability of bedside resuscitation equipment to rapidly treat sustained ventricular arrhythmias, if needed; indeed, the very early phase of an acute myocardial infarction is the most crucial phase, in which patients are at higher risk of fatal arrhythmias and cardiac arrest.

2. Get 12-lead ECG and set ECG monitoring to detect life-threatening arrhythmias and ST-segment changes (Steg et al., 2012).
3. Collect blood samples for evaluating markers of myocardial necrosis (preferably cardiac troponin).
4. Place intravenous access.
5. Take patients anamnesis and physical exam, in order to (1) recognize contraindications to recommended treatments, (2) assess signs of hemodynamic instability or left heart failure, and (3) determine baseline neurologic function (particularly if fibrinolytic therapy is to be given).

Adjunctive Medical Therapy

Most patients arrive at the hospital without the assistance of the EMS. At hospital arrival, patients who have not yet received aspirin or nitrates should receive them, immediately after the working diagnosis of STEMI is made. Soon after, morphine (if necessary) and oxygen supplementation (if necessary), other antiplatelet and anticoagulant agents (accordingly to the reperfusion strategy), as well as statin, beta-blocker, and angiotensin converting enzyme (ACE)-inhibitors should be given otherwise contraindicated (**Tables 1–4**).

The objective of the adjunctive therapy is to slow down the progression of ongoing myocardial ischemic necrosis, by means of:

– improving the oxygen myocardial demand–supply (oxygen supplementation, nitrates, ACE-inhibitors, and beta-blockers);
– antagonizing some of the pathophysiological mechanisms involved in the progression of the intracoronary thrombus: (1) platelet aggregation and activation (antiplatelet and anticoagulant agents), (2) vasoconstriction (nitrates and beta-blockers), (3) sympathetic activation (morphine, ACE-inhibitors, and beta-blockers), and (4) plaque instability (statins).

Aspirin

The great benefit of platelet aggregation inhibition therapy in patients with acute myocardial ischemia has been largely demonstrated. The use of aspirin (**Table 1**) versus placebo is associated with a decrease (>50%) in death or myocardial reinfarction (RISC Group, 1990; Cairns et al., 1985). Both American and European guidelines (Steg et al., 2012; O'Gara et al., 2013) recommend a loading dose of aspirin (162–325 mg) as soon as possible, irrespective of the reperfusion strategy (primary PCI, fibrinolysis) and even in late-comers (patients arriving at medical attention too late for reperfusion or patients who did not receive reperfusion for other reason). Moreover, indefinite low-dose aspirin (75–100 mg) is beneficial for secondary prevention (low-dose aspirin still has a protective role in ischemic events, but causes less bleeding than higher doses) (Steg et al., 2012; O'Gara et al., 2013).

Nitrates

Nitroglycerin (**Table 1**) has an endothelium-independent vasodilatory effect on the coronary and peripheral vascular beds. The administration of sublingual nitroglycerin followed by i.v. nitrates may be useful in order to relieve anginal symptoms and decrease cardiac workload in patients with uncontrolled hypertension or congestive heart failure. Hypotension, right ventricular infarction,

Table 1 Initial adjunctive therapy (Steg et al., 2012; O'Gara et al., 2013)

Drug	*Suggested dose*	*Caution/contraindication*
Aspirin	Primary PCI: loading dose 150–300 mg orally (or 80–150 mg i.v.) Fibrinolysis: starting dose 150–500 mg orally (or 250 mg i.v.) Not reperfusion: starting dose 150–500 mg orally Maintenance dose 75–100 mg/day	Active bleeding at admission. Severe chronic. Kidney disease. Allergy
Nitroglycerin	● 0.4 mg sublingual every 5 min up to 3 doses as BP allows ● i.v. dosing to begin at 10 mcg/min; titrate to desired BP effect	Suspected RV infarction. SBP <90 mmHg or if SBP >30 mmHg below the baseline. 5′-phosphodiesterase inhibitors (<24–48 h).
Morphine	● 4–8 mg i.v. initially, with lower doses in elderly ● 2–8 mg i.v. every 5–15 min if necessary	Hypotension. Bradycardia. Known hypersensitivity
Oxygen	● 2–4 L/min via nasal cannula ● Increase rate or change to face mask as needed	Caution with chronic obstructive pulmonary disease

i.v., Intravenous; *BP*, blood pressure; *RV*, right ventricular; *SBP*, systolic blood pressure; *PCI*, percutaneous coronary intervention.

Table 2 Other antiplatelet therapy (Steg et al., 2012)

Drug	*Setting*	*Suggested dose*	*Caution/contraindication*
$P2Y_{12}$ inhibitors			
Clopidogrel	Primary PCI	Loading dose 600 mg orally	Active bleeding. Use of repaglinide
	Fibrinolysis	Loading dose:300 mg orally (<=75 years old)	
	Not reperfusion	75 mg/day orally	
	Maintenance dose	75 mg/day orally	
Prasugrel[a]	Primary PCI	Loading dose 60 mg orally	Prior stroke. Transient ischemic attack. Liver disease (moderate-to-severe)
	Maintenance dose	10 mg/day (5 mg/day in pts < 60 Kg)	
Ticagrelor	Primary PCI	Loading dose: 180 mg orally	
	Maintenance dose	90 mg twice a day	
GP IIb/IIIa-inhibitors			
Abciximab	Primary PCI	Bolus of 0.25 mg/kg i.v. and 0.125 μg/kg/min infusion (max. 10 μg/min) for 12 h.	Active bleeding. Coagulation disorders. Severe hypertension
Eptifibatide	Primary PCI	Double bolus of 180 μg/kg i.v. (given at a 10-min interval), followed by an infusion of 2.0 μg/kg/min for 18 h.	
Tirofiban	Primary PCI	25 μg/kg over 3 min i.v., followed by a maintenance infusion of 0.15 μg/kg/min for 18 h.	

PCI, percutaneous coronary intervention; *i.v.*, intravenous; *GP IIb/IIIa*, glycoprotein IIb/IIIa.
[a]Prasugrel is not recommended in patients ≥ 75 years or in body weight < 60 kg.

Table 3 Anticoagulant medication (Steg et al., 2012)

Drug	*Setting*	*Suggested dose*	*Caution/contraindication*
UFH	Primary PCI	• 70–100 U/kg i.v. bolus without GPIIb/IIIa inhibitors • 50–60 U/kg i.v. bolus with GPIIb/IIIa inhibitors	Active bleeding. Thrombocytopenia with antiplatelet antibody in the presence of enoxaparin or heparin. Severe renal impairment. Severe liver disease
	Fibrinolysis[a]	60 U/kg i.v. bolus (max. 4000 U) followed by an i.v. infusion of 12 U/kg (max. 1000 U/h) for 24–48 h.	
	Not reperfusion	As in fibrinolysis	
Enoxaparin	Primary PCI	0.5 mg/kg i.v. bolus	
	Fibrinolysis	- *In pts. <75 years*: 30 mg i.v. bolus followed 15 min later by 1 mg/kg s.c. every 12 h until hospital discharge for a maximum of 8 days The first two doses should not exceed 100 mg. - *In pts. >75 years*: no i.v. bolus; start with a first subcutaneous dose of 0.75 mg/kg with a maximum of 75 mg for the first two subcutaneous doses. - *In pts. with creatinine clearance of <30 mL/min*, the subcutaneous doses are given once every 24 h.	
	Not reperfusion	As in fibrinolytic Tp.	
Bivalirudin	Primary PCI	0.75 mg/kg i.v. bolus followed by i.v infusion of 1.75 mg/kg/h for up to 4 h after the procedure as clinically warranted. Later, 0.25 mg/kg/h may be continued for 4–12 h as clinically necessary	
Fondaparinux	Fibrinolysis	2.5 mg i.v. bolus followed by a subcutaneous dose of 2.5 mg once daily up to 8 days or hospital discharge	

PCI, percutaneous coronary intervention; *UFH*, unfractionated heparin; *i.v.*, intravenous; *GP*, glycoprotein IIb/IIIa.
[a]*Target aPTT*: 50–70 s or 1.5–2.0 times that of control to be monitored at 3, 6, 12, and 24 h.

Table 4 Other adjunctive therapy (O'Gara et al., 2013)

Therapy	*Drug*	*Suggested dose*	*Caution/contraindication*
Beta-blocker	Metoprolol	• Tartrate 25–50 mg every 6–12 h orally, then transition over next 2–3 days to twice-daily dosing of metoprolol tartrate or to daily metoprolol succinate; titrate to daily dose of 200 mg as tolerated • Tartrate i.v 5 mg every 5 min as tolerated up to 3 doses; titrate to heart rate and BP	Signs of heart failure. Low output state. Increased risk of cardiogenic shock. Prolonged first-degree or high-grade. AV block. Reactive airways disease
	Carvedilol	6.25 mg twice daily, titrate to 25 mg twice daily as tolerated	
ACE-inhibitors	Lisinopril	2.5–5 mg/day to start; titrate to 10 mg/day or higher as tolerated	Hypotension. Renal failure. Hyperkalemia
	Captopril	6.25–12.5 mg 3 times/day to start; titrate to 25–50 mg 3 times/day as tolerated	
	Ramipril	2.5 mg twice daily to start; titrate to 5 mg twice daily as tolerated	
	Trandolapril	Test dose 0.5 mg; titrate up to 4 mg daily as tolerated	
ARB	Valsartan	20 mg twice daily to start; titrate to 160 mg twice daily as tolerated	Hypotension. Renal failure. Hyperkalemia
Statins	Atorvastatin	80 mg daily	Caution with drugs metabolized via CYP3A4, fibrates. Monitor for myopathy, hepatic toxicity. Combine with diet and lifestyle therapies. Adjust dose as dictated by targets for LDL cholesterol and non–HDL cholesterol reduction

ARB, Angiotensin receptor blockers; *i.v.*, intravenous; *AV*, atrioventricular; *ACE*, angiotensin converting enzyme.

or patients who have taken phosphodiesterase type 5 inhibitors (for erectile dysfunction or pulmonary hypertension) in the previous 48 h should be excluded from the administration of nitrates (Steg et al., 2012).

Morphine

Morphine (**Table 1**) is the most common analgesic used in STEMI patients, in order to relieve pain. Relief of pain is important because severe pain is associated with sympathetic activation that causes vasoconstriction and increases the workload of the heart and the risk of ventricular arrhythmias. The use of morphine may have some side effects, such as nausea and vomiting, hypotension with bradycardia, and respiratory depression (Steg et al., 2012). The hypotension and bradycardia will usually respond to atropine and the respiratory depression to naloxone (0.1–0.2 mg i.v.) (Steg et al., 2012). On the routine use of morphine in the prehospital setting, some controversies exist. Indeed, there is evidence of no benefit from prehospital morphine use, in terms of in-hospital complications and 1-year mortality (Puymirat et al., 2016).

Oxygen

Supplemental oxygen (**Table 1**), administered by mask or nasal prongs, is recommended in patients with an arterial saturation (SaO_2) < 90–95%, respiratory distress, and acute heart failure. The effects of systematic administration of oxygen in normoxic patients with STEMI, or in patients without heart failure or dyspnea, remain unclear (Cabello et al., 2016; Stub et al., 2015).

Other Antiplatelet Agents

Given that platelet activity plays a critical role in the formation and progression of intracoronary thrombus, efforts to inhibit platelet function are paramount to the management of STEMI patients. Inhibition of platelet aggregation can be achieved by different mechanisms of action, either by blockade of membrane receptors or by interaction with intracellular signaling pathways (Gresele et al., 2011). Available agents are *aspirin* (acetylsalicylic acid), which targets cyclooxygenase-1, inhibiting thromboxane A2 formation and inducing a functional permanent inhibition in platelets; *P2Y12 antagonists*, which attenuates the secondary responses to adenosine diphosphate (ADP) released by activated platelets, inhibiting activation of the glycoprotein IIb/IIIa complex and platelet aggregation; and *glycoprotein IIb/IIIa inhibitors* (abciximab, tirofiban, and eptifibatide), which target the final common pathway of platelet aggregation.

$P2Y_{12}$ Inhibitors

The $P2Y_{12}$ inhibitors are useful for further inhibiting platelet activation and aggregation. The choice of the $P2Y_{12}$ receptor blocker (*Clopidogrel*, *Prasugrel*, and *Ticagrelor*) depends on the reperfusion strategy.

Clopidogrel (**Table 2**) is a second-generation thienopyridine that irreversibly antagonizes the platelet $P2Y_{12}$ ADP receptor. Clopidogrel added to aspirin reduces the risk of death and other cardiovascular events in who will be treated with fibrinolysis (Steg et al., 2012; Chen et al., 2005a; Sabatine et al., 2005). However, in the setting of primary PCI, current guidelines prefer ticagrelor or prasugrel, because they have been proven to be superior to clopidogrel in large outcome trials in the risk of death and other major cardiovascular events at 1-year follow-up (Wiviott et al., 2007; Wallentin et al., 2009; O'Gara et al., 2013; Steg et al., 2012).

Prasugrel (**Table 2**) is a third-generation thienopyridine $P2Y_{12}$ inhibitor, which is metabolized to its active form more quickly and fully than clopidogrel, and thus has a more potent and consistent effect (Gurbel et al., 2012). The TRITON trial compared the use of prasugrel versus clopidogrel in patients with acute coronary syndromes receiving aspirin. The study showed that the use of prasugrel was associated with a reduction in risk of cardiovascular death, nonfatal myocardial infarction, and nonfatal stroke, but an increased risk of major bleeding (Wiviott et al., 2007). Therefore, prasugrel is contraindicated in patients with prior stroke/transient ischemic attack or active pathological bleeding. Lower body weight (<60 kg) and age ≥ 75 years are relative contraindications (Steg et al., 2012).

Ticagrelor (**Table 2**) is a new $P2Y_{12}$ receptor blocker. Unlike clopidogrel or prasugrel, ticagrelor is not a thienopyridine. It is a direct-acting agent with a reversible effect, which does not require biotransformation and binds reversibly to the $P2Y_{12}$ receptors, antagonizing ADP signaling and platelet activation. The PLATO trial compared ticagrelor to clopidogrel in patients with acute coronary syndromes treated with aspirin and other standard therapy. Results showed that ticagrelor reduces the composite of cardiovascular death, myocardial infarction, or stroke at 12 months, without an increase in the rate of overall major bleeding, but with an increase in the rate of non-procedure-related bleeding (Wallentin et al., 2009).

Dual Antiplatelet Therapy

Dual antiplatelet therapy (DAPT) is the combination of aspirin and one ADP-receptor blocker (clopidogrel, prasugrel, or ticagrelor). The duration of DAPT is a matter of discussion. After coronary intervention and stent placement, struts are triggered for acute intracoronary thrombosis until a complete reendothelialization of the coronary artery. To reduce the risk of acute stent thrombosis after primary PCI, the period of DAPT, preferably with prasugrel or ticagrelor, should be up to 12 months in all STEMI patients, with a strict minimum of 1 and 6 months for patients receiving bare-metal stent and drug-eluting stent, respectively (Wiviott et al., 2007; Wallentin et al., 2009; Steg et al., 2012). DAPT with clopidogrel is indicated in addition to aspirin in adjunct to fibrinolysis (while prasugrel and ticagrelor have not been studied and should not be given) for a minimum of 14 days if coronary angiography and subsequent PCI do not increase the recommended duration of DAPT (O'Gara et al., 2013; Anderson and Morrow, 2017).

Glycoprotein IIb/IIIa (GPIIb/IIIa) Inhibitors

Abciximab, tirofiban, and eptifibatide inhibit the final common pathway of platelet activation and are the most potent antiplatelet agents (**Table 2**). Their role in the management of acute myocardial ischemia has changed through the past years. Once they were widely used. With the advent of DAPT, GPIIb/IIIa inhibitors have slowly lost their importance in routine low-risk PCI (Subban and Sarat Chandra 2013), but GPIIb/IIIa inhibitors should be considered for bailout therapy if there is angiographic evidence of massive thrombus, slow or no-reflow or a thrombotic complication (Steg et al., 2012).

Anticoagulant Agents

Benefits of the use of anticoagulant agents (**Table 3**) in STEMI patients are strongly supported by several pieces of evidence, either in patients managed invasively (primary PCI) or conservatively (fibrinolysis), and even in those STEMI patients not undergoing reperfusion. The management of acute coronary syndromes with anticoagulants can be achieved by three classes of drugs: (1) *unfractionated heparin* (UFH) and the *low molecular weight heparins* (LMWH), which are indirect thrombin inhibitors; (2) *bivalirudin*, which is a direct thrombin inhibitor (Lefkovits and Topol, 1994); and (3) *fondaparinux*, which is a synthetic heparin and an indirect inhibitor of factor Xa. The choice of the anticoagulant agent depends on the reperfusion strategy.

UFH and LMWH. It is widely demonstrated that the use of UFH in association with aspirin in the acute phase on an acute coronary syndrome reduces the incidence of myocardial infarction and death (Oler et al., 1996; RISC Group, 1990). UFH is recommended both in patients undergoing primary PCI and in those receiving fibrinolysis (Steg et al., 2012). *Enoxaparin* can be used instead of UFH both in patients receiving primary PCI or fibrinolysis. UFH is preferred in patients undergoing primary PCI, whereas enoxaparin is preferred in patients receiving fibrinolysis (Steg et al., 2012; Murphy et al., 2007).

Bivalirudin. The use of bivalirudin over UFH and GPIIb/IIIa inhibitors is recommended in patients undergoing primary PCI (Steg et al., 2012). The superiority of bivalirudin over the combination of UFH + GP IIb/IIIa inhibitor is driven by a reduction in bleeding, associated with an initial increase in stent thrombosis, which disappears after 30 days (Steg et al., 2012; Mehran et al., 2009; Stone et al., 2008).

Fondaparinux. Fondaparinux is not recommended in patients undergoing primary PCI because fondaparinux increases catheter-related thrombosis during PCI (Yusuf et al. 2006a,b).

Triple Antithrombotic Therapy

The triple antithrombotic therapy is the combination of aspirin, an ADP-receptor antagonist, and an anticoagulant agent. In STEMI patients who are not undergoing reperfusion therapy, the association between aspirin, UFH, and clopidogrel reduces in-hospital mortality and does not significantly increase the risk of major bleeding (Bugiardini et al., 2015).

Beta-Blockers

The beneficial role of beta-blockers (**Table 4**) in the very early phase of STEMI is well known (O'Gara et al., 2013; Steg et al., 2012; Bugiardini et al., 2016; Chen et al., 2005b). They exert these benefits by improving left ventricular function and in-hospital survival rate through reducing infarct size. Current guidelines recommend that *oral beta-blockers* should be initiated in the first 24 h in all STEMI patients without contraindications, such as signs of heart failure, evidence of a low-output state, and increased risk for cardiogenic shock (O'Gara et al., 2013; Steg et al., 2012). The use of *i.v. beta-blockers* should be considered in STEMI patients with ongoing ischemia or high blood pressure or tachycardia, without signs of heart failure or other contraindications (O'Gara et al., 2013; Steg et al., 2012).

Angiotensin Converting Enzyme Inhibitors

In STEMI patients with evidence of heart failure, left ventricular systolic dysfunction (ejection fraction <40%), diabetes, or an anterior infarct the use of ACE-I (**Table 4**) is indicated within the first 24 h (unless contraindicated). In patients intolerant to ACE-I, an angiotensin receptor blocker, preferably valsartan, is an alternative (O'Gara et al., 2013; Steg et al., 2012).

Statins

The beneficial effect of statins (**Table 4**) has been widely demonstrated not only for secondary prevention (Baigent et al., 2005), but also in the early phase of myocardial infarction (Schwartz et al., 2001; Cannon et al., 2004). Therefore, early high-intensity statin therapy should be administered in all STEMI patients, regardless of lipid profile (O'Gara et al., 2013; Steg et al., 2012). The PROVE-IT trial compared standard statin therapy (40 mg of pravastatin daily) with intensive statin therapy (80 mg of atorvastatin daily), showing that an intensive lipid-lowering regimen provides greater protection against death or major cardiovascular events than does a standard regimen (Cannon et al., 2004).

Reperfusion Therapy

Reperfusion therapy is the primary therapeutic goal. Reperfusion therapy is indicated in all patients with persistent ST-segment elevation (or presumed new left bundle branch block) and symptoms of ongoing ischemia.

Dissolution or removal of the intracoronary thrombus provides the best chance for mortality reduction. The atherosclerotic coronary artery plaque rupture causes intracoronary platelet aggregation, platelet activation, fibrin deposition, and downstream myocardial ischemia and necrosis. The latter is time dependent: every minute wasted increases the risk of heart failure, patient morbidity, and death. For every 30 min of ischemia, mortality increases 8–10% (Pinto et al., 2006; O'Gara et al., 2013).

Reperfusion therapy (**Fig. 1**) can be performed by pharmacological (fibrinolysis) or mechanical catheter-based (primary PCI) approaches (O'Gara et al., 2013; Steg et al., 2012).

Percutaneous Coronary Intervention

Primary PCI is defined as an emergent percutaneous catheter intervention in the setting of STEMI, without previous fibrinolytic treatment. Primary PCI is the recommended reperfusion therapy over fibrinolysis if performed by an experienced team within 120 min from FMC (O'Gara et al., 2013; Steg et al., 2012). Primary PCI should be done within 12 h from symptom onset, but even later if symptoms and ST-segment elevation are still there or have been stuttering. When primary PCI cannot be performed within 120 min from FMC, fibrinolysis should be considered, particularly if it can be given in a prehospital setting (e.g., in the ambulance) and within the first 30 min of symptom onset (Bonnefoy et al., 2002, 2009; Morrison et al., 2000; Pinto et al., 2011; Steg et al., 2012). The superiority of primary PCI has been well established by several randomized clinical trials that compared primary PCI with in-hospital fibrinolytic therapy (Zijlstra et al., 1999; Keeley et al., 2003; Andersen et al., 2003; Steg et al., 2012). Primary PCI is effective in securing and maintaining coronary artery patency and avoids some of the bleeding risks of fibrinolysis. The advantages of primary PCI over fibrinolysis include lower rates of early death, reinfarction, and intracranial hemorrhage.

According to current international guidelines, during primary PCI, in patients with significant multivessel disease, only the infarct-related artery (culprit lesion) should be treated, unless the patient is in cardiogenic shock or has persistent ischemia after PCI of the supposed culprit lesion (Steg et al., 2012). However, more recently, three randomized trials showed reductions in ischemia-driven revascularization and variable effects on the risks of recurrent myocardial infarction and death with PCI of nonculprit stenosis (Wald et al., 2013; Engstrøm et al., 2015; Gershlick et al., 2015).

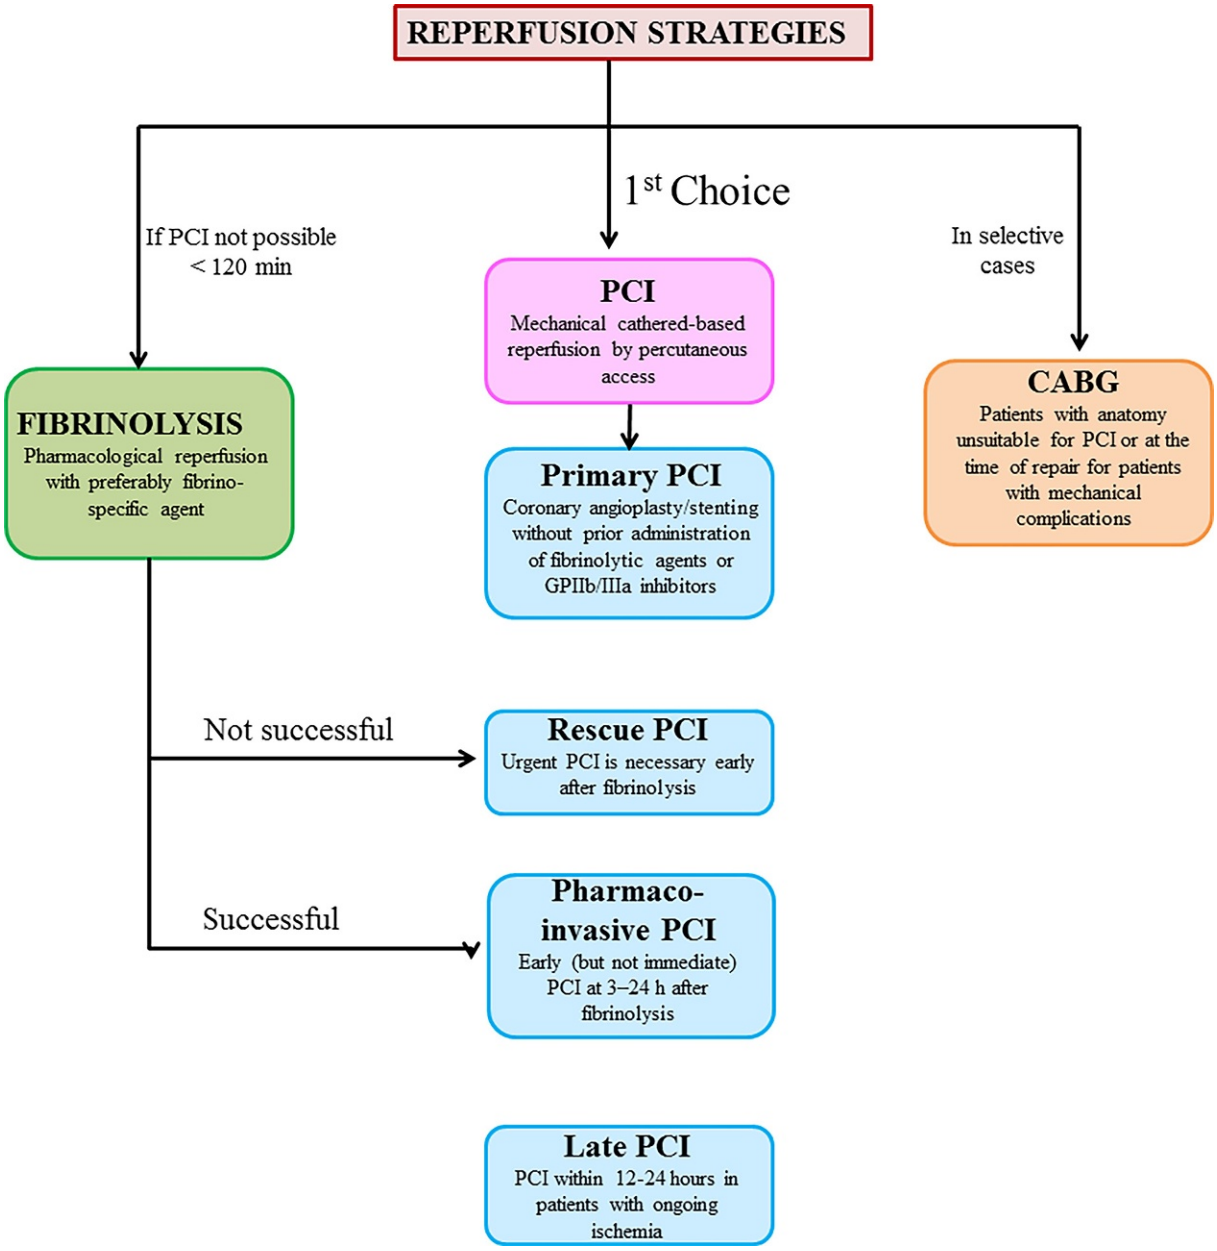

Fig. 1 Reperfusion strategies in STEMI patients (Steg et al., 2012; O'Gara et al., 2013). *PCI*, percutaneous coronary intervention; *CABG*, coronary artery bypass surgery; *GP IIb/IIIa*, glycoprotein IIb/IIIa inhibitors.

The use of stent over balloon angioplasty alone (Pinto et al., 2011; Steg et al., 2012) should be preferred because it reduces the incidence of restenosis and the rate of reintervention. For the same reason, stents coated with medication (drug-eluting stents) should be preferred to bare-metal stents. However, since drug-eluting stents carry a high risk of intracoronary acute thrombosis, prolonged DAPT is mandatory in all patients receiving drug-eluting stents. Thus, drug-eluting stents should be preferred over bare-metal stents if the patient has no contraindications to prolonged DAPT (indication for oral anticoagulation or estimated high long-term bleeding risk) and is likely to be compliant.

If primary PCI is performed by an experienced radial operator, the radial access over the femoral access should be preferred, given the lower rate of accessible bleeding (Steg et al., 2012).

During PCI, it can be reasonable to perform aspiration thrombectomy; but routine thrombectomy does not reduce mortality, recurrent myocardial infarction, heart failure, or cardiogenic shock, and might increase the risk of stroke within 30 days (Jolly et al., 2015; Fröbert et al., 2013).

Fibrinolysis

More than 30 years ago, multiple large randomized trials began to show the benefit of fibrinolytic therapy (FTT Collaborative Group, 1994) as one of the major advances in the treatment of acute STEMI. With the following arrival of primary PCI, fibrinolysis is nowadays reserved for STEMI patients presenting within 12 h from symptom onset and without contraindication to fibrinolysis, when primary PCI cannot be performed by an experienced team within 120 min (preferably 90 min) from FMC (Pinto et al., 2011; Steg et al., 2012). The greatest benefits are observed when fibrinolysis is performed within 2 h from symptom onset. The recommended absolute and relative contraindications to fibrinolysis (Steg et al., 2012) are given in **Fig. 2**.

Fibrinolytic agents are divided into two categories:

1. Nonfibrin-specific agents: streptokinase (antigenic).
2. Fibrin-specific agents: alteplase (tPA), reteplase (rPA), and tenecteplase (TNK-tPA).

Fibrin-specific agents (tenecteplase, alteplase, and reteplase) should be preferred over nonfibrin specific agents (Steg et al., 2012). Streptokinase is generally a less costly option than other fibrinolytics, but related outcomes are inferior. In the GUSTO-1 trial, alteplase was shown to reduce 30-day mortality when compared with streptokinase (GUSTO investigators, 1993). Both reteplase and tenecteplase have a similar beneficial effect as alteplase, but they are easier to administer (GUSTO III Investigators, 1997; Van De Werf et al., 1999). Moreover, tenecteplase is associated with a lower rate of noncerebral bleedings and less need for blood transfusion. **Table 5** shows the recommended doses of fibrinolysis agents.

The major complication after fibrinolysis is stroke (FTT Collaborative Group, 1994), especially during the first day after treatment. Cerebral hemorrhages are responsible for early strokes, whereas later strokes are more frequently thrombotic or embolic. The rate of intracranial bleeding ranges from 0.9% to 1.0%, whereas the rate of major noncerebral bleeds (bleeding complications requiring blood transfusion or that are life-threatening) ranges from 4% to 13% (GUSTO III Investigators, 1997; Van De Werf et al., 1999; Berkowitz et al., 1997). Patients receiving streptokinase may present hypotension and rare severe allergic reactions. The readministration of streptokinase should be avoided.

PCI After Fibrinolysis

PCI can be performed after fibrinolysis in three timely different manners.

Rescue PCI. Patients who continue to show signs of persistent ischemia after fibrinolysis, such as worsening or sustained chest discomfort, hemodynamic instability, or lack of resolution of ST elevation (by at least 50% in the worst lead at 60–90 min), should be promptly considered for an immediate coronary angiography with a window to PCI (O'Gara et al., 2013).

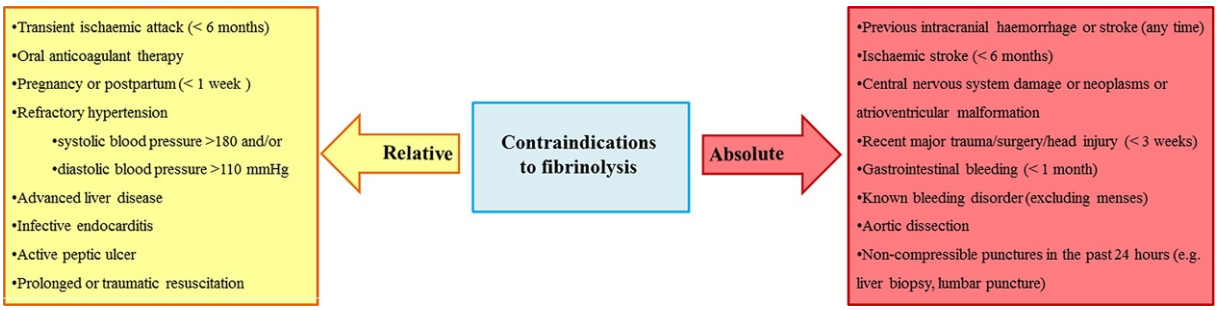

Fig. 2 Absolute and relative contraindications to fibrinolysis (Steg et al., 2012; O'Gara et al., 2013).

Table 5 Fibrinolytic agent (Steg et al., 2012)

Fibrinolytic agents	*Dose*
Streptokinase (SK)[a]	1.5 million units over 30–60 min i.v.
Alteplase (tPA)	15 mg i.v. bolus
	0.75 mg/kg (up to 50 mg) over 30 min i.v.
	0.5 mg/kg (up to 35 mg) over 60 min i.v.
Reteplase (r-PA)	10 units + 10 units i.v. bolus, given 30 min apart
Tenecteplase (TNK-tPA)	Single i.v. bolus (30 mg, if <60 kg; 35 mg, if 60–70 kg; 40 mg, if 70–80 kg; 45 mg, if 80–90 kg; 50 mg, if ≥90 kg)

[a]Contraindication: prior SK or anistreplase.

Early PCI (pharmacoinvasive strategy). The pharmacoinvasive strategy consists in early (but not immediate) PCI after fibrinolysis, that is at 3–24 h post thrombolysis. In contrast with facilitated PCI, in which PCI is performed very early after fibrinolytic therapy and has shown no benefit, recent studies have underlined the potential beneficial effect of the pharmacoinvasive strategy (Cantor et al., 2009; Di Mario et al., 2008).

Facilitated PCI. In this approach, PCI is performed very early after fibrinolytic therapy (within an hour of the initial pharmacotherapy). After early promising results, numerous studies have shown no benefits while suggesting potentially harmful complications and outcomes (increased risk of ischemic events, bleeding, and mortality) (ASSENT-4 PCI investigators, 2006; Zalewski et al., 2011; Ellis et al., 2008; Armstrong et al., 2013).

Coronary Artery Bypass Surgery

Coronary artery bypass surgery (CABG) nowadays has been substituted in most cases by primary PCI and is reserved for those STEMI patients with a coronary anatomy not suitable for PCI and ongoing ischemia or cardiogenic shock, or severe HF. In addition, CABG is performed during open heart surgery aimed at repairing STEMI mechanical complications (Pinto et al., 2011; Steg et al., 2012).

Patients Without Reperfusion Therapy

Patients who do not reach the hospital within 12 h from symptoms onset, or who have contraindications to pharmacological or mechanical reperfusion strategies, should be treated as soon as possible with an optimal medical therapy, including antiplatelet agents and anticoagulant, beta-blocker, ACE-I, and statins, unless otherwise contraindicated (O'Gara et al., 2013; Steg et al., 2012).

Management of STEMI with Normal Coronary Arteries

A patient having "normal" coronary angiography is defined as a patient in which no visible disease, or nonobstructive atherosclerotic coronary disease (epicardial artery stenosis <50%) are detectable at coronary angiography (Bugiardini and Bairey Merz, 2005; Hochman et al., 1999). In this setting, STEMI is diagnosed by clinical and electrocardiographical signs, but when the patients undergo coronary angiography, no critical lesions are detectable. Approximately 7% of STEMI patients do not show a culprit coronary lesion. Many of these patients are young women (frequently under 50 years old). In fact, 10% of women with STEMI show no culprit lesion, compared with 6% of men with the same disease (Tun and Khan, 2000; Hochman et al., 1999; Bugiardini and Bairey Merz, 2005). Furthermore, patients with normal angiograms and acute coronary syndrome seldom have cardiovascular risk factors or prior history of angina or myocardial infarction (Khan and Ansari, 1998). The etiology of this condition can be related to ischemic cardiac causes, such as coronary artery vasospasm (Ong et al., 2008), endothelial erosion (Yahagi et al., 2015), thrombophilic states (Mansourati et al., 2000; Da Costa et al., 1998, 2001; Lande et al., 1998; Larsen et al., 2005), microvascular dysfunction (Diver et al., 1994), and in situ thrombosis or embolization from a distal source with spontaneous lysis (Sharifi et al., 1995). Nonischemic causes include viral myocarditis, cardiomyopathies, pulmonary embolism (Gerbaud et al., 2012; Agewall et al., 2011), psychological factors (Ho et al., 1998), as well as the use of cocaine and methamphetamines (Minor et al., 1991; Chen, 2007.). Diagnosis requires both cardiac and noncardiac investigations and adequate drug screening. These patients present fewer complications, such as malignant arrhythmias, heart failure, and hypotension, and have been thought to have a better prognosis than patients with obstructive disease (Raymond et al., 1988; Sharifi et al., 1995.). However, recent evidence has shown that, contrary to this common belief, prognosis is not so benign, especially in women (Bugiardini and Bairey Merz, 2005; Larsen et al., 2005; Gehrie et al., 2009; Kang et al., 2011). Indeed, these patients have 2% event rate of death and myocardial infarction (Bugiardini et al., 2006). Therefore, they need to be treated with optimal medical therapy, which includes aspirin, ADP receptor antagonist, anticoagulant agent, statins, ACE-I, and calcium channel blockers, all of which have been shown to either increase survival or quality of life. Beta-blockers should be avoided when cocaine abuse is suspected (Chandrasekaran and Kurbaan, 2002).

Management of Right Ventricular Infarction

Approximately one in three patients with an inferior STEMI has a right ventricular infarction. Right ventricular involvement should be investigated in all patients with inferior STEMI. Hypotension, clear lung fields, and raised jugular venous pressure are typical of right ventricular infarction (O'Gara et al., 2013; Steg et al., 2012). The treatment of right ventricular infarction is the same as the left ventricular infarction, with the exception of diuretics and vasodilators (nitrates), which should not be included as they may cause a worsening of hypotension. Moreover, fluid loading that maintains filling pressure is essential in the treatment of this type of infarction. Atrial fibrillation or atrioventricular (AV) block, more frequently affecting these patients, should be treated as soon as possible (O'Gara et al., 2013; Steg et al., 2012).

Management of Arrhythmias

Sinus Bradycardia

Sinus bradycardia does not need any treatment, except when accompanied by severe hypotension. In this case, patients should be treated with i.v. atropine. Temporary pacing is indicated for symptomatic bradyarrhythmias unresponsive to medical treatment (O'Gara et al., 2013; Steg et al., 2012).

Supraventricular Arrhythmias

Atrial fibrillation is the most common arrhythmia complicating STEMI (incidence ranging from 6% to 28%), and is often accompanied by severe left ventricular failure (Thomsen et al., 2010; Schmitt et al., 2009; Steg et al., 2012). The administration of beta-blockers or possibly nondihydropyridine calcium antagonists (e.g., diltiazem and verapamil), if there are no clinical signs of acute heart failure, is recommended to guarantee an adequate rate control and reduce myocardial oxygen demand (Steg et al., 2012). In patients with acute heart failure or hypotension and concomitant atrial fibrillation with rapid ventricular response, amiodarone or i.v. digitalis are indicated (Steg et al., 2012). When pharmacological agents are not able to guarantee an adequate rate control in patients with atrial fibrillation and ongoing ischemia, immediate electrical cardioversion is recommended (Steg et al., 2012).

Atrioventricular Heart Block

Bradyarrhythmias and heart block are typically secondary to inferior myocardial infarction and are often self-limiting (Reed et al., 2017). First-degree heart blocks do not require treatment. Patients with second-degree Type I AV block (Mobitz I or Wenckeback) rarely develop adverse hemodynamic effects; when these patients develop adverse hemodynamic effects atropine should be the first therapeutic option, if it fails a pacing electrode should be implanted. Second-degree Type II (Mobitz II) AV block and third-degree AV block should be always considered for the insertion of a pacing electrode, certainly in the cases where bradycardia causes hypotension or heart failure (Steg et al., 2012). If the hemodynamic disturbance is severe, consideration should be given to AV sequential pacing (Steg et al., 2012). After the acute phase of STEMI, permanent pacing is indicated in patients with (1) persistent third-degree AV block, (2) persistent second degree AV block associated with bundle branch block, and (3) transient Mobitz II or third-degree AV associated with new-onset bundle branch block (Steg et al., 2012).

Ventricular Arrhythmias

Ventricular arrhythmias are the most frequent arrhythmias in the acute phase of STEMI. Ventricular arrhythmias can be classified based on time of onset: early arrhythmias arise in the first 48 h and are caused by ischemia, while secondary arrhythmias occur after 48 h and are usually due to the formation of scar tissue and the process of remodeling. In a recent study, the incidence of nonsustained ventricular tachycardia was 13%, while both sustained ventricular tachycardia and ventricular fibrillation had an incidence of 3%.

Sustained and/or hemodynamically unstable ventricular tachycardia and ventricular fibrillation require immediate and direct current cardioversion. Hemodynamically stable patients with sustained ventricular tachycardia may be treated with i.v. amiodarone, but conversion rates are low (Steg et al., 2012).

In patients with left ventricular ejection fraction <40% (assessed by echocardiography at least 40 days after the acute event), an evaluation of the risk of sudden cardiac death should be performed to consider the necessity of an implantable cardioverter-defibrillator (Steg et al., 2012).

Long-Term Management of STEMI Patients

Secondary prevention strategies are necessary to prevent recurring cardiovascular events and subsequent hospital readmissions and premature death. Patients who suffered from STEMI are considered to have a chronic coronary heart disease and are therefore at higher risk of subsequent cardiovascular events, including myocardial infarction, stroke, and death. In order to successfully prevent recurring major cardiovascular events, it is important to educate patients and their families on the importance of changes in lifestyle habits and compliance in medical therapy in terms of increasing survival and quality of life. This educational process, along with an ideal therapeutic regimen, should be instated before dehospitalization (O'Gara et al., 2013). International guidelines recommend a long-term management of STEMI patients which includes both lifestyle changes and medical therapy, and are briefly summarized in **Fig. 3**.

Lifestyle, Risk Factors, and Comorbidities

Smoking cessation is considered the most important factor of all secondary prevention measures (Thomson and Rigotti, 2003; Steg et al., 2012). When smoking cessation is successful and the prothrombotic effect of smoking is removed, the rate of death

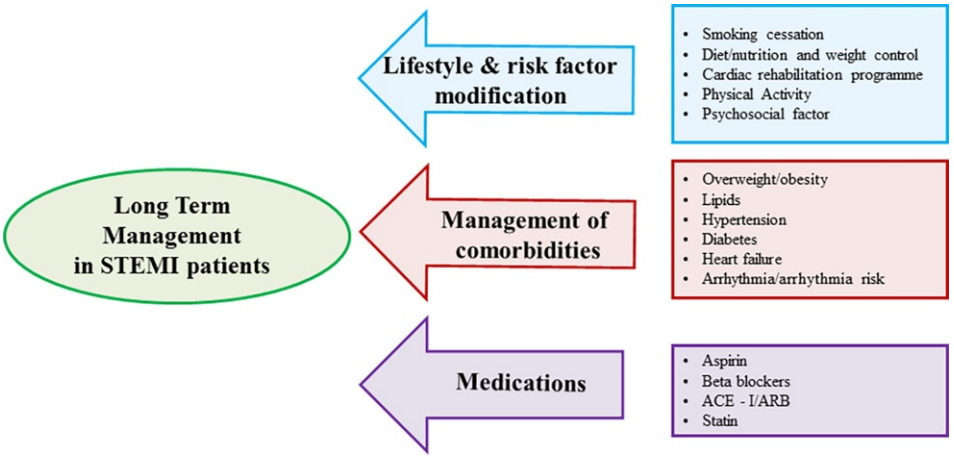

Fig. 3 Long-term management in STEMI patients (Steg et al., 2012; O'Gara et al., 2013). *STEMI*, ST-segment elevation myocardial infarction; *ACE-I*, angiotensin converting enzyme inhibitors; *ARB*, angiotensin receptor blockers.

decreases significantly when compared with patients who continued smoking. Likewise, obesity, especially central or abdominal obesity, is another major risk factor for cardiovascular disease. Even though there is little evidence of a correlation between loss of weight and reduction in mortality, guidelines recommend an ideal body mass index (BMI) of 25 kg/m^2 (Steg et al., 2012). Healthy eating habits, such as the Mediterranean diet and regular physical activity (30 min of moderate intensity aerobic exercise at least five times per week) are very important (Knoops et al., 2004; Steg et al., 2012). Following an acute myocardial infarction, systolic blood pressure should be kept <140 mmHg, but not <110 mmHg (Bangalore et al., 2010). In this complex context, the role of cardiac rehabilitation programs becomes of great utility for the reduction of risk related to chronic coronary heart disease. Cardiac rehabilitation includes exercise training, education on heart-healthy living, and counseling to reduce stress and help patients return to an active life (Cardiac Rehabilitation, 2017, www.nhlbi.nih.gov; Ades, 2001; Smith et al., 2011; Kwan and Balady, 2012).

Optimal Medical Therapy

Aspirin and other antiplatelet therapy

The protective role of aspirin on the risk of subsequent myocardial infarction, stroke, and vascular death in secondary prevention is undisputed (Hennekens et al., 1997). A maintenance dose 75–100 mg/daily should be taken indefinitely after STEMI. Clopidogrel (75 mg/day) is an alternative in patients who are intolerant to aspirin (Steg et al., 2012).

Dual antiplatelet therapy

The combination of aspirin and an ADP-receptor blocker (clopidogrel, prasugrel, or ticagrelor) is recommended to reduce the risk of stent thrombosis after PCI (Wiviott et al., 2007; Wallentin et al., 2009). DAPT must be continued in all STEMI patients undergoing primary PCI or fibrinolysis for up to 12 months (Steg et al., 2012).

Triple antithrombotic therapy

In patients with a clear indication for oral anticoagulation, the optimal duration of triple therapy (aspirin, ADP receptor antagonist, and oral anticoagulant) is still unknown. In each patient, the relative risks of bleeding and stent thrombosis should be considered (O'Gara et al., 2013; Steg et al., 2012).

Beta-blockers

The administration of beta-blockers should begin in the hospital and be continued after dehospitalization in all STEMI patients without contraindications (O'Gara et al., 2013; Steg et al., 2012).

ACE-I

Long-term use of ACE-I should be considered in all STEMI patients without a contraindication, especially in those with evidence of heart failure, left ventricular systolic dysfunction, diabetes, or an anterior infarct (Steg et al., 2012). However, some studies have shown that ACE-I may reduce the risk of death, recurrent myocardial infarction and heart failure in all patients with coronary artery disease regardless of left ventricular function (Yusuf et al., 2000; Flather et al., 2000).

Statins

The beneficial effects of statin therapy in secondary prevention are unequivocal (Baigent et al., 2005). The goal of lipid-lowering therapy after STEMI is the achievement of LDL-cholesterol serum levels $\leq$1.8 mmol/L (70 mg/dL) within 4–6 weeks (Steg et al., 2012). In addition, intensive statin therapy incrementally reduces LDL cholesterol levels and rates of nonfatal cardiovascular events. The most frequent complication associated with statins is myalgia. More severe yet rare complications include rhabdomyolysis and occasionally liver dysfunction (Golomb and Evans, 2008). Recently, two new agents (*ezetimibe* and *evolocumab*) in combination with a statin molecule (specifically simvastatin) have shown very promising results. *Ezetimibe* is a nonstatin agent, which reduces the absorption of cholesterol from the gastrointestinal tract through the action on Niemann–Pick C1-like 1 (NPC1L1) protein (Sudhop et al., 2002). The IMPROVE-IT trial showed that ezetimibe in addition to statin therapy compared to simvastatin alone lowered LDL-cholesterol and the risk of cardiovascular events (Cannon et al., 2015). *Evolocumab* is a new class of drug which is a monoclonal antibody that inhibits proprotein convertase subtilisin–kexin type 9 (PCSK9) and has recently emerged for effectively reducing LDL cholesterol levels (Giugliano and Sabatine, 2015). The FOURIER trial showed that inhibition of PCSK9 with evolocumab added to statin therapy lowers LDL-cholesterol levels and reduces the risk of cardiovascular events when compared with placebo (Sabatine et al., 2017).

Introduction

Despite the reduction in the mortality rates, myocardial infarction (MI) remains a major cause of morbidity and mortality worldwide. Mortality rates after ST-segment elevation myocardial infarction (STEMI) are high, especially in the prehospital setting (50% of the deaths occur prior to hospital arrival) (Dudas et al., 2011). Moreover, survivors of STEMI face a substantial risk of short- and long-term cardiovascular adverse events, such as recurrent MI, stable angina, arrhythmias, heart failure (HF), stroke, and increased mortality risk. Acute atherothrombotic therapy, thrombolysis, and revascularization followed by long-term antiplatelet therapy reduce the adverse events but put these patients at higher bleeding risk. The prognosis of the individual patient depends mainly on the patient risk profile, clinical presentation, complications, and acute phase management, such as reperfusion strategies. Patient education and adherence to secondary prevention therapy have a crucial role in long-term prognosis. Therefore, knowledge concerning prognosis after STEMI is necessary to improve patient care and outcome.

Short-Term Mortality

Short-term (in-hospital or 30 day) mortality from STEMI has declined in the past two decades, which can be seen as a demonstration of the increasing use of reperfusion strategies, shortening of the total ischemic time, and increasing use of adjunctive therapies (Rogers et al., 2000; Roe et al., 2010; Schiele et al., 2010; Jernberg et al., 2011; Nallamothu et al., 2015). Currently, the short-term mortality rate of STEMI is estimated to range between 5% and 6% (O'Gara et al., 2013). Yet, in-hospital and 30-day mortality rates of patients with STEMI vary substantially across reports ranging from 3.0% to 13.3% (Gibson et al., 2008; Tatu-Chitoiu et al., 2009; Chung et al., 2014, 2015; Bugiardini et al., 2014, 2016a,b; Smith et al., 2015; Cenko et al., 2016; Kristensen et al., 2014). Outcomes are likely to be influenced by several clinical factors, such as age, sex, systolic blood pressure on presentation, heart rate, Killip class, ejection fraction, comorbidities, anatomic location of the STEMI, number of diseased vessels, flow, time, and adherence to reperfusion and preventive therapies (Steg et al., 2012; O'Gara et al., 2013). Among the factors with greater impact on mortality is the optimal use of reperfusion strategy. In patients, not undergoing any reperfusion therapy, the mortality remains high with rates ranging from 13% to 16%. Reperfusion using thrombolysis is associated with approximately 7% mortality rate, while the lowest mortality rates are reported for patients undergoing primary percutaneous coronary intervention (PCI) (3%–5%) supporting its key role in the decline of mortality rates seen in STEMI patients over these last two decades (Cenko et al, 2016; Bugiardini et al., 2014; Tatu-Chitoiu et al., 2009; Fassa et al., 2005). Greater implementations of STEMI networks and rapid reperfusion therapies, higher uptake of effective secondary preventive therapies, the availability of resources, policy initiatives, and variations in population cover may explain some of the differences in the reported mortality rates between registries and different geographical regions (Chung et al., 2014; Kristensen et al., 2014; Bugiardini et al., 2016a,b).

Long-term Mortality

Long-term mortality in patients with STEMI follows similar patterns of those seen in short-term outcomes. In the prereperfusion era, long-term mortality rates in patients with STEMI were reported nearly 20% at 1 year, rising to 30% at 5 years, with an annual mortality rate of 5% per year, most likely due to recurrent MI (Law et al., 2002). In the reperfusion era, the reported mortality rates

range from 4.2% at 1-year to 23.3% at 5 years (Haim et al., 2000; Kaul et al., 2004; Barbagelata et al., 1997; Pedersen et al., 2014; Weintraub et al., 2012; Stone et al., 2011). However, recent studies have shown that noncardiac death accounts in over 60% of long-term mortality cases in patients with STEMI. Accordingly, in contemporary STEMI patients treated with primary PCI, cardiac death is responsible for over 8% and 14% of mortality cases at 1 year and 5 years, respectively. The risk of annual cardiac mortality is reported to be less than 1.5% in these patients (Pedersen et al., 2014). A meta-analysis of 23 randomized clinical trials and over 7000 patients with STEMI, evaluated the outcomes of primary PCI as compared to thrombolysis. Overall, long-term (6–18 months) mortality was higher in patients undergoing thrombolysis as compared to primary PCI (approximately 13% vs. 9%) (Keeley et al., 2003). Long-term mortality declined substantially when data from the Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock (SHOCK) trial, which enrolled high-risk patients in cardiogenic shock, were excluded. Excluding from the analysis patients with cardiogenic shock gives the following estimates on long-term mortality: 7% in the thrombolysis group versus 5% in the primary PCI group (Keeley et al., 2003). Similarly to short-term mortality, long-term outcomes are influenced by many prognostic factors. Among them, the strongest are age, comorbidities such as diabetes mellitus and HF, clinical presentation, time to reperfusion, the outcome of reperfusion therapy, i.e., complete restoration of coronary blood flow, and adherence to long-term secondary prevention therapies.

Sudden Cardiac Death

The reputed incidence of sudden cardiac death (SCD), after STEMI, ranges from 2% to 4% per year (Berger et al., 1992; Solomon et al., 2005). The incidence of SCD declines exponentially over time from MI. The higher incidence is reported in the first-month post-MI ranging from 1.2% to 1.4% per month as compared to 0.14% per month after 2 years (Adabag et al., 2008; Solomon et al, 2005; Zaman and Kovoor, 2014). In a recent report, the overall SCD occurred in over 15% of patients with STEMI treated with primary PCI. The median time to SCD occurrence was 2.7 years (range 1.3–5 years) (Pedersen et al., 2014). Left ventricular (LV) dysfunction is the strongest predictor of SCD. In the Valsartan in Acute Myocardial Infarction (VALIANT) trial, the incidence of SCD was markedly higher in patients with left ventricular ejection fractions (LVEF) $\leq$30% (2.3% in the first-month post-MI). Yet over half of the SCD occurred in patients with an LVEF of 31%–40% (incidence 0.90% in the first-month post-MI) (Solomon et al., 2005). According to the above-mentioned concept, prophylactic implantation of a defibrillator improves survival and should be considered as a recommended therapy as shown by the The Multicenter Automatic Defibrillator Implantation Trial II (MADIT-II). The MADIT-II trial included patients with prior MI and LVEF <30% and showed a 30% reduction in the adjusted hazard of SCD with implantable cardioverter-defibrillator (ICD) therapy at nearly 2 years follow-up (Moss et al., 2002)

Nonfatal Adverse Events

Nonfatal recurrent MI, recurrent ischemia, stroke, and bleeding are important complications after STEMI that strongly influence short- and long-term patient outcome. In the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial, 30-day rates of nonfatal recurrent MI, recurrent ischemia, stroke, and major life-threatening bleeding in patients treated with thrombolysis were 4.0%, 19%, 1.4%, and 0.4%, respectively (GUSTO Investigators, 1993). In a meta-analysis of clinical randomized trials, 30-day rates of nonfatal recurrent MI, recurrent ischemia, stroke, and major bleeding in patients treated with thrombolysis were 7%, 21%, 2%, and 4%, respectively, whereas in patient rated with primary PCI were 3%, 7%, 1%, and 8%, respectively (Keeley et al., 2003). Long-term (6–18 months) rates of nonfatal recurrent MI and recurrent ischemia were 9% and 39%, respectively, in patients treated with thrombolysis and compared to 5% and 23% in patients who underwent primary PCI (Keeley et al., 2003). Contemporary trials and registry studies report rates of reinfarction, stroke, and major bleeding around 2%, 1%, and 2.8% respectively (Tobbia et al., 2013; Spencer et al., 2007). A recent registry study that assessed long-term outcomes (median follow-up 5 years) of STEMI patients treated with primary PCI reported an incidence of reinfarction, and composite of stroke, and bleedings around 6.3% and 5.6%, respectively. The median time to the occurrence of reinfarction was 8 months (range 6 days to 4.9 years) and occurrence of stroke and bleedings was 2 years (range 5 months to 4.5 years) (Pedersen et al., 2014). A longitudinal study (5.6 years of follow-up) evaluated the rate and timing of post-MI stroke found that the majority of stroke events occurred in the first month after the MI (22.6 per 1000 persons/month), most of which were ischemic. Similar to the other nonfatal adverse outcomes, the rates of post-MI strokes showed a gradual decline with an incidence of 0.9 per 1000 persons/month at 5-year follow-up (Witt et al., 2005). In the Thrombolysis in Myocardial Infarction Phase II (TIMI-II) trial, patients who experienced a nonfatal reinfarction had a twofold increase in the cumulative 3-year mortality rate (14.1% vs. 7.9%) (Mueller et al., 1995). In a posthoc analysis of GUSTO-I and GUSTO-IIb trials, symptomatic recurrent ischemia doubled the risk of reinfarction or mortality at 30 days, although the risk of reinfarction or mortality declined gradually at 6 months and 1 year, patients with hemodynamic instability maintained a higher the long-term risk (Betriu et al., 1998; Armstrong et al., 1998). Likewise, silent (not symptomatic) recurrent ischemia is associated with a worse prognosis in these patients (Bugiardini et al., 1991; Solimene et al., 1993). Patients who experience a stroke or major bleeding events are at higher mortality risk. Post-MI stroke events were associated with an almost threefold increase in the mortality risk irrespective of follow-up time (Witt et al., 2005). In the Global Registry of Acute Coronary Events (GRACE), major bleeding events in patients with MI accounted for over 10% of hospital mortality (Spencer et al., 2007). Risk factors for nonfatal outcomes after STEMI include older age, women, comorbidities such as diabetes, HF or shock, prior history of stroke and renal failure, anemia, use of fibrinolytic therapy, and antithrombotic therapy (O'Gara, et al., 2013).

Complications After STEMI

HF and cardiogenic shock complicate from 5% to 19% of patients with STEMI occurring in most cases during the first 24 h from hospital admission (**Figs. 1** and **2**). Patients presenting with HF or cardiogenic shock are at increased risk for mortality, reinfarction, and other adverse events. Using the Killip classification (Killip and Kimball, 1967) (**Fig. 1**), which stratified patients presenting with acute MI based on physical findings that can suggest HF, pulmonary edema or cardiogenic shock, the GRACE and National Registry of Myocardial Infarction II (NRMI-II) registries reported in-hospital mortality rates ranging from 17% to 21% in patients presenting with HF (Killip class II and III) as compared to those without HF (4%–7%) (Steg et al., 2004; Wu et al., 2002; Pedersen et al., 2014; Singh et al., 2007). Cardiogenic shock is associated with even higher mortality rates ranging from 40% to 70%, especially in the absence of aggressive medical care. The SHOCK trial showed that 6-month mortality rates were lower in patients with STEMI presenting with cardiogenic shock who underwent revascularization therapy (50% vs. 63%) (Hochman et al., 1999). A recent posthoc analysis of GUSTO-I trial showed that in this subset of STEMI patients, reperfusion with thrombolysis was associated with a 50% mortality rate at 30-day and 70% mortality rate at 11 years (Singh et al., 2007). Therefore, these patients should undergo prompt reperfusion regardless of time delay (O'Gara, et al., 2013; Steg et al., 2012).

Ventricular fibrillation (VF) and sustained ventricular tachycardia (VT), (**Fig. 2**) are common life-threatening complications after STEMI (**Fig. 2**). In the prereperfusion era, the incidence of VF/VT was high ranging from 4% to 40% (O'Doherty et al., 1983; Bigger et al., 1977). In the reperfusion era, the incidence of VF/VT has declined substantially, ranging from 3% to 10% in patients treated with thrombolysis (Volpi et al., 1998; Newby et al., 1998) and 6% in patients treated with primary PCI (Mehta et al., 2009). In the Assessment of Pexelizumab in Acute Myocardial Infarction (APEX AMI) trial, where patients with STEMI undergoing primary PCI were evaluated, 90% of the cases of VF/VT occurred in the first 48 h (primary VF/VT) from presentation (Mehta et al., 2009). The overall 3-month mortality rates were higher in patients who experienced VF/VT (23% vs. 3.6%). Late VF/VT (after the end of the primary PCI) was associated with a fivefold increase in 3-month mortality as compared with those patients who experienced early VF/VT (before primary PCI) (Mehta et al., 2009). The prognostic factors associated with the occurrence of VF/VT are reported to be higher Killip classes, hypotension, male sex, lower preprocedural (lower than 1) and postprocedural (lower than 3) TIMI blood flow grades, electrolyte disturbances, and ST-segment resolution less than 70% (Mehta et al., 2009; Volpi et al., 1998; Gheeraert et al., 2006). Administration of early (within 24 h) beta-blockers is associated with a reduction in the occurrence of VF/VT and reduced mortality rates (Mehta et al., 2009; Bugiardini et al., 2016b).

Atrial fibrillation (**Fig. 2**) is the common supraventricular tachycardia following STEMI with an incidence ranging from 6% to 22% (O'Gara et al., 2013; Schmitt et al., 2009). In the Cardiac Arrhythmias and Risk Stratification after Acute Myocardial Infarction (CARISMA) study, the long-term incidence of atrial fibrillation after MI in patients with LVEF <40% was approximately 30% at 2 years follow-up (Jons et al., 2011). Atrial fibrillation after STEMI has important prognostic implications as it is associated with

Killip classification

Killip Class	Clinical signs	Incidence	Mortality
Class I	No clinical signs of heart failure	33% to 79%	2% to 6%
Class II	Rales or crackles in the lungs, an S3 gallop, and elevated jugular venous pressure	12% to 38%	8% to 17%
Class III	Manifest acute pulmonary edema	5% to 10%	27% to 38%
Class IV	Cardiogenic shock, systolic blood pressure <90 mmHg, evidence of low cardiac output	3% to 19%	40% to 70%

higher mortality, reinfarction, stroke, cardiogenic shock, and HF (Jons et al., 2011; Crenshaw et al., 1997). Atrial fibrillation requires oral anticoagulant therapy exposing these patients to increased risk for future bleeding events. The strongest clinical factors associated with the incidence of atrial fibrillation were found to be HF, Killip Class IV, and older age (Schmitt et al., 2009).

Bradycardias (**Fig. 2**) such as atrioventricular blocks and interventricular conductions defects can develop in approximately 4% of patients, especially in inferior/posterior STEMI (Hreybe and Saba, 2009).

Mechanical complications (**Fig. 2**) such as mitral regurgitation, ventricular septal rupture, left ventricular wall rupture, and ventricular aneurysm occur in the first 24 h (the majority) to 1 week after the clinical presentation. These conditions are associated with high mortality rates approaching 20%–60%, especially in the setting of ventricular septal rupture, and left ventricular wall rupture (O'Gara et al., 2013).

Acute pericarditis (**Fig. 2**) after STEMI has shown a decline in the incidence following reperfusion strategies with either fibrinolysis or primary PCI. The incidence of early (periinfarction) pericarditis is reported in around 12% of the nonreperfused patients, 5% in those patients treated with fibrinolysis (Correale et al., 1993; Wall et al., 1990), and 4% in those patients who underwent primary PCI (Imazio et al., 2009). The presence of a pericardial friction rub in the first 48–72 h after STEMI is associated with larger infarct size, higher incidence of anterior wall MI, and three-vessel disease, LV dysfunction and, consequently, increased short- and long-term mortality (Wall et al., 1990; Correale et al., 1993). The incidence of Dressler syndrome (late pericarditis or post-cardiac injury syndrome) was reported to be as low as 0.1% in contemporary patients treated by primary PCI. Dressler syndrome is usually self-limited and carries a relatively good prognosis, although some patients will experience recurrences (O'Gara, et al., 2013; Imazio et al., 2009).

Readmissions Rates Following STEMI

The overall rate of unplanned 30-day readmissions following STEMI is reported to range from 10% to 30%. Complication of revascularization procedures such as coronary angiography or PCI during index hospitalization, higher Killip classes, women (especially if less than 65 years old), elderly patients, those with diabetes, chronic pulmonary disease, anemia, longer index hospitalization stay, baseline quality of life, and depression are among the strongest factors associated with increased 30-day readmission rate after STEMI (Dreyer et al., 2015; Hess et al., 2016; Dunlay et al., 2012; Tisminetzky et al., 2015; Joynt et al., 2011; Curtis et al., 2009; National Quality Measures Clearinghouse (NQMC), 2015). Unplanned readmission rate is an indicator of the quality of care, therefore early risk stratification and collaboration between physicians and patients could prevent part of early readmissions.

Risk Stratification After STEMI

Given the increasing number of therapeutic options and the wide spectrum of risk in STEMI patients, risk stratification is not simply a hospital admission or predischarge commission, but it requires attention all throughout the continuum of postdischarge care. So, the current report will distinguish early prehospital or in-hospital risk stratification that should be done within the first four to six hours of hospitalization and late hospital risk stratification that is performed before or sometimes immediately after discharge.

Early Prehospital or In-Hospital Risk Stratification Using Prognostic Scores

The three major determinants of early prognosis in STEMI include (1) the extent of myocardial injury, (2) the extent of coronary artery disease, and (3) the instability of the disease and its refractoriness to management. Scores represent a simple, convenient method of risk stratification, in which a number of independent risk factors on presentation are shown to have prognostic significance. The Global Registry of Acute Cardiac Events (GRACE) risk score is a prominent example of the scoring system. It was calculated for 6-month mortality and was subsequently refined for 30-day outcomes (Eagle et al., 2004; Huang et al., 2016). The GRACE risk score measures different aspects of the extent of myocardial damage such as Killip Class, heart rate, systolic blood pressure, ST-segment deviation, raised cardiac enzymes, and resuscitation from cardiac arrest. It combines this information with other possible related variables such as age and serum creatinine concentration (**Fig. 3**). The Thrombolysis in Myocardial Infarction (TIMI) risk score focuses on 30-day as well as 1-year mortality (Morrow et al., 2000, 2001). The TIMI risk score seems to look more at the extent of coronary artery disease and its instability including predisposing factors such as diabetes mellitus, hypertension, or the prior occurrence of angina pectoris (**Fig. 4**). The Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications (CADILLAC) risk score was used to predict the 30-day and 1-year mortality and was based on patients treated with primary PCI (Halkin et al., 2005). As so, it gives primarily an overview of the extent of coronary artery disease and the pathophysiology of coronary blood flow. The advantage of these scoring systems is that they summarize important prognostic information of the disease in a single number, confidence limits can be easily calculated, and survival rates can be easily compared between given treatments.

Estimation of Long-Term Prognosis

A major issue in the management of STEMI is the risk stratification of those individuals who have survived the initial hospital admission, and are being prepared for discharge. Despite a substantial improvement in intrahospital assessment and care, patients

still have a considerably high incidence of medium to long-term adverse outcomes. Remarkably, approximately one-quarter of the patients in the NRMI-III database (Morrow et al., 2001) were found to be at high risk, using the TIMI risk score. At 3 years follow-up, the benefit of primary PCI was restricted to those at high risk, whereas a trend toward high mortality was seen in the majority of patients at low risk (Thune et al., 2005). Hence, once the issues of early risk assessment and the establishment of the response to reperfusion have occurred, a profile of risk should be established by characterizing the presence of inducible ischemia, the extent of

LV functional impairment, and the occurrence of malignant ventricular arrhythmias. Simply acquired clinical electrocardiographic (ECG) variables contain important prognostic information. Old and new prospective cohort studies have identified that ST shifts at 24-h ECG recordings are factors independently predictive of postdischarge outcome (Bugiardini et al., 1995; Manfrini et al., 2003; Richardson et al., 2009). These data imply plausible pathogenetic mechanisms that fit with the widely accepted notion of the disease. ST-segment shifts could reflect instability where persistence of acute stimuli may cause waxing and waning of intracoronary thrombosis and related transient myocardial ischemia. ST-segment shifts could trigger fatal arrhythmias (Pozzati et al., 1996). Signal-averaged ECG studies may be useful to identify those patients at risk for malignant ventricular arrhythmias (Steg et al., 2012; O'Gara et al., 2013). In addition, fundamental to risk stratification is the recognition that LV function is the most powerful predictor of survival. All patients should have an assessment of their LVEF in order to enhance profiling of their risk and guide medical therapy. If the LVEF is $\leq$40%, once medical therapy is optimized and after at least 1-month has intervened, then an automatic implantable defibrillator should be implanted (Steg et al., 2012; O'Gara et al., 2013). If coronary anatomy is not established as part of the initial reperfusion strategy, then a functional noninvasive test should be undertaken in order to establish the need for angiography. Profound early ischemia with standard stress tests identifies patients at relatively high risk of a subsequent cardiac event and coronary arteriography is indicated. Postinfarction residual ischemia carries a poor prognosis but is readily amenable to treatment, usually by coronary revascularization. In summary, long-term risk stratification depends critically on the underlying mechanism of disease. A better understanding of the significance of each prognostic factor is needed to quantify its strength and assess its relative importance in different subsets of patients.

Using Prognostic Scores for Late In-Hospital Risk Stratification

Risk stratification "*over time*" *is* a dynamic process, altered by a patient's changing clinical conditions. There is, therefore, a need for a risk stratification method that can be easily quantifiable at the bedside, and used as an additional component of an existing early risk stratification scoring system. Current areas of research try to address this issue. The dynamic TIMI risk score is an updated stratification model of the classic TIMI risk score (Amin et al., 2013) and includes hospital events. It also includes the concurrence of diabetes, hypertension body weight, and time delay to treatment. It is designed for the prognosis of all-cause mortality at 1 year. The baseline TIMI risk score has 0–14 potential points (**Fig. 4**), the dynamic TIMI risk score has a total of 0–29 potential points, with 0–15 points assigned based on the above mentioned in-hospital events. Scores 0–2 and all scores $\geq$8 are collapsed into a single category (**Fig. 5**). There is an approximate 25% absolute increase in 1-year mortality after discharge between a low score (0/1) and a high score ($\geq$8). These data are rational, and the underlying concept even more. Over time, a patient's condition can change, altering estimated mortality. The strength of a prognostic factor may be greater during one period of time than another.

Anatomy of the Vasculature

Our overall goal is to provide the reader with a basic overview of cardiovascular structure with special emphasis on the human condition. Additionally, we discuss how this structure impacts cardiovascular function. We hope this overview will provide the reader the foundation upon which further exploration of cardiovascular structure/function can be elicited.

Evolution of the Cardiovascular System: A Very Brief Overview

The human cardiovascular system is a closed, endothelial cell-lined system with complex variation in vessel structure that is essential for its dynamic and diverse functions. Additionally, the human system is powered by a two-sided, four-chambered heart that moves blood directionally and circulating oxygenated and deoxygenated blood. Also, an independent lymphatic system that at its most proximate end connects with the cardiovascular system is present throughout the human body. It should be noted this configuration is rare in the animal kingdom. Indeed, no invertebrate possesses a closed, endothelial cell-lined system or a heart (Bettex et al., 2014; Monahan-Earley et al., 2013). Further, vertebrates, of which the human being is a member, compose only 3% of living animals. Two points emerge from this discussion. First, the cardiovascular system that we will describe later does not reflect the majority of circulatory systems seen in the animal kingdom. Our focus is on the complexity and nuance of the human condition. Second, it should be noted that there is incredible diversity in the systems that transport blood and fluids in organisms of the animal kingdom. Evolution of the human cardiovascular system is intertwined with the structure of systems seen in less complex animal models and reflects the diversity in pressures driving adaptive changes in cardiovascular structure over time. The reader is encouraged to explore the vast literature on diversity in cardiovascular structure and evolution of the cardiovascular system as the current structure and function of the human heart, and blood vessels are a reflection of that history.

Overall Structure and Function of the Human Cardiovascular System: An Overview

In simplest terms, the role of the cardiovascular system is to transport blood, and indeed, this is the underlying function driving all its activities. Still, there is a huge diversity of function in movement of blood in the human body. We will consider the diversity of cardiovascular function in the context of each component of the system. One can first subdivide the cardiovascular system into its heart and vascular tree. The heart is the centralized pump that receives blood into its left and right atria and expels blood from its left and right ventricles. Blood vessels of the cardiovascular tree distribute blood to and from the diverse components of the body to enable diverse interaction with those tissues and organs.

The Heart

The heart is the central organ of the cardiovascular system and is specifically constructed to generate high-pressure blood flow in a coordinated manner by conduction of an electric signal throughout the heart. Gross anatomically, the heart is housed in the pericardial sac. This sac and the heart are covered by a continuous simple squamous epithelium (mesothelium) creating a pericardial space between the outer sac and the surface of the heart. The major blood vessels entering and exiting the heart are

housed within the mesentery of the pericardial sac. Pericardial fluid is secreted by this epithelium and serves as a lubricant on which the heart can slide as it pumps blood. Inflammation of this space can cause the very painful pericarditis (Mann et al., 2014).

Four main chambers make up the functional area of the heart: the right and left atrium and the right and left ventricle. Fig. 1 gives a schematic representation of human heart structure. Blood returns to the heart via the pulmonary vein and vena cava entering the left and right atria. Blood flows from the atria to the ventricles through the atrioventricular (AV) valves, which prevent regurgitation to blood and ensure unidirectional flow. The right side of the heart is specialized for pulmonary circulation, which delivers deoxygenated blood to the lungs in order to supply oxygen to the blood. Deoxygenated blood enters the right atrium from the inferior and superior vena cava. Once in the right atrium, blood is pumped through the tricuspid valve (right AV valve) into the right ventricle. The right ventricle pumps the deoxygenated blood through the pulmonary semilunar valve into the pulmonary artery, which immediately branches into the left and right pulmonary arteries that enter the lungs. Once the blood has been oxygenated in the lungs, blood flows into the left atrium from the pulmonary vein, where it is pumped through the bicuspid valve (left AV valve) into the left ventricle. The thick myocardium of the left ventricle pumps sending the blood through the aortic semilunar valve into the aorta with high pressure to the tissues of the body (systemic circulation). The left and right ventricles are separated by the interventricular septum. The majority of this septum consists of a thickened muscular domain, the muscular interventricular septum, and a thinner and smaller membranous interventricular septum. The left and right atria are divided by the interatrial septum, which is thinner than the interventricular septum due to the smaller forces exerted by the atria as compared with the ventricles. The two AV valves (bicuspid and tricuspid valves) have fibrous cords known as the chordae tendineae that extend to muscular fibers connected to the walls of the ventricle called papillary muscles. Atria are much thinner than their ventricular counterparts and largely serve as a momentary holding place for blood returning to the heart.

The heart, much like arterial and venous systems, is arranged in three layers or laminae. The outermost domain is the epicardium, which has the aforementioned outer mesothelial cell layer. Subjacent to this mesothelium is a connective tissue layer that houses coronary blood vessels and nerves supplying the heart. Adipose cells also reside in the epicardium and may build up with age or in a diseased state. This layer is analogous to the tunica adventitia of vessels although the mesothelial layer is not seen

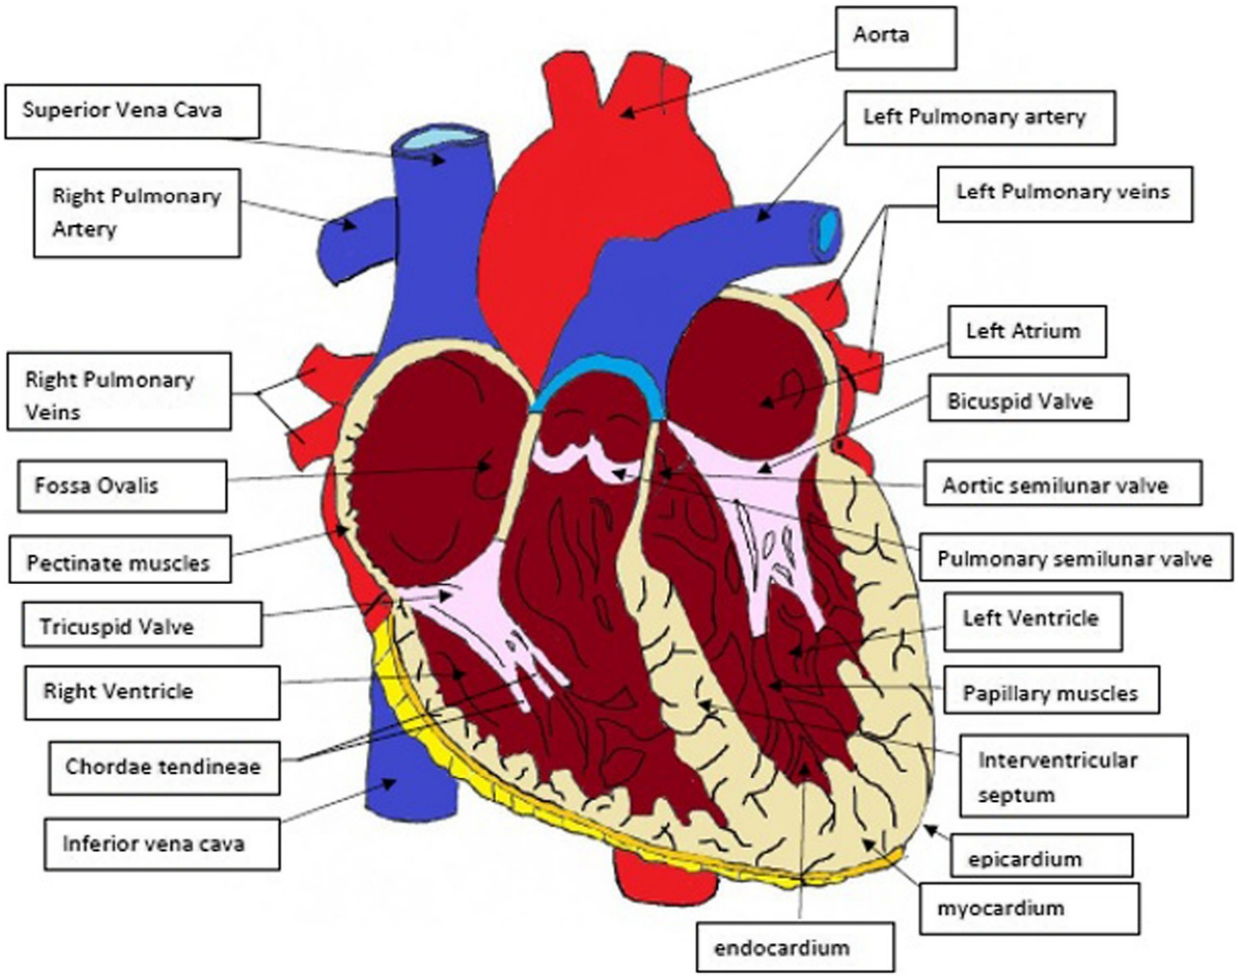

Fig. 1 Overall structure of the human heart. This schematic representation depicts the basic structure of the human heart.

in vessels (see in the succeeding text). The next layer inward is the myocardium. The major cell type occupying this layer in terms of mass is the cardiac myocyte. The myocardium is also populated by connective tissue cells and fibers that play an important role providing elasticity and, at the same time, rigidity to the heart wall. Additionally, there is an extensive capillary pool that embraces every myocyte of the myocardium. While the general structure of the myocardium is similar in the atria and the ventricles, the biggest difference between the atria and ventricles exists in this muscular layer with a much thicker layer comprising the ventricles. The third innermost layer, the endocardium, lines the heart chambers and all valvular structures housed within. This layer is made up of endothelium that faces the heart lumen and the subendothelial connective tissue space.

While the three tunics are present throughout the heart, great variation is observed in the thickness and shape of the heart walls principally due to variation in the myocardium. Most obviously, the ventricular myocardium is much thicker than its atrial counterpart (see **Fig. 1**). The ventricles are largely solid muscular structures, but the myocardium and endocardium become trabeculated in the deep region adjacent to the heart lumen. These irregularly shaped structures are called trabeculae carneae and reside in both left and right ventricles. The inner right atrium has a patterned scalloped inner surface of pectinate muscles, while the left atrium has rather smooth appearance.

Cardiac muscle is capable of spontaneous cell depolarization and is able to contract without an external stimulus from the nervous system. The steady, rhythmic heart beat is maintained by a series of cells innervated by the autonomic nervous system. The heart beat is initiated at the sinoatrial (SA) node, which is the pacemaker of the heart and is located at the intersection of the right atrium and the superior vena cava (**Fig. 2**). Modified cardiac myocytes called conduction system myocytes are present in this node and throughout the remainder of the conduction system. Myocytes of the conduction system are often larger and have fewer and more disorganized myofibrils (see **Fig. 3**). Additionally, they express differing contractile proteins (Gonzalez-Sanchez and Bader, 1985). SA node generates a muscular impulse that spreads throughout the myocardium of the right and left atria. At the right AV valve, the AV node picks up the impulse and relays the signal to the ventricles through the bundle of His (**Fig. 2**); again, specialized cardiomyocytes carry electric impulses through this portion of the conduction system. In the interventricular septum, the bundle of His further divides into left and right bundle branches serving the right and left ventricles. These bundles further divide and ultimately connect Purkinje fibers. Purkinje fibers branch out into the myocardium and make junctional contact with working myocytes. Purkinje fibers are the terminal component of the conduction system and electric conduction, and accompanying contraction continues through working cardiac myocytes. The positioning and conductivity of these modified myocytes are critical in the coordinated contraction of working cardiac myocytes, and their disruption caused by developmental or disease problems can have highly deleterious results in heart function (Milan and MacRae, 2005; Christoffels et al., 2010; Sylva et al., 2014; Neary and Breckenridge, 2013).

It is important to understand the structure of cardiac myocytes in the context of heart structure and function. Adult human cardiomyocytes have an intricate cellular structure to enable the regulation and coordination of electric flow and contraction. While both cardiac and skeletal myocytes are striated, significant differences between the two cell types exist. Most human cardiomyocytes are binucleated, the result of a lack of cell cleavage in the last round of mitosis during heart development (Ahuja et al., 2007), whereas skeletal myocytes may have hundreds of nuclei per cell resulting from the fusion of myoblasts in development. Next, cardiac myocytes are often branched with branching myofibrils, whereas skeletal myocytes are cylindrical and unbranched (**Fig. 4**). The branching nature of the cardiac myocyte and its myofibrils is essential for the multidirectional nature of their contraction in the pumping of blood. Additionally, cardiac muscle has intercalated disks, myocyte-to-myocyte junctions that allow the conduction of action potentials from one muscle cell to another via a modified gap junction. Intercalated disks also contain desmosomal and adherence junctional components that are essential in the transmission of force from myocyte to myocyte. Skeletal muscle does not

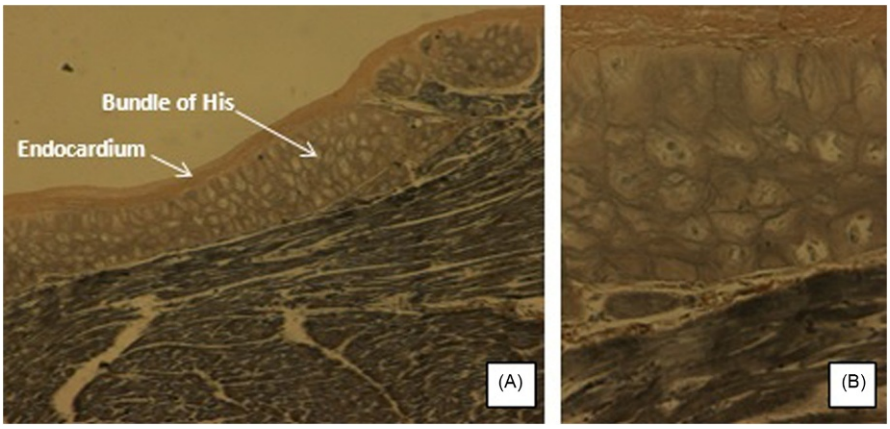

Fig. 2 Distinction between myocytes of the working myocardium and conduction system. This histological section depicts the left side of the interventricular septum with the ventricular lumen seen at the upper left of *panel A*. Myocytes of the bundle of His are seen as larger, lighter staining cells just beneath the endocardium. The higher-power view in *B* demonstrates the conduction system myocytes are larger in size and lighter stains indicating that these cells contain fewer myofibrils.

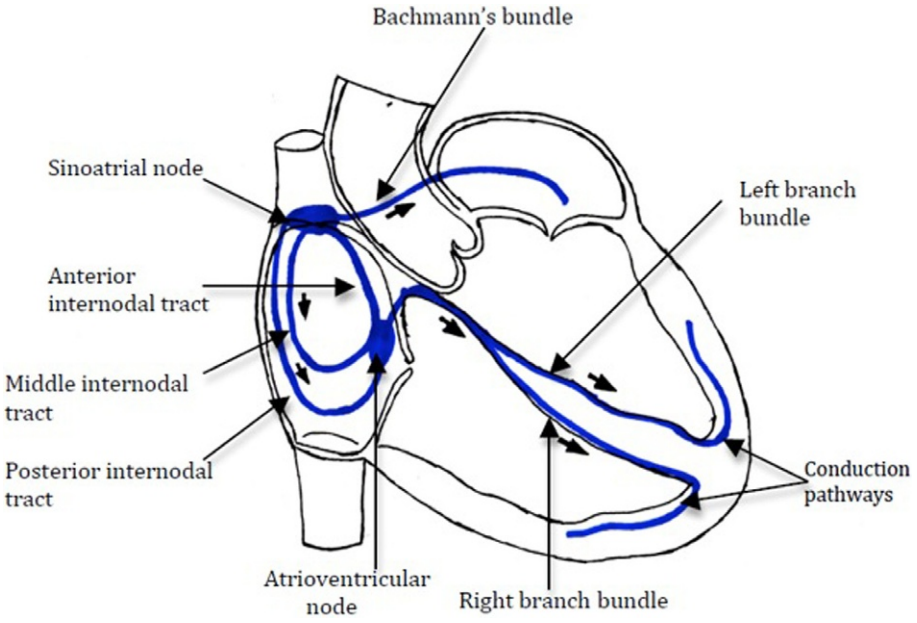

Fig. 3 Schematic diagram of the cardiac conduction system. Components of the human conduction system are given here.

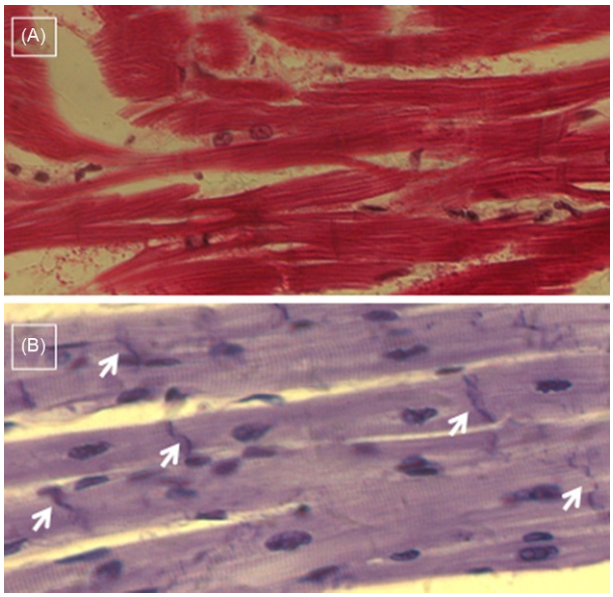

Fig. 4 Histology of working cardiac myocytes. In *panel A*, the branching nature of working cardiac myocytes can be readily seen in this trichrome stain. Darkly stained intercalated disks *(arrows)* are very apparent in toluidine blue-stained section of *panel B*. These structures contain myocyte/myocyte junctions enabling the transmission of force and electricity in the myocardium.

conduct electricity or force from muscle cell to muscle cell. Cardiac muscle cells contain transverse tubules (T tubules) and sarcoplasmic reticula similar to skeletal muscle cells but arranged somewhat differently. T tubules, which are inward extensions of the cell membrane, bring the depolarization signal to juxtaposed extensions of the sarcoplasmic reticulum. After receiving this signal, the sarcoplasm releases calcium to initiate the coordinated contraction of all sarcomeres within the myocyte. T tubule system is most prominent in myocytes of the ventricles and less in the atria. This is due to the greater number of myofibrils in the ventricular cells and the need to bring electric conduction to all of them simultaneously. In addition, the sarcoplasmic reticula do not fully encircle the myofibrils as they do in skeletal muscle but are found between them. This brief discussion of the subcellular structure of the cardiac myocyte is presented to give context in the description of the cardiovascular system. For a deeper understanding of T tubule system, see Ibrahim et al. (2011). Additionally, the reader is encouraged to explore the literature and texts for a more in-depth description of this interesting cell type.

The Blood Vessels

There are three major subdivisions of the vascular tree: arteries, capillaries, and veins. Arteries deliver blood from the heart to capillary beds positioned throughout the tissues/organs of the entire body. Capillaries serve as the major fluid/material/cell exchanger of the cardiovascular system to and from the body space. Lastly, veins return blood from the diverse and broadly positioned capillary beds of the body to the heart. It should be emphasized that there is great diversity of structure and function between each of these three categories but that diversity is also seen within each vessel type. Yet, at the same time, these vessels are a continuum of shared component parts serving the overarching function of blood transport throughout the body.

Overall structure

Arteries and veins ofttimes run in tandem throughout the body. This offers an excellent opportunity to examine the overall differences in the structure of these two vessel types. Even a quick look at Fig. 5 reveals the general differences seen in veins and their partner arteries. Note that the vein is larger than the accompanying artery. While the artery is smaller in diameter, its wall is thicker than the vein. The larger and more flaccid vein has the capacity to hold/store more blood than its arterial partner. Conversely, the smaller diameter of the artery and the constructive nature of its wall are important in regulating blood flow. The size and shape differences seen here are maintained throughout the vascular tree.

There are three distinct domains that make up the vessel walls of the cardiovascular tree. A high-power view of the mid-sized vessels seen in Fig. 5 illustrates these domains and how they differ in arteries and veins (Fig. 6). The innermost domain of a blood vessel facing the lumen is the *tunica intima*. Abutting the lumen, the tunica intima consists of an endothelial sheet and its subjacent basal lamina. In larger vessels, the intima may also contain a small connective tissue component in its structure. In smaller arteries and veins, this connective tissue component becomes very attenuated and is absent in capillaries. The middle domain in the generalized structure of vessels is termed the *tunica media*. This domain shows great variation in its size and composition ranging from scores of layers of smooth muscle cells and associated connective tissue laminae in the aorta to a complete absence in capillaries. Composition of this domain varies hugely in its resident cells and extracellular matrix. Note that the tunica media of the vein in Fig. 6 has only one or two layers of smooth muscle whereas the artery has 10–12 layers. The last and outermost layer, the *tunica adventitia*, is a connective tissue domain that links vessels to the connective tissue of the organ in which the vessel resides. Indeed, the boundary between the tunica adventitia and surrounding connective tissue space can be somewhat arbitrary. The diversity, form, and function of these domains will be discussed in the following description of the vessel types. With this background in mind, let us discuss individual components of the cardiovascular tree.

Another important consideration in understanding the overall structure and function of blood vessels is the variation in blood pressure seen throughout the system. Fig. 7 shows the systolic and diastolic blood pressures in the various vessel types discussed later. In a healthy individual, systolic and diastolic blood pressure leaving the heart is 120 over 80, and these pressures are seen in the large arteries proximate to the heart. Interestingly, blood pressures drop precipitously at the terminal arterial vessels, arterioles (discussed later), and very low pressure is observed in the capillary beds and venous return. Dealing with variant blood pressures plays a large role in the structural/functional relationships in the vascular tree.

Arteries

The overarching function of the arterial tree is to deliver/distribute blood to organs of the body. Important in the consideration is that the total volume of blood in the body is much smaller than the volume of the entire cardiovascular network; that is, there is not enough blood to fill all the blood vessels in the body at the same time if all vessels were in a relaxed or fully opened state. Also, the

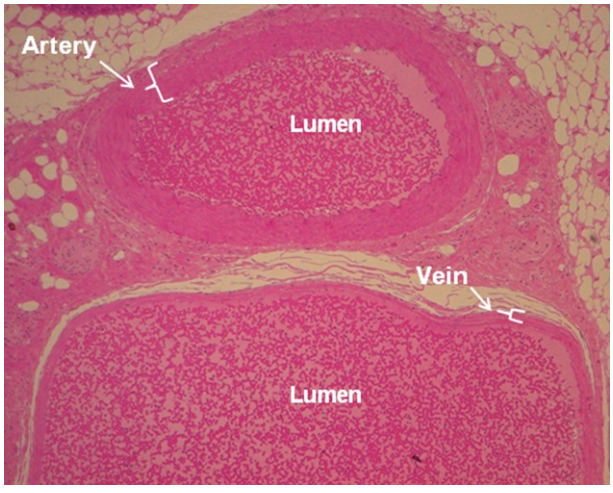

Fig. 5 Histological structure of the vascular tree. This cross section through a mid-sized artery and accompanying vein provides an example of the overall configuration of the vascular tree. Note that the luminal diameters of the vein and artery vary greatly as does the thickness of the vessel walls *(brackets)*.

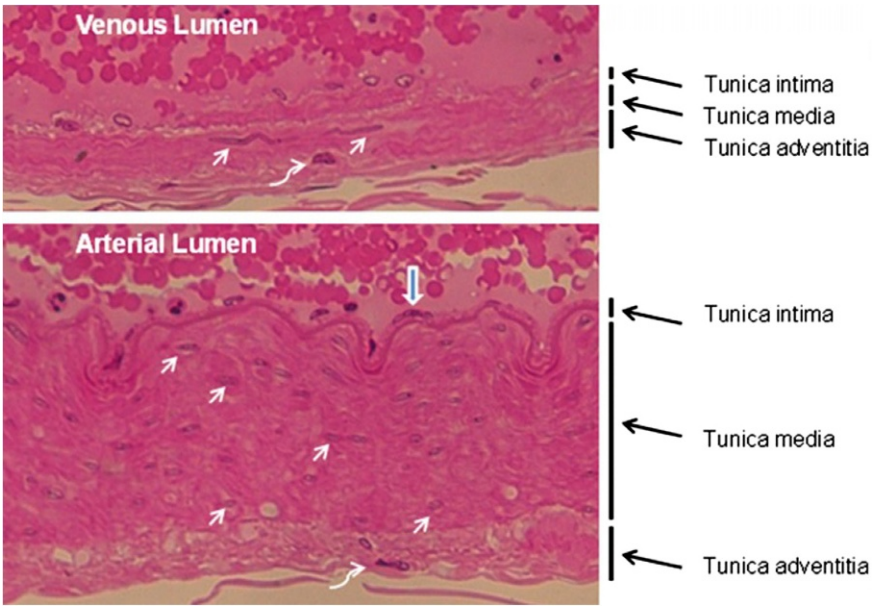

Fig. 6 Differences in venous and arterial vessel walls. This is a higher magnification of the vessels seen in **Fig. 5**. Note the overall variation in wall thickness between the two vessels and the relative thickness of the arterial tunica media compared with its venous partner. The *arrow with the blue interior* marks the nucleus of an endothelial cell in the arterial tunica intima. The *arrowheads* denote smooth muscle nuclei in both vessel types; the vein has a media consisting of only one or two smooth muscle cells, whereas the artery has 10–12 of these cells in its media. The *curved arrow* in both the venous and arterial walls marks a fibroblast of the tunica adventitia. These nuclei are typically more heterochromatic than smooth muscle counterparts giving them a darker blue color in this H and E stain.

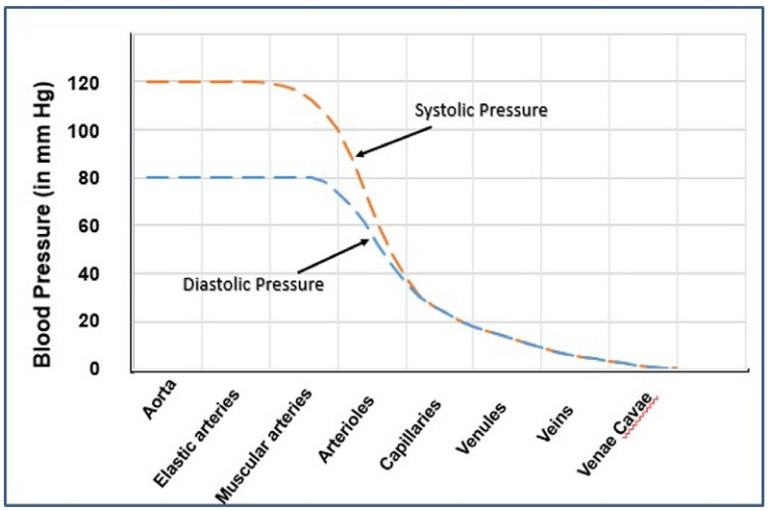

Fig. 7 Variations in systolic and diastolic blood pressure in different vessels of the cardiovascular tree. Systolic and diastolic blood pressure in the aorta and other elastic arteries is maintained at 120/80. These pressures decrease greatly in the muscular/distributing arteries and arterioles. Capillaries and veins have constant pressures less than 20 mmHg. Obviously, the structure and function of these varying vessels are intimately tied to the blood pressures observed within.

potential pool for housing blood is much greater in the venous side of circulation. Thus, the body senses where and when blood is needed, and the arterial tree responds by constricting and relaxing specific blood vessel pathways so that blood is delivered to the proper locale. The mechanism by which this is achieved is given in the succeeding text. There are three major subdivisions of the arterial tree: elastic and muscular arteries and arterioles. As one might expect, there are huge differences in the composition of the three tunicae in these vessels.

Elastic arteries

As the blood leaves the ventricles of the heart, the first type of vessel encountered is an elastic artery being either the aorta or pulmonary artery. The stroke volume of right and left ventricles is just under 100 ± 15 mL in a 150 pound man (Maceira et al.,

2006). Considering that healthy individuals have heart rates from 60 to 100 beats min^{-1}, these arteries are under tremendous strain dealing with rapid and constant volume changes. The structure of the elastic arterial wall is built to withstand this turbulence.

The tunica intima of elastic arteries is thicker than seen in other vessels. From the lumen outward, endothelial cells, oriented longitudinally along the vessel, are first seen. Next, a connective tissue space abutting the endothelial basal lamina extends to the inner boundary of the tunica media and accounts for the relatively thicker nature of the tunica intima. The thicker nature of the tunica intima in large elastic arteries is likely important in allowing distensibility of the vessel. Moving away from the vessel lumen, the tunica media is next seen. The smooth muscle cells of this layer have their longitudinal axis oriented perpendicular to the long axis of the vessel and are thus seen in longitudinal fashion in cross sections of the elastic artery. Elastic sheets and collagen fibers are situated between the layers of smooth muscle and give the entire tunica media its distinctive alternating pattern of smooth muscle cells and elastic laminae (**Fig. 8**). Elastin, collagen, and all other components of the laminae and interstitial matrix are secreted by smooth muscle cells of the media. The tunica media of elastic arteries has numerous smooth muscle cells with alternating elastic laminae; the aorta of humans may have 70 or more elastic laminae with accompanying layers of smooth muscle. By definition, the innermost elastic lamina is called the internal elastic lamina and constitutes the inner boundary of the tunica media. In turn, the external most lamina is defined as the external elastic lamina and is the external boundary of the tunica media. Interestingly, the embryonic source of smooth muscle cells in elastic arteries is diverse with specific descendants of these progenitors populating specific domains of the vessels (Pfaltzgraff and Bader, 2015). These regional differences in derivation of smooth muscle may underlie variation in vascular physiology and disease response. Exterior to the outermost elastic lamina is the tunica adventitia, which is composed primarily of connective tissue. This connective tissue blends with connective tissue of the surrounding area and serves to integrate the vessel into the specific region of the body.

In the human body, elastic arteries extend from the pulmonary trunk and the aorta and its major branches including the common carotid, brachiocephalic, vertebral, pulmonary, subclavian, and common iliac arteries. The aorta and pulmonary artery are very large vessels with a significantly large luminae and diameters, which are tapered as the cardiovascular tree becomes more distant from the heart (compare **Figs. 8** and **9**, which have been at the same magnification). Interestingly, the larger vessels and their accompanying veins need their own blood supply to survive. This capillary system is called the vasa vasorum, meaning "vessels of the vessel" and bring oxygenated blood to the outer vessel wall.

Muscular arteries

There is a gradual transition from a purely elastic artery to a purely muscular artery. A decrease in overall size and luminal diameter of the vessels accompanies this transition. Thus, the exact anatomical position when an elastic artery becomes a muscular artery is somewhat arbitrary. Examples of muscular (also termed distributing) arteries are the branchial, ulnar, and radial arteries of the arm and the femoral, popliteal, and tibial arteries of the leg. In the head and neck region, arteries distal to the brachiocephalic artery take on the characteristics of muscular arteries. The tunica intima of these vessels is thinner than that of an elastic artery but has the same characteristic features. This tunic and the internal elastic lamina are often seen in a distinctly scalloped fashion in tissue preparations (**Fig. 9**). This is likely due to the contraction of vesicular smooth muscle upon fixation. The tunica media is bounded by the prominent internal elastic lamina with its scalloped shape and at its periphery by a more fragmented external elastic lamina with the intervening space filled by smooth muscle. These vessels have elastin and collagen throughout their tunica media, but there is not the distinctive configuration into elastic laminae seen in elastic arteries. The tunica adventitia as seen in other vessels is predominantly composed by connective tissue that blends with the connective tissue proper of the surrounding organ. Ofttimes, the tunica adventitia of these arteries and the accompanying veins are conjoined (see arrows in **Fig. 9**). From a proximal to distil position in the

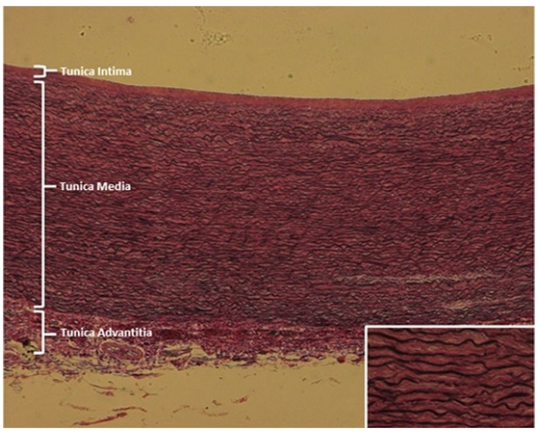

Fig. 8 Histological section of the human aorta (an elastic artery). This low-power view of the aorta stained with an elastin stain shows the three distinct tunicae of the vessel; the intima, media, and adventitia. The *purple structures* in the tunica media are the elastic laminae produced by the intervening smooth muscle of this region. The higher-power *inset* shows the "wavy" purple elastic laminae with the pink-stained smooth muscle. This arrangement allows for the rhythmic expansion and recoil of the elastic aorta.

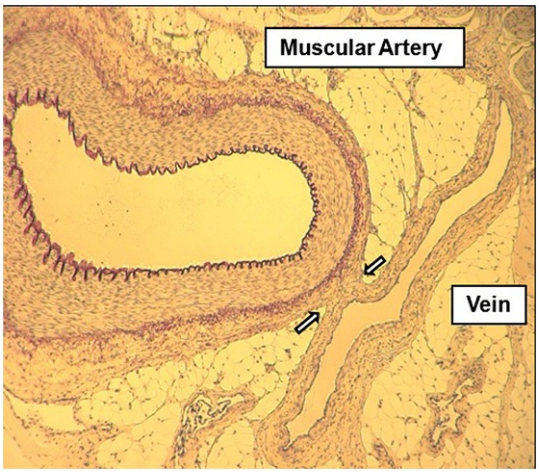

Fig. 9 Histology of muscular artery with an accompanying vein. A cross section of a muscular artery and its accompanying vein is seen in this elastin-stained specimen. The distinct internal elastic lamina is seen in its characteristic "scallop" shape. At this power, the tunica intima, lying toward the luminal side of the internal elastic lamina, is difficult to detect. The external elastic lamina is more fragmented in appearance and separates the tunica media from the tunica adventitia. The *arrows* in this figure show a region of where the adventitia of this artery and its accompanying vein merge. Note the collapsed nature of the vein versus the artery and that the venous wall is predominately made up of the tunica adventitia. Further, the magnification of this specimen is the same as seen in **Fig. 4**, the depiction of the elastic aorta. Note the difference in the relative size of the vessels and especially their tunica media.

arterial tree, muscular/distributing arteries decrease in total size and luminal diameter and have a reduced amount of elastic tissue in their tunica media. The number of smooth muscle cells in the tunica media also attenuates.

The major function of muscular arteries is regulating the "selective" distribution of blood. The muscular tunica media of muscular arteries is proportionately the largest muscular component of any blood vessel and is most active in vasoconstriction. In considering this function, think of blood flow after you have consumed a large meal. Your body senses the presence of food stuffs in your digestive tract, and the relaxation of smooth muscle in muscular arteries serving the gut provides a larger volume of blood to those organs. The same is true when running a race. Blood is preferentially distributed to skeletal muscles of the extremities and, simultaneously, diverted from the gut. This large-scale regulation of blood distribution is coupled with a more fine-scaled regulatory system, the arteriole, which is next in our discussion.

Arterioles

The terminal unit of the arterial tree is the arteriole, which is directly adjacent to the capillary bed. The lumen of these vessels tapers to just under 40 mm. The tunica intima of arterioles is highly attenuated consisting of an endothelium and accompanying basal lamina with scarcely any connective tissue components. The tunica media houses one to five layers of smooth muscle with little if any elastin. A thin tunica adventitia is present and, as always, blends with the surrounding connective tissue of the organ.

The major function of arterioles is to regulate the flow and, thus, the volume of blood entering capillary beds. When arteriolar smooth muscle is relaxed, blood flows into adjoining/distal capillaries, and the entire bed is filled in blood. Conversely, when arteriolar smooth muscle contracts, blood flow is lessened to distal capillaries and, thus, to that region of the body. Lastly, it is important to understand that blood pressure drops precipitously at the arteriole/capillary border (**Fig. 10**). Given the extremely delicate nature of the capillary wall, this decrease in pressure is essential in capillary function.

Capillaries

Capillaries are the most distal component of the cardiovascular system. Throughout the body, they are the anastomosing connection between arterial and venous vessels. Capillaries are by far the most prevalent members of the vascular tree, and approximately 60,000 miles of capillaries are present within the human body (Siddiqui, 2011). The human brain alone has 100 billion capillaries extending 400 miles (van Tellingen et al., 2015). Concerning gas, fluid, and material exchange, the capillary is the "business end" of the cardiovascular system. These beds anastomose within the connective tissue space of organs such that all cells of the supplied area are within one to three cell widths from a capillary. The luminal diameter of capillaries is approximately 9–10 μm, marginally larger than a red blood cell (RBC). White blood cells that have larger diameters reshape/redistribute their cytoplasm to pass through capillary beds. Interestingly, intermittent thoroughfare channels (also known as metarterioles and also depicted in **Fig. 10**) provide an "express route" to move blood more directly to the venous return virtually bypassing the capillary bed. These vessels do not have the robust layer of smooth muscle seen in arterioles at their proximal/arterial end. Instead, a single, discontinuous layer of smooth muscle is seen at the arterial/proximate region of the thoroughfare channel. This smooth muscle layer gradually subsides toward the venous/distal region of this channel. In this way, when arterioles in one region of the body collectively close, arterial blood is quickly shunted through these thoroughfares to the venous return making this blood available for other parts of the organism that are in greater need of blood.

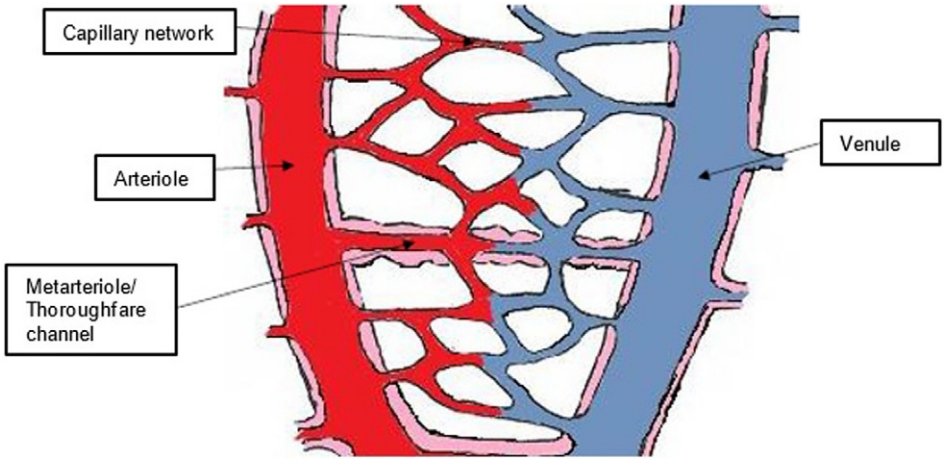

Fig. 10 Arterioles, capillaries, and venules. This schematic depicts the arteriole system leading to a capillary bed. Arterioles regulate the flow of blood to capillary beds through constriction and dilation of their terminal orifices. A metarteriole/thoroughfare channel is also shown. This vessel can provide a direct shunt from the arteriole to venous pole, thus avoiding the capillary bed. Venules, at the distal end of the capillary bed, are the first component in the venous return.

The overarching function of capillaries is to enable exchange of oxygen, fluids, nutrients, carbon dioxide, and other substances between the cardiovascular system and other body compartments. Capillaries have the same basic structure throughout the body, although critical variation in structure/function is noted later. In essence, capillaries are a continuation of the tunica intima seen in arteries and veins. Capillaries consist of an inner endothelium resting on a basal lamina, which is secreted by the endothelium. While a definitive tunica media and adventitia are absent in capillaries, specific mesenchymal cells are seen intermittently adjacent to the basal lamina of the capillary. One of these cell types is called the pericyte. This cell is connective tissue cell with contractile properties. Other connective tissue cells with phagocytic and fibroblastic properties are also scattered along the capillary network. This basic structure is modified throughout the body depending on the particular function of each capillary bed.

There are three major subcategories of these vessels: continuous, fenestrated, and discontinuous capillaries. We give an example of each capillary as a means of describing their varying function.

Continuous capillaries, as the name implies, have a continuous endothelial sheet of cells at the luminal surface with a continuous subjacent basal lamina (**Fig. 11**). Cell/cell junctions insure that the luminal blood is restricted to the vessel while the attenuated endothelial cytoplasm promotes exchange of materials from the blood supply to the surrounding tissue. Let us consider the blood supply to the lung as a means of discussing the structure and function of continuous capillaries.

Deoxygenated blood originating from the right ventricle enters the lung via the elastic pulmonary artery. This artery quickly branches into muscular distributing arteries that roughly follow the branching pulmonary tree that supplies the lungs with air. Many orders of branching and subdivision follow in both systems until the airway is reduced to a single epithelial sheet called the terminal alveolus, while the cardiovascular system ends in continuous capillaries. As seen in the accompanying figure, these two simple squamous epithelia rest on a shared basal lamina. Thus, the structure between the air of the outside world and the lumen of your cardiovascular system is reduced to two attenuated epithelial sheets and a common basal lamina. It is important to remember that the endothelial cells in the lungs form a continuous capillary system. While the cells are very attenuated and very closely associated with the epithelia of the airways, the continuous nature of these capillaries keeps the blood within the cardiovascular system preventing you from drowning in your own blood. Thus, the complex branching of the airway and bloodstream results in a simple cellular arrangement where inhaled oxygen is in close proximity to RBCs.

A similar configuration of continuous capillaries is seen in the brain and spinal cord, in smooth, skeletal and cardiac muscle, and in most of the connective tissue compartments of your body. Indeed, continuous capillaries are the most prevalent capillary seen in the human body.

The next type of capillary seen in the body is the fenestrated capillary. These vessels are present where more extensive fluid interchange between the cardiovascular system and the organ/body compartment takes place. Examples are the glomeruli of the kidneys, villi of the small intestine, and endocrine glands. Fenestrated capillaries are continuous in nature with a continuous basal lamina but have domains within the endothelial cell where very thin windows or fenestrae reside (**Fig. 11**). These windows are thinner than the diameter of a single plasma membrane and vary in diameter. Interestingly, with the great advances science has made over the past years, the definitive structure of capillary fenestrae has not been resolved although factors influencing their development have been identified (Satchell and Braet, 2009).

Fenestrae vary in number and size in different populations of capillaries, but it should be noted that transport across these structures is in the range of molecules and not at the level of intact cells. Obviously, fluid exchange is a major function in the kidney. Glomeruli of the kidney are the most distal structures of the nephron and are intimately associated capillary beds. The capillaries within the glomeruli actually have small opening or gaps within their fenestrae and have a mildly elevated hydrostatic pressure that pushes fluids out of the vessel across the associated basal lamina. Glomerular epithelial cells (called podocytes) have gaps between

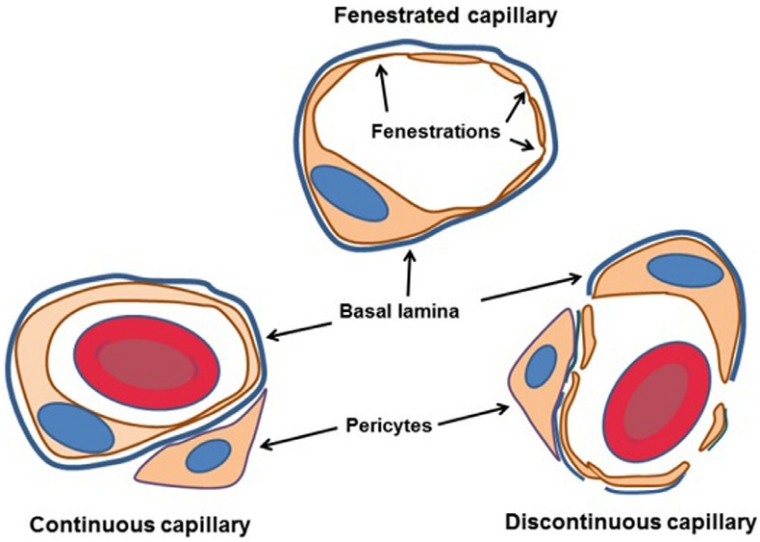

Fig. 11 Capillary structure. The three major types of capillaries are depicted. At the lower left, a continuous capillary is seen in cross section with its continuous endothelial lining, continuous basal lamina, and an associated pericyte. A fenestrated capillary with its "windowed" fenestrations is seen at the top and middle. At the lower right, a discontinuous capillary is shown with gaps in both the cellular endothelial lining and basal lamina of this vessel type. The relative size of these vessels can be discerned by comparing the diameter of the red-colored RBC (6–8 μm in the human) to the capillary lumen.

cells allowing the passage of fluids, ions, and small molecules into the initial nephric space. This is the first step in production of urine and the elimination of excise fluids from the cardiovascular system. The configuration of the capillaries within the glomerulus promotes the movement of fluids out of the blood system to the urinary tract.

The third major capillary form is the discontinuous capillary. This type of capillary is found in regions of the body where whole-cell entry and exit from the cardiovascular system is observed and includes organs such as the liver, spleen, and bone marrow. In this setting, gaps in the endothelial cell sheet occur with accompanying spaces in the subjacent basal laminae (Fig. 11). Hematopoiesis is a major function of the blood marrow, and newly matured red and white cells can freely migrate from the stroma through discontinuous endothelial cells in the marrow to enter the blood stream. Conversely, blood flow in the spleen is virtually an open system where cells, such as RBCs, exit the cardiovascular system and are surveyed by resident splenocytes. These splenocytes can determine which RBCs are ready to be eliminated due to their age (remember that human RBCs function to deliver oxygen for 120 days and then are eliminated in the spleen by those splenocytes). RBCs that have not reached 120 days of maturity are not eliminated and return to the bloodstream through the same discontinuous capillaries and exit the spleen to continue their duties in gas exchange.

It is interesting how nature and evolution have conserved the overall function of capillaries in these three different settings while, at the same time, promoting variation to meet the varying needs of a complex organism such as the human being.

Veins

From a cursory glance at veins, one sees a rather boring trip back to the heart for blood. But, a closer look reveals interesting properties in these vessels.

The venous return begins with the postcapillary venules. These vessels have the three tunics, but they are highly attenuated (see Figs. 5, 6, and 9). Endothelia of postcapillary venules can be continuous or discontinuous, basically following the pattern seen in the accompanying capillary bed. The tunica media of these vessels is very slight housing pericytes, fibroblasts, reticular cells, and smooth muscle cells. These cells are usually no more than one or two cell layers in thickness that are ofttimes seen individually. The adventitia is also very thin and blends with surrounding connective tissue. Postcapillary venules are an important component in fluid and cell exchange from the vascular tree throughout the body.

Veins can be categorized as small, medium, or large and are accompanied by their arterial partner throughout the body (Figs. 5 and 9). In histological analyses, defining one vessel as small, medium, or large vein is somewhat arbitrary as transition from one category to the next is gradual. As one might expect, the venous vessel size and luminal diameter increase the closer they are to the heart. The luminal diameter of a vein may be four or five times larger than its accompanying artery anywhere along the cardiovascular tree. All veins are composed of the three tunics. In general, the tunica adventitia is proportionately larger than seen in arteries and makes up the majority of the vessel wall. The tunica media is proportionately smaller, and the boundary between these two tunics is often difficult to define. Smooth muscle is limited in even the largest vessels. The tunica intima contains the standard cellular and extracellular components and is thinner than its arterial counterpart.

A major consideration in the analysis of the venous return is their gross anatomical position relative to the heart. The flow of blood throughout the venous tree is largely powered by the overall movement and position of the body and not by the vessels themselves; remember smooth muscle is not prominent in veins. Indeed, gravity is a major driving force in venous blood flow.

Think about sitting at your desk for long periods of time and noticing that your feet feel "puffy." That is in part due to a lack of body movement and an accumulation of fluids in your lower extremities.

Veins can be thought of as supra- or infracardiac; that is, they are located above or below the heart. Gravity is a positive factor in blood flow in vessels located above the heart, while it is a negative factor in vessels located below the heart. Infracardiac veins have valves that protrude into the vessel lumen. These valves are an extension of the tunica intima having an endothelial covering with a slight connective tissue core. These structures are essential in preventing backflow of blood in infracardiac veins.

Lymphatic Vessels

The overall function of this system is to transport fluids, materials, and cells from the tissue space of the body through a series of lymphatic tissues/nodes back to the major veins entering the heart where the lymph is again reunited with blood. The lymphatic system is highly integrated throughout the human body with the notable exceptions of cartilage, bone, thymus, teeth, and the central nervous system. Unlike the cardiovascular tree, flow in the lymphatic system is unidirectional with all flow from the periphery of the body back to the heart. Lymph, the fluid present in this system, is a filtrate of blood. Fluid that exits the cardiovascular tree moving into the tissue space throughout the body is an essential component of that domain. The lymphatic system is basically an open circulatory tract with an open connection to the tissue space of the body, and lymph can freely move between the tissue space and lymphatics. Lymphatic capillaries, the distal most component of the lymphatic system, are composed of a simple endothelium with an accompanying basal lamina. This endothelium is largely discontinuous and lacks the accompanying connective tissue components seen in blood capillaries. These lymphatic capillaries are somewhat larger than the blood capillary and often have a flattened appearance. Lymphatic vessels increase in diameter and size as they move proximally in the body. Still, the vessel wall remains very thin relative to arteries and veins in the same body regions. Valves, like those of the infracardiac venous system, are present in larger lymphatic vessels. The larger lymphatic vessels do have a limited amount of connective tissue and the occasional pericyte or smooth muscle cell. Distinguishing definitive tunics is difficult even in the largest vessels of this system.

As noted earlier, fluid from the diverse tissue compartments of the body freely enters the lymphatic tree at its distal branches. This fluid that also contains particulate matter and cells of the lymphoid system moves proximally as branches converge to form larger vessels. These larger vessels encounter a series of lymph nodes in the neck, groin, and axillary regions of the body. Lymph nodes have a connective tissue capsule that is penetrated by these vessels. Vessels that feed into the node are termed afferent vessels. Circulation within the node in essentially open lymph is surveyed by cells of the lymphatic system. Infectious microorganisms, damaged cells, and particulate debris in the lymph are eliminated or attacked by macrophages, plasma cells, and lymphocytes that are present in the node. The open sinuses of the node converge and form a single efferent lymphatic vessel that emerges from the node opposite to the region where afferent vessels enter. This vessel proceeds proximally and, ofttimes, encounters another node. In this case, the vessel would be then considered an afferent vessel. Like the cardiovascular tree, lymphatic vessels continue to join together making ever larger vessels. The two largest lymphatic vessels, the thoracic duct and the right lymphatic duct, connect with the venous return in the region of the neck, reuniting lymph with its parental blood.

To reiterate, fluids leaving the cardiovascular system are placed in diverse compartments of the body's connective tissue space. This fluid can freely enter the lymphatic system that transports it back toward the heart. Along the way, lymph is filtered and monitored by the lymph nodes until it is returned to the blood system. Thus, the two circulatory systems operate in a parallel yet connected manner.

Overall Summary

In reflecting on the structure and function of the cardiovascular system, one understands that there is great variation in its components. Yet, there are also concatenating themes that remain constant in these diversities. We hope this presentation will provide a groundwork upon which the reader can then explore this vital component in biological systems.

Epidemiology and Risk Factors

Sudden cardiac death (SCD) is defined as unexpected, nontraumatic death occurring within 1 hour of the onset of new or worsening symptoms (witnessed arrest) or, if unwitnessed, within 24 h of last being seen alive. By definition, a patient with SCD does not survive. When the patient survives, the event is termed aborted SCD or sudden cardiac arrest (SCA) (Priori et al., 2015; Zipes et al., 2006).

The clinical presentation of SCD generates a broad differential diagnosis. However, in both males and females over the age of 30, SCD is most commonly associated with ischemic heart disease (Priori et al., 2015). SCD may be preceded by cardiovascular symptoms such as chest pain, dyspnea, palpitations, presyncope, or syncope, but many individuals have no symptoms prior to their SCD event. The proximal cause of SCD in most instances is either ventricular fibrillation (VF) or ventricular tachycardia (VT). However, in a significant minority of cases, asystole or pulseless electrical activity is the initial documented rhythm. In these cases, the potential etiologies are more numerous and may include noncardiac causes (Priori et al., 2015; Zipes et al., 2006).

The most common causes of SCD are listed in **Table 1**. Broad categories of SCD include those related to ischemic heart disease, nonischemic structural heart disease, primary electrical disease, and noncardiac disease (**Fig. 1**).

SCD is common with an annual worldwide incidence that ranges from 1.4 per 100,000 in females to 6.8 per 100,000 person-years in males (Priori et al., 2015). Of the approximately 17 million cardiovascular deaths per year worldwide, SCD accounts for approximately 4.25 million (25%) of them. Other data suggest a lower overall incidence. Using death certificate data, it is estimated that SCD accounts for approximately 15% of all deaths in western nations (Zipes et al., 2006). In fact, death certificate data may overestimate the incidence since many deaths may be attributed to SCD but are actually unexplained. For example, extrapolated data from the Oregon Sudden Unexpected Death Study (SUDS) suggests that SCD accounts for only around 5.6% of all deaths in the United States (Zipes et al., 2006).

SCD incidence increases with age. The incidence of SCD in younger populations (<30 years) is 100-fold lower than that in older individuals (Zipes et al., 2006). Females are relatively protected from the risk of SCD until the postmenopausal years when incidence then approaches that of males. However, even in younger females, conventional coronary artery disease (CAD) risk factors are predictive of SCD events. Genetic factors play a role in SCD at multiple steps in the pathophysiologic pathway (Arking et al., 2011; Bezzina et al., 2010). At least two studies have described a familial propensity for SCD as the initial presentation of CAD. Mutations and polymorphisms modulate the risk of SCD associated with both CAD- and non-CAD-related events. Some studies have demonstrated an increased risk of SCD in African Americans compared to Caucasians while Hispanic individuals may be at lower risk (Zipes et al., 2006).

Relative to other causes of death, SCD accounts for a very significant proportion of events (Stecker et al., 2014). In males, SCD incidence exceeds that of other causes of death including individual cancers (lung, prostate, and colorectal), accidents, chronic respiratory diseases, diabetes, and cerebrovascular disease. In females, SCD incidence is similar to that of lung cancer and cerebrovascular disease and is higher than that of other causes of death including breast cancer, colorectal cancer, Alzheimer's disease, and accidents. When expressed as years of potential life lost, the impact of SCD is impressive (Kuriachan et al., 2015).

At the time of their SCA, nearly 50% of people were not known to have structural heart disease (Priori et al., 2015). Accordingly, in this patient population, risk stratification is particularly challenging. Furthermore, 40% of SCD occurs in individuals with known heart disease but with a left ventricular ejection fraction (LVEF) greater than 40% (Wellens et al., 2014). Our ability to predict SCD

Table 1 Major causes of sudden cardiac death

Ischemic heart disease
Coronary artery disease with myocardial infarction or angina
Coronary artery embolism
Nonatherogenic coronary artery disease (arteritis, dissection, congenital coronary anomalies)
Coronary artery spasm
Nonischemic heart disease
Hypertrophic cardiomyopathy
Dilated cardiomyopathy
Valvular heart disease
Congenital heart disease
Arrhythmogenic right ventricular cardiomyopathy
Myocarditis
Cardiac tamponade
Acute myocardial rupture
Aortic dissection
No structural heart disease
Idiopathic ventricular fibrillation/J-wave syndrome
Brugada syndrome
Long QT syndrome with torsades de pointes
Familial sudden cardiac death
Commotio cordis
Noncardiac disease
Pulmonary embolism
Intracranial hemorrhage
Drowning
Pickwickian syndrome
Drug overdose/toxicity
Central airway obstruction
Sudden infant death syndrome

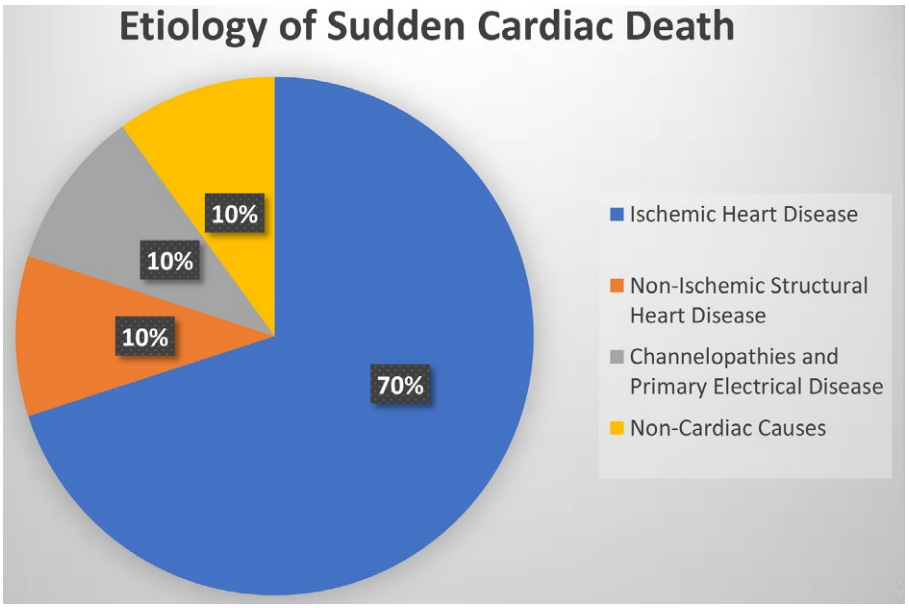

Fig. 1 Etiology of sudden cardiac death (all ages).

in this population is also limited. The remaining (approximately 10%) incidence of SCD affects individuals with known structural heart disease and an LVEF less than 40%. It is, therefore, not surprising that current risk stratification tools and therapies such as implantable cardioverter defibrillators (ICDs) have had only a modest impact on the overall problem of SCD (Stecker et al., 2014; Wellens et al., 2014). Inherited channelopathies account for only 2% of all SCD. Because the majority of SCD events occur in

individuals without known structural heart disease, efforts to prevent SCD should be directed toward the identification and modification of conventional risk factors.

The risk factors for SCD in older adults (age >35) are similar to those for ischemic heart disease and include tobacco smoking, systemic hypertension, dyslipidemia, and diabetes (Kuriachan et al., 2015). In the Framingham population, smoking conferred a 2-fold increased risk of SCD. Furthermore, in one study, people who continued to smoke after their aborted SCD had a risk of recurrent SCA of 27% over the subsequent 3 years compared to 19% in those who stopped smoking (Stecker et al., 2014). Obesity also confers an increased risk of SCD in patients with CAD (Wellens et al., 2014). There is conflicting data with respect to sedentary lifestyle as a risk factor for SCD. The risk of SCD is increased (approximately 17-fold) during vigorous physical activity especially in those who are generally sedentary (approximately 74-fold). However, the absolute risk of SCD during a single episode of vigorous exercise is very low (1 per 1.51 million episodes of exercise) (Albert et al., 2000). Furthermore, regular participation in physical exercise attenuates the overall risk of SCD both during exercise and at rest. Psychosocial stressors also increase the risk of SCD. Major disasters such as earthquakes and war increase the incidence of SCD in affected populations (Kark et al., 1995). Heavy alcohol consumption, defined as six or more drinks per day, increases the risk of SCD, while moderate alcohol consumption, defined as one to two drinks per day, may decrease the risk of SCD (Albert et al., 1999). In contrast, caffeine intake has not been shown to be a risk factor for SCD. Higher levels of long chain n-3 polyunsaturated fatty acids (eicosapentaenoic acid and docosahexaenoic acid; "fish oil") measured in plasma and in red cell membranes are associated with a lower risk for SCD (Albert et al., 2002a). Higher serum C-reactive protein (CRP) levels, a marker of generalized inflammation, have been shown to be associated with increased risk of SCD (Albert et al., 2002b). In 97 cases of SCD among apparently healthy men in the Physicians Health Study, serum CRP levels in the highest quartile were associated with a 2.78-fold increased risk compared to men in the lowest quartile (Albert et al., 2002b). Prospective studies are required to evaluate the impact of direct treatment or mitigation of these risk factors on the incidence of SCD.

In the patient population with established structural heart disease and LVEF >40% several risk stratification tools have been evaluated including tests of autonomic nervous system function (heart rate variability, heart rate turbulence, baroreceptor sensitivity, and, more recently, imaging assessment of cardiac sympathetic activity) (Clements et al., 2016; Exner et al., 2007; Huikuri et al., 2010). In addition, electrocardiographic markers of electrophysiological instability (ventricular premature beat frequency and complexity, QT interval prolongation, QT dispersion, microvolt T-wave alternans) have also been employed as potential risk stratification tools. To date, none of these markers have demonstrated independent, incremental predictive value for the future occurrence of SCD over LVEF alone. Ongoing randomized trials such as Risk Estimation Following Infarction Noninvasive Evaluation-ICD efficacy (REFINE-ICD) (clinicaltrials.gov) and AdreView™ Myocardial Imaging for Risk Evaluation-A Multicentre Trial to Guide ICD Implantation in NYHA Class II & III Heart Failure Patients With 30% ≤ LVEF ≤ 35% (ADMIRE-ICD) (clinicaltrials.gov) are directly assessing combinations of these biomarkers for their ability to select patient populations that have a mortality advantage in randomized fashion in order to clarify risk in this patient cohort.

SCD in Young Persons (Aged 35 Years and Under)

SCD in a young individual (aged 35 years and under) is an especially devastating event because of both its unexpected nature and because of the number of years of life lost. A 3-year prospective study of the general population in Australia and New Zealand performed between 2010 and 2012 identified 490 SCD events that occurred in people aged 1–35 years (Bagnall et al., 2016). The overall incidence of SCD in this age group was estimated to be 1.3 per 100,000. Of these events, the highest incidence was in the 31–35 age category. In this age group, CAD was the dominant etiology. SCD events in the youngest patient cohort (<30 years of age), where a diagnosis could be established, were predominantly due to cardiomyopathies and channelopathies. In the entire cohort, 65% of events occurred either during sleep or at rest (Bagnall et al., 2016). In the population aged 30 and under, approximately 40% of SCD events were unexplained after conventional toxicology and a complete autopsy examination. In 57% of those patients whose SCD events were classified as unexplained, molecular autopsy was performed. Genetic analysis related to candidate genes related to SCD in these 113 patients whose SCD was initially unexplained revealed an inheritable etiology of SCD in 31 patients (27%) (Bagnall et al., 2016). During clinical follow-up, a familial cardiac condition was identified in another 13% of these patients.

From these data, the authors concluded that the addition of genetic testing to the standard clinical investigation, including autopsy, significantly amplified the identification of a potential SCD etiology in this relatively young population. Such testing may have a role in the screening, risk stratification, and follow-up of immediate family members of the decedent (so-called cascade screening) (Bagnall et al., 2016)

Noncardiac Causes of SCD

Most studies have evaluated causes of death using medical records and death certificates. A small population study in Japan, in which 78% of the subjects had an autopsy, suggested that the major causes of sudden death were heart disease (49%), stroke (33%), and aortic aneurysm/dissection (12%) (Nagata et al., 2013).

Neurologic Disorders

Central nervous system disorders that can directly (or indirectly via cardiac interaction) result in sudden death include epilepsy, ischemic stroke, intracranial bleeding, and traumatic head injury (Kuriachan et al., 2015; Finsterer and Wahbi, 2016).

Uncontrolled epilepsy may lead to Sudden Unexplained Death of Epilepsy (SUDEP). Among patients with epilepsy, the incidence of SUDEP is 6/1000 patient-years. SUDEP is usually triggered by a generalized tonic–clonic seizure. It is believed that rare channelopathies may predispose to both epilepsy and SCD. Apnea, bradycardia, and asystole have also been implicated, as has the use of certain antiseizure medications. Finally, associated stress-induced cardiomyopathy (Takutsubo) may also play a role (Finsterer and Wahbi, 2016).

Intracerebral catastrophes, such as stroke and major intracranial bleeding/injury, can cause ECG changes and autonomic imbalance. The ECG changes may include QT-interval prolongation and torsade de pointes VT. Accordingly, it is possible that associated arrhythmias (severe bradycardia or VT/VF) are responsible for SCD in these instances. Patients with these neurologic disorders may also be predisposed to SCD due to underlying cardiovascular disease and an inflammatory state (Kuriachan et al., 2015; Finsterer and Wahbi, 2016).

Preventative treatments include good medical control of a seizure propensity and measures to reduce the incidence of stroke and cerebral injuries including blood pressure control and appropriate anticoagulation for patients with atrial fibrillation. Cardiac monitoring after cerebral catastrophes is important for recognition of related cardiac arrhythmias.

Acute Aortic Syndromes

The acute aortic syndromes include entities that disrupt aortic integrity with complications ranging from aortic rupture to organ ischemia and death. These syndromes include aortic dissection, aneurysm expansion, trauma, penetrating ulcer, and intramural hematoma (Kuriachan et al., 2015; Bonaca and O'Gara, 2014).

Patient risk factors for an acute aortic syndrome include age and hypertension. Loss of tensile strength due to Marfan's syndrome, Ehlers–Danlos syndrome, familial thoracic aortic aneurysm disease, and the aortopathy associated with congenital bicuspid aortic valve also increase risk. Cocaine use is a risk factor due to the increases in blood pressure and heart rate that it produces.

Treatment imperatives include rapid diagnosis, control of blood pressure and shear stress with β-blockers and vasodilators, and early surgical intervention (Kuriachan et al., 2015; Bonaca and O'Gara, 2014).

Electrolyte, Metabolic, and Endocrine Derangements

Life-threatening arrhythmias may result from electrolyte imbalances (especially hypokalemia and hypomagnesemia), metabolic derangements (including acid–base disorders), and severe endocrine disorders (especially hypothyroidism, hyperthyroidism, and hypercatecholaminergic states). Treatments are focused on the underlying disorder and acute correction of electrolyte, metabolic, and endocrine imbalances. Arrhythmias can also accompany eating disorders and aggressive treatments intended to correct them. Weight reduction in obesity and refeeding in anorexia should be controlled with attention to electrolyte fluctuations (Priori et al., 2015).

One major patient group prone to metabolic and electrolyte derangements are those on dialysis. Dialysis patients have a high mortality rate and up to 43% of their deaths are cardiac, with most being due to a cardiac arrhythmia. Risk factors for SCD in dialysis patients include electrolyte shifts, hypervolemia and hypovolemia, left ventricular hypertrophy, systolic and diastolic heart failure, CAD, hyperphosphatemia, sympathetic overactivity, and autonomic dysfunction (Kanbay et al., 2010).

The prevention of SCD in dialysis patients is challenging. During dialysis, care is taken to minimize electrolyte shifts. Traditional medical therapies for CAD, such as statins, have lesser benefits in dialysis patients, suggesting that the role of coronary plaques in SCD may be less important in dialysis patients (Ritz and Wanner, 2008). β-Blockers not only decrease ischemia but also have antiarrhythmic and sympathoinhibitory effects. Accordingly, they also decrease sudden deaths and increase the survival probability of cardiac arrest in diabetic patients on dialysis. Survival benefits from angiotensin-converting enzyme inhibitor (ACE-I) and angiotensin receptor blocker (ARB) treatments have also been demonstrated (Ritz and Wanner, 2008).

ICDs play a major role in the prevention of SCD in many predisposed patient populations. Many of the major trials demonstrating the benefits of ICDs excluded patients with end-stage renal disease. To date, no randomized trials of ICD use have been performed in patients with end-stage renal disease. Nevertheless, a patient with end-stage renal disease is considered for an ICD if survival expectation exceeds 1 year and functional status is good, especially in those patients who have survived aborted SCD (Lehrich et al., 2007). The comorbidities in this patient population generate competing nonarrhythmic causes of death and lead to higher ICD complication rates, thereby limiting the benefits of ICD therapy. Although the benefits have been difficult to document, dialysis staff should have basic life-support training and an external cardiac defibrillator should be on-site.

Medication-Related SCD

Many drugs can cause proarrhythmia that may lead to syncope and sudden death (Kuriachan et al., 2015). The most common mechanism of this proarrhythmia is suppression of the rapid component of the delayed rectifier potassium current (I_{Kr}) resulting in

prolongation of the QT interval and torsade de pointes VT (Li et al., 2010). Risk factors for this form of proarrhythmia include other factors that prolong the QT interval including hypokalemia, hypomagnesaemia, bundle branch block, bradycardia, CHF, inherited long QT abnormalities, and female sex. Accordingly, patients with a QTc greater than 460 msec should be exposed to additional QT prolonging drugs only under close observation.

The noncardiovascular drugs associated with this form of proarrhythmia include certain antibiotics, psychotropic medications, and diuretics (by magnesium and potassium depletion) (Li et al., 2010). A web-based listing of potential culprit medications is available at www.crediblemeds.org.

Cardiovascular drugs may also be proarrhythmic (Kuriachan et al., 2015). Vaughn Williams Class III antiarrhythmic drugs (amiodarone, dronedarone, dofetilide, ibutilide, and sotalol) are potassium channel blockers that prolong QT and may produce torsade de pointes VT. Such agents must be administered with close monitoring of QT intervals, maintenance of normal potassium and magnesium levels, and assurance of normal renal function for those agents that are so excreted (dofetilide, sotalol) (Li et al., 2010). Vaughn Williams Class Ia antiarrhythmic agents (disopyramide, procainamide, quinidine) are also potassium channel blockers that prolong QT and may produce torsade de pointes VT. In addition, these drugs and other Class I agents (lidocaine, mexiletine, propafenone, flecainide) are sodium channel blockers that may prolong QRS duration. Class I antiarrhythmic agents have been associated with SCD particularly in patients with underlying structural heart disease and myocardial fibrosis (Echt et al., 1991). Accordingly, Class I agents are usually reserved for patients with no structural heart disease. Vaughn Williams Class II antiarrhythmic agents (β-blockers) and Class IV agents (nondihydropyridine calcium channel blockers) may result in sinus and/or AV nodal suppression bradycardia especially if used in high doses or in combination.

Although many recreational drugs may result in SCD, the one most implicated is cocaine. Studies in Europe report that 1%–4% of young adults have used cocaine in the previous year (Kuriachan et al., 2015; Morentin et al., 2014). Cocaine is an indirect sympathomimetic agent and may increase blood pressure, increase heart rate, increase ventricular contractility, and lower VT threshold placing users at risk for myocardial infarction, major hemorrhages, and arrhythmias. Up to 9% of young adults with SCD were recent cocaine users (Kuriachan et al., 2015; Morentin et al., 2014).

Clearly, the best prevention of sudden death related to proarrhythmic drug effects is to limit the use of these agents and to carefully monitor their effects when they are used, particularly when therapy is first prescribed and shortly after dosage increments.

Other Causes of Noncardiac Sudden Death

Other causes of noncardiac sudden death are extremely rare and include pulmonary hemorrhage, massive pulmonary embolism, chronic obstructive pulmonary disease, asthma, rupture of esophageal varices, and rupture of ectopic pregnancy. Prevention of sudden death from these causes mainly involves diagnosis and treatment of the underlying disorder (Kuriachan et al., 2015).

Clinical Approach to Investigation of SCA

The approach to investigation of the survivor of SCA involves the following components (Krahn et al., 2010):

1. assessment for reversible causes
2. assessment for structural heart disease
3. assessment for primary electrical disease when there is no significant structural heart disease
4. evaluation of family members if an inheritable syndrome is suspected or identified

Table 2 lists some of the potentially reversible causes that are associated with SCA.

Assessment of the cardiac arrest survivor begins with a complete history and physical examination that includes evaluation of the presence of symptoms or signs suggestive of underlying structural heart disease (Krahn et al., 2012). The patient's ingestion history and medication list (both prescribed and nonprescribed) should be appraised for the possibility of drug- or toxin-induced arrhythmia or electrolyte disturbance. A three-generation family history should include careful review for the presence of SCA (often called a massive heart attack by patients) (Dorian and Krahn, 2016), syncope, neuromuscular disorders, unexplained drowning, sudden infant death, and sensorineural deafness. Laboratory testing should be performed immediately upon presentation to assess for electrolyte, acid–base, and metabolic abnormalities that may aid in diagnosis or that might require immediate treatment. However, the natural tendency to ascribe SCA to mild electrolyte abnormalities is to be avoided as such abnormalities may be the result of rather than the cause of the cardiac arrest (Kuriachan et al., 2015).

Serial ECG evaluation should be performed to screen for myocardial ischemia or infarction, conduction abnormalities, and repolarization or depolarization abnormalities. Continuous ECG telemetry monitoring may identify nonsustained and sustained arrhythmias or reversible myocardial ischemia.

Invasive coronary angiography should be performed in most cardiac arrest survivors to seek CAD that may require intervention. When coronary spasm is suspected, provocative testing with either ergonovine or acetylcholine may be performed. Noninvasive computed tomography coronary angiography may also be of value to rule out the presence of CAD and coronary artery anomalies when coronary angiography is not to be performed.

Pulmonary embolism
Tension pneumothorax

Adapted from Kuriachan, V. P., Sumner, G. L. and Mitchell, L. B. (2015). Sudden cardiac death. *Current Problems in Cardiology* **40**, 133–200.

Cardiac imaging is indicated to assess cardiac structure and function, to stratify risk in terms of adverse clinical outcomes, and to guide therapeutic intervention. Clinical experience and experimental data indicate that there is often significant myocardial stunning and global impairment of left ventricular function in the first few days after a SCA event. Accordingly, in SCA survivors, formal assessment of left ventricular systolic function should be repeated approximately 1 week after the event.

2D echocardiography will identify many important etiologies of SCA including CAD (focal wall motion abnormalities), hypertrophic cardiomyopathy (asymmetric left ventricular hypertrophy), arrhythmogenic right ventricular cardiomyopathy (ARVC) (right ventricular wall motion abnormalities and aneurysms), aortic stenosis, and nonischemic dilated cardiomyopathies (global left ventricular systolic dysfunction). Nevertheless, cardiac magnetic resonance imaging (cMRI) is now considered the gold standard for assessment of cardiac volumes and function. In addition to those conditions listed above, cMRI may be useful to clarify or rule out the diagnosis of myocarditis, cardiac sarcoidosis, and cardiac amyloidosis. Furthermore, cMRI is more sensitive for the detection of right ventricular wall motion abnormalities which are of importance in the diagnosis of ARVC. Using the technique of late gadolinium enhancement, cMRI can also quantify the extent and distribution of myocardial scar. Finally, T2-weighted imaging, which identifies unbound myocardial water, characterizes myocardial edema associated with inflammatory conditions such as myocarditis, sarcoidosis, and acute ischemia (Krahn et al., 2010).

Exercise testing may be performed to provide a functional assessment and to expose symptoms and signs of exercise-related myocardial ischemia, myocardial dysfunction, or arrhythmia. Exercise testing is of particular value in the diagnosis of catecholamine-dependent arrhythmias including catecholaminergic polymorphic ventricular tachycardia (CPVT) and long-QT interval syndrome (LQTS). A failure to increase systolic blood pressure by at least 20 mmHg with exercise identifies a potentially high-risk individual with HCM.

Approximately 5%–10% of SCA survivors have neither structural heart disease nor a noncardiac etiology for their event (Krahn et al., 2010). Such individuals are considered to have a primary electrical disorder. Pharmacological challenge testing with epinephrine and with a Class Ic sodium channel blocker (procainamide, ajmaline, or flecainide) may unmask the otherwise subtle ECG abnormalities in conditions such as congenital LQTS, CPVT, and Brugada syndrome (BrS). When a graded epinephrine infusion elicits an absolute increase in the QT interval of at least 30 milliseconds then congenital LQTS-1 should be strongly considered. When the same infusion elicits polymorphic VT or bidirectional VT, the diagnosis of CPVT is supported. Similarly, when a Class IC antiarrhythmic drug infusion elicits a Type I BrS pattern ECG (>2 millimeters J-point elevation and coved ST-T segment elevation in leads V1 and V2), a diagnosis of BrS is likely (Kuriachan et al., 2015).

Transvenous catheter electrophysiologic studies (EPS) are not routinely performed in the assessment of SCA. In a patient with a structurally normal heart, lack of inducibility of VT or VF with programmed stimulation does not necessarily predict a favorable outcome, and an ICD would be indicated regardless of the results of such testing. In patients with manifest Wolff–Parkinson–White (WPW) syndrome, EPS may identify an accessory connection with a very short refractory period. Ablation of the accessory connection would then be indicated.

When an inheritable condition such as congenital LQTS, BrS, CPVT, or ARVC is identified, the patient and immediate family members may benefit from genetic testing. One study evaluated the yield of systematic advanced cardiac imaging and provocative testing in patients with unexplained SCA. In 63 patients with SCA of unknown cause, a diagnosis was obtained with advanced testing in 56% of patients. Targeted genetic testing revealed causative mutations in 47% of the 63 patients. (Krahn et al., 2010). In addition, of the 64 immediate family members screened, 24% were subsequently treated for their clinically silent and previously undiagnosed SCD risk.

Role of the Molecular Autopsy

The use of clinical forensic autopsy has declined significantly from its use in up to 50% of cases 50 years ago to less than 10% in 2008. However, over the same time frame, the development and availability of genetic testing to evaluate selected patients for

potential SCD risk has grown. Recently, published data from the Scripps Translational Science Institute (Torkamani et al., 2016) showed that molecular autopsy can provide important data to suggest a likely or possible etiology of SCD in 40% (10/25) of a series of sequential cases. The authors suggest that more comprehensive sharing of phenotypic and genetic data between databases may lead to the identification of even more SCD genotype/phenotype correlations (Torkamani et al., 2016). Doing so would provide important risk quantification information for living relatives of SCD victims.

Preventative Therapies

When an individual patient is identified at being at a higher risk of SCD, preventative therapies are considered. The most appropriate preventative therapies are a function of the underlying cause of the higher SCD risk. Specific therapies are discussed further in chapters dealing with specific etiologies. This chapter will only address the preventative therapies that are considered in patients with a demonstrated ischemic cardiomyopathy or nonischemic congestive cardiomyopathy in whom the most common pathways to SCD are VT and VF.

In patients with a demonstrated ischemic cardiomyopathy or nonischemic congestive cardiomyopathy the prevention of SCD begins with optimizing the treatment of the underlying structural heart disease. Indeed, randomized clinical trials in such patients have demonstrated that VT/VF, SCD, cardiovascular death, and all-cause mortality are reduced with beta-adrenoreceptor blocking agents; with hydroxymethylglutaryl coenzyme-A reductase inhibitors (statins) in patients with ischemic cardiomyopathy and possibly also in patients with nonischemic cardiomyopathy; and with renin–angiotensin–aldosterone system suppression by angiotensin-converting enzyme (ACE) inhibitors, by ARB, or by aldosterone blockers (Mitchell, 2008). In contrast, Vaughn Williams Class I antiarrhythmic drugs prevent VT/VF at the expense of an increase in SCD and all-cause mortality, Class III antiarrhythmic drugs prevent VT/VF with variable, drug-specific, effects on SCD and all-cause mortality, and digoxin may increase the incidence of VT/VF and SCD (Mitchell, 2008).

The ICD was conceived not to prevent VT/VF but rather to react to VT/VF so that the ventricular dysrhythmia does not result in SCD. Current ICDs reliably detect VT/VF and react with automatic antitachycardia pacing and automatic shock therapies to terminate the VT/VF with remarkable efficacy. Such devices do not obviate SCD but do dramatically reduce its probability. Of course, an ICD would be expected to provide the greatest survival benefit in patients with ischemic cardiomyopathy or nonischemic congestive cardiomyopathy that have a higher risk of future VT/VF episodes. The best predictor of a future episode of VT/VF is a past episode of VT/VF that occurred in the absence of a transient or completely reversible cause. In this regard, a first episode of VT/VF that develops in the 48 h after the onset of an acute ST-segment elevation myocardial infarction is not considered to portend a higher risk of future episodes. The risk of future episodes of VT/VF in such a patient is not demonstrably higher than that of patients with an equivalent myocardial infarction who did not develop VT/VF in the first 48 h after their infarction (Zipes et al., 2006). The vast majority of other patients who have experienced sustained VT/VF are a higher risk of future episodes and, when an ICD is used for prevention of SCD in such patients, the indication is referred to as being for the secondary prevention of SCD.

Three large, randomized clinical trials—the Antiarrhythmics Versus Implantable Defibrillator (AVID) trial (AVID Investigators, 1997), the Cardiac Arrest Study Hamburg (CASH) (Kuck et al., 2000), and the Canadian Implantable Defibrillator Study (CIDS) (Connolly et al., 2000a)—evaluated the efficacy of ICD therapy versus amiodarone therapy (1.3% of the total population of these trials received sotalol therapy rather than amiodarone therapy) for the secondary prevention of SCD. An individual patient-level meta-analysis of their results (Connolly et al., 2000b) reported that, after a mean follow-up of 2.33 years, arrhythmic deaths occurred at an annual rate of 2.7% in ICD-treated patients compared to 5.7% in amiodarone/sotalol-treated patients (Hazard ratio (HR), 95% CI, *p*-value: 0.49, 0.36–0.67, $p < 0.001$). In the absence of an effect on nonarrhythmic cardiac death or noncardiac death, this difference in arrhythmic death rates translated into a difference in annual all-cause mortality rates of 8.8% in ICD-treated patients compared to 12.3% in amiodarone/sotalol-treated patients (HR, 95% CI, *p*-value: 0.73; 0.60–0.87, $p < 0.001$) (**Fig. 2**). In this meta-analysis, the advantage of ICD therapy over amiodarone/sotalol therapy was restricted to patients with an LVEF ≤ 0.35. The secondary prevention ICD trials did not include patients with hemodynamically stable VT. Nevertheless, an analysis of the patients that were screened for participation in AVID but were not enrolled compared the outcomes patients with hemodynamically stable VT and patients with hemodynamically unstable VT and found that patients with underlying structural heart disease who presented with hemodynamically stable VT have a subsequent mortality rate that is at least as high as that of patients presenting with hemodynamically unstable VT suggesting that hemodynamically stable VT may be a marker for subsequent risk of hemodynamically unstable VT/VF and sudden death (Raitt et al., 2001). These studies have informed practice guidelines that recommend placement of an ICD in all patients with structural heart disease who have sustained VT or VF in the absence of a reversible cause. Some guidelines give an equivalent recommendation for chronic amiodarone therapy in patients with an LVEF >0.35.

Patients with structural heart disease but no previous episodes of sustained VT/VF who are considered to be at higher risk of future episodes of VT/VF are considered for an ICD for the purpose of primary prevention of SCD. Such instances are predicated on the ability to select patients at higher future risk of VT/VF. To date, the only predictor of a future first episode of VT/VF that has been demonstrated to select a patient population that was then shown to have a survival benefit from placement of an ICD in a randomized clinical trial is depressed left ventricular systolic function defined as a LVEF ≤ 0.35. A total of eight randomized clinical trials have evaluated the advantages, disadvantages, and risks of ICD therapy versus placebo therapy, antiarrhythmic drug therapy, or both in patient populations selected, at least in part, by virtue of significant depression in LVEF (Theuns et al., 2010).

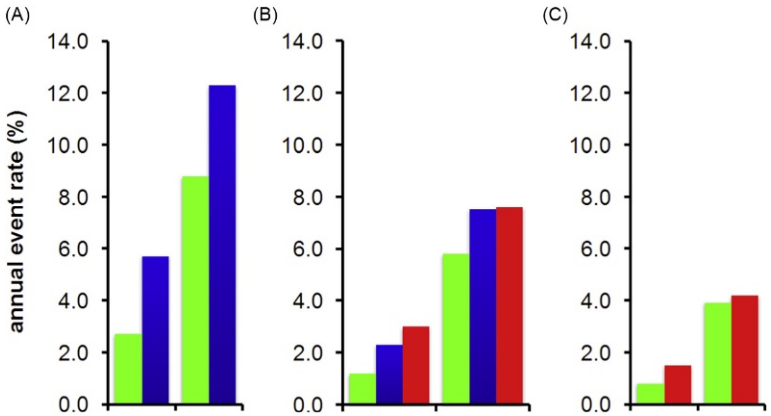

Fig. 2 Annual event rates for arrhythmic death (*left column group in each panel*) and for all-cause mortality (*right column group in each panel*) for patients treated with an ICD (*green columns*), for patients treated with antiarrhythmic drugs (almost exclusively with amiodarone) (*blue columns*), and for patients treated with neither (*red columns*). Panel A shows results of a meta-analysis of randomized trials of ICD therapy for secondary prevention of SCD. Panel B shows results of the SCD-HeFT randomized trial of ICD therapy for primary prevention of SCD. Panel C shows results of the DANISH randomized trial of ICD therapy for primary prevention of SCD in patients with well-treated nonischemic congestive cardiomyopathy. The annual event rates are higher in patient populations a prior life-threatening ventricular tachyarrhythmia (secondary prevention trials—Panel A) than they are in patient populations without a prior life-threatening ventricular tachyarrhythmia (primary prevention trials—Panels B and C). The annual event rates are higher in less contemporary patient populations that include patients with either ischemic or nonischemic congestive cardiomyopathy (Panel B) than in more contemporary patient populations that only include patients with nonischemic congestive cardiomyopathy (Panel C). Nevertheless, in each patient population the probability of arrhythmic death is halved by an ICD compared to control with or without antiarrhythmic drug therapy. Whether or not the ICD advantage with respect to arrhythmic death translates into a reduction in all-cause mortality is dependent on other factors.

No patient-level meta-analysis of the results of these trials has been reported. Accordingly, to derive annualized mortality rates in patients evaluated for a primary prevention ICD that might be compared to those of patients evaluated for a secondary prevention ICD the results of the largest of these trials, the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) (Bardy et al., 2005), are cited here. After a median follow-up of 3.79 years, arrhythmic deaths occurred at an annual rate of approximately 1.2% in ICD-treated patients compared to approximately 2.3% in amiodarone-treated patients (statistics for this comparison not provided) and compared to approximately 3.0% in placebo-treated patients (HR, 95% CI, *p*-value: 0.40, 0.27–0.59, $p < 0.001$). In the absence of an effect on nonarrhythmic cardiac death or noncardiac death, these differences in arrhythmic death rates translated into differences in annual all-cause mortality rates of 5.8% in ICD-treated patients compared to 7.5% in amiodarone-treated patients (statistics for this comparison not provided) and compared to 7.6% in placebo-treated patients (HR, 97.5% CI, *p*-value: 0.77, 0.62–0.96, $p < 0.001$) (Fig. 2). In SCD-HeFT, the advantage of ICD therapy over amiodarone therapy and over placebo therapy was not a function of whether the underlying structural heart disease was ischemic or nonischemic. Similarly, a meta-analysis of SCD-HeFT and the other seven randomized primary prevention ICD trials in patients with ischemic cardiomyopathy or with nonischemic congestive cardiomyopathy similarly did not demonstrate a difference in response to ICD therapy in these two patient population groups. However, more recently, the Danish Study to Assess the Efficacy of ICDs in Patients with Nonischemic Systolic Heart Failure on Mortality (DANISH) (Kober et al., 2016) randomly assigned patients with a nonischemic congestive cardiomyopathy and a LVEF $\leq$0.35 to receive or not to receive an ICD in addition to optimal medical therapy and, when indicated, cardiac resynchronization therapy (CRT) (58% of each group). This study randomized 1116 patients. After a median follow-up of 5.6 years, arrhythmic deaths occurred at an annual rate of approximately 0.8% in ICD-treated patients compared to approximately 1.5% in control patients (HR, 95% CI, *p*-value: 0.50, 0.31–0.82, $p = 0.005$). The SCD rates in DANISH were substantially lower than those of the other trials described above, an observation that may reflect advances in both medical therapy and CRT in this patient population (Fig. 2). Both nonarrhythmic cardiac death and noncardiac death occurred statistically nonsignificantly more often in the ICD-treated group. Accordingly, the difference in arrhythmic death rates did not translate into a statistically significant difference in annual all-cause mortality rates of approximately 3.9% in ICD-treated patients compared to approximately 4.2% in control patients (HR, 95% CI, *p*-value: 0.87; 0.68–1.12, $p = 0.28$). A subsequent meta-analysis of DANISH and the other five randomized controlled trials of ICD therapy for the primary prevention of SCD in 2970 patients with nonischemic congestive cardiomyopathy reported a statistically significant 23% risk reduction in all-cause mortality in favor of ICD therapy [HR 0.77, 95% CI (0.64, 0.91)] (Golwala et al., 2016).

Most patients with ischemic cardiomyopathy or nonischemic dilated cardiomyopathy who are candidates to receive a CRT pacemaker are also candidates to receive an ICD, and many patients who are candidates to receive an ICD are also candidates to receive a CRT pacemaker. The outcomes following use of the monotherapy devices (CRT or ICD) have been compared to use of a combined CRT defibrillator (CRT-D) in nine randomized controlled or two-arm prospective studies in patients with congestive heart failure. A meta-analysis of their results (Deng et al., 2015) reported that, compared to use of a CRT-D, use of a CRT pacemaker was associated with a higher follow-up incidence of all-cause mortality (HR, 95% CI, *p*-value: 1.46; 1.19–1.78, $p < 0.001$) and compared to use of a CRT-D, use of an ICD alone was associated with a higher follow-up incidence of all-cause mortality (HR, 95% CI, *p*-value:

1.27; 1.06–1.52, $p = 0.009$) in patients who are candidates for both devices. The ventricular reverse remodeling that accompanies a patient's favorable response to CRT pacing might be expected to reduce the frequency and severity of follow-up VT/VF episodes given the well-recognized association between left ventricular systolic function and ventricular arrhythmogenesis. Data supporting this contention include a systematic review of six cohort studies that compared the follow-up incidence of appropriate ICD therapies between CRT-D recipients who were responders to CRT pacing and CRT-D recipients who were nonresponders to CRT pacing (Chatterjee et al., 2015). Four trials defined responders to CRT pacing as those whose LVEF improved to ≥ 0.35. The annual rate of appropriate ICD therapies was significantly lower in patients who were so defined as modest responders to CRT pacing at 5.4% than in patients who were not responders to CRT pacing at 11.5% ($p < 0.001$). Two trials defined responders to CRT pacing as those whose LVEF improved to ≥ 0.45. The annual rate of appropriate ICD therapies was significantly lower in patients who were so defined as significant responders to CRT pacing at 2.3% than in patients who were not responders to CRT pacing at 8.2% ($p < 0.001$).

Conclusion

SCD is one of the most common single causes of death in developed nations. Although very significant advances in the understanding of SCD and in the prevention of SCD have been made over the past decade, the persistence of the epidemic of SCD indicates that there is more to be done both with respect to new knowledge creation and with respect to implementation of the knowledge already in hand.

Introduction

Atrial fibrillation (AF) is the most common arrhythmia in the world. Its detrimental effects stem from atrioventricular (AV) dyssynchrony causing hemodynamic compromise and left atrial (LA) stasis resulting in thromboembolism. AF is associated with a fivefold increased stroke risk (Kannel et al., 1998), a threefold increased risk of heart failure (Wang et al., 2003), and a twofold increased mortality risk (Wang et al., 2003). Patients may experience palpitations, fatigue, exercise intolerance, and dyspnea. Patients frequently require anticoagulation, which predisposes to bleeding complications and hemorrhagic stroke (Mitchell et al., 2013). The inadequacies of pharmacologic management and catheter intervention have justified a role for surgical ablation.

Mechanisms

Proposed electrophysiological mechanisms of AF include random ectopic depolarization of atrial tissue, rapid and irregular depolarization of a single focus, and reentrant circuits (Moss, 2003; Cox et al., 1991). Moe (1962) proposed the multiple wavelet hypothesis that AF was maintained by multiple changing wave fronts that randomly reentered the atria. Allessie et al. (1985), in an animal model of cholinergic AF, demonstrated that at any one time, multiple wavelets were present during AF. Factors contributing to the electrophysiological substrate that determines whether AF is initiated and/or sustained include a trigger, the atrial refractory period, the conduction velocity, and atrial geometry. A critical mass of atrial tissue is required to support a reentrant circuit (Byrd et al., 2005).

Haissaguerre et al. (1996) demonstrated that the trigger for AF originated in the pulmonary veins (PVs) in most patients with paroxysmal AF (PAF). However, up to a third of the triggers lie outside the PVs (Lee et al., 2005). Electrically excitable cardiac muscle extends 1–4 cm beyond the ostium of the PVs (Spach et al., 1972). Pacemaker tissue has been shown to be present in the PVs during development (Blom et al., 1999).

AF is characterized by anatomical, electrical, cellular, and structural remodeling (SRM). SRM characterized by interstitial fibrosis is well described in AF. Late gadolinium enhancement MRI (LGE-MRI) can identify SRM and stratify patients likely to benefit from ablation. McGann et al. (2014) showed that the extent of LA wall fibrosis on LGE-MRI strongly correlates with ablation outcome and histological evidence of remodeling. Arrhythmia recurrence following catheter ablation was significantly higher when $\geq$30% fibrosis was present on preprocedural MRI scans.

Indications for Surgical Ablation

The indications for surgical ablation of AF are detailed in the 2012 Expert Consensus Statement of the Heart Rhythm Society Task Force on Catheter and Surgical Ablation of AF (European Heart Rhythm Association (EHRA) et al., 2007).

Stand-alone AF

Symptomatic AF refractory to medical therapy
Failed catheter ablation
Contra-indications to anticoagulation
LA thrombus
High-risk patients with persistent AF who suffered a cerebrovascular event while anticoagulated

Concomitant AF

Symptomatic AF, regardless of whether antiarrhythmic medication has been started.

Asymptomatic AF when surgical ablation would not significantly add to operative risk (Lancaster et al., 2016a).

Contra-indications

Patients with a LA of >8 cm, significant LA fibrosis/calcification on imaging, or age >85 years are considered to have relative contraindications since recurrence rates tend to be high (Damiano et al., 2011a).

Surgical Principles

The Cox-Maze procedure consists of a series of incisions in both atria designed to theoretically interrupt the macroreentrant circuits that sustain AF, leaving a pathway for the sinus node to activate both atria and the AV node. By restoring sinus rhythm (SR) and AV synchrony while maintaining atrial transport function, the Cox-Maze procedure has the potential to reduce the risk of thromboembolism, stroke, and hemodynamic compromise associated with AF.

Pulmonary Vein Isolation or Cox-Maze Procedure?

The catheter mapping performed by Haissaguerre et al. (1996) was performed in patients with "stand-alone" AF. Approximately 60% of patients with PAF have PV triggers (Cox, 2014). Pulmonary vein isolation (PVI) works well in a small group of patients with isolated PAF and normal-sized left atria, short-term AF, and contraindications to anticoagulation. However, the late results with PVI alone have been relatively poor in the catheter ablation literature (Boersma et al., 2012) and have also had high late recurrence rates in some surgical series (Boersma et al., 2012). Data from Washington University would strongly support that PVI alone should never be performed. The minimal requirement for successful late outcomes is isolation of not only the PVs, but all of the posterior left atrium. Without this, late results have shown a success rate of less than 30% at 5 years (Henn et al., 2015).

Patients with non-PAF (NPAF) have more complex mechanisms that may involve multiple rotors, non-PV focal sources, and both macro- and microreentrant circuits. In this situation, simple PVI is no longer effective.

A retrospective review compared patients who underwent a Cox-Maze procedure ($n=100$), with those who had a limited Cox-Maze procedure ($n=7$), or PV isolation alone ($n=23$). Freedom from AF was 90%, 86%, and 59% in the in the Cox-Maze procedure group, limited Cox-Maze procedure group, and PV isolation alone group, respectively (Melby et al., 2006). Since surgeons deal primarily with concomitant AF, Haissaguerre's observation even in PAF may not be applicable in our surgical patients.

LA or Biatrial Maze?

A common dilemma is the necessity to perform right atrial lesion sets. Two metaanalyses (Barnett and Ad, 2006; Zheng et al., 2016) concluded that biatrial surgical procedures were more effective than left-sided procedures in eliminating AF. Sixty-nine studies (5885 patients) were included in the metaanalysis by Ad et al. Biatrial surgical procedures (range, 92.0%–87.1%) demonstrated superior freedom from AF at all-time points compared with LA surgical procedures (range, 86.1%–73.4%). At 3 months, 1, 2, and 3 years, the freedoms from AF were 92% versus 86%, 89% versus 76%, 86% versus 75%, and 87% versus 73%, respectively.

Since the mechanisms of AF in the individual patient are rarely well defined, we usually default to performing a biatrial lesion set, as this has had excellent long-term success rates in restoring SR. In patients with PAF, of short duration (<1 year), no LA enlargement (LA diameter <4.5 cm) and no RA enlargement or right-sided pathology (i.e., tricuspid regurgitation, pulmonary hypertension), we have performed a full left-sided Cox-Maze lesion set with good late results. However, this represents less than 10% of patients referred for surgical ablation at Washington University.

Concomitant AF

The three groups of patients with concomitant AF, who represent the vast majority of patients undergoing cardiac surgery, are those undergoing aortic, coronary, or mitral surgery (Cox, 2014).

CABG and AVR patients

PVI alone is not an adequate or appropriate approach in these patients. Patients require a Maze procedure. The surgical dilemma in this situation is the need to open the LA, which many surgeons are reluctant to do. Adding a Maze procedure does not increase the morbidity or mortality of patients undergoing coronary surgery (Ad et al., 2012a).

Ad et al. (2012a) reported 485 patients who underwent the Cox-Maze procedure of whom 95 had a Cox-Maze with an AVR or CABG (Cox-Maze/AVR = 30; Cox-Maze/CABG = 47; Cox-Maze/AVR/CABG = 18). 4255 patients with no history of AF underwent AVR or CABG without surgical ablation (AVR = 422; CABG = 3518; AVR/CABG = 315).

In unadjusted analyses, the Cox-Maze group was similar to the non-Cox-Maze group on perioperative permanent stroke (1.1% vs. 1.4%), prolonged ventilator time (>24 h) (6.3% vs. 6.1%), renal failure requiring dialysis (1.1% vs. 1.2%), readmissions within 30 days of discharge (12.6% vs. 8.3%), and operative mortality (within 30 days; 1.1% vs. 1.7%). The Cox-Maze group did have significantly more patients who developed perioperative pneumonia (5.3% vs. 1.9%) and reoperation for bleeding (5.0% vs. 2.0%) although none of the bleeding was related to the atriotomies or LA appendage (LAA) amputation.

All 95 patients who underwent the Cox-Maze procedure were propensity score matched with patients who did not undergo the Cox-Maze. Addition of the Maze procedure did not predict receipt of intraoperative blood products (OR, 0.83; CI, 0.28–2.54) or postoperative blood products (OR, 0.63; CI, 0.25–1.57), permanent stroke (0.55; 0.07–4.35), prolonged ventilation (>24 h) (0.78; 0.31–1.93), renal failure requiring dialysis (0.76; 0.09–6.20), or operative mortality (0.34; 0.04–2.72), in the propensity score-matched groups.

Mitral valve surgery patients

Patients with AF undergo a Maze procedure, as the LA has to be opened to perform mitral surgery.

Technology

Surgical ablation devices either use a unipolar energy source or bipolar clamps. Unipolar energy sources (cryothermy, unipolar radiofrequency (RF) energy) radiate either heat or cold from a single source, in an unfocused fashion and can cause collateral damage (Gillinov et al., 2001). Transmural lesions are difficult to create from the epicardial surface on the beating heart, due to the heat sink effect of circulating blood (Santiago et al., 2003).

Radiofrequency

RF energy uses an alternating current between 100 and 1000 kHz which is high enough to prevent rapid myocardial depolarization and the induction of ventricular fibrillation, yet low enough to prevent tissue vaporization and perforation. Lesions are created through thermal injury. Resistive heating occurs within a narrow rim of tissue in direct contact with the electrode. Passive conduction continues from this interface to create deeper lesions.

With bipolar RF ablation, focused energy is delivered between two closely approximated electrodes embedded in the jaws of a clamp, thereby creating discrete lesions. This reduces collateral damage. The device continuously measures tissue conductance to assess transmurality (Damiano et al., 2007). When the conductance drops to a stable minimum level, the lesion is deemed to be transmural. Bipolar ablation enables shorter ablation times but is incapable of fully ablating the right and LA isthmuses (Damiano et al., 2007). Newer unipolar RF ablation devices have been developed with suction adherence to aid in minimally invasive applications.

The COBRA Fusion Surgical Ablation System (AtriCure, Inc.) is a suction-assisted, combined bipolar/monopolar linear RF device designed to reduce the heat sink effect of circulating blood and allow ablation on the beating heart (Lancaster et al., 2016b).

Cryoablation

The two sources of cryothermal energy are nitrous oxide and argon, which at one atmosphere of pressure reach temperatures of _89.5 degrees C, and _185.7 degrees C, respectively (Lee et al., 2009). Cryoablation causes tissue injury through the freezing and rewarming process. Acutely, ice crystals disrupt cell membranes, whereas, chronically, microvascular damage leads to local tissue ischemia. Cryoablation preserves the fibrous skeleton of the heart, making it safe for use around valvular tissue, but is ineffective on the beating heart. Cryolesions take longer to create (1–3 min) (Lee et al., 2009).

The ability of bipolar clamps to create reliable transmural lesions on the beating heart has been confirmed in chronic animal models (Melby et al., 2006).

Operative Techniques

The Cox-Maze IV Procedure

Preoperative planning

A transthoracic echocardiogram is performed to determine LA size and detect the presence of LA thrombus and valve disease (Lawrance et al., 2016). A contrast chest computed tomography (CT) scan is performed to rule out PV stenosis in patients who have failed catheter ablation. Patients scheduled to have a right mini-thoracotomy (RMT), receive a CT angiogram of the aorta, iliac, and femoral arteries, if they are older than 40 years, or have peripheral vascular disease (PVD) or risk factors for PVD. Coronary angiography is performed to define coronary anatomy and stenosis (Robertson et al., 2014). Antiarrhythmic and rate-control medication should be continued until the day of the procedure. Patients on warfarin or a novel anticoagulant are transitioned to intravenous heparin (Robertson et al., 2014).

Surgical access

The Cox-Maze procedure can be performed through a median sternotomy or a RMT. A RMT approach is used for stand-alone AF ablation and in patients undergoing concomitant mitral or tricuspid valve surgery. Median sternotomy is reserved for patients with contraindications to the RMT approach (PVD that precludes femoral cannulation for cardiopulmonary bypass (CPB), prior right thoracotomy, severe LV dysfunction, or chest wall deformities) (Lawrance et al., 2016), and when the maze procedure is performed in conjunction with aortic or coronary surgery.

Ablation principles

The essential prerequisites for an effective ablation are lesion transmurality and continuity. The only guarantee of effectiveness of a procedure is the creation of a fully transmural lesion, from either the epicardial or the endocardial surface (Melby et al., 2013). Very small gaps in ablation lines have the ability to conduct impulses, thereby emphasizing the importance of creating complete and continuous lesions (Melby et al., 2008). A continuous LA isthmus lesion to the mitral annulus is critically important. Gaps in this ablation line can lead to LA flutter which is often more symptomatic than AF.

Each RF ablation line is created by performing two to three sets of firings of the bipolar RF clamp, to ensure a transmural lesion. For each set, the clamp is left in place and ablations are repeated until the ablation time falls below 10 s. All cryoablations are performed for 3 min at a temperature less than −40°C.

Sternotomy approach

The Cox-Maze procedure has been well described by Dr Damiano's group (Lawrance et al., 2016). A median sternotomy is performed and CPB is initiated. The absence of LA clot is confirmed by TEE. Cardioversion is performed after the administration of IV amiodarone, if the patient is in AF and there is no LA clot.

PV isolation

Pacing thresholds are measured from each PV. All four PVs are dissected and isolated. The intraatrial septum is completely dissected to remove the fat. A generous cuff-of atrial tissue is clamped between the jaws of bipolar RF clamp and the clamp is fired to ensure electrical isolation between the PVs and the LA. Isolation is confirmed by documenting exit block demonstrated by a failure to epicardially pace from each of the PVs.

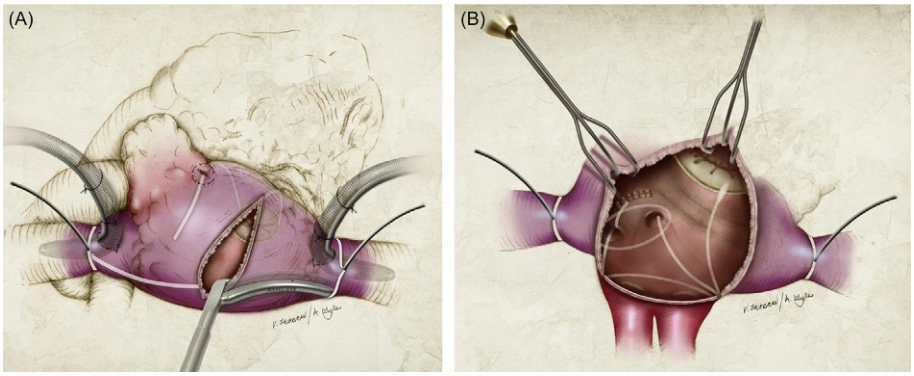

Fig. 1 CMIV lesion set as performed through a sternotomy. (A) Right atrial lesion set. RF ablations consist of SVC/IVC ablation and RA free wall ablation. Cryoablations include linear cryoablations through a purse-string suture to the 10 o'clock position of the tricuspid valve annulus and through the superior aspect of the atriotomy to the 2 o'clock position of tricuspid valve annulus. (B) Left atrial lesion set. Bipolar RF ablation lines consist of bilateral pulmonary vein isolations, ablations between the left superior pulmonary vein and amputated atrial appendage, pulmonary vein roof and floor connecting ablations, and ablation between the inferior aspect of the atriotomy to mitral valve annulus. Cryoablations include linear epicardial cryoablation over the coronary sinus and at the mitral valve annulus. Reproduced from Lawrance, C. P., Henn, M. C., Damiano, R. J., Jr. (2016). Surgery for atrial fibrillation. *Heart Failure Clinics* **12**(2), 235–243. With permission from Elsevier.

Right atrial lesion set

The RA lesion set is performed on the beating heart (Fig. 1A).

Appendage lesions: Through a purse-string suture at the base of the RA appendage, a RF lesion is created across the free wall of the RA, toward the superior vena cava (SVC), and down the aortic side of the RA appendage to avoid the SA node region. The linear cryoprobe is inserted through the purse-string suture, and an endocardial cryoablation is created down to the tricuspid valve annulus at the 10 o'clock position.

Free wall lesion: A vertical atriotomy is made from the intraatrial septum toward the AV groove. This incision should be at least 2 cm from the first free wall ablation to avoid an area of slow conduction.

Tricuspid annulus cryolesion: From the superior extent of this incision, a linear cryoprobe is used to create an endocardial cryoablation down to the tricuspid annulus at the 2 o'clock position.

Intercaval lesion: From the inferior aspect of the RA incision, RF lesions are placed along the lateral aspects of the SVC and the inferior vena cava (IVC).

LA lesion set

The aorta is cross-clamped, and the heart is arrested using cold blood cardioplegia (Fig. 1B).

LAA: The LAA is amputated. Through the amputated LAA, an RF ablation line is created into either of the left PVs. The LAA is oversewn.

Left atrium: A standard left atriotomy is performed. The bipolar RF clamp is used to create ablation lines from the inferior and superior aspects of this incision to the left inferior and superior PVs, respectively. A third bipolar RF lesion is placed from the inferior aspect of the atriotomy, across the atrial floor, toward the mitral annulus. This lesion heads toward the junction of the P2–P3 scallop of the mitral valve in patients with a right dominant circulation, and toward the posterior commissure if the patient has a left dominant circulation. This ablation should cross the coronary sinus in the space between the right coronary artery and the circumflex artery.

The AV groove containing thick tissue is located here and requires cryoablation to bridge the 1–2 cm gap from the end of the RF ablation line to the mitral annulus. To complete the LA lesion set, the coronary sinus is ablated in line with the isthmus lesion by performing cryoablation from the epicardial surface. This often requires use of a monopolar device from the epicardial surface to ensure transmurality. The mitral isthmus line is the "Achilles heel" of the LA lesion set and prevents postoperative atrial flutter. This lesion requires both bipolar and unipolar energy, due to the thickness of the AV groove and the inability of the bipolar clamp to reach the annulus. Failure to create the mitral annulus lesion is associated with a higher incidence of postoperative atrial flutter.

The left atriotomy is closed. The aorta is unclamped after dearing, and the patient is weaned from CPB. Epicardial right atrial and ventricular wires are placed. The chest is closed after securing hemostasis.

Right mini thoracotomy

Preparation

The patient is positioned supine with the right chest elevated 45° and the hips flat (Saint et al., 2014). TEE is performed to characterize the mitral regurgitation, and detect the presence of AR, a patent foramen ovale or LA clot. Significant aortic insufficiency is a contraindication to this approach. Both groins are prepped for femoral cannulation.

The right femoral artery and vein are exposed through a subinguinal incision and cannulated. Cannula position is verified by TEE. The right pleura is entered through the 4th Interspace, through a 5–6 cm RMT incision. Normothermic CPB is initiated. The right lung is deflated. If in AF, the patient is cardioverted.

PV isolation

The right PVs are ablated similar to that described in the sternotomy approach.

Right atrial lesion set

The right atrial lesion set is performed through three separate purse strings during CPB on the beating heart (Fig. 2A).

Intercaval lesion: The first purse string is placed just above the intraatrial septum between the IVC and SVC. RF lesions to the SVC and IVC are placed through the first purse string, similar to that described in the sternotomy approach.

Free wall lesion: An RF line of ablation is created through this purse string similar to that described in the sternotomy approach. This RF lesion substitutes for the vertical atriotomy in the sternotomy approach. Care is taken not to ablate over the AV fat pad to prevent right coronary artery injury.

Tricuspid annulus cryolesion: At the superior extent of this lesion, a second purse string is placed, through which an endocardial cryolesion is placed to the TV annulus, at the 2 o'clock position.

Appendage lesions: A third purse string is placed at the base of the RA atrial appendage. RF and cryolesions are created similar to that described in the sternotomy approach.

The endocardial cryoablations are performed with the heart beating. The circulating warm blood through the right coronary prevents injury from cryoablation.

LA lesion set

This lesion set is performed after aortic cross clamping and administration of cold blood cardioplegia. Through a left atriotomy the mitral valve and PVs are exposed (Fig. 2B).

LAA: The LAA is oversewn from the endocardial side.

Left atrium: The LA ablation lines are similar to that described in the sternotomy approach. To complete the isolation of the posterior LA, the two ablation lines to the left inferior and superior PVs are connected behind the PVs and along the lateral ridge by performing endocardial cryoablations.

The left atriotomy is closed. The aorta is unclamped after dearing, and the patient is weaned from CPB. Epicardial right atrial and ventricular wires are placed. The femoral vessels are decannulated. Distal femoral arterial flow is confirmed by Doppler. The groin and chest are closed after obtaining hemostasis.

Pitfalls

1. Postoperative bleeding

   Bleeding can occur from the atriotomy incisions or from the LAA, which tends to be friable.

2. Coronary artery injury

   RF energy and cryoablation can damage coronary arteries (Roberts-Thomson et al., 2009). Bipolar RF ablation acutely has been shown not to damage the coronary arteries. However, the late histological changes are unknown. Cryoablation has been associated with intimal hyperplasia and has been implicated in late coronary stenoses.

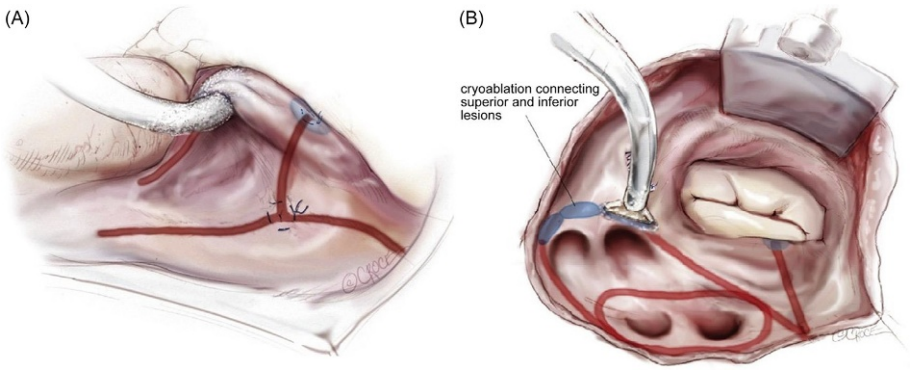

Fig. 2 CMIV lesion set as performed through a right mini sternotomy. (A) Right atrial lesion set. Three separate purse-string sutures and replacement of right atriotomy with a line of bipolar RF ablation. All other lesions are identical to the sternotomy approach. (B) Left atrial lesion set. Left pulmonary vein isolation is achieved through sequential endocardial cryoablation, and LAA is oversewn in two layers endocardially. All other lesions are identical to the sternotomy approach. Reproduced from Lawrance, C. P., Henn, M. C., Damiano, R. J., Jr. (2016). Surgery for atrial fibrillation. *Heart Failure Clinics* **12**(2), 235–243. With permission from Elsevier.

3. PV isolation
   Repeat ablations are necessary if exit block is not achieved.
4. Posterior LA isolation
   The posterior LA is an important source for the triggers and drivers that initiate and maintain AF (Ndrepepa et al., 2003). The box lesion reduces the critical mass of atrial tissue available for sustaining AF (Voeller et al., 2008). Isolating the entire posterior LA yields significantly higher freedom from AF and antiarrhythmic drugs (AADs). This finding is consistent with data from the electrophysiology laboratory, in which wide-area circumferential ablation of the posterior LA was more effective than targeting only the PVs (Oral et al., 2003).

Postoperative Management

Postoperative junctional and atrial tachyarrhythmias (ATAs) are not uncommon but usually resolve spontaneously after several days. Patients with stable ATAs are usually rate controlled pharmacologically and are DC cardioverted if ATAs persist. It is preferable to wait 1–3 weeks, before cardioversion, to allow postoperative inflammation to subside. Antiarrhythmic medication is not commenced until the return of SR, particularly in patients with bradyarrhythmias.

If heart block develops, AV sequential pacing is used. About 5% of patients will require a permanent pacemaker after a Cox-Maze procedure and the incidence increases with age (Robertson et al., 2013).

Warfarin is initiated postoperatively after the return of SR and is continued for at least 3 months. Warfarin is discontinued after 3 months, if the patient has no ATAs, off antiarrhythmic medication on prolonged monitoring (at least a 24-h Holter) and shows no atrial stasis on echocardiography.

Monitoring

Recommendations for follow-up and standardized outcomes reporting are provided in the 2012 Heart Rhythm Society consensus statement (Calkins et al., 2012). Recurrence is defined as any episode of AF, flutter, or atrial tachycardia (collectively referred to as ATAs) of at least 30 s duration that occurs after a 3-month blanking period. Success rates are reported as the percentage of patients free from ATAs, in the absence of class I and III AADs. Patients are seen at 3 months following ablation and then every 6 months for at least 2 years. Rhythm assessment at a minimum includes 24-h Holter monitoring at 6- and 12-months, and ECGs at each postoperative visit.

A prospective multicenter study, comparing conventional intermittent methods of monitoring with continuous monitoring using an implantable loop recorder (ILR), showed an increasing trend in compliance when using ILR (93%) compared to ECG (85%) and Holter monitoring (76%) (Damiano et al., 2016). Freedom from ATAs was not different between these modalities. Implantable devices are useful in patients who are unlikely to return for follow-up. The major limitations of the ILR devices are (1) a limited storage capacity and (2) a high rate of false-positive readings.

Surgical Results: Cox-Maze Procedure

The Cox-Maze procedure is the gold standard in surgical ablation and is the interventional procedure with the single highest success rate of terminating AF. Henn et al. (2015) reported a 5-year freedom from ATAs with and without AADs of 78% and 66%, respectively in a cohort of 576 patients. Ad et al. (2015) demonstrated 5-year freedom from ATAs with and without AADs of 85% and 71%, respectively in a cohort of 120 patients.

Damiano et al. (2003) examined the long-term efficacy of the Cox-Maze procedure in patients with ischemic heart disease. In 47 patients undergoing coronary grafting with a concomitant Maze procedure, 98% of patients were free of AF, at a mean follow-up of 5.7 years. 19% required a permanent pacemaker postoperatively. 78% of these patients had a preoperative diagnosis of sick sinus syndrome which is a known risk factor. Most patients were off warfarin and AADs. No patient had a cerebrovascular accident during follow-up.

When AF ablation is performed concomitant to other cardiac procedures, it is necessary to consider the incremental risk incurred by a concomitant AF ablation. In patients undergoing mitral surgery, the postoperative mortality rate was 4.6% in those not undergoing a Cox-Maze IV procedure versus 2.9% in those who did (Saint et al., 2013).

Risk factors for recurrence (Damiano et al., 2011b) at 1 year include (1) failure to perform a box lesion, (2) increasing LA size, with a probability of recurrence exceeding 50% once the LA approaches 8 cm (Byrd et al., 2005) and (3) early ATAs, which are likely a marker of more advanced pathology within the atrial substrate.

LA Appendage

Most strokes due to AF have their origin in the trabeculated portions of the LAA (Cox, 2013). Several percutaneous and surgical methods for closing the LAA have been developed. The ACC/AHA Guidelines for the Management of Patients with Valvular Heart

Disease recommend amputation of the LAA at the time of mitral surgery to reduce the risk of thromboembolism (Bonow et al., 2008).

It is believed that elimination of the LAA debulks the LA, eliminates potential focal LAA triggers, and decreases macroreentrant circuits and conduction abnormalities within the LAA (Hocini et al., 2011).

Surgical techniques to isolate the LAA include (1) suture ligation, (2) clipping, (3) excision, and (4) stapling with or without excision (Ailawadi et al., 2011). These techniques are imperfect and sometimes traumatic to the appendage. Unsuccessful appendage closure is defined as the presence of: (1) a patent appendage due to dehiscence of the suture or staple line; (2) a color flow jet between the LA and the LAA, or (3) a residual pouch in the LAA <1 cm in maximal length after closure (Damiano, 2008).

Moreover, when using techniques that do not remove the appendage, studies have documented residual blood flow through the closure line into the appendage in up to one-third of patients.

Patients with persistent flow into the appendage have a greater likelihood of LA thrombus (Kanderian et al., 2008). A retrospective study from the Cleveland Clinic of 137 patients reported successful LAA closure in 73%, 23%, and 0% of patients who underwent surgical excision and closure, suture ligation, and staple exclusion, respectively (Kanderian et al., 2008).

In a study reported by Aryana et al. (2015), complete appendage ligation (cLAA) was detected in 64%, incomplete ligation (ISLL) in 24%, and a residual LAA stump in 12%. Spontaneous systemic embolization (SSE) occurred in 2% of patients with cLAA versus 24% with ISLL and 0% with LAA stump ($P=0.006$). ISLL emerged as the sole predictor of SSE in a multivariate analysis. Anticoagulation is recommended in this high-risk cohort.

The only reliable techniques appear to be surgical excision and clipping (Damiano, 2008). Evidence indicates that less-invasive procedures that suture exclude or staple the appendage are inadequate (Kanderian et al., 2008).

Minimally Invasive Surgery for AF

The development of new ablation technology has not only simplified and shortened the Cox-Maze procedure but has also spurred interest in minimally invasive procedures on the beating heart. New devices use parallel bipolar electrodes to create lesions from the epicardial surface, in an attempt to mitigate the heat sink effect, and improve the efficacy of ablation on the beating heart. However, compared to bipolar clamps, these devices are not as reliable at creating lesions that are both transmural and continuous (Watanabe et al., 2014). Other innovations include chest wall soft tissue retractors, atrial retractor systems, lighted dissectors, LAA occlusion devices, and high definition endoscopes.

The most frequently performed minimally invasive procedure on the beating heart for stand-alone AF uses the bilateral video-assisted mini-thoracotomy or thoracoscopic approach. A RF bipolar device is used for PVI with or without ganglionic plexus disruption, division of the ligament of Marshall and LAA exclusion (Wolf et al., 2005).

The longest-term outcomes reported with this technique (Wolfe technique) include 139 patients in whom freedom from ATAs off AADs was 52%, 28%, and 29% for paroxysmal, persistent, and long-standing persistent AF, at 5-year follow-up (Zheng et al., 2013). The bilateral mini-thoracotomy approach for PVI has been modified to a bilateral, completely thoracoscopic approach. La Maeir and colleagues have recently reported on a unilateral thoracoscopic approach via the left chest (La Meir, 2013).

A multicenter report on the bilateral approach showed success rates of 93% for PAF, 96% for persistent AF, and 71% for permanent AF, with 61% of these patients able to discontinue AADs and 65% discontinuing anticoagulation therapy (Beyer et al., 2009). The complication rate was 13% and included pacemaker implantation, phrenic nerve injury, hemothorax, and transient ischemic attacks. Kasirajan et al. (2012) reported a freedom from AF of 80% off antiarrhythmic medication, at a mean follow-up of 16.5 months in 118 patients. Permanent pacemakers were required in 2% of the patients.

Notwithstanding the inferior results of minimally invasive PVI compared to those of the Maze procedure, surgical PVI is superior to catheter ablation in patients with PAF and small left atria. In the FAST trial, 124 patients with short-duration AF, LA dilation (>4.0 cm), and previous failed catheter ablation were randomized to surgical PVI or catheter ablation. For surgical PVI, the 12-month freedom from ATAs off AADs was 66% versus 37% for catheter ablation ($P=0.002$) although there was a 23% surgical complication rate due to a high rate of pneumothorax (Boersma et al., 2012).

Some centers have used additional epicardial ablation lines to construct an extended LA lesion set, to address the suboptimal outcomes of stand-alone PVI in patients with NPAF. A recent report of 229 patients with persistent AF, undergoing the “5 box” lesion set demonstrated a 92% freedom from ATAs off AADs at 2 year follow-up although only 37 patients were included at this time point (Sirak, 2012).

Hybrid Procedures

The hybrid approach leverages the ability of the surgeon to perform epicardial ablations, with the electrophysiologist’s ability to map lines of block, identify breakthrough conduction, and perform endocardial catheter ablation to complete lesion sets.

Advantages of the hybrid approach include (1) the ability to confirm conduction block, (2) the ability to close identified gaps, (3) reduction of phrenic nerve and esophageal injury, (4) reduced risk of tamponade due to an open pericardium, and (5) reduced risk of embolism from catheter ablations (as fewer ablations are used) (Lawrance et al., 2015).

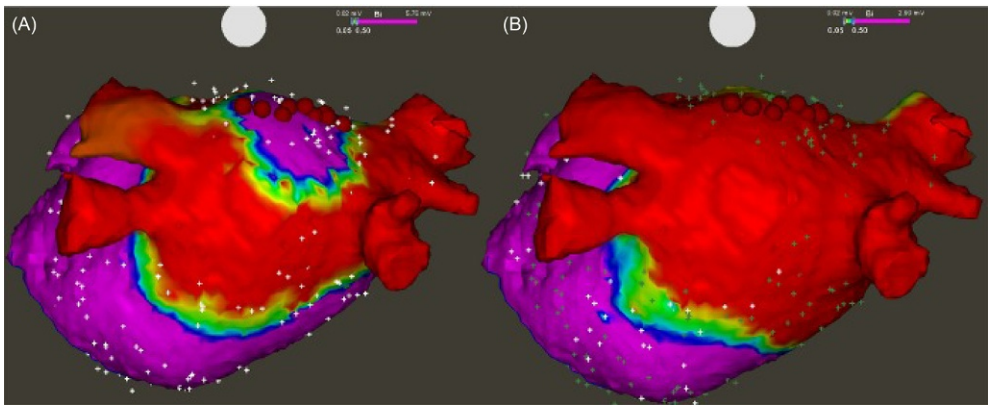

Fig. 3 Bipolar voltage map of the left atrium after epicardial radiofrequency thoracoscopic ablation, posterior view. (A) All four pulmonary veins were found isolated, while a gap was found in the middle of the roof line allowing electrical activation of the posterior wall. *Red dots* show sites that were reablated with endocardial touch-up. (B) Remapping after ablation revealed no potentials in the posterior wall, which confirmed a complete box-lesion. Reproduced from Bulava, A., Mokracek, A., Hanis, J., Kurfirst, V., Eisenberger, M. and Pesl, L. (2015). Sequential hybrid procedure for persistent atrial fibrillation. *Journal of the American Heart Association* **4**(3), e001754. With permission from Wiley Blackwell.

The disadvantages of hybrid approaches include: (1) long operative times when compared with catheter or surgical ablation alone, (2) higher complication rates in some centers, and (3) lack of good ablation technology to create the connecting lesions (Lawrance et al., 2015).

Hybrid procedures can be performed in either single-stage or two-stage fashion. A single-stage approach avoids a second procedure and hospitalization (Pison et al., 2012). A sequential two-stage procedure might be more cost-effective in identifying patients with AF recurrence after surgical ablation and treat these patients with a subsequent percutaneous endocardial ablation (Mahapatra et al., 2011).

A common hybrid procedure involves minimally invasive bilateral video-assisted thoracoscopic approach using a bipolar RF clamp and a surface bipolar linear probe to create lesions on a beating heart. This procedure is done under general anesthesia with TEE guidance and single lung ventilation. The lesions include bilateral PVI, and roof and floor lines to complete the "box lesion" and isolate the posterior LA. The ligament of Marshall is divided and the LAA is clipped. Epicardial mapping is performed to confirm PVI.

The endocardial portion is performed through a femoral vein approach. A transseptal sheath is placed for left heart access. RF ablation of the cavotricuspid isthmus is performed. Catheter mapping of the PVs, the posterior LA wall, and the mitral isthmus line is performed, to confirm isolation or electrical reconnection. If an electrical reconnection is suspected, detailed mapping is performed to determine sites of earliest potential, and these regions are ablated until all gaps are closed and electrical silence is achieved (Gelsomino et al., 2014).

Bulava et al. (2015) investigated the sequential (staged) hybrid method, which consists of a surgical thoracoscopic RF ablation procedure (PVI using an ablation clamp (Isolator Synergy; Atricure) and roof and inferior lines using a linear pen device (Bipolar linear pen; Atricure)), followed by RF catheter ablation 6–8 weeks later in 50 patients with long-standing persistent AF and a dilated LA (>45 mm) (**Fig. 3**). During catheter ablation, all four PVs were isolated in 74% of the patients; the roof line was complete in 34%, while the inferior line was complete in 60%, resulting in an overall box-lesion success rate of only 30% (**Fig. 4**).

Despite direct visualization of the epicardial RF lesions, and the use of multiple ablations, acutely observed electrical isolation was only temporary in many patients. Maturation of epicardial "burns" allows easier identification of target points during subsequent endocardial mapping. This highlights the ineffectiveness of epicardial RF ablations in creating transmural linear lesions and the potential importance of delaying the endocardial phase of the procedure (Bulava et al., 2015). Twelve months after the completed hybrid ablation, 94% were in SR. Surgical ablation was associated with a 13.7% major complication rate.

Convergent Approach

The convergent approach avoids lung deflation (Gehi et al., 2013). It employs an abdominal transdiaphragmatic approach to the pericardium to access and ablate the posterior LA. Following this, a standard left-sided endocardial ablation is performed to complete and confirm PVI. Initial results demonstrated SR with and without AADs of 80% and 52%, respectively, at 12 months in 73 patients (Geršak et al., 2014). An 11% complication rate was reported.

Monolateral Right Thoracic Approach

A staged approach consisting of the monolateral right thorascopic approach and endocardial catheter ablation has been performed. The epicardial "box" lesion is performed using a RF monopolar or combination monopolar/bipolar RF device with suction

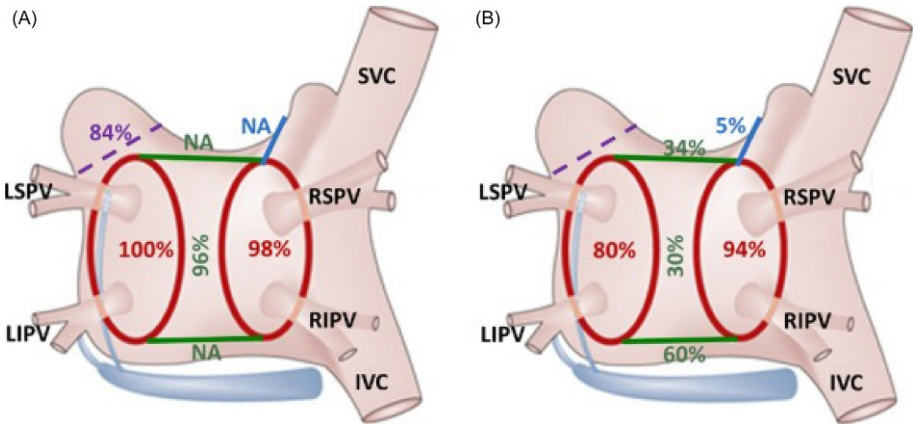

Fig. 4 Success rate of surgical thoracoscopic epicardial radiofrequency isolation of pulmonary veins, linear ablation lines connecting both superior and inferior pulmonary veins, and the trigone line connecting the right superior pulmonary vein across the left atrial roof toward the noncoronary aortic cusp as they were assessed (A) immediately after the ablation during surgery and (B) during the electrophysiological examination 6–8 weeks following the index procedure. Percentage of deployed left atrial appendage clips is also depicted (*violet color*). *IVC*, inferior vena cava; *LIPV*, left inferior pulmonary vein; *LSPV*, left superior pulmonary vein; *NA*, not applicable; *RIPV*, right inferior pulmonary vein; *RSPV*, right superior pulmonary vein; *SVC*, superior vena cava. Reproduced from Bulava, A., Mokracek, A., Hanis, J., Kurfirst, V., Eisenberger, M. and Pesl, L. (2015). Sequential hybrid procedure for persistent atrial fibrillation. *Journal of the American Heart Association* **4**(3), e001754. With permission from Wiley Blackwell.

adherence followed a month later by transcatheter endocardial ablation. At a mean follow-up of 28 months (range: 1–55 months), 87.5% of patients were in SR (Muneretto et al., 2012).

The limitation of this approach as well as the convergent approach is the inability to exclude the LAA. They have therefore been modified to include LAA ligation with the LARIAT suture delivery device (Bartus et al., 2013) (SentreHEART, Inc., Redwood City, CA).

In a systematic review of nine observational studies that each included more than 10 patients and at least 3-month follow-up, freedom from ATAs off AADs at 12 months in 335 patients ranged from 86% to 92% when bipolar RF energy was used, and 37%–89% with monopolar RF energy. Complications occurred in 4% of patients, including three conversions to sternotomy (Gelsomino et al., 2014).

An additional report detailed outcomes in 78 patients who underwent simultaneous thoracoscopic PVI and endocardial catheter ablation with at least 1-year follow-up (median follow-up of 24 months). Freedom from ATAs off AADs at last follow-up was 87% overall and 88% in NPAF although this includes the 13% of patients who underwent repeat catheter ablation for recurrent ATAs (Pison et al., 2014). Complications occurred in 8% of patients.

A recent systematic review of 1877 patients undergoing stand-alone minimally invasive surgical procedures for AF ablation found the Cox-Maze procedure to be superior to both beating heart epicardial ablation and hybrid procedures in terms of major complications and freedom from ATAs at 12 months (Je et al., 2015).

Conclusion

The greatest potential to impact the overall AF burden is in patients with concomitant cardiac disease. A review of the Society of Thoracic Surgeons database from 2005 to 2010 demonstrated that 62,152 concomitant ablations were performed compared to 4893 stand-alone ablations (Ad et al., 2012b).

The RMT Maze procedure is the only minimally invasive ablation technique that fully replicates the complete lesion set of the Cox-Maze procedure. For stand-alone AF ablation, minimally invasive PVI has demonstrated inferior results to those of the Maze procedure in NPAF and should therefore be considered only for patients with PAF and small LAs. The techniques for minimally invasive PVI and extended LA lesion sets, in contrast, are a closer approximation of a beating-heart Maze procedure. Hybrid procedures represent an alternative strategy for extending the atrial lesion set.

The goal of an entirely epicardial, minimally invasive, off-pump ablation procedure with high efficacy has remained elusive. The ideal surgical treatment for AF would consist of a patient-tailored lesion set using devices that consistently achieve transmurality and continuity through a minimally invasive approach.

Takotsubo syndrome (TTS), also known as Takotsubo cardiomyopathy, stress cardiomyopathy, and broken heart syndrome, is an acute and typically reversible heart failure often precipitated by a period of intense emotional or physical stress (Lyon et al., 2016; Templin et al., 2015). Its name is derived from the ampulla-shaped fishing pots used by Japanese fisherman to catch octopi (Sharkey et al., 2011). Characterized by a regional hypocontractility in one or more left ventricular segment, with a relative hypercontractile spared segment, TTS patients present as an acute coronary syndrome, yet no culprit coronary pathology can be found on angiography (Tranter et al., 2013). The most common apical TTS variant occurs when the apical myocardium is hypocontractile and the basal myocardium is hypercontractile; the mid-LV may or may not be involved (Tranter et al., 2013). Atypical variants include solely mid-LV hypocontractility, or basal hypocontractility, with or without mid-LV involvement and biventricular TTS. Since its initial description in 1990 after an earthquake in Japan (Satoh et al., 1990), recognition of the disease has increased, particularly due to the use of early coronary intervention in cases of seemingly cardiac chest pain (Shao et al., 2012).

Causes of TTS are numerous and include emotional stress, physical stress, sepsis, hyper-catecholamine endocrine disorders (e.g., pheochromocytoma, thyrotoxicosis), electroconvulsive therapy, sepsis, anesthetic induction, acute exacerbations of respiratory disease, and epilepsy (Lyon et al., 2016).

The pathophysiology is complex and incompletely understood. Preclinical animal models of TTS have been created by a number of research groups (Izumi et al., 2009; Shao et al., 2013; Paur et al., 2012; Ueyama et al., 2002; Cao et al., 2015), whereas studies of the pathophysiology of the human disease are mostly limited to endomyocardial biopsy samples (Nef et al., 2010) and epidemiological data (Schneider et al., 2013). There have been no randomized controlled trials assessing different therapeutic strategies for TTS, and therefore current clinical management is based on a *primum non nocere* principle, with supportive therapies favored for low-risk (stable) TTS patients and intensive care-based strategies (e.g., extracorporeal circulatory support) for high-risk (unstable) TTS patients who develop profound cardiogenic shock (Lyon et al., 2016). General advice is to avoid catecholamine-based positive inotropes and β2-agonist bronchodilators and these drugs can trigger TTS and may worsen a preexisting case.

Epidemiology

It is estimated that 1%–2% of acute coronary syndrome patients will be diagnosed with TTS (Gianni et al., 2006), although the actual figure may be higher as the size of a potentially large cohort of patients that either suffer an out-of-hospital cardiac arrest or do not suffer a high enough degree of LV dysfunction to attend hospital (subclinical TTS). In a study of 33,506,402 patients carried out in the United Stated, TTS accounted for 0.02% of hospitalizations, with risk factors including smoking, hyperlipidemia, anxiety, and alcohol abuse (Deshmukh et al., 2012).

In the German TTS registry, over 90% of TTS patients are female, with a mean age of 66 years, although disease characteristics were similar between males and females. TTS is also more common in elderly people, with less than 10% of cases occurring in those under 50 years of age (Deshmukh et al., 2012; Pilgrim and Wyss, 2008). Furthermore, TTS patients over the age of 75 years have an increased mortality rate (Citro et al., 2012). There has often been the assertion that TTS is a disease primarily affecting the

postmenopausal woman (Schneider et al., 2013), and there is limited evidence to show that patients previously taking hormone-replacement therapy may have reduced complications from an episode of TTS (Patel et al., 2013).

Diagnosis

A TTS patient will typically present with cardiac chest pain and dyspnea, mimicking an acute coronary syndrome (Tranter et al., 2013). ECG abnormalities are present in the acute phase (<12 h from symptom onset) in almost all cases of TTS (Lyon et al., 2016), namely ST-segment elevation and/or depression, left bundle branch block, T-wave inversion, and QT prolongation. T-wave inversion in aVr with no negative T-wave in V1 is particularly sensitive for TTS (Kosuge et al., 2012). QT prolongation can be profound, and daily ECG monitoring is suggested to risk stratify for *torsade de pointes* arrhythmia, a potentially fatal form of ventricular tachycardia (Ahn et al., 2011).

TTS is a diagnosis made after the exclusion of culprit coronary pathology. All patients, even when there is a high suspicion of TTS over an acute coronary syndrome, should undergo urgent coronary imaging, usually diagnostic angiography. This can be followed by left ventriculography which will confirm TTS with the Takotsubo shape and myocardial dysfunction affecting >1 coronary artery territories.

Echocardiography is also a valuable imaging modality in both diagnosis and monitoring, particularly to detect the presence of acute complications including LV apical thrombus, mitral valve regurgitation, left ventricular outflow tract obstruction, and decreasing cardiac function.

To date, a clinically validated specific biomarker for TTS has not been reported. There is limited evidence to suggest that NT-proBNP could be used to risk-stratify patients with TTS, as lower levels of NT-proBNP are associated with a more favorable prognosis (Lyon et al., 2016).

Cardiac magnetic resonance can provide further information about the contractile deficit present in the heart, acute myocardial inflammation of the affected segments, and right ventricular involvement where present (Eitel et al., 2011). Furthermore, myocardial edema consistent with the anatomical region of hypocontractility can help to rule-in TTS as a diagnosis (Joshi et al., 2010; Iacucci et al., 2013).

Pathophysiology

There have been a number of proposed mechanisms for the hypocontractility seen in TTS: with the recent reclassification of Takotsubo cardiomyopathy to TTS (i.e., a clinical diagnosis based on a collection of symptoms and signs), a single mechanistic pathway is not required, and a number of pathological processes could lead to regional hypocontractility.

The frequently described precipitating stressful event or catecholamine administration (e.g., dobutamine stress echocardiography, Epi-Pen injection) suggests catecholamine excess to be central to the development of TTS, with perhaps a predisposition for increased "gain" through the sympathetic axis (i.e., an increased catecholamine release for the same emotional/physical stimulus). An increased incidence of TTS in people with a Type D personality has been reported consistent with higher susceptibility to a given stressful trigger (Compare et al., 2013). Serum catecholamine levels have been shown to be increased at the time of presentation and remain acutely elevated (Wittstein et al., 2005).

Proposed hypotheses for TTS include multivessel vasospasm, left ventricular outflow tract obstruction, direct myocardial catecholamine stunning, and a cardio-circulatory interaction; it is unlikely that a single coronary vessel pathology could cause the whole apex to dysfunction as this is perfused by more than one artery, and the frequency of the "wrap-around" left anterior descending artery is not higher in TTS patients compared to MI controls (Hoyt et al., 2010). These hypotheses are covered in depth in a number of reviews (Tranter et al., 2013; Omerovic, 2011; Redfors et al., 2013). Acute effects of high dose epinephrine on β2-adrenergic receptor signaling to a cardioprotective but negative inotropic secondary messenger signaling pathway in the ventricular myocardium may play a role (Lyon et al., 2008). Endomyocardial biopsy samples have shown a number of changes that show a metabolic dysfunction and cardioprotective phenotype in the setting of a high catecholamine load, and myocardial edema appears to correlate well with the area of dysfunction, although this may be merely epiphenomenal (Nef et al., 2008, 2009; Shao et al., 2013; Perazzolo Marra et al., 2013). There is conflicting evidence of a genetic susceptibility to TTS, with some studies showing a GRK5 polymorphism that acts as an endogenous beta-blocker could be a risk factor (Spinelli et al., 2010; Novo et al., 2015; Figtree et al., 2013).

Management

During the acute phase many TTS patients have a high risk of complications and require close monitoring before recovery occurs. Risk stratification may be helpful at admission to identify those at highest risk (Lyon et al., 2016). Acquired QT prolongation in the acute phase predisposes to *torsade de pointes* and ventricular arrhythmias, and therefore continuous ECG monitoring in a coronary care unit or high dependency unit is advised which access to resuscitation and electrical cardioversion. Monitoring of cardiac function through echocardiography will help the clinician to risk stratify TTS patients, with the most severe cases with cardiogenic

shock requiring interventions such as extracorporeal membrane oxygenation or a temporary left ventricular assist device. If pharmacological inotropic support is required, a low-dose levosimendan infusion may be of benefit (Paur et al., 2012; Santoro et al., 2013); administration of sympathomimetics such as isoprenaline, dobutamine, and epinephrine is generally contraindicated (Lyon et al., 2016) and was associated with an increased mortality in the InterTak registry (Templin et al., 2015).

Long-Term Prognosis for TTS Patients

There are conflicting reports for the long-term morbidity and morality for patients after a single episode of TTS, but in a recent study using the SWEDEHEART registry, mortality at 3 years post-TTS episode was similar to patients who had a STEMI (Redfors et al., 2015). However, other studies have found that TTS did not increase mortality compared to controls matched for age and gender (Molina et al., 2014; Elesber et al., 2007).

Conclusion

TTS is a form of acute heart failure that is typically triggered by a stressful stimulus or stimuli, typically presenting with acute cardiac chest pain and ECG changes similar to an acute coronary syndrome. The diagnosis requires culprit coronary pathology to be excluded, and TTS is characterized by a hypocontractile apical myocardium coupled to a hypercontractile basal myocardium, although anatomical variants do exist. Due to its relatively recent discovery (1990), its pathophysiology is poorly understood, but is likely to be multifactorial. Epidemiological data showed an increased prevalence among postmenopausal females, although it can be observed in younger women and ~10% of cases are male. As the disease is typically self-limiting, treatment should be supportive, with mechanical support in intensive care settings to treat cardiogenic shock and other rare but severe complications. Further work is required, both in basic and clinical science, to understand the mechanisms and optimal treatment strategies for TTS.

Cigarette smoking remains the number one preventable cause of death worldwide, and it contributes significantly to cardiovascular disease (CVD) (World Health Organization, 2016). The extraordinary burden of CVD and related diseases caused by tobacco products is even more remarkable in that the pandemic is entirely manmade. A combination of commercial marketing and physical addiction sustains the CVD epidemic, and tobacco is the major human risk factor. Tobacco marketing creates the illusion that smoking is desirable and thus encourages nonsmokers to experiment with tobacco usage. Physical addiction to nicotine then forces continued usage, making it extremely difficult for many smokers to quit. Smokers need the chronic exposure to the numerous risk factors in the cigarette and other toxic substances due to continue smoking to maintain some concentration of nicotine, and then they have the hazards of smoking to the health.

Over the past decades, a large body of evidence has clearly indicated that exposure to smoking is associated with increased risks of CVD and accelerated atherosclerosis. The CVD risk attributable to smoking increases sharply at low levels of tobacco consumption and with exposure to secondhand smoke. The harmful effects of smoking on CVD and atherosclerosis are attenuated by smoking cessation, however. This article focuses on the relationship between smoking and CVD, the effects of smoking on the atherosclerotic process, the benefits of smoking cessation, the progress in smoke-free legislation, and the prevention of CVD.

Smoking and CVD

Smoking is an independent major risk factor for all types of CVD, including coronary heart disease (CHD), stroke (Jee et al., 1999), sudden cardiac death (SCD) (Kannel et al., 1975), aortic aneurysm (Lee et al., 1997), and peripheral artery disease (PAD) (Murabito et al., 2002). The incidence of myocardial infarction (MI) is sixfold higher in women and threefold higher in men who smoke 20 or more cigarettes daily compared to never smokers (Njolstad et al., 1996). According to the INTERHEART study conducted across 52 countries, smoking was responsible for 36% of the population attributable risk (PAR) of a first MI (Yusuf et al., 2004). In a meta-analysis of data from 32 studies, the overall relative risk (RR) for stroke related to smoking was 1.5 (95% confidence interval (CI), 1.4–1.6) (Shinton and Beevers, 1989). The RRs altered across the subtypes of stroke: 1.9 for ischemic stroke, 0.7 for hemorrhage stroke, and 2.9 for subarachnoid hemorrhage (Shinton and Beevers, 1989).

Most SCDs are due to CVD. In multivariate analyses of the combined data from the Framingham Heart Study and the Albany Study, which followed men aged 45–64 years, smoking was the SCD risk factor with the highest statistical significance (Kannel et al., 1975). Current and recent former smokers had an increased risk of aortic aneurysm compared to long-time former smokers and never smokers (odds ratio (OR), 2.63; 95% CI, 1.53–6.21) (Lee et al., 1997). The Framingham Offspring Study demonstrated an increased risk of PAD among current smokers (OR, 2.0; 95% CI, 1.1–3.4) compared to noncurrent smokers (Murabito et al., 2002). Moreover, smoking increases all-cause mortality and CVD mortality. The adjusted hazard ratios (HRs) during a 35-year follow-up period for current smokers compared with never smokers were 1.62 (95% CI, 1.40–1.88) and 1.63 (95% CI, 1.24–2.13), respectively, and those who persisted in smoking cessation had no increased risk of death compared with never smokers (Qiao et al., 2000).

Patients with established CHD who were active smokers had increased risk of recurrent coronary events compared to those who were nonsmokers (RR, 1.51; 95% CI, 1.10–2.07) (Rea et al., 2002) and for SCD (HR, 2.47; 95% CI 1.46–4.19) (Goldenberg et al., 2003). Among patients who successfully underwent percutaneous coronary intervention for CHD, those who continued to smoke had higher risks of Q-wave infarction (RR, 2.08; 95% CI, 1.16–3.72) and death (RR, 1.44; 95% CI, 1.04–2.04) than nonsmokers (Hasdai et al., 1997). After coronary artery bypass graft (CABG), persistent smokers had elevated risks of cardiac death (RR, 1.75; 95% CI, 1.30–2.37) and revascularization (RR, 1.41; 95% CI, 1.02–1.94) compared to the CABG patients who gave up smoking for at least 1 year after surgery (van Domburg et al., 2000).

Dose and Duration of Smoking Exposure and CVD

A clear dose-response relationship exists between the number of cigarettes smoked daily and the risk of CVD; another clear dose-response relationship exists between an individual's smoking duration and the risk of CVD. In the INTERHEART study, compared with never smokers, even a very small number of daily cigarettes (i.e., <5) was associated with a higher risk of CHD; the risk increased by 5.6% for every additional cigarette smoked (OR, 1.056; 95% CI, 1.05–1.06) (**Fig. 1**) (Teo et al., 2006). In addition, the odds of an MI were ninefold higher among those who smoked ≥40 cigarettes daily compared to never smokers (Teo et al., 2006). Similarly, the risk of stroke related to smoking increased with the number of cigarettes smoked daily, and this risk was present for even a small number of cigarettes; those who smoked <10 cigarettes daily still had an increased risk of stroke compared to never smokers (RR, 1.37; 95% CI, 1.24–1.52) (Shinton and Beevers, 1989).

An increased risk of CHD was also observed with a longer duration of smoking regardless of the number of cigarettes smoked daily (Burns, 2003). In the Nurses' Health Study, the number of cigarettes smoked daily and the smoking duration were linearly associated with the SCD risk among current smokers (Sandhu et al., 2012). Even small to moderate cigarette consumption (1–14 per day) was associated with a significant 1.84-fold (95% CI, 1.16–2.92) increase in SCD risk, and every 5 years of continued smoking was associated with an 8% increase in SCD risk (HR, 1.08; 95% CI, 1.05–1.12) (Sandhu et al., 2012).

Type of Tobacco Used

Available evidence suggests that all types of smoking increase the risk of developing CVD. A cohort study of 17,774 men followed for 14 years showed that, compared to never smokers, the men who smoked cigars were at a higher risk of incident CHD (RR, 1.27; 95% CI, 1.12–1.45) in a dose-dependent manner: the RRs were 1.20 (95% CI, 1.03–1.40) for the men who smoked <5 cigars per day and 1.56 (1.21–2.01) for those who smoked >5 cigars daily (Iribarren et al., 1999). A longitudinal cohort of 16,932 Norwegian men exhibited a significantly increased risk of CVD, CHD, and stroke deaths from pipe smoking (Tverdal and Bjartveit, 2011). The RRs for those who smoked 14 g of tobacco or more daily compared to never smokers were 3.35 (2.28–4.91) for death from CVD, 3.34 (2.02–5.51) for death from CHD, and 3.76 (1.61–8.78) for death from stroke, in a dose-dependent manner (Tverdal and

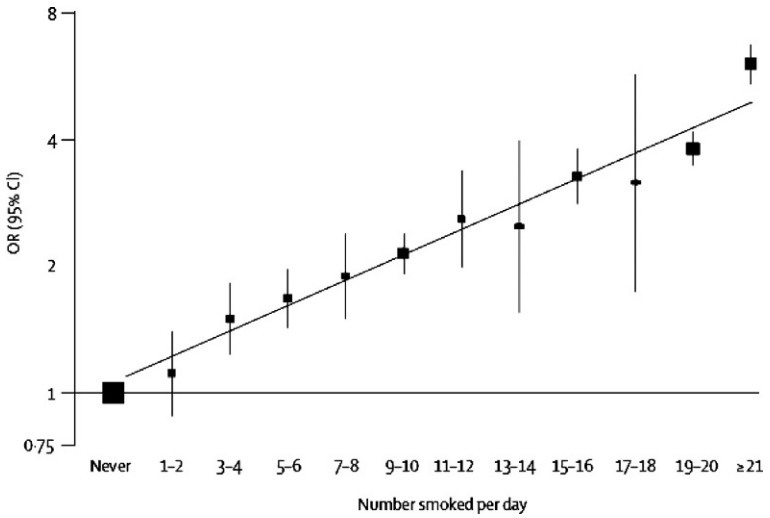

Fig. 1 Risks of myocardial infarction (MI) with increasing numbers of cigarettes smoked compared with never smokers, from the INTERHEART study conducted across 52 countries. The risk increased by 5.6% for every additional cigarette smoked (OR, 1.056; 95% CI, 1.05–1.06). At least 21 cigarettes smoked per day represent approximately 1.5 cigarette packs, associated with an OR of 6.00–7.00. Reprinted from Teo, K. K., Ounpuu, S., Hawken, S., Pandey, M. R., Valentin, V., Hunt, D., Diaz, R., Rashed, W., Freeman, R., Jiang, L., Zhang, X., Yusuf, S. and Investigators IS. (2006). Tobacco use and risk of myocardial infarction in 52 countries in the INTERHEART study: a case-control study. *Lancet* **368**, 647–658 with permission from Elsevier.

Bjartveit, 2011). No or only minor differences were found between pipe smokers and cigarette smokers in mortality from any cause and the specified CVD diseases (Tverdal and Bjartveit, 2011).

In the INTERHEART study of a case–control investigation in 52 countries, the use of other forms of tobacco was largely confined to specific regions (Teo et al., 2006). Smoking beedies (or bidis; a thin hand-rolled tobacco cigarette (i.e., indigenous to South Asia)) alone was associated with an increased risk of acute MI (OR, 2.89; 95% CI, 2.11–3.96), similar to the OR associated with cigarette smoking (Teo et al., 2006). Chewing tobacco alone was associated with an OR for acute MI of 2.23 (95% CI, 1.41–3.52), and smokers who also chewed tobacco had the highest increase in risk (OR, 4.09; 95% CI, 2.98–5.61) (Teo et al., 2006). The INTERHEART study found that the risk of MI increased with all forms of tobacco use, including different types of smoking and chewing tobacco. The use of snuff and other types of smokeless tobacco is increasing, particularly among adolescents and young adults. However, the CVD risks related to smokeless tobacco are not well-established and deserve further investigation (Gupta et al., 2004).

Women

Sex differences exist in the adverse effects of smoking. A systematic review and meta-analysis of 75 prospective cohort studies demonstrated that female smokers were 25% more likely to develop CHD than male smokers (female-to-male RR ratio, 1.25; 95% CI, 1.12–1.39) (Huxley and Woodward, 2011). Female smokers are more likely to experience adverse events after acute coronary syndrome (ACS) than male smokers (Howe et al., 2011). These findings suggest that tobacco-control programs should consider women, particularly in those countries where smoking among young women is increasing in prevalence.

Race and Ethnicity

The risk of CVD associated with cigarette smoking persists across all races. Smoking was identified as a significant risk factor for CVD among Hispanic populations (Mendelson et al., 1998) and Asian populations (Kiyohara et al., 1990; Ueshima et al., 2004). In the INTERHEART case–control study, the PAR for acute MI in current smokers ranged from a low of 33.1% (95% CI, 29.7–36.6) in China and Hong Kong to a high of 53.3% (46.2–60.3) in Australia and New Zealand (Teo et al., 2006). The PAR for other world regions fell within this narrow range, showing that the PAR for current tobacco smoking is consistent and high across the globe (Teo et al., 2006).

Secondhand Smoke Exposure and CVD

Exposure to secondhand smoke increases the risk of CVD in never smokers. Large epidemiologic studies have estimated a 20% higher risk of CHD among never smokers exposed to secondhand smoke (Steenland et al., 1996; Wells, 1994). A meta-analysis of 18 epidemiologic (10 cohort and 8 case–control) studies also found a 25% increased risk of CHD (95% CI, 1.17–1.32) related to a dose-dependent exposure to secondhand smoke (He et al., 1999). In the INTERHEART study, secondhand smoke was associated with an incremental increase in the risk of acute MI related to exposure; the OR was 1.24 (1.17–1.32) in individuals who were least exposed (1–7 h/week) and 1.62 (1.45–1.81) in individuals who were most exposed (>21 h/week) (Teo et al., 2006). Findings from the Nurses' Health Study indicated that compared with women not exposed to secondhand smoke, the RR of CHD was 1.58 (95% CI, 0.93–2.68) among women who reported occasional exposure and 1.91 (95% CI, 1.11–3.28) among those reported regular exposure (Kawachi et al., 1997).

Secondhand smoke may also be associated with extracoronary vascular disease. A large cross-sectional study of 60,377 women in China showed an association between stroke in the women and smoking by their husbands (Zhang et al., 2005). The prevalence of stroke increased with the duration of smoking and with the number of cigarettes smoked daily (Zhang et al., 2005). Secondhand smoke exposure among never smokers is potentially a modifiable risk factor for CVD. Before–after studies have indicated that laws that limit public and workplace smoking may result in a rapid decrease in the risk of ACS in both smokers and nonsmokers (Callinan et al., 2010). One meta-analysis estimated that the rate of hospitalization for acute MI decreased 12 months after the implementation of smoking restriction laws (0.83, 95% CI, 0.80–0.87) (Lightwood and Glantz, 2009).

Smoking and Atherosclerosis

Various clinical imaging techniques have been used to confirm the association of smoking and atherosclerosis directly. The Multi-Ethnic Study of Atherosclerosis (MESA) evaluated the relationship between smoking and the severity of modality-determined subclinical atherosclerosis (McEvoy et al., 2015). Current and former smoking were associated with subclinical atherosclerosis at three anatomically distinct sites: coronary artery calcification (CAC), carotid intima-media thickness (IMT), and ankle-brachial index (ABI) (McEvoy et al., 2015). A Japanese population-based study also demonstrated strong associations between current and former smoking and subclinical atherosclerosis in multiple vascular beds such as CAC, carotid IMT, ABI, and aortic artery

calcification (AoAC), with a dose-dependent relationship with cumulative pack-years exposure or smoking intensity (Hisamatsu et al., 2016). A significant relationship between current or former smoking and CAC was also reported in other cohorts (Jockel et al., 2009; LaMonte et al., 2005; Loria et al., 2007; Rasmussen et al., 2013). Similarly, carotid IMT (Richey Sharrett et al., 2004; Raitakari et al., 2003; Baldassarre et al., 2009; Howard et al., 1994) and AoAC (El-Saed et al., 2013) findings associated with smoking have been confirmed.

Endothelial dysfunction is a well-established response to CVD risk factors, and it precedes the development of atherosclerosis. Smoking was associated with endothelial dysfunction in a dose-dependent manner, as assessed by flow-mediated dilatation in asymptomatic young adults (Celermajer et al., 1993). Several large autopsy studies have found an association between cigarette smoking and atherosclerosis in the major coronary arteries (Strong and Richards, 1976; Berenson et al., 1998; Zieske et al., 1999). The Bogalusa Heart Study examined autopsy data from 93 children and young adults (age range 2–39 years) who had died principally from trauma and for whom data on risk factors were available (Berenson et al., 1998). Investigators observed that cigarette smoking increased the percentage of the intimal surface involved with fibrous plaques in the aorta (1.22% in smokers vs. 0.12% in nonsmokers, $p = 0.02$) and fatty streaks in the coronary vessels (8.27% vs. 2.89%, $p = 0.04$) (Berenson et al., 1998). Similar associations between smoking and early stage atherosclerosis were observed in the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study (Zieske et al., 1999). These autopsy studies indicate that even among young smokers, atherosclerotic plaque progresses faster and to a greater degree than among nonsmokers.

Mechanisms Underlying the Links Between Smoking and CVD

The evidence linking smoking exposure to various CVDs is clear, although the mechanisms underlying these associations have not been fully elucidated (Ambrose and Barua, 2004). Multiple factors are likely involved, since smoking exerts a variety of effects that may contribute to atherogenesis (Ambrose and Barua, 2004). Atherosclerosis is considered a critical player in the pathophysiology of smoking-induced CVD (Ambrose and Barua, 2004), and the adverse effects of atherosclerosis can be reduced by smoking cessation (Johnson et al., 2010).

Smoking is associated with an adverse effect on serum lipids (i.e., elevated low-density lipoproteins (LDL) and triglycerides and reduced high-density lipoproteins (HDL)) and insulin resistance (Craig et al., 1989; Reaven and Tsao, 2003). Free radicals generated by smoking also damage lipids, resulting in the formation of proatherogenic oxidized particles, specifically oxidized low-density lipoprotein cholesterol (Miller et al., 1997; Heitzer et al., 1996). In addition, smoking enhances the prothrombotic state through an elevation of blood fibrinogen concentrations, an increased platelet activity, an increased expression of tissue factors, and the inhibition of tissue plasminogen activator release from the endothelium (Newby et al., 1999; Matetzky et al., 2000). Smoking also activates the sympathetic nervous system, elevating heart rate and blood pressure, and constricting peripheral and coronary arteries (Winniford et al., 1986; Narkiewicz et al., 1998).

Smoking and passive smoking can impair the functionality of endothelium-dependent vasodilation in coronary arteries and reduce coronary flow reserve (Sumida et al., 1998; Barua et al., 2001; Kaufmann et al., 2000). The decline in endothelial function is caused by oxidative stress from oxidized LDL and reduced nitric oxide (Barua et al., 2001; Kaufmann et al., 2000; Kugiyama et al., 1996; Mazzone et al., 2001). Moreover, smoking has been related to higher levels of C-reactive protein, fibrinogen, homocysteine (Bazzano et al., 2003), soluble intercellular cell adhesion molecule-1 (sICAM-1), and soluble vascular cell adhesion molecule-1 (sVCAM-1) (Mazzone et al., 2001). These findings indicate that inflammation and hyperhomocysteinemia could be important factors by which smoking promotes the pathogenesis of atherosclerosis.

Smoking Cessation

Smoking cessation is a key element in both the primary and secondary prevention of CVD. Among individuals without prior CHD, the reduction in cardiac events after quitting smoking ranged from 7% to 47% (Multiple Risk Factor Intervention Trial Research Group, 1982; Hjermann et al., 1981; Hurt et al., 2012). The risks of CHD associated with cigarette smoking decrease relatively soon after smoking cessation is initiated, and the risks continue to decrease over time (U.S. Department of Health and Human Services, 1990).

Smoking cessation improves outcomes in patients with known CHD. In a meta-analysis of 20 prospective cohort studies with a follow-up period of ≥ 2 years among 12,603 patients with known CHD, of whom 5659 gave up smoking and 6944 continued to smoke, the RR of mortality in the patients who gave up smoking was 0.64 (95% CI, 0.58–0.71) compared with those who continued to smoke (Critchley and Capewell, 2003). A retrospective cohort study of 2619 patients discharged after a first MI, with never smokers as the reference, found a multivariable RR for recurrent CHD of 1.17 (95% CI, 0.93–1.43) for former smokers and 1.51 (95% CI, 1.10–2.07) for current smokers (Rea et al., 2002). Compared with never smokers, the RR among former smokers decreased progressively with time since smoking cessation (RR, 1.62 (95% CI, 1.02–2.61) for the duration <6 months; 1.60 (0.97–2.60) for 6–18 months; 1.48 (0.76–2.51) for 18–36 months; and 1.02 (0.54–1.86) for 36 months or more; P for trend $= 0.01$) (Rea et al., 2002).

This finding indicates that patients who gave up smoking after having suffered an MI had reductions in the risk for recurrent CHD over time; within 18–36 months, the risk was almost similar to that of never smokers. In addition, the relative benefits of smoking cessation were shown to be similar in young and old patients with CHD (Hermanson et al., 1988).

Smoking cessation was also associated with a reduction in the risk of SCD primarily in patients with CHD (Goldenberg et al., 2003; Peters et al., 1995; Vlietstra et al., 1986; Hallstrom et al., 1986). In a prospective study with a mean follow-up period of 8.2 years, patients with known CHD who gave up smoking experienced a significant reduction in SCD risk (HR, 1.06; 95% CI, 0.70–1.62) compared to those who had never smoked (Goldenberg et al., 2003). However, there are limited data on the impact of smoking cessation on SCD risk among individuals without known CHD (Sandhu et al., 2012; Gordon et al., 1974). In the Framingham study, male smokers aged <65 years at study entry who subsequently stopped smoking cut their rate of SCD by almost 50% compared to those who continued to smoke over 18 years of follow-up (Gordon et al., 1974). The Nurses' Health Study among women without known CVD at baseline found that the risk of SCD decreased linearly over time after smoking cessation and was equivalent to that of never smokers after 20 years of cessation (Sandhu et al., 2012). The risk of stroke also decreases over time after smoking cessation. For total and ischemic stroke, excess risks among women who stopped smoking largely disappeared 2–4 years after cessation, independent of age at cessation and the number of cigarettes smoked per day (Kawachi et al., 1993).

Some community-based studies of participants without known CVD have reported an association between smoking cessation and measures of atherosclerosis in multiple vascular beds (McEvoy et al., 2015; Hisamatsu et al., 2016; Jockel et al., 2009). In the MESA multiethnic cohort, the associations of smoking with CAC, carotid IMT, and ABI decreased over time in former smokers (McEvoy et al., 2015). Similarly, in a general Japanese population, time since cessation was linearly associated with lower burdens of coronary, carotid, aortic, and peripheral atherosclerosis (Hisamatsu et al., 2016). A 1-year prospective investigation of the impact of smoking cessation on endothelial function in over 1500 smokers revealed that endothelial function improved significantly in smokers who had successfully given up smoking compared to the baseline function (although these subjects gained an average of 5 kg), but it did not improve in those who continued to smoke (Johnson et al., 2010).

Smoke-Free Legislation and CVD

Most of the available studies conducted worldwide regarding smoke-free legislation and CVD observed that legal smoking regulations and the implementation of fully tobacco-free areas in public spaces or workplaces decreased the local rate of hospitalization due to heart attacks (such as acute MI) soon after the legislation was implemented (Sargent et al., 2004; Bartecchi et al., 2006; Barone-Adesi et al., 2006; Khuder et al., 2007; Juster et al., 2007; Tan and Glantz, 2012). Here, we describe several examples from the United States and Italy.

Helena, Montana, United States

The city of Helena, Montana, is a geographically isolated area that had a population of 68,140 people in 1998. The city's regulations to prohibit smoking in public places and workplaces were implemented from Jun. to Dec. 2002. There was only one hospital in this area, and all individuals with an acute MI were conveyed to this hospital. This research (Sargent et al., 2004) was carried out using the medical records of all inpatients admitted to the hospital from Dec. 1997 to Nov. 2003, by the Poisson analysis. The number of hospitalizations with acute MI within the 6 months after the smoking prohibition regulations were started was 24 cases, which was 16 cases (95% CI, −31.7 to −0.3) less, that is, 40% lower compared to the mean number of cases (approximately 40 cases per month) before the regulations. In the area surrounding Helena during the same period, the number of heart attacks increased by 5.6 cases, from 12.4 cases to 18 cases per month. This difference showed a statistically significant decrease between inside and outside Helena.

These results suggested that the legal regulations to make fully tobacco-free areas in public places and workplaces decreased the number of heart attacks soon after the regulation in this population. Moreover, the rate of heart attacks in this area increased again after the regulations were canceled, to 38 cases over the 6 months after the cessation of the regulations.

Pueblo, Colorado, United States

Based on the results obtained in the earlier-mentioned study, this study (Bartecchi et al., 2006) examining the implementation of smoke-free areas in public places and hospitalization rates was carried out in Pueblo, Colorado, which is geographically similar to Helena, Montana. The hospitalization rates for AMI in Pueblo were assessed each 1.5 years before and after the implementation of a smoke-free ordinance. These AMI rates were also compared with those of another geographically isolated but proximal community, El Paso, Colorado, that did not have a smoke-free ordinance. Between Jan. 1, 2002 and Dec. 31, 2004, a total of 855 patients were hospitalized with AMI in Pueblo. A reduction in AMI hospitalization was observed in the 1.5-year period after the ordinance's implementation among residents living within Pueblo's city limits (RR, 0.73; 95% CI, 0.63–0.85). No significant changes in the AMI rate were observed among the residents outside the Pueblo city limits (RR, 0.85; 95% CI, 0.63–1.16) or in El Paso (which no longer had smoke-free public places and workplaces) during the same period (RR, 0.97; 95% CI, 0.89–1.06). The reduction in AMI rate within Pueblo differed significantly from changes in the control group (El Paso).

Piedmont, Northern Italy

In Jan. 2005, the Italian Government banned smoking in all indoor public places, including cafés, bars, restaurants, and discos. This study (Barone-Adesi et al., 2006) evaluated whether the national law banning smoking in public resulted in a short-term reduction in hospital admissions for AMI, by analyzing the hospital discharge records of the Piedmont region in northern Italy. The rates of admission for AMI before the ban (Oct.–Dec. 2004) and after the ban's introduction (Feb.–Jun. 2005) were analyzed. Each period was compared with the corresponding period 12 months before. Among persons aged under 60, the number of admissions for AMI decreased significantly after the introduction of the ban: from 922 cases in Feb.–Jun. 2004 to 832 cases in Feb.–Jun. 2005 (sex- and age-adjusted rate ratio, 0.89; 95% CI, 0.81–0.98). No effect was found among persons aged $\geq$60. This study was estimated that the observed reduction in active smoking after the introduction of the ban could account for a 0.7% decrease in admissions for AMI during the study period, suggesting that most of the observed effect (11%) might be due to the reduction of passive smoking.

Bowling Green, Ohio, United States

In Mar. 2002, the city of Bowling Green, Ohio, implemented a clean indoor air ordinance banning smoking in workplaces and public places. Compared with a matched control city (Kent, Ohio) with no clean indoor air ordinance, the largest reduction in hospital admissions was for CHD, for which the rate in Bowling Green decreased significantly by 39% after 1 year and by 47% after 3 years following the implementation of the ordinance (Khuder et al., 2007). The findings of that study suggest that clean indoor air ordinances lead to a reduction in hospital admissions for CHD.

The State of New York, United States

Another study (Juster et al., 2007) examined whether the 2003 implementation of a comprehensive smoking ban in New York State was associated with reduced hospital admissions for CVDs. In 2004, there were 3813 fewer hospital admissions for AMI than would have been expected in the absence of the comprehensive smoking ban. Direct healthcare cost savings of $56 million were realized in 2004. There was no reduction in the number of admissions for stroke.

A Meta-Analysis of Hospitalizations for Cardiac Events and Cerebrovascular Diseases

A random-effect meta-analysis (Tan and Glantz, 2012) was conducted to determine the relationship between smoke-free legislation and hospital admissions or death from cardiac events and cerebrovascular diseases. The studies were identified by using a systematic search for relevant studies published before Nov. 30, 2011. Changes in hospital admissions (or deaths) in the presence of a smoke-free law, the duration of follow-up, and the smoking prohibition laws' comprehensiveness (i.e., workplaces only; workplaces and restaurants; or workplaces, restaurants, and bars) were recorded. Forty-five studies of 33 smoke-free laws with the median follow-up of 24 months were included. Comprehensive smoke-free legislation was associated with significantly lower rates of hospital admissions (or deaths) for three of the following diagnostic groups: coronary events (RR, 0.848; 95% CI, 0.816–0.881), other heart disease (RR, 0.610; 95% CI, 0.440–0.847), and cerebrovascular accidents (RR, 0.840; 95% CI, 0.753–0.936). Thus, smoke-free legislation was associated with a lower risk of smoking-related cardiac events and cerebrovascular diseases, with more comprehensive laws associated with greater reductions in the risks.

Prevention of CVD

Two complementary approaches are needed to reduce the devastating effects of tobacco on health. In the long term, progress depends on the systematic application of primary prevention measures that can reduce the initiation of tobacco use by young people and end the smoking pandemic during the second half of the 21st century. In the near term, substantial reductions in smoking-attributable CVDs can be achieved by providing counseling and treatment to facilitate smoking cessation among the millions of people around the world who currently smoke.

A variety of community-based interventions have proven effective in reducing tobacco consumption and decreasing smoking initiation when these measures are applied as part of comprehensive tobacco control (Centers for Disease Control and Prevention, 1999). They include regulatory approaches (restrictions on tobacco marketing, laws ensuring clean indoor air, and the enforcement of laws restricting minors' access to tobacco), economic approaches (e.g., increasing the price of cigarettes through excise taxes, thereby decreasing demand), and counter marketing campaigns to redefine social norms regarding tobacco use. It is possible to prevent tobacco use by young people if measures that have been proven to be effective are applied.

Most current smokers want to quit smoking. Approved therapies include nicotine replacement (gum, patch, inhaler, nasal spray), sustained-release bupropion hydrochloride, and behavioral treatment. The latter methods are most effective when they include practical counseling (problem solving/skills training), social support as part of treatment, and help with securing social support outside of treatment. The combination of pharmacologic and behavioral treatment enables 20%–25% of persons attempting to quit smoking to remain abstinent 1 year after treatment (U.S. Department of Health and Human Services, 2000). However, tobacco dependence frequently involves relapse, and it is best characterized as a chronic disease that may require periodic treatment.

Introduction

The total artificial heart (TAH) offers complete mechanical circulatory support (MCS) for patients with biventricular heart failure as a bridge-to-transplantation. By replacing the two native ventricles and four native valves, this device is very invasive and also unique in that it removes the risks associated with dysfunctional native myocardium. Understandably, utilization of TAHs is limited to very sick patients, a fact due to its associated risks and also the widespread implantation of ventricular assist devices. We believe that the TAH provides the best option for an important and growing subset of patients, and that technological advances with the device may promote increased utilization in the future. This article provides a comprehensive overview of the TAH as it relates to its history, current indications, technique of surgical implantation, postoperative management, outcomes to date, and future developments.

Historical Perspective

The TAH is founded in concepts of both MCS and cardiac transplantation, and thus its development has been touched by many pioneers of cardiac surgery.

The discovery of heparin by Jay McLean in 1916 was foundational to all subsequent work (McLean, 1959). In the 1920s and 1930s, Alexis Carrel teamed with Charles Lindbergh to develop a perfusion system to preserve the explanted organs of fowls and cats (Carrel, 1935). In 1935, John Gibbon successfully bypassed the heart and lungs of a cat, a concept Gibbon conceived while famously witnessing a patient expire from a massive pulmonary embolus (Gibbon, 1937).

A more modern version of the TAH began to appear in 1937, when Russian surgeon Vladimir Demikhov developed a device to aid in transplantation of dog lungs: its design featured two adjacent pumps driven by an external motor and a transcutaneous drive shaft (Kwann-Gett et al., 1969). Additional strides were made in 1948, when William Sewell developed a pump system which was pneumatically powered, thereby creating the pressurized system upon which many current pumps depend (Eli Whitey Museum, www.eliwhitney.org). In 1952, Forest Dodrill bypassed the left ventricle of a 41-year-old male for 50 min to perform a mitral valve repair through a left anterolateral thoracotomy in what is considered to be the first successful machine-supported open heart operation in a human (Dodrill et al, 1952). In 1953, John Gibbon again made his mark, utilizing a heart–lung machine to close an atrial septal defect in an 18-year-old woman (Gibbon, 1954).

Initial efforts at creating a complete cardiac replacement artificial organ in the United States began as one of the several scientific initiatives advocated during the Kennedy administration in the 1960s. In 1964, the National Institute of Health launched an artificial heart program, fostering the development of partial and full cardiac replacement devices. Parallel efforts began in Texas and Cleveland on circulatory replacement systems. In 1963, William DeBakey implanted the first left ventricular assist device (LVAD) in a human at Baylor University in Houston, Texas, though the patient expired 4 days later (Debakey, 1971).

In 1967, Christiaan Barnard completed the first human-to-human cardiac transplantation in South Africa (Barnard, 1967), followed shortly thereafter by U.S. transplants overseen by Kantrowitz (1998) and Norman Shumway (Haller and Cerruti, 1968). Motivated by these events, in 1969 Denton Cooley performed the first human implantation of a TAH (Cooley et al., 1969). It occurred on April 4, 1969 after a failed ventricular resection procedure for the enlarged heart of Mr. Haskell Karp, who could not be weaned from heart–lung machine, resulting in Denton Cooley implanting a Liotta-TAH in this 47-year-old man. The patient regained consciousness, was extubated, and then bridged to transplant after 64 h of TAH support but died after 32 h posttransplant due to pneumonia. 12 years later, Cooley implanted his second artificial heart (Cooley et al., 1981), this time with a pneumatic dual-chambered Akutsu TAH, in a patient who survived 39 h postimplant.

In 1982, the Jarvik-7-100 TAH, a pneumatically powered, biventricular, pulsatile pump, was implanted by William DeVries (DeVries et al., 1984). The patient Dr. Barney Clark survived 112 days postoperatively, and due to this impressive survival, many consider this to be the first successful implantation of a TAH. The second implantation of this device occurred in November 1984 and extended the life of William Schroeder by 620 days postoperatively (Altman, 1986).

The rising enthusiasm over heart transplantation in the early years of 1980, along with the development of new immunosuppressive drugs and the influence of increased regulatory guidance, evolved the initial indication for TAH from destination therapy to bridge to heart transplantation (BTT).

In recent years only the SynCardia CardioWest TAH has been continuously used as a TAH, achieving worldwide reliable results as BTT, with more than 1300 implants at the time of writing (SynCardia, www.syncardia.com). Ownership of the device changed hands to CardioWest in 1992, and the device was renamed as the CardioWest TAH, with subsequent CE Mark in Europe in 1999 and Food and Drug Administration (FDA) approval in 2004 as a bridge-to-transplantation. A second renaming in 2010 resulted in the device currently known as the SynCardia TAH (**Figs. 1** and **2**). New TAHs have recently been adopted or entered in the commerce, though with very limited available clinical data, paving the way for the next generation of TAH technology.

Current Role of Total Artificial Hearts

Approved Devices

The SynCardia TAH (SynCardia Systems LLC, Tuscon, Arizona) is currently the only FDA-approved TAH, and it has gained CE Mark (Europe) and Health Canada approval as well. The SynCardiaTAH is a pulsatile biventricular device which completely replaces the native ventricles and all four cardiac valves orthotopically. It weighs 160 kg and attaches to the native atria via synthetic cuffs. A four-layered polyurethane diaphragm within each polyurethane ventricle is pneumatically driven, with a with a maximum stroke volume of 70 mL and maximum cardiac output of 9.5 L per minute. Four Medtronic-Hall mechanical tilting disc valves maintain unidirectional flow. Air pressure as well as device monitoring and backup power supplies are provided by an external console which is connected to the device by drivelines, which pierce the skin. The console is a large unit on wheels which requires patients to remain admitted within the hospital. More recently, a Freedom portable driver console has allowed patients to be discharged from the hospital.

Indications

The SynCardia TAH is indicated for use as abridge-to-transplantation for transplant-eligible patients at imminent risk of death from biventricular failure (Parker et al., 2014; Feldman et al., 2013; Thanavaro et al., 2014). This necessitates that patients meet criteria for transplantation (Mehra et al., 2016) and are actively listed for transplant (**Table 1**).

Several additional criteria specific to the TAHs include New York Heart Association (NYHA) class IV, adequate patient size (body surface area (BSA) 1.7–2.5 m^2), and adequate patient chest size (a distance of $\geq$10 cm from inner table of the sternum to the anterior vertebral body of the 10th thoracic vertebra).

Contraindications

Absolute contraindications for TAH implantation include patient inability to receive anticoagulation (**Table 1**). A relative contraindication is patient size less than 1.7 m^2, as this has been found to be associated with worse survival following TAH implantation (Kawaguchi et al., 1990). A second relative contraindication is a small chest size, defined as a distance of $<$10 cm between inner table of the sternum to the anterior vertebral body of the 10th thoracic vertebra, for fear that the device may compress the inferior vena cava (IVC) or pulmonary veins. Finally, despite the fact TAH is now approved as destination therapy for a very limited subset patients based on FDA humanitarian use device (HUD) designation, the large majority of TAHs are implanted as a BTT and therefore contraindications to heart transplantation (**Table 1**) apply for TAHs.

Table 1 Indications and contraindications to total artificial hearts and cardiac transplantation

Indications and contraindications to TAH (Mehra et al., 2016; Parker et al., 2014; Feldman et al., 2013; Thanavaro et al., 2014)	*Indications and Contraindications to Cardiac Transplantation (Mehra et al., 2016)*
Indications: ● Approved for transplant and on transplant list, with compatible heart not currently available ● Irreversible biventricular dysfunction refractory to optimal medical therapy Absolute contraindications: ● Inability to take anticoagulation Relative contraindications: ● BSA <1.7 m^2 ● Distance of <10 cm between inner table of the sternum to the anterior vertebral body of the 10th thoracic vertebra ● Pregnancy	Indications: ● NYHA class III or IV heart failure refractory to optimal medical therapy, including intravenous inotropes ● Debilitating ischemia not amenable to revascularization ● Recurrent, symptomatic ventricular arrhythmias refractory to medical therapy, implantable cardioverter defibrillator therapy, and surgical treatment Absolute contraindications: ● Pulmonary hypertension (PVR >6 Woods units despite maximal therapy) ● Significant reversible hepatic dysfunction (e.g., bilirubin >3.0 mg/dL) ● Severe cerebrovascular disease ● Active substance users (including alcohol) ● Poor compliance with drug regimens Relative contraindications: ● Age >70 years ● Obesity >35 kg/m^2 ● Diabetes with end-organ damage (other than nonproliferative retinopathy) or persistent poor glycemic control (glycosylated hemoglocin [HbA1c] $>7.5\%$) ● Significant irreversible renal dysfunction (e.g., eGFR <30 mg/mL/1.73 m^2) ● Severe lung disease ● Active peptic ulcer disease ● Uncorrected abdominal aortic aneurysm greater than 4 to 6 cm ● Peripheral vascular disease not amenable to surgical or percutaneous therapy ● Active infection (except in the setting of severe device complication, which is a status 1A criterion) ● Systemic infection with immune suppression risk (ehuman immunodeficiency virus, hepatitis B virus, cytomegalovirus) ● Active malignancy ● Osteoporosis ● Tobacco use ● Patient with insufficient social support system

TAH indicates total artificial heart; *NYHA*, New York Heart Association; *BSA*, body surface area; *PVR*, pulmonary vascular resistance; *eGFR*, estimated glomerular filtration rate.

Evidence for Total Artificial Hearts

TAHs vs. Optimal Medical Therapy

The evidence supporting use of TAHs in patients with advanced heart failure was proven by a landmark study published in 2004 (Copeland et al., 2004). This nonrandomized, prospective trial followed 95 transplant-eligible patients at risk for imminent death due to irreversible biventricular cardiac function despite maximum medical therapy, who were implanted with a CardioWestTAH. 81 patients within this cohort met all study criteria and were compared to 35 control patients who met identical criteria but in whom a device was not implanted. The TAH was associated with significantly improved near- and long-term outcomes. At 30 days posttransplant, the percentage of patients deemed to have been treated successfully (defined as alive, in NYHA class I/II, not bedridden, off-ventilator, and not requiring dialysis) was 69% in the device group and 37% in the control group ($P=0.002$). The group with implanted TAHs also had greater survival to transplantation (79% vs. 46%, $P<0.001$) and 1-year survival (70% vs. 30%, $P<0.001$) (Fig. 3). The authors concluded the CardioWest TAH "prevents death in critically ill patients who have irreversible biventricular failure and are candidates for cardiac transplantation." Among this very sick cohort of patients, frequent adverse events with the TAH within 30-days postimplant included infection (77% of patients), bleeding (62%), hepatic dysfunction (37%), respiratory dysfunction (36%), and renal dysfunction (31%). Several recent case series have shown similar rates of treatment success and complications, and an increasing number of patients surviving beyond 1-year postimplant (Torregrossa et al., 2014a,b; Copeland et al., 2012; Kirklin et al., 2015).

TAHs vs. Ventricular Assist Devices

Ventricular assist devices (VADs) are the predominant form of implanted MCS. Beginning June 2006, the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) has compiled data on MCS device utilization in >15,000 patients from 158 participating hospitals and has regularly published reports on trends regarding relative use and outcomes. During this time period, LVADs without right ventricular support have represented 92% of implanted MCS devices, while TAHs have comprised 2% (Kirklin et al., 2015).

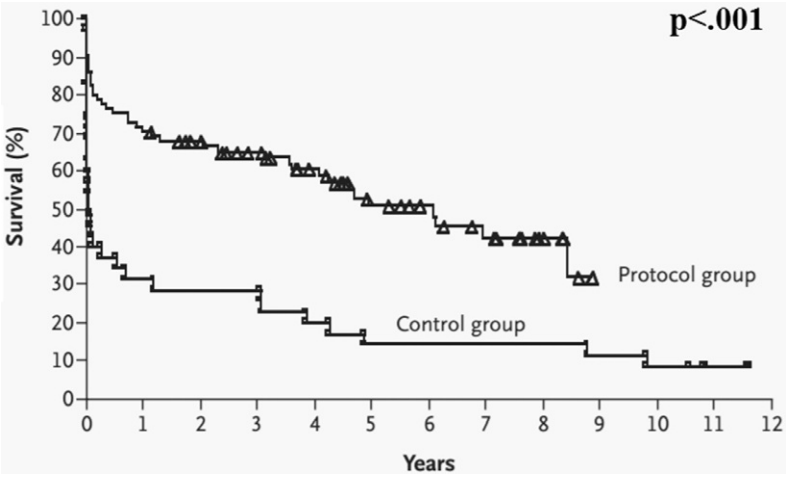

Fig. 3 Overall survival rate among patients implanted with a total artificial heart (protocol group) and patients with similar baseline status who did not receive an artificial heart. Data from Copeland, J. G., Smith, R. G., Arabia, F. A., et al. (2004). Cardiac replacement with a total artificial heart as a bridge to transplantation. *New England Journal of Medicine* **351**, 859–867.

The dominance of LVADs can be directly traced to a randomized trial published in 2001, which found improved 2-year survival with LVADs compared to medical therapy in heart-failure patients ineligible for transplantation (Rose et al., 2001). Since then, LVAD practice patterns have been continuously refined, with two additional randomized trials being particularly influential: a first finding continuous-flow devices to provide improved survival compared to pulsatile-flow device (Slaughter et al., 2009), and a second finding improved 6-month outcomes with magnetically levitated centrifugal-flow pumps versus axial-flow pumps (Mehra et al., 2017). These data have kept the LVADs front of mind for providers as a successful option for MCS, and the combination of this familiarity and LVAD approval as both bridge-to-transplant and destination therapy has helped maintain LVAD market dominance. Patients with borderline biventricular failure are often considered candidates for LVADs, based on the logic that improved left heart flow rates will improve right heart function. Additionally, INTERMACS data have consistently found patients implanted with LVADs have superior survival to patients implanted with biventricular support devices (Kirklin et al., 2015): while this is undoubtedly due in large part to patient selection of sicker patients receiving biventricular support, the association remains. No randomized data exist directly comparing these LVADs and TAHs.

For patients requiring unequivocal biventricular support, an alternative option to TAHs is the biventricular assist device (BiVAD), which augments the native ventricles and valves as opposed to replacing them. In the most recent INTERMACS report, BiVADs comprise approximately 5% of implanted MCS devices (Kirklin et al., 2015). Recent data have shown comparable or improved outcomes with TAHs as compared to BiVADs. A retrospective study of patients across 16 French centers who required biventricular support and were implanted with a paracorporeal BiVAD ($n=255$, 67%), TAH ($n=90$, 24%), or implanted BiVAD ($n=38$, 10%) between 2000 and 2010 found similar actuarial survival with each device but significantly decreased stroke rates with TAHs as well as a trend toward improved survival with TAHs among patients who required support greater than 90 days (Kirsch et al., 2012). In the most recent INTERMACS publication (Kirklin et al., 2015), patients with a TAH implanted between 2012 and 2014 had a 3-year survival rate of 60% which was superior to cohorts of patients implanted with BiVAD between 2008–11 and 2012–14 (Fig. 4). This trend toward improved outcomes with the TAH relative to BiVADs in the modern era bears watching, and the authors of the study note "early and midterm survival with a TAH is currently somewhat better than BiVAD support, but the patient groups may not be comparable." Patient survival for the cohort with TAHs implanted between 2012 and 2014 was constant after 1 year, representing durable life support with modern TAHs and device management. It is our opinion that the TAH is superior to the BiVAD due to its larger and more linear cannulas, thereby allowing flow rates and decreasing turbulent flow and associated thromboembolism.

Surgical Technique

Device Preparation

Arterial outflow conduits are prepared by first preclotting three times with the patient's own blood, approximately 30 cc for each graft each time, streteched, and then left to dry for 5 min before preclotting again. The exterior of the grafts are then coated with a mixture of cryoprecipitate, calcium, and topical thrombotic to serve as an adhesive. They are once again stretched and left to dry. This should be very early in the operation so as to allow time for preclotting. If patients have been heparinized, such as scenarios when there is a late decision to implant a TAH, the arterial conduits are preclotted with a combination of heparinized blood, protamine, and thrombin.

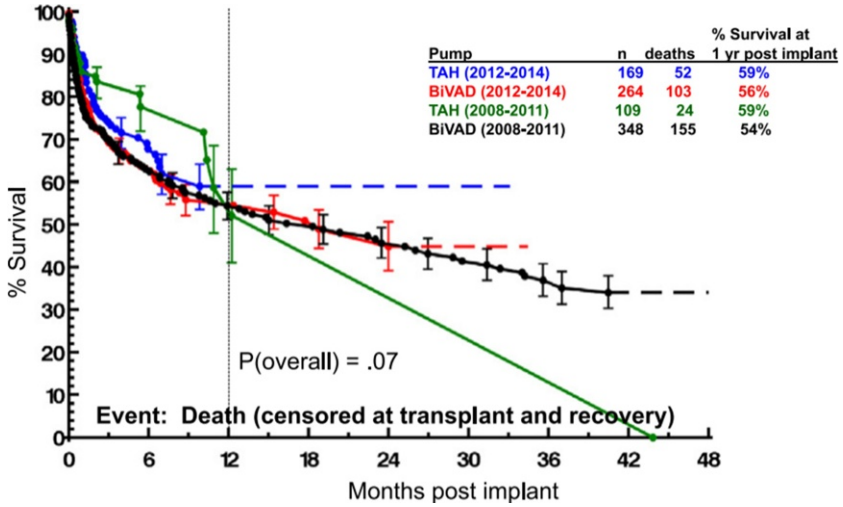

Fig. 4 Actuarial survival curves stratified by biventricular assist device (BiVAD) vs. total artifical heart and by Era. Data from Kirklin, J. K., Naftel, D. C., Pagani, F. D., et al. (2015). Seventh INTERMACS annual report: 15,000 patients and counting. *Journal of Heart and Lung Transplantation* **34**, 1495–1504.

The atrial cuff, or "quick connect," edges are trimmed in a circular fashion so that 5–7 mm of the cuff remains. These cuff edges will be sewed to the native atria and serve as connection points for the artificial ventricles.

Patient Preparation

The patient is positioned supine and general anesthesia is induced. Previous surgical scars are noted and marked. We then mark the skin at future exit sites for drive lines. The exit site of the left drive line is the left midclavicular line, 7–10 cm below the costal margin, and the exit site of the right drive line is 5 cm medial to the left's. Note that a distance of 5 cm is required to prevent the development of skin necrosis between the two sites. Central venous access is gained and a transesophageal echocardiogram probe inserted (TEE). A Swan-Ganz catheter is not required. Peripheral vessels should be exposed for planned or emergency cannulation, including for peripheral cardiopulmonary bypass institution.

Sternotomy and Access

The procedure is performed through a median sternotomy. Exposure of the heart and great vessels is similar to that of heart transplantation, with dissection of the aorta and pulmonary artery minimized in anticipation of planned future surgery. Heparin is administered. Aortic and bicaval cannulation are performed in a standard fashion, with both venous cannula through the right atrium to preserve the cava for subsequent transplant. Caval tapes may be utilized for both venous cannula, though we find this unnecessary with vacuum-assisted bypass. Cardiopulmonary bypass is instituted.

Cardiac Excision

The aorta is clamped. The heart may be arrested or fibrillated.

The excision differs from that of transplantation in that it preserves the two atria, the two annulus of the tricuspid and mitral valves, and 2 cm of ventricular muscle. The heart should be freed posteriorly down to the level of the pulmonary veins. We begin with an excision in the acute margin of the right ventricle with a #10 scalpel or other large blade, parallel and 1 cm anterior to the right atrioventricular groove. The incision is then extended with a scalpel or knife, anteriorly and clockwise along across the right ventricular outflow tract and proximal to the pulmonary valve while preserving as much pulmonary artery as possible. We again return to the acute margin of the right ventricle and extend the initial incision posteriorly and anticlockwise toward the interventricular septum. Pacing wires are transected if present.

Next we focus on the left ventricle, incising the inferior wall with care to preserve the mitral valve and annulus as well as 2 cm of left ventricular muscle. The incision is continued counterclockwise around the left ventricle through the lateral and then anterior walls. We transect the ascending aorta at the sinotubular junction. The aortic root is dissected from the roof of the left atrium. The aortic root and valve are excised while preserving the atrio-mitral curtain; aortic root tissue close to the curtain is preserved, as this tissue supports later anastomoses. The bilateral ventriculectomy is completed, and the excised ventricles are removed from the operative field.

Atrial Cuffs

Preparation for the anastomses of the atrial cuffs begins with trimming the remaining ventricular muscle such that a 1-cm cuff remains attached to the atrioventricular valves. Pacing leads are identified and divided at the entrance of the SVC, and intracardiac

portions are dissected from the endocardium; the extracardiac portions will be removed lateral after heparin reversal but before chest closure. Central venous catheters within the right atrium should be trimmed if they lie close to the tricuspid valve. The mitral and tricuspid valves are hallowed, removing leaflet tissue, chordae, and papillary muscles but preserving the annuli. We oversew the coronary sinus from within the atrium to prevent bleeding from the transected sinus and oversew the left atrial appendage in preference to external ligation to prevent adhesion formation which may complicate future transplant. The atrial septum should be inspected for defects and these should be closed if present.

The cuff of the left atrial quick connect device is sutured to the left atrial tissue using continuous 3-0 prolene suture. In the area of the aortic-mitral curtain, sutures will pass through the right fibrous trigone and aortic root. A second running 3-0 prolene suture is performed to complete a double suture line and ensure total hemostasis. The same process is repeated on the right. Care should be taken with the depth of the sutures into the left atrium, especially near the pulmonary veins, as the amount of scarring around these sutures will affect the availability of nonfibrosed tissue for future transplant anastomoses. We do not regularly test the anastomosis with pressurized saline injections. Felt strips may be utilized to support the atrial suture line, though we avoid this technique because it may result in excessive scarring and thus complicate future transplantation.

Arterial Conduits

The distal ends of the arterial outflow conduits and the transected ends of the great arteries are anastomosed. The conduits are trimmed to size, with the aortic conduit generally being 3–4 cm and the pulmonary conduit being 5–6 cm. Anastomoses are performed with 4-0 prolene sutures in a continuous end-to-end fashion, again layered twice.

Ventricle Implantation

We begin by suturing two large Gore-Tex sheets to the atrioventricular groove so that the implanted ventricles and atrial suture lines will not communicate with the posterior, inferior, and lateral pericardium. This will prevent adhesion formation and facilitate future device explantation prior to transplantation. The ventricle drivelines are then tunneled through the skin at the points marked previously, in a manner similar to chest tube placement: a skin incision is made with a scalpel, followed by enlargement with a clamp, passing of a 40 French chest tube through the pericardium into the clamp, and pulling of the chest tube through. Driveline tubing is passed through the tubes on the left, then the right.

The left ventricle is connected first (Fig. 5). Two Mayo clamps are used to grasp one end of the left atrial quick connect, gasping at two positions separated by 1/4th of the circumference of the cuff, and traction is provided to facilitate insertion of the ventricle

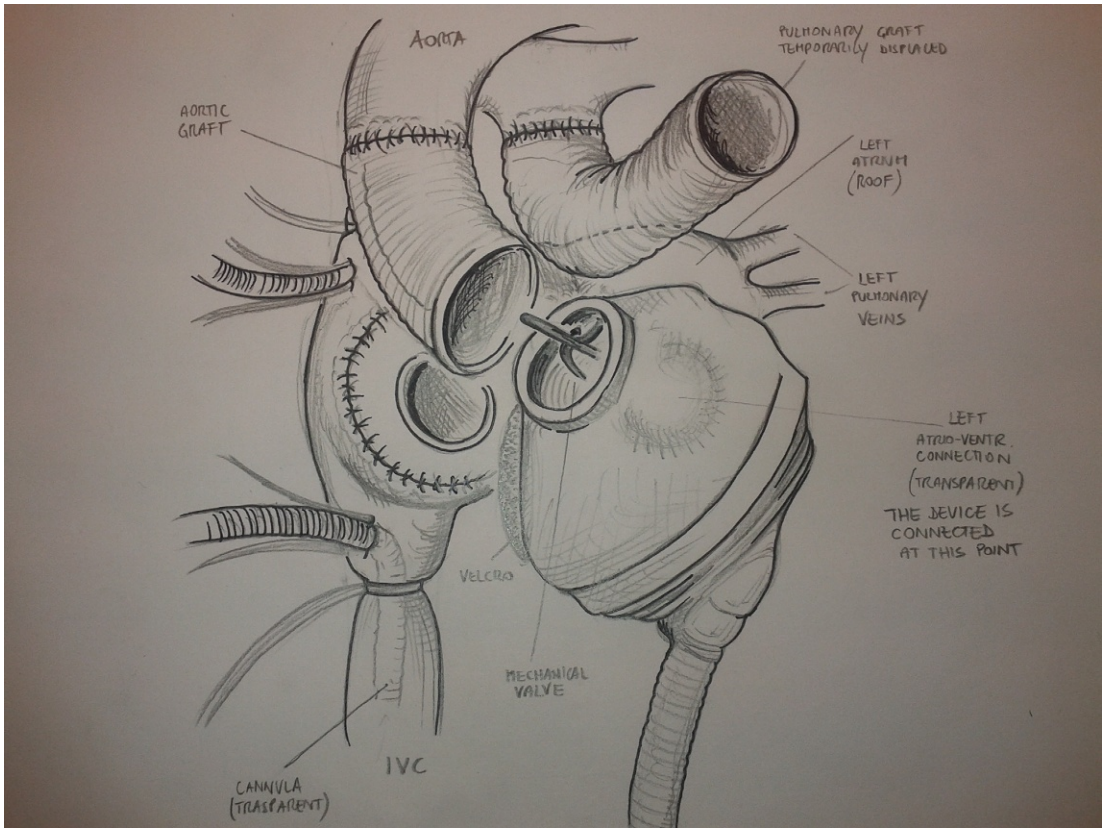

Fig. 5 Implantation of the total artificial heart. Courtesy of Z Fabio.

connect. The ventricle is rotated in place to properly align the outflow of the ventricle with the arterial conduit. The aortic cross-clamp is removed briefly under low flow to allow filling of the aortic conduit, and aortic quick connect is inserted into the ventricle in a manner which prevents kinking or tension on the arterial conduit. If kinking exists, the arterial quick connect should be disconnected via a spatula/flat instrument placement between the quick connect and the ventricular connection. Once the ventricular–arterial connection is sufficient, the patient is placed in steep Trendelenburg and the aortic graft is vented with a needle.

The right ventricle is connected in a similar fashion. The atrial connect is sutured first. The distal cava and right atrium should be deaired by briefly occluding the venous bypass cannula until blood flows out of the atrium. The right ventricle is rotated and the pulmonary conduit is connected, again ensuring satisfactory lie. The pulmonary conduit and aorta are deaired with a needle. The cross-clamp is removed. The patient is again placed in Trendelenburg and the lung ventilated. Pump flow rates are begun with low-flow initially, with deairing through the aortic vent. Further deairing may be performed with assistance of TEE and gentle manual compression of the heart, with this complete process taking 10–15 min. This time will allow the TAH pump, the heart to regain its normal rate, and the patient to be weaned from bypass.

Closure

Protamine is administered, and hemostasis is ensured by meticulous inspection of all anastomotic sites with the patient at physiologic pressures. Bypass cannula are removed in a normal fashion. The Gore-Tex membrane is wrapped around the anterior and lateral surfaces of both ventricles and the drivelines. A saline breast implant or tissue expander may be inserted inferior to the ventricles within the pericardium to maintain apical pericardial space, as contraction of the pericardial cavity is a rare but avoidable occurrence with artificial hearts which complicates future transplantation. The chest is closed in a standard fashion with particular care during sternal closure, as mediastinitis and sternal dehiscence are catastrophic events for TAH patients. For large patients, closure devices other than simple wires may be considered.

Challenging Implantation Scenarios

Small Patients

A patient BSA of less than 1.7 m^2, or a distance between the sternum and the anterior vertebral body of less than 10 cm, is traditionally considered relatives contraindication to the SynCardia TAH (**Table 1**). Small BSAs have been associated with worse outcomes post-TAH implantation, though some centers have reported successful implantation in many patients of BSA less than 1.7 m^2 with similar or superior outcomes to patients of large size (Leprince et al., 2005). A small chest size predisposes patients to a risk of compression of the IVC and left-sided pulmonary veins by the device.

In this settings we utilized several techniques, which in totality cause the ventricles to lie mostly to the left of the sternum and the left ventricle to lie in the left pleural cavity (as opposed to the usual placement where the right ventricle is immediately posterior to the sternum).

The diaphragmatic attachment of the pericardium must be mobilized and the left pleura is opened to allow the device to sit more leftward and posterior in the chest. A Gore-Tex membrane should be wrapped around the left ventricle to prevent lung adherence to the device. The device is then anchored by its ventricles to a rib on the left chest wall, which laterally displaces the TAH away from the IVC and left pulmonary veins. This anchoring is achieved with umbilical tape, heavy silk, or polyester suture, which is wrapped three times around the main body of the left artificial ventricle. The two ends of the tape or suture are then tunneled outside the chest through an intercostal space and tied around one of the ribs. Position of the ventricle is finetuned by echocardiographic and hemodynamic evaluation combined with observation of the TAH fill-volumes. Once the ideal position is identified, the suture or tape is tied. Further adjustments to device positioning may be required when the sternum is closed.

It is critical to confirm via echocardiogram that there is laminar flow into all left-sided veins and the IVC prior to chest closure, and additionally that ventricular filling is maintained after closure. If attempts to close the chest result in severe venous obstruction despite corrective maneuvers, the chest is left open and the patient returned to intensive care, and chest closure can be reattempted at a later date. Rarely, if chest closure cannot be accomplished, then musculocutaneous flap closure may be required.

Complex Congenital Heart Disease

Patients with complex congenital heart disease and end-stage cardiomyopathy are strong candidates for TAH implantation, as most intracardiac anomalies will be improved by excision of the native ventricles. For these patients, the TAH is implanted in a similar way to orthotopic heart transplantation, though there are some situations where congenital cardiac disease poses unique surgical challenges for TAH implantation: in the setting of single ventricular physiology or transposition of the great vessels.

In case of failed "Fontan" operations, the TAH has been implanted after constructing a "neo right atrium" (neo RA) in order to fit the right atrial quick connector (Rossano et al., 2014). The extracardiac conduit and IVC are both separated from the right pulmonary artery, which is reconstructed with a bovine pericardial patch or autologous tissue explanted from the failing heart. A 24 or 26 mm Gore-Tex graft is then inserted between the SVC and IVC to serve as the neo RA. The left atrial cuff is prepared in a standard fashion and any interatrial communication is addressed. The neo RA tubing graft is opened in a generous elliptic shape in order to accommodate the right atrial quick connector. The outflow grafts are then sutured in an end-to-end fashion on the aorta

and end-to-side fashion at the pulmonary artery bifurcation. The length of the pulmonary graft is generally longer than the usual six to seven cm and should be addressed before proceeding with the distal anastomosis.

The SynCardia TAH has also been used in cases of congenital corrected transposition of the great arteries (Adachi and Morales, 2014). In this situation, implantation is made difficult by the position of the great arteries (aorta and pulmonary artery): with the aorta anterior and leftward to the pulmonary artery, the right and left pumps must be implanted in a parallel rather than a normal crisscross arrangement.

Extracorporeal Membrane Oxygenation

Pulmonary edema is often present in cardiogenic shock patients requiring biventricular support, and patients may be on extracorporeal membrane oxygenation (ECMO) to maintain adequate oxygenation either at the time of TAH implantation or afterward.

Veno-arterial (VA) ECMO may be undertaken but will result in two parallel circuits. This causes reduced flow through the TAH, which may predispose patients to thrombosis of the mechanical valves. Therefore, VA ECMO it is not ideal if prolonged ECMO is anticipated.

Veno-venous (VV) ECMO is preferable, as it allows the ECMO and TAH circuits to run in series with maximal flows on both devices. For patients who require ECMO to wean from bypass, our preferred approach is to draw blood from the infrahepatic IVC and return it to the right atrium (Hosseinian et al., 2014). This is done by placing a femoral venous cannula and advancing it such that the tip lies in the intrahepatic portion of the inferior IVC. The ECMO outflow cannula is a separate venous cannula placed in the other femoral vein or a subclavian vein, which is advanced a few centimeters into the right atrium under sonographic guidance. Blood returning via the SVC is not oxygenated. If ECMO is anticipated preoperatively, then cannule are placed before instituting cardiopulmonary bypass, with final adjustment of outflow cannula position made under direct vision after excision of the native heart to ensure adequate distance of the cannula tip from the right-sided atrioventricular valve. This allows the explantation of VV ECMO at the bedside of the patient. Adequate distance between the tips of both cannulas should be ensured to avoid short-circuit phenomenon.

For patients who develop respiratory failure postimplant, a single dual-lumen catheter may be placed via the internal jugular vein. Care must be taken when introducing the cannula with the Seldinger technique, so as not to entrap the wire or the cannula into the mechanical right atrioventricular valve of the TAH.

Postoperative Management

Early Postoperative Management

Antibiotics are administered preoperatively as prophylaxis against infection and should be continued for 24 h after implantation. Lifelong anticoagulation is mandatory to prevent device thrombosis. This should be achieved with warfarin and the target international normalized ratio (INR) is 2.5–3.5 (Feldman et al., 2013). Patients are prescribed aspirin and potentially another oral anticoagulant, especially if thromboembolic events occur. Expected hemodynamic changes include increased diastolic pressure, increased diastolic flow, and decreased pulse pressure. Arterial lines are required for hemodynamic monitoring postoperatively and should be compared against console readings. Standard blood measurements must be gathered regularly to ensure sufficient end-organ perfusion and to identify metabolic changes.

Late Postoperative Management

Late management includes rehabilitation and education. The wheeled console may be cumbersome and prevents hospital discharge but is intended to allow ambulation; a newer portable device console is available and permits discharge. Note that complications are common in the postoperative period including bleeding, infections, and thrombosis: judicious monitoring is required.

Complications

The most frequent complications following TAH implantation are bleeding and infection. Bleeding may be secondary to surgery or diffuse coagulopathy. This can contribute to infection and transfusion-related complications. Diffuse coagulopathy may result from changes such as dilutional thrombocytopenia and exposure to antithrombicand antiplatelet agents, and patients may be treated with platelets, fresh frozen plasma, or cryoprecipitate. Significant refractory bleeding may require a return to the operating room.

Device-specific infections may occur within the implanted device, at the sternal wound or the drivelines. Antibiotic prophylaxis preoperatively is required. Should infections arise, judicious treatment with antibiotics should be undertaken, and may be followed with surgical drainage, vacuum-assisted wound closure, and device exchange. Endocarditis may only be definitively treated by device removal. Infection is generally not a contraindication to heart transplant. In the landmark study of 95 patients implanted with TAHs, the most common infections immediately posttransplantation were respiratory and genitourinary (Copeland et al., 2004). Note that in long-term follow-up, mortality and bleeding events were increased among patients with BSA $<1.8\ m^2$ (Torregrossa et al., 2014a,b).

Additional complications with the device are rare but may have significant consequences. The most significant device malfunctions reported was a perforation of one of the four layers of the device diaphragm, which occurred once in 12,000 patient-days of device support of the landmark study (Copeland et al., 2004), and three times in a study of TAH patients who survived beyond 1 year (Torregrossa et al., 2014a,b); this was the cause of three deaths. Issues with device fit is more common and may be corrected with simple repositioning or surgical treatment, though the risk of improper device fit is low if the device is meticulously implanted. Hypotension or hypertension should be managed carefully with the console, inotropic agents, vasopressors, and vasodilators. End-organ perfusion must be maintained to minimize the risk of secondary complications such as renal dysfunction, hepatic dysfunction, respiratory dysfunction, and neurologic events. Proper anticoagulation is additionally required to reduce the risk of thromboembolic events.

Long-Term Outcomes

Several case series have reported the rates of successful bridge-to-transplantation to be approximately 75%, and 1 year-survival on the device to be approximately 65% (Copeland et al., 2004, 2012; Kirklin et al., 2015). In a study of 47 patients supported by the SynCardia TAH beyond 1 year, 72% of patients were successfully bridged to transplantation (Torregrossa et al., 2014a,b).

1-year and 5-year postimplant survival rates of patients who successfully bridged to transplant with the TAH are70%–80% and 60%–65%, respectively (Copeland et al., 2004). At the time of writing, the longest patient survival on SynCardia TAH was in a Turkist man who was actively being supported beyond 4.6 years (SynCardia, www.syncardia.com).

The Future of Total Artificial Hearts

The TAH has several distinct and achievable frontiers for improvement. Among these are approval as destination therapy, continuous flow systems, methods of powering the device which do not break skin and therefore decrease associated infections, components which reduce the rate of thrombosis, hemolysis, and inflammation, and the ability to support small patients.

The SynCardia TAH is currently enrolling patients to investigate it suitability as a destination therapy. The company is also developing a 50 mL device, intended to better support small patients than the current 70 mL device.

The AbioCor TAH (Abiomed, Danvers, MA) was approved by the FDA for humanitarian device exemption (HDE) status in 2006 but is no longer being utilized or developed by the company due to unproven efficacy. However, several of its features may be utilized in future artificial hearts. This device was fully implantable and utilized a battery system which transferred energy across the skin, thereby obviating the need for skin incisions. It also weighed 1 kg and thus allowed impressive patient mobility.

Devices Under Development

The continuous flow total artificial heart (CFTAH) is being developed by Cleveland Clinic and features a continuous flow pump (Fukamachi et al., 2010). It measures six cm by 10 cm, is comprised of biocompatible titanium and plastic, and is without mechanical valves, flexing membranes, sensors, or actuators (**Fig. 6**). Conceptualized differently, this pump is a combined right and LVAD connected to a single axial rotor. This system senses inlet systemic and pulmonic pressures and self-modulates speed of rotor to generate separate and appropriate pressures within the left and right heart (Shiose et al., 2010). This device has proven viability in calves, with durability and extended battery life being two remaining issues.

The Carmat TAH (CARMAT, Velizy-Villacoublay, France) features a unique design which is part prosthesis and part bovine (Mohasci and Leprince, 2014). It consists of two chambers, each with a flexible biomembrane-separating hydraulic fluid from blood (**Fig. 7**). Force is created through the hydraulic fluid to display the blood. The aspect of the membrane interfacing with the blood is comprised of bovine pericardium to improve biocompability: while it has been shown to reduce platelet adhesion and blood cell deposition on the membrane, it raises concerns of low mechanical durability. The device also self-modulates cardiac output by measuring the patient's level of physical activity and responding accordingly. Clinical trials of the device began in Europe in December 2013, with the first patient living 75 days. Development of this device is being lead by Dr. Alain Carpentier.

Finally, the BiVACOR TAH (BiVACOR, Inc., Houston, Tx, USA) is a device which utilizes third-generation magnetic suspension technology (Timms et al., 2008) (**Fig. 8**). Two centrifugal impellers are mounted to a single rotating hub, with flow balancing achieved with rotor movement along the shared axis (Greatrex et al., 2010). The expected benefit is that this design reduces device thrombus formation, with this benefit seen in clinical trials of the magnetically levitated HeartMate III LVAD versus the HeartMate II (Mehra et al., 2017).

Areas of Future Growth

Between 2012 and 2014, destination therapy was the device strategy in 44% of patients implanted with a continuous flow LVAD or BiVAD (Kirklin et al., 2015). However, the SynCardia TAH is only approved as a bridge-to-transplantation. An ongoing trial is

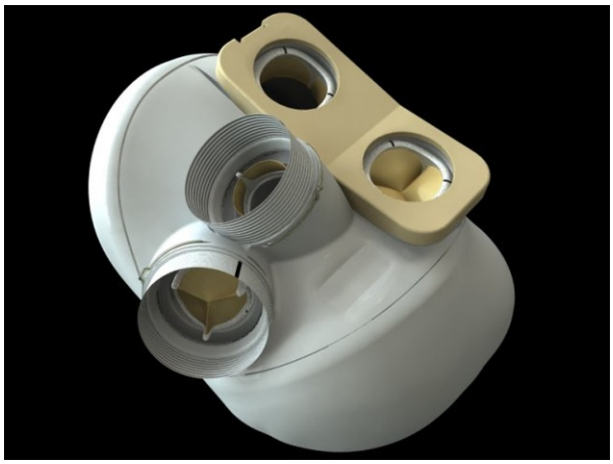

Fig. 7 Carmat total artifical heart. Reproduced with permission from CARMAT.

currently enrolling patients to investigate TAH outcomes for patients requiring MCS for destination therapy, an important area of potential growth for this technology.

Truly increasing the utilization of TAHs will likely require more comparative data showing increased benefit for TAHs against the BiVAD and potentially the LVAD. This is not unreasonable given that in the INTERMACS registry, the cause of mortality for continuous flow VAD patients was due to causes potentially avoided with TAHs: multisystem organ failure (19.5% of deaths), right ventricular failure (5.5%), device malfunctions (4.6%), and congestive heart failure (4.1%) (Kirklin et al., 2015).

Conclusions

The TAH provides durable MCS as a bridge-to-transplantation for patients at an imminent risk of death secondary to biventricular failure. The predominant device is the SynCardia TAH, which has been approved and utilized for more than a decade. Indications and surgical techniques are well established, with the result being consistent outcomes and high rates of successful transplant.

Fig. 8 BiVACOR total artifical heart. Reproduced with permission from BiVACOR, Inc.

Utilization is limited by its indication as a bridge-to-transplantation, the invasiveness and complexity of devices, and the prevalence of VADs. However, future utilization may increase as the population ages, the technology advances, its indications broaden, and data convince the medical community of its benefit.

Transcriptomics:An Overview

The remarkable progress achieved in the "omics" field has successfully improved the understanding of cardiovascular disease (CVD) pathophysiology by comprehensively interrogating disease states at the molecular level (Ozsolak and Milos, 2011). Transcriptomics, the simultaneous study of ribonucleic acid (RNA) transcripts and their expression patterns at a genome-wide level, is a particularly promising tool. The transcriptome is the sum of RNA transcripts that comprehend messenger RNAs, ribosomal and transfer RNA, and regulatory noncoding RNAs (Ozsolak and Milos, 2011).

Transcriptomic approaches include microarray-based methods where tens of thousands of transcripts are simultaneously analyzed by chemically labeling RNA molecules and subsequent hybridization to probes on the microarray. With the novel RNA sequencing technologies, a population of RNA is converted to a cDNA library which is subsequently sequenced in a high-throughput base-by-base manner to obtain short sequences, providing a much better and deeper coverage for detection of low abundance transcripts.

This chapter describes the methodological underpinnings in the transcriptomics field and provides an overview about recent advances of transcriptomics in the cardiovascular field.

RNA, Gene Expression, and Transcriptomics

RNA has long been considered as the messenger molecule between genes and proteins, where RNA is transcribed from DNA to messenger RNA (mRNA) and subsequently translated into protein (Siemelink and Zeller, 2014).

 https://doi.org/10.1016/B978-0-12-809657-4.99572-3

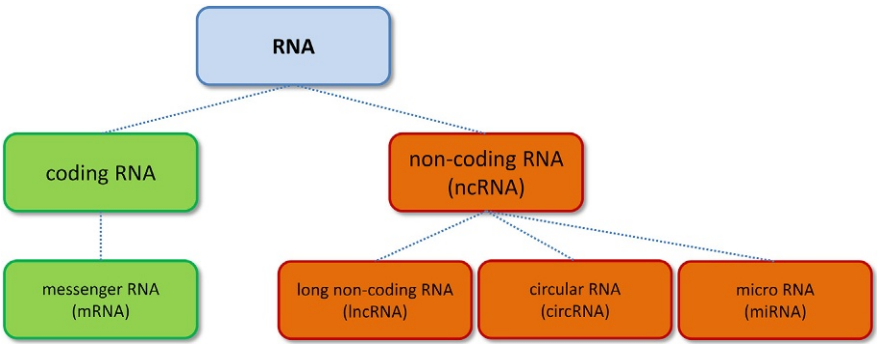

Fig. 1 Overview of RNA molecules. Ribonucleic acids can be categorized into protein-coding and noncoding RNAs; mRNAs are translated into proteins, while several noncoding RNAs, including lncRNAs, circRNAs, and miRNA, are not translated into proteins (Devaux, 2016).

In recent years, noncoding RNA species have been characterized including micro-RNAs (miRNAs), long noncoding RNAs (lncRNAs) and circular RNA (**Fig. 1**). miRNAs are endogenous, noncoding small RNAs of about 22 nucleotides regulating gene expression at a posttranscriptional level (Fichtlscherer et al., 2011). miRNAs are the best investigated ncRNAs so far. Since their discovery in 1993 (Lee et al., 1993) approximately 1800 miRNAs have been annotated (www.mirbase.org). miRNAs are produced by all cell types and interact mainly with the 3′ untranslated region (of protein-coding genes thereby inhibiting the translational process). They are involved in a broad range of biological processes and their dysregulation impacts disease development (Small and Olson, 2011).

lncRNAs cover RNA molecules over 200 nucleotides and are observed in a wide range of tissues. lncRNAs are transcribed from either intergenic regions, from introns of protein-coding sequences or from antisense strand of genes (Boon et al., 2016). In contrast to miRNA sequences, the primary sequence of lncRNAs is only poorly conserved. The number of lncRNAs within cells is believed to be around 9000 (Pennisi, 2012). They exert a broad repertoire of functions and have been linked to differentiation and developmental processes and disease (Mercer et al., 2009; Ponting et al., 2009).

Circular RNAs have been known for some time, however, only recently this class of ncRNAs gained interest. Due to their circular state these RNA molecules are highly stable, and show an evolutionary conservation. circRNAs can be reproducibly detected at high levels in peripheral blood and other body fluids.

The number of RNA transcripts represents the amount at which the corresponding gene is expressed ("gene expression") and reflects the cell function and gene regulation. Measuring and analyzing gene expression can give an insight into regulation and effects of the corresponding gene, while a transcriptomics analysis investigates all RNA transcripts of the cell simultaneously.

Technology for RNA Transcript Detection

Recent advances in technology enabled the detection and measurements of RNA transcripts, by using microarrays or sequencing as high-throughput techniques, or polymerase chain reactions as low-throughput technology. qPCR is mainly used for verification of results obtained by microarrays and/or sequencing technologies. In general, such experiments involve the following steps: (1) RNA sample collection, (2) sample purification, (3) sample processing, (4) detection of transcripts, (5) data analysis and visualization, and (6) validation. These steps are complemented by additional technology-specific processes as detailed below.

Microarray technology

Transcriptomics analyses often rely on microarray technology, assessing thousands of transcripts (mRNA, miRNA, ncRNA) on a genome-wide scale in parallel. It allows to rapidly screen the entire transcriptome by chemically labeling and hybridizing RNA molecules to probes on the microarray. The main advantages of the microarray technology include low costs, high-throughput applicability, large coverage, and straightforward data analysis, while it is limited by the large amount of RNA required, limited dynamic range for quantification, the semiquantitative approach and the detection of predefined transcripts (Siemelink and Zeller, 2014). Generally, the main steps involved in a microarray experiment are (1) RNA sample collection, (2) sample purification, (3) reverse transcription (cDNA synthesis), (4) sample labeling, (5) hybridization and washing, (6) scanning of the probe array, and (7) visualization and data analysis (**Table 1**, **Fig. 2**).

Most microarrays are manufactured as spotted microarrays, self-assembled arrays, or in situ synthesized arrays (Bumgarner, 2013). In spotted microarrays oligonucleotides are synthesized and deposited onto a glass slide, while in situ synthesized arrays can be produced by inkjet oligo synthesis methods or photolithography methods (e.g., Affymetrix GeneChip, Agilent), and self-assembled arrays are manufactured using the BeadArray technology (e.g., Illumina Bead Chip). The Affymetrix GeneChip arrays rely on standardized assays and reagents, and instrumentation is provided within the platform. The GeneChip probe arrays are oligonucleotide microarrays being produced in a highly standardized manner using photolithography applying predefined masks and producing 25-mer probes of known sequence. Performing a GeneChip experiment includes different steps: (1) obtaining RNA samples, (2) target amplification and sample labeling, (3) injection of the labeled sample into the probe and hybridizing, (4) probe

Table 1 Microarrays as a high-throughput transcriptomics technology. Using microarray technology involves different analytical and computational steps which are specific for this technology, including wet lab procedures (sample labeling, hybridization and washing, and probe scanning) and dry lab procedures (data preprocessing and data analysis)

Microarrays	
Wet lab	• User-specific dyes can be chosen • Platform-specific protocol exists • Straightforward visualization of the experiment • Technical batch effects can occur • External hardware and software required, which may be platform-specific
Dry lab	• Identification and removal of batch effects • Various approaches available, no gold standard • Analysis can be complex

Here, several exemplary technology-specific steps are categorized into wet lab and dry lab procedures, along with their advantages and challenges.

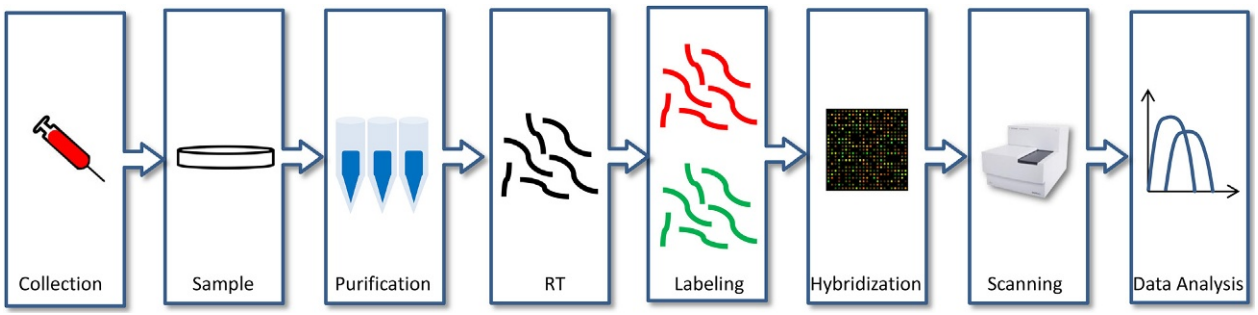

Fig. 2 Overview of the main steps involved in a microarray experiment. Generally, the following steps are involved: Sample collection, RNA sample collection, sample purification, reverse transcription (RT), sample labeling, hybridization and washing, scanning of the probe array, and visualization and data analysis.

array washing and staining, and (5) scanning of the probe array in the Affymetrix GeneChip scanner (Dalma-Weiszhausz et al., 2006). In contrast, the Bead Chips from Illumina use the BeadArray technology, with gene-specific probes attached to beads and assembled into arrays. Basically, it is based on a high-density silica bead-based microarray technology, covering each bead with hundreds of thousands of copies of a specific oligonucleotide acting as the capture sequences in a given Illumina assay.

Next-generation RNA-sequencing

Along with evolving deep-sequencing technology, next-generation RNA-sequencing (RNA-Seq) has become a novel and powerful method for quantifying RNA transcripts at a high-throughput, high-resolution, and high-quality genome-wide transcriptome scan (Wang et al., 2009). A typical RNA-Seq uses deep-sequencing technologies involving the following steps: (1) RNA fragmentation to convert long RNAs into a library of cDNA fragments, (2) addition of sequencing adaptors to each cDNA fragment, (3) high-throughput sequencing of short cDNA fragments, (4) alignment of sequence reads with reference transcriptome, and (5) generation of a base-resolution expression profile for each gene (Wang et al., 2009) (**Table 2**).

In an RNA-Seq experiment, first, RNAs are converted into a library of cDNA fragments through RNA fragmentation or DNA fragmentation. Subsequently, sequencing adaptors are added to each cDNA fragment and a short sequence is obtained from each cDNA using high-throughput sequencing technology (NGS). The resulting sequence reads are aligned with the reference genome or transcriptome, and classified as exonic reads, junction reads or poly(A) end-reads, which are subsequently used to generate a base-resolution expression profile for each gene (Wang et al., 2009).

RNA-Seq clearly outperforms microarray technology in terms of throughput, resolution, and dynamic range, while it includes splice variants, unknown RNAs, and RNAs too short to be captured by microarrays. However, RNA-Seq is more expensive than microarray technology, as it requires large data storage, computation resources, and advanced bioinformatics resources for subsequent data analysis (Wang et al., 2009; Siemelink and Zeller, 2014; Wu et al., 2014) (**Table 3**).

Real-time quantitative polymerase chain reaction

Many applications require verification of individual transcripts as obtained from microarrays or RNA-Seq experiments. Real-time quantitative polymerase chain reaction (RT qPCR) is a well-established, but low-throughput technology for monitoring the amplification of a single cDNA molecule serving as an independent validation of preperformed experiments. The quantification is performed in comparison to a housekeeper gene (relative) or to the standard curve (absolute). PCR is a low-throughput technology for measuring the expression of individual or a small amount of transcripts, and, thus, is often applied for validation or verification.

Table 2 RNA-Seq as a high-throughput transcriptomics technology. Using RNA-Seq technology involves different analytical and computational steps which are specific for this technology, including wet lab procedures (sequencing, mapping, annotation, and assembly) and dry lab procedures (data analysis)

RNA-Seq	
Wet lab	• High-throughput • High resolution • High dynamic range • RNA library construction can be biased • Expensive • Large data storage required • Polymorphisms, which occur when sequence reads align to multiple locations of the genome
Dry lab	• Advanced and complex bioinformatics approaches required • Bioinformatics tools available, but various approaches available, no gold standard • Computational expensive • Can be difficult to reconstruct and tease apart all splicing isoforms

Here, several exemplary technology-specific steps are summarized, along with their advantages and challenges.

Table 3 Comparison of transcriptomics technologies (microarrays, RNA-Seq, qPCR)

	Microarray technology	*RNA-Seq technology*	*qPCR*
Throughput	High	High	Low
Resolution	Medium	High	Low
Dynamic range	Medium	High	Low
Expenses/costs	Medium	High	Low
Coverage	High	High	Low
Data storage	Medium	High	Low
Data analysis	Easy	Complex	Easy
Batch effects	Possible	Possible	Possible as plate effects
Aim of analysis	Discovery	Discovery	Mainly validation/verification

The three technologies mainly differ on the level of experiment costs and time, amount of transcripts that can be analyzed, coverage, resolution, data storage, and data analysis.

Table 4 qPCR as a low-throughput transcriptomics technology for target verification. Using qPRC technology involves different analytical and computational steps which are specific for this technology, including wet lab procedures (primer design and PCR reaction) and dry lab procedures (data analysis)

qPCR	
Wet lab	• Low-throughput • Transcript-specific • Time-consuming for a large number of transcripts • Transcript for normalization required
Dry lab	• For validation or verification rather than for transcriptomics analysis • Easy to interpret and analyze • Software available • No gold standard

Here, several exemplary technology-specific steps are summarized, along with their advantages and challenges.

A single RT qPCR reaction is characterized by the PCR cycle at which fluorescence first rises above threshold background levels (threshold cycle, Ct), and consequently, results in a low Ct value if the RNA levels are large (Jozefczuk and Adjaye, 2011). A general workflow of RTqPCR involves multiple steps: (1) RNA isolation, (2) primer design, (3) reverse transcription to obtain cDNA from RNA, (4) cDNA amplification, (5) PCR reaction, and (6) data analysis (Thermofisher) (**Table 4**). As a result, the nucleic acids are quantified either relatively (fold-difference in expression using a reference transcript) or absolutely (exact number of DNA molecules). Due to its low throughput, RT qPCR is nowadays mainly used for validation of individual RNA transcripts.

Detection and measuring of noncoding RNA

Recent advances allow the detection and measurement of noncoding RNA along with coding RNA transcripts. Using microarray technology, different platforms exist that cover the whole-transcriptome (e.g., Affymetrix GeneChip Human Gene ST Array, Affymetrix Gene Chip miRNA Array, Agilent SurePrint Human Gene Expression Microarray, Illumina BeadArray), detecting both

coding and noncoding transcripts. However, due to the large amount of unknown ncRNAs, the annotation of the corresponding probes is still challenging (Zhang et al., 2015a). Using sequencing technology to measure ncRNAs allows detecting the exact transcript on a single nucleotide resolution (Zhou et al., 2011), independent on the availability of a priori transcript information or genome sequence (Veneziano et al., 2015). However, for annotating transcript sequences, reference transcriptomes are needed. Again, unknown ncRNA cannot be annotated without corresponding a priori information.

Computational Methods for Transcriptome Analyses

High-throughput technology (microarray and RNA-Seq experiments) detects and measures the whole transcriptome. Subsequently, technology-specific approaches are applied for quantifying expression levels, including preprocessing and normalization in microarray experiments, while RNA-Seq experiments involve sequencing, mapping, and assembly (**Tables 1** and **2**). Subsequently, based on such processed data, gene expression levels can be directly quantified, or, in more complex analyses, combined with other data types to handle more advanced scientific questions [e.g., TWAS (gene expression and phenotype data), eQTL (gene expression and genomic data)]. Alternatively, large gene expression data sets can be combined and meta-analyzed, or, in a follow-up study, analyzed in a longitudinal expression analysis (**Table 5**).

Preprocessing and normalization of data from microarray experiments

Transcriptome data derived from microarray experiments can suffer from technical variation, that is, batch effects. A recent study analyzing Illumina gene expression microarray data identified technical factors to substantially influence signal intensity values, including the chip assignment, RNA amplification batch, RNA isolation batch, and the sample storage time, and the authors concluded that adjusting for such batch effects had improved the reliability of subsequent data analyses (Schurmann et al., 2012).

Often, microarray experiments are performed to compare expression levels between different conditions (e.g., disease vs. healthy, different medication, different time points) on a transcript level. However, before such analysis can be done, the microarray data must be adjusted for technical effects, and several data transformations are needed to identify and exclude invalid measurements, to adjust chip intensities, and to select transcripts that are significantly differentially expressed between two conditions. Such transformations include data normalization which adjusts the individual hybridization intensities (e.g., unequal quantities of input RNA, differences in labeling, systematic biases in measured expression levels) to balance them appropriately so that meaningful biological comparisons can be made (Quackenbush, 2002). Multiple computational methods for gene expression data normalization have been proposed, among which loess normalization (Bolstad et al., 2003), RMA (Irizarry et al., 2003), MAS (Affymetrix), GCRMA (Wu and Irizarry, 2005), and dChip (Li and Wong, 2001) are well-established methods. Loess normalization is a locally weighted regression approach, which models the intensity-dependent trends by a regression curve. RMA (robust multiarray average) uses a convolution background correction, quantile normalization, and summarization using median polish, while GCRMA is a similar approach which computes the background in a different manner. In contrast to RMA, MAS5 normalizes each array independently and sequentially, while RMA uses a multichip model. Additionally, MAS5 uses data from mismatch probes to calculate a robust average, while RMA does not use mismatch probes. Different benchmark studies on the Golden Spike data has intensively analyzed and benchmarked these methods for normalizing Affymetrix gene expression data (Choe et al., 2005; Pearson, 2008).

Sequencing, mapping, and assembly of data from RNA-Seq experiments

RNA-Seq uses deep-sequencing technology, such as Illumina IG (18516045, 18451266), Applied Biosystems SOLiD (Cloonan et al., 2008) or Roche 454 Life Science (Emrich et al., 2007, Barbazuk et al., 2007), revealing short reads that have to be mapped to a reference genome (e.g., SOAP (Li et al., 2008b), MAQ (Li et al., 2008a), and RMAP (Smith et al., 2008)). For low-copy repetitive sequences, multimatch short reads can be proportionally assigned based on the number of reads mapped to their neighboring unique sequences (Mortazavi et al., 2008), while for longer sequence reads paired-end sequencing strategy can be applied that determine short sequences from both ends of DNA fragment (Campbell et al., 2008). For a detailed overview refer to Wang et al. (2009). Alternatively, reads can be assembled into contigs, followed by an alignment into the final genomic sequence. Multiple de novo RNA-Seq assemblies have been developed, for example, DETONATE (RSEM-EVAL and REF-EVAL) (Li et al., 2014), Trans-ABySS (Robertson et al., 2010), or Trinity (Grabherr et al., 2011).

Table 5 Computational methods for transcriptome analyses

Computational method	*Description*
Transcriptome-wide association study (TWAS)	Investigates the association between gene expression and trait or phenotype
Expression quantitative trait loci (eQTL)	Represents genomic loci that contribute to variation in gene expression levels
Meta-analysis	Statistical study that systematically assesses and combines multiple studies quantitatively by statistically pooling estimates from individual studies into one meta-analytical estimate
Longitudinal expression analysis	Measures and analyzes gene expression at different time points

Quantification of expression levels

To quantify the differences in gene expression levels, an expression ratio can be computed. This ratio can be either a simple ratio (e.g., disease/healthy), or a log-transformed ratio [e.g., log (disease/healthy)]. The advantage of the simple ratio is their intuitive understanding, although they treat up- and down-regulated transcripts differently (e.g., upregulation by a factor of 2: $2/1=2$; downregulation by a factor of 2: $1/2=0.5$). This limitation can be solved by log transforming the data (e.g., upregulation by a factor of 2: $\log_2(2/1)=1$; downregulation by a factor of 2: $\log_2(1/2)=-1$), providing an intuitive understanding of up- and down-regulation of transcripts.

To assess a transcript's statistical significance level, *P*-values are computed, corrected for multiple testing (e.g., Bonferroni, Benjamini-Hochberg) if more than one transcript is assessed. P-values can be computed by comparing their differential expression level to a random distribution (Nitsch et al., 2009), by computing a simple *t*-test or a regularized *t*-test [e.g., Cyber-T (Baldi and Long, 2001)]. Alternatively, a standard score (*z*-score) can be computed which is the signed number of standard deviations a transcript is above the mean; here, a positive *z*-score indicates an upregulation, while a negative *z*-score indicates a downregulation of a transcript. Often, a *z*-score threshold of -1.96 and $+1.96$ is used to assess a statistical significance of a transcript, corresponding to a *P*-value of 0.05 and a 95% confidence interval.

Transcriptome-wide association studies

In relation to a genome-wide association study (GWAS), assessing the association between genetic variation and trait or phenotype, a transcriptome-wide association study (TWAS) investigates the association between gene expression and trait or phenotype. A recent TWAS leveraged imputed gene expression to identify significant expression-trait associations. For imputing gene expression, an integrative approach was suggested that combines gene expression measurements with summary association statistics from large-scale GWAS to identify genes whose cis-regulated expression is associated with complex traits. For examples, this approach was applied to gene expression data from blood and adipose tissue measured in ~3000 individuals, revealing 69 new genes significantly associated with obesity-related traits (BMI, lipids, and height) (Gusev et al., 2016).

Expression quantitative trait loci

Genomic loci that contribute to variation in gene expression levels are represented by expression quantitative trait loci (eQTLs). Studies could show that cis-eQTLs, that is, those that map to the nearby location of their corresponding gene, outnumber trans eQTLs, that is, those that map far from the location of their corresponding gene (Dixon et al., 2007; Goring et al., 2007). While *cis*-eQTLs directly influence gene expression, trans-eQTLs are not directly involved in regulating gene expression.

eQTLs are identified by studying a population of genetically different individuals. To detect those variants [single nucleotide polymorphisms (SNPs)] that influence gene expression, the genotype and transcriptome for each individual has to be collected and quantified. Next, eQTLs are identified by comparing the genotypes with the expression levels using association or linkage analysis. Subsequently, statistical analyses determine whether a given variant has an effect on the expression of a given gene: those genes that have significantly higher expression levels for one allele than for the other alleles influence the expression of the corresponding gene (Albert and Kruglyak, 2015).

A recent study performed a genome-wide eQTL analysis in a European population, revealing three regions of the genome reproducibly associated with specific patterns of gene expression. Two of these regions overlap genetic variants previously known to be involved in the susceptibility to type 1 diabetes, celiac disease, and hypertension. Genes whose expression is modulated by these genetic variants may act as mediators in the causal relationship linking the variability of the genome to complex disease. These findings illustrate how integration of genetic and transcriptomic data at an epidemiological scale can help decipher the genetic basis of complex diseases (Rotival et al., 2011).

Meta-analysis for combining multiple gene expression data sets

Sometimes there is a need to systematically review or assess multiple gene expression studies, whether it is to increase statistical power or to generalize conclusions based on studies from different origin. A meta-analysis is a statistical study that systematically assesses and combines multiple studies quantitatively by statistically pooling estimates from individual studies into one meta-analytical estimate, while its outcome can include a more precise estimate of the effect under study that the individual studies would reveal (Haidich, 2010). As a precondition of a meta-analysis and to ensure a harmonization of the heterogeneity of the data and phenotypes, the individual gene expression data sets to be pooled should be harmonized in terms of gene identifiers, gene expression values (e.g., fold change, log fold change, odds ratio, risk ratio), and—if applicable—applying consistent preprocessing and normalization, or mapping and assembling methods. Recently, a tool called ARepA has been developed for standardized acquisition and analysis of high-throughput and heterogeneous biological data, facilitating the retrieval and standardization of microarray gene expression data from different sources (Börnigen et al., 2015). The Expression Atlas represents a valuable integrated database of gene and protein expressions in different organisms, providing information on gene expression patterns under different biological conditions (e.g., knock-out), and including microarray and RNA-Seq data. In a large meta-analysis, all underlying expression data sets of the Expression Atlas were reanalyzed to assure consistency and, subsequently, to detect promising expression patterns under the condition of the underlying experimental setup (Kapushesky et al., 2012).

After harmonizing the individual gene expression data sets, the effect sizes of the individual studies are pooled into a weighted meta-analytical effect size. Here, the concept of weighting reflects the value of the evidence of the individual study (Haidich, 2010). There are different statistical models to pool the effects of the studies, the most prominent being an unsupervised data integration

model (Börnigen et al., 2015), supervised data integration model [e.g., Bayesian model (Huttenhower et al., 2009; Börnigen et al., 2016)], fixed-effects model (Schmidt et al., 2009), or random-effects model (Schmidt et al., 2009; Börnigen et al., 2015). An unsupervised data integration model can be applied for homogeneous data sets without training data, while a supervised model (e.g., Bayesian model) requires prior knowledge for training. Additionally, a random-effects model allows heterogeneity of the individual study results, while a fixed-effects model requires homogeneity across all individual studies (Haidich, 2010).

A recent meta-analysis incorporated three population-based cohorts from different tissues to identify novel associations between cardiovascular risk factors and the transcriptome (Schurmann et al., 2012). Detailed statistical analyses revealed technical factors substantially influencing signal intensity values, especially the Illumina chip assignment, the RNA amplification batch, the RNA isolation batch, the sample storage time, and RNA integrity number (RIN), while biological factors effecting signal intensity values included the tissue, gender, and age. To overcome these technical and biological effects, a harmonized workflow was established to ensure consistent and harmonized sample processing in each cohort, including sample storage, RNA isolation, RNA amplification, hybridization, scanning, and data preprocessing. Additionally, appropriate covariate adjustment, that is, for technical covariates was implemented to reduce the unexplained variance.

Longitudinal expression analysis

Measuring and analyzing gene expression at different time points (longitudinal gene expression) is a well-established approach to study the effects of drug treatment or disease progression on gene expression. As longitudinal expression analyses require a direct comparison or integration of measurements from different time points, similar challenges apply to what was observed during meta-analyses (see above). A recent study investigated such batch effects occurring in longitudinal gene expression, in particular the time at which the RNA was collected, assay and scanning differences if applicable, and storage time (Müller et al., 2016). To minimize the influence of such batch effects, a harmonized workflow was suggested, involving a harmonized protocol for sample collection, handling, and storage, RNA isolation and processing, hybridization, and scanning. This workflow was applied at all time points in the same way to reveal harmonized measurements. Again, this procedure is concordant with a meta-analysis (Schurmann et al., 2012).

Application of Transcriptomics in CVDs: Examples

Due to technical and methodological advances, in particular NGS methods, gene expression analyses have been widely established in the field of CVD to identify novel disease-related genes, genes responding to treatment, transcripts as diagnostic markers of gene expression signatures, and to study molecular biomarkers aiming at improving our understanding of the molecular mechanisms of CVD, facilitating the development of personalized medicine in CVD, and reducing the mortality rates in CVD (Wu et al., 2014). Biomarkers play an important role in CVD, serving either as diagnostic indicators, or as predictors of prognosis. In CVD, most of the biomarkers are proteins, while protein coding RNAs and ncRNAs (e.g., miRNAs) in blood cells might also be useful cardiovascular biomarkers in the future (Devaux, 2016). Consequently, the study of the transcriptome to identify novel biomarkers in CVD is an emerging field. Examples of studies using transcriptomics analyses for biomarker identification as presented in **Table 6**.

Large Scale Transcriptomics Analysis

A meta-analysis of large-scale transcriptomics data sets

The MetaXpress (Meta-Analysis of Gene Expression) Consortium published a recent meta-analysis investigating the influence of body-mass-index (BMI) as a cardiovascular risk factor on gene expression patterns in whole blood (Homuth et al., 2015). Here, the authors analyzed microarray gene expression profiles from almost 2000 individuals in two large independent population-based cohort studies, namely the Study of Health in Pomerania (SHIP-TREND) (Volzke et al., 2011) and the Cooperative Health Research in the Region of Augsburg (KORA F4) (Holle et al., 2005). Whole-blood mRNA levels were measured on Illumina HumanHT-12 v3 BeadChips and scanned using the Illumina Bead Array Reader, while preprocessing and normalization included quantile normalization and log transformation. The subsequent meta-analysis of gene expression included linear regression models to assess the association between BMI with gene expression patterns in both cohorts individually before combined. To combine the gene expression data from both cohorts, the authors computed z-scores based on the sample sizes of the cohorts. This meta-analysis revealed in a set of 3762 genes significantly associated with BMI after adjusting for multiple testing. Subsequent analyses identified extensive BMI-associated alterations of the whole-blood transcriptome, three gene expression signatures associated with increased BMI, as well as a BMI-associated genes involved in insulin signaling and protection against oxidative stress. These results demonstrate the power of meta-analyses in gaining novel insight into the pathomechanisms of metabolic syndrome and type 2 diabetes.

Identification of gene expression signatures by transcriptomics analysis

Grouping several mRNAs into a combined set can reflect a broader picture of the pathophysiological mechanisms and pathways, and thus for the understanding of disease pathobiology, and might be useful for prioritizing novel therapeutic targets for treating the disease. Consequently, the combination of different mRNAs to a gene expression signature might prove to be a powerful biomarker for CVD. To date, a number of studies have been published examining whole blood gene expression profiling to identify subjects at risk for CVD.

Table 6 Examples of biomarkers discovered by transcriptomics

Biomarker	*Cardiovascular phenotype*	*Reference*

Transcriptomics has been an emerging field for identifying novel biomarkers in CVD. Such studies revealed novel genes, miRNAs, and lncRNAs as novel biomarkers in different cardiovascular phenotypes.

To study the cardiovascular risk factors blood pressure and hypertension, a recent meta-analysis of genome-wide gene expression profiles was performed using six independent cohort studies (Huan et al., 2015). First, differentially expressed genes in blood pressure were determined, which were subsequently replicated. Next, a meta-analysis was performed, identifying 34 differentially expressed genes associated with blood pressure traits. Such genes defined the gene expression signature for blood pressure, and were attributable for 5%–9% of blood pressure variability. Subsequently, these signature genes were further integrated with eQTLs and GWAS results in an effort to differentiate downstream transcriptomic changes due to blood pressure from putatively causal pathways involved in blood pressure regulation.

Another recent study investigated whether gene expression patterns in peripheral blood correlate with the severity of coronary artery disease and whether these patterns correlate with the extent of atherosclerosis in the vascular wall (Sinnaeve et al., 2009). Here, blood from 120 patients with CAD was selected, revealing a gene expression signature 160 genes to be correlated with the severity of CAD. Molecular pathways covered by these 160 genes included angiogenesis, inflammatory response, apoptosis, cell adhesion, cell growth, arrest and cell-cell communication, lipid homeostasis as well as immune response. This study showed that a large-scale expression analysis of peripheral blood cells can identify gene expression patterns or signatures whose expression correlates with the severity of angiographically documented coronary artery atherosclerosis.

In the Personalized Risk Evaluation and Diagnosis in the Coronary Tree (PREDICT) study, a whole blood 23 gene expression score was developed and validated for the assessment of obstructive CAD in nondiabetic patients (Elashoff et al., 2011). This score was further evaluated in the multicenter COMPASS study with regard to the diagnostic accuracy in symptomatic patients referred for myocardial perfusion (Thomas et al., 2013). This gene expression score was a significant predictor of CAD and resulted, at a predefined threshold, in a high sensitivity and high negative predictive value making this score an extremely promising and one of the best examples of the value of transcriptomics-based biomarkers in the cardiovascular field today.

An integrative network analysis of transcriptomics data reveals deeper insights into the molecular mechanisms

Along with large-scale meta-analyses, integrative approaches play an emerging role. In general, integrative approaches involve different types of experimental data (e.g., transcriptomics, genomics, and interactomics) that will be first harmonized (i.e., standardization of gene identifier and data format), and subsequently, computationally integrated into one data set. This integrated data set then includes the combination of all original information from the experimental data sources.

A recent study integrated blood pressure GWAS with mRNA expression profiles as a coexpression network and applied network biology approaches, revealing transcriptomic signature for blood pressure at the single-gene and coexpression network module (Ding et al., 2015). This study identified gene subnetworks entailing molecular interactions between key drivers and genes related to blood pressure. Consequently, one of the top driver, *SH2B3*, was validated in a mouse model, revealing a significant number of genes predicted to be regulated by *SH2B3* in gene networks were perturbed in $Sh2b3^{-/-}$ mice, demonstrating an exaggerated pressor response to angiotensin II infusion. This finding may help to identify novel targets for the prevention or treatment of hypertension.

A large-scale eQTL analysis reveals susceptibility to CVD

An eQTL analysis associates gene expression measurements with genetic variants. A study investigating the monocyte transcriptome as a potent integrator of genetic and nongenetic influences of relevance for disease pathophysiology and risk assessment performed an eQTL analysis for CVD risk factors in a population-based cohort study (Zeller et al., 2010). The results identified expression traits significantly associated with at least one risk factor, and genome-wide interaction analyses suggested that genetic variability and risk factors mostly acted additively on gene expression.

From the Transcriptome to Biomarkers

ST2 in myocardial infarction: From discovery toward an early marker of CVD

After being discovered as an interleukin-1 receptor family member (Kakkar and Lee, 2008; Ciccone et al., 2013), the ST2 mRNA was identified as being exceptionally upregulated in cardiac myocytes subjected to mechanical strain (4.7 ± 0.9-fold) (Weinberg et al., 2002). ST2 was identified as the major inducible transcript by mechanical strain. Additionally, ST2 was induced by interleukin-1β, while additive and synergistic effects of strain and strain plus interleukin-1β were not observed, suggesting common pathways for induction of ST2 by stimuli. Additional experiments showed that neither treatment with angiotensin II, nor Interleukin-4, nor lipopolysaccharides induced the biomechanical induction of ST2, suggesting that oxidant signaling pathways do not mediate induction of ST2, and that the induction of ST2 is not indiscriminate for multiple pathways. An in vivo experimental setting in mice showed significantly increased serum levels of ST2 after MI compared with sham operated mice, revealing that ST2 is induced after myocardial infarction (MI). Translating these results into human, ST2 protein levels were measured in serum, resulting in increased levels in MI patients, and suggesting an association between the extent of myocardial injury or biomechanical load and ST2 in the circulation (Weinberg et al., 2002).

From the Transcriptome to Molecular Diagnostic Tools

Novel myocardial gene expression signatures of heart failure by RNA-Seq

To identify gene signatures for heart failure (HF) RNA-Seq was applied in resolution case control study. The transcriptomes of the left ventricle tissue were sequenced, and the sequenced short reads were aligned to the hg19 reference genome using Tophat (Trapnell et al., 2009), and log ratios for all transcripts were computed to assess their differential expression using Cufflinks (Roberts et al., 2011). Such obtained differentially expressed genes were used to classify heart failure status in a set of 313 individuals using Affymetrix Human Exon ST1.1 arrays, which were subsequently preprocessed and normalized using ComBat (Johnson et al., 2007). The results of this study showed that using the gene signatures identified from this small RNA-Seq data set enabled to classify individuals with failing or nonfailing hearts, and the misclassification rates of individuals with different heart failure status were one to three times lower than those obtained from microarray data. These results are likely due to the highly accurate gene expression measurements obtained from RNA-Seq and careful selection of feature vectors in classification (Liu et al., 2015).

The Noncoding Transcriptome

Noncoding transcriptome analyses in CVD: miRNAs

In most noncoding transcriptome analyses in CVD, miRNAs have been investigated, as they are stable, easily detectable and because of their influence on of a wide variety of target genes (Lee et al., 2007). In most cases, miRNAs have been analyzed as noninvasive biomarkers (singly or as signature) in CVD (Meder et al., 2008; Keller et al., 2011).

As an examples, a genome-wide study reported alterations of all of the expressed miRNAs analyzed in the peripheral blood of AMI (acute myocardial infarction) patients (Meder et al., 2011), revealing a set of 121 miRNAs to be significantly dysregulated. As these results were solely based on single point measurements and blood samples, obtained at different times after the onset of symptoms, the authors performed a proof-of-concept study to investigate the kinetic changes of the whole blood miRNome in the early stage of suspected myocardial infarction at five predefined time points using microfluidic primer extension arrays and to replicate the results in an independent cohort using qPCR (Vogel et al., 2013). Here, they identified a signature of seven consistently dysregulated miRNAs as an early biomarker of AMI, including miR-566, -1291, -7-1*, -1254, -455-3p, -380*, and -636. Additionally, two novel biomarkers (miR-1915 and miR-181c*) were identified to be associated with early myocardial infarction.

lncRNAs and circular RNAs

In the last years, the knowledge of lncRNA has expanded widely. However, the cellular origin of circulating lncRNAs is often unclear (Skroblin and Mayr, 2014) and little knowledge on the causal involvement in the underlying disease is currently available.

A recent transcriptomics analysis of heart failure patients showed the potential of lncRNAs as biomarkers in CAD (Archer et al., 2015). Higher levels of LIPCAR (long intergenic noncoding RNA predicting cardiac remodeling) were associated with a higher risk of cardiovascular mortality in HF patients in addition to traditional risk factors. The lncRNA CARMEN (Ounzain et al., 2015) was identified by a genome wide profiling of the cardiac transcriptome and was found to be a crucial regulator of cardiac cell differentiation and homeostasis. Most recently, lncRNA CoroMarker (Yang et al., 2015) and LncPPARδδ (Cai et al., 2016) were identified as predictive biomarkers for CAD.

Even though the existence of circRNAs has been known for some time, only recently this class of ncRNAs gained interest. Due to their circular state these RNA molecules are highly stable recent study revealed over 9000 candidate circRNAs detected in heart tissue (Werfel et al., 2016) and further studies are ongoing to dissect the role and potential of circular RNAs in CVD.

Summary and Future Direction

Due to technological and methodological advances, large-scale transcriptomics analyses can be performed to gain deeper insight into underlying molecular mechanisms, but also to identify novel disease genes or cardiovascular biomarkers to serve as risk factors, diagnostic indicators, or predictors of prognosis. An exemplary workflow is shown in **Fig. 3**.

In the future, single-cell transcriptomics based on single-cell RNA-Seq (scRNA-Seq) technology may play a promising role in understanding diseases and associated biological processes at a high resolution. It is designed to investigate expression profiles at the cell level and, thus, increases the discovery power as compared to the population-averaged RNA-Seq technology (Khera and Mehta, 2014; Poirion et al., 2016). Despite the large amount of bioinformatical approaches that have been developed throughout the years, there is still a need for novel methods as the amount and complexity of high-throughput and heterogeneous data sets and types are increasing. Additionally, novel approaches will be needed to improve the translation into the clinical application.

Systems medicine, a novel field using interdisciplinary approaches, emerged as a powerful tool to study complex and multifactorial diseases, including CVD, and in particular risk assessment, prevention, and treatment as well as biomarker and drug development need to be improved in the future. Due to the interdisciplinary nature, many challenges have to be faced, such as establishing interdisciplinary and an appropriate infrastructure (wet lab, dry lab, study center), setting up large size study cohorts, processing samples and phenotypes, analyzing the data, and translation into the clinical application (Haase et al., 2016; **Fig. 4**).

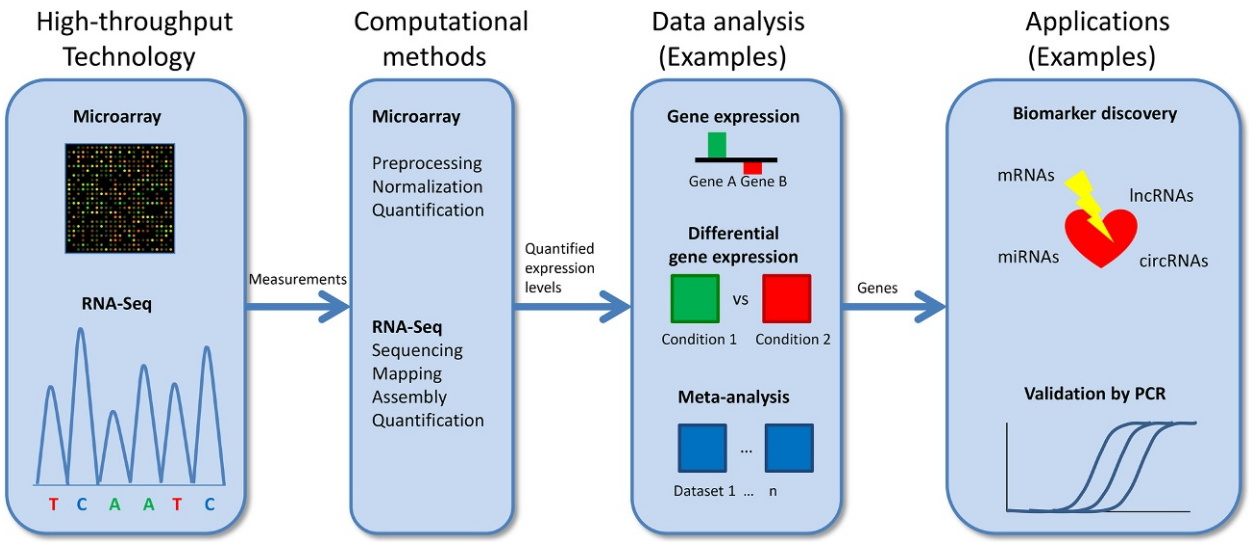

Fig. 3 Workflow of an exemplary transcriptomics analysis including detection and computational technology. High-throughput technology (microarrays and RNA-Seq) detects and measures gene expression, which is subsequently processed by technology-specific computational approaches, resulting in quantified gene expression levels. These expression levels can be analyzed in different manners, for example, a simple gene expression analysis, a differential gene expression analysis, or a multi-experiment meta-analysis. Finally, such retrieved genes can be subsequently validated by PCR and applied as novel biomarkers, for example.

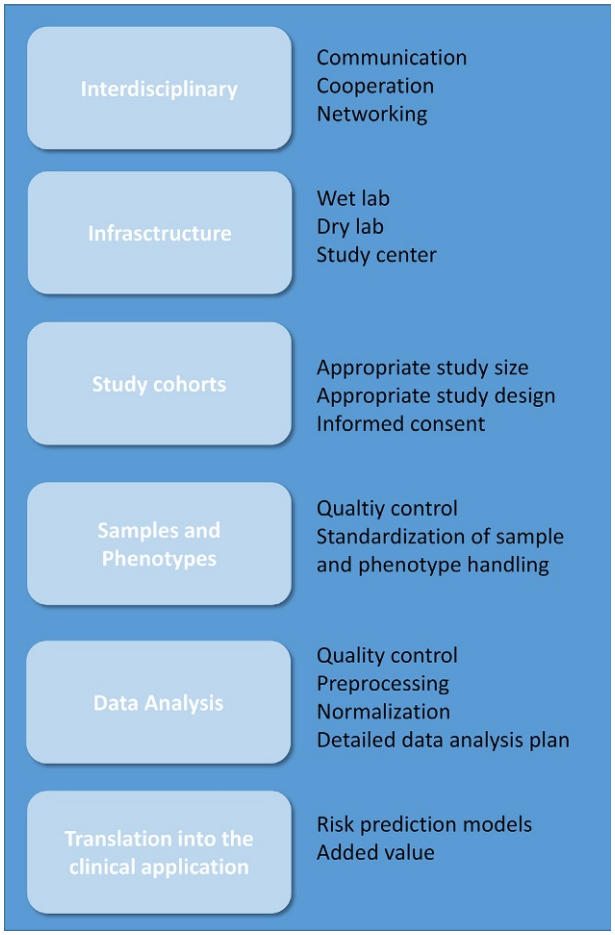

Fig. 4 Challenges for systems medicine. The major challenges that can be observed in the systems medicine field include working in interdisciplinary teams, installing appropriate infrastructure, initiating study cohorts, performing quality control of samples, phenotypes, and data, appropriate handling of sample and phenotype, performing data analysis, and subsequently, translating novel findings into clinical applications.

Introduction

Having been the leading cause of death for many decades (CDC, 2009), coronary heart disease (CHD) has been one of the focus areas of research efforts. However, CHD is a complex disease involving the interplay of multiple genetic and environmental risk factors (Schwartz et al., 2012) and thereby dissecting such complexities has been a formidable challenge. On top of such challenge also lies the difference of CHD risks between sexes (Jousilahti et al., 1999) or among ethnicities (Finkelstein et al., 2004), along with the associated behavioral difference (Ram and Trivedi, 2012), which blurs the line between genetic and environmental factors.

Studies on risk factors to CHD have grown from the traditional set, such as hypertension, smoking status, age, and diabetes mellitus (O'Donnell and Elosua, 2008), to a more sophisticated set, such as C-reactive protein, coronary artery calcium (CAC) score, and lipoprotein (a) (Akhabue et al., 2014), in the hope for early prognosis and to ultimately reduce the public health burden of CHD. On the other front, numerous genome-wide association studies (GWAS) have been performed to discover novel genetic variants that may predispose individuals to CHD (O'Donnell and Nabel, 2011). Recent advances in such studies include multiple discoveries of rare variants that elevate risks to CHD (Zanoni et al., 2016). Nonetheless, none of such studies addresses the complex interplay between genetic and environmental factors, which may explain the disease pathophysiology at molecular level.

Advances in transcriptomic and epigenomic technologies have enabled the whole-genome profiling beyond genetics. These advances present the opportunity to examine the impact of gene regulation in relation to CHD, which has the potential to dissect the interaction of genetic factors, disease activity, metabolism, and environmental factors (Aziz et al., 2007; Huan et al., 2012). This article highlights several studies in these areas. The goal is to help the readers understand how each technology has been used in cardiovascular disease research in synthesizing evidence for research and clinical applications.

Brief Overvies of CHD GWAS

Technological advances of high-throughput DNA microarray technology has opened many opportunities in investigating the genetic predisposition of various diseases, including CHD. In general, the association was carried out using variations of regression model, one genetic variant, or single nucleotide polymorphism (SNP), at a time. As the microarray technology advances, more and more SNPs can be fit into one microarray, and thus bring concern about controlling the Type I errors. Several attempts have been performed, but variants declared significant typically at $p < 5 \times 10^{-8}$ Bonferroni threshold. This threshold was taken as the standard because it was postulated that there are about 1 million haplotype blocks exist in human genome. Such p-value threshold is close to the result of a simulation study (Dudbridge and Gusnanto, 2008).

Among the first genetic locus found significantly associated with CHD using this technology is the 9p21.3 locus (McPherson et al., 2007; Helgadottir et al., 2007; Samani et al., 2007). As genotyping technologies became cheaper and more accessible, many more studies were able to genotype more participants and therefore increasing the number of significantly associated SNPs. Some landmark studies include the Framingham 100 K study (Larson et al., 2007), the Myocardial Infarction Genetic Consortium (Myocardial Infarction Genetics Consortium et al., 2009), the CARDIoGRAM Consortium (Schunkert et al., 2011), the Coronary Artery Disease (C4D) Genetics Consortium (Coronary Artery Disease Genetics consortium, 2011), CARDIoGRAMPlusC4D Consortium (CARDIoGRAM Consortium et al., 2013), and the 1000 Genomes-based (1000 Genomes Consortium et al., 2012) Coronary Artery Disease (Nikpay et al., 2015). The last of these studies encompasses over 60,000 cases and 123,000 controls, investigating over 9.5 million variants (Nikpay et al., 2015). Such massive undertaking validated 55 previously known loci and discovered 10 new ones. Among the findings of the 55 known loci reside in lipid genes, such as *PCSK9*, *LIPA*, *LPL*, *LDLR*, *APOB*, and

 https://doi.org/10.1016/B978-0-12-809657-4.99574-7

ABCG5, or in inflammation genes, such as *IL6R* and *CXCL12*. Among the novel loci are in genes with unknown effect on CHD, except genes such as nitric oxide synthase 3 (*NOS3*).

Such studies have been on populations of European ancestry, which have different haplotype structure from populations of other ethnicities (Lonjou et al., 2003). Thus, studies in non-European population may lead to the discovery of novel CHD loci. For example, CHD association study done on a multiethnic cohort has failed to replicate many of the findings in European ancestry (Franceschini et al., 2011). Another study in cohorts of African ancestry also failed to replicate such CHD findings, but do replicate findings from European-ancestry cohorts for CHD risk factors (Lettre et al., 2011). On the other hand, many of such findings do replicate in East Asian (Marigorta and Navarro, 2013) and South Asian Consortium (CARDIoGRAM Consortium et al., 2013) populations.

The subsequent technology, the whole genome sequencing (WGS), has afforded much higher resolution than that of microarray and the examination of rarer variants (Hurd and Nelson, 2009). Such technology is presently very costly, thus hampering the adoption. Nonetheless, there are some pilot studies (Chambers et al., 2012), but these studies have been underpowered due to the low number of samples. The upcoming Trans-Omics for Precision Medicine (TOPMed) of the National Heart, Lung, and Blood Institute (NHLBI) will bring the total number of WGS samples to over 120,000 (https://www.nhlbiwgs.org/). Such precision medicine initiative will realize the advantages of the WGS technology.

Transcriptome

RNA is the product of DNA transcription with various biological roles. The level of RNA indicates the level of expression of the underlying gene, giving rise to the term "gene expression." RNA generally functions as a messenger between DNA and protein. The regulation of RNA, and thereby its expression levels, is known to be tissue-specific (Ong and Corces, 2011). There are multiple types of RNA, with the most prominently discussed being the messenger RNA (mRNA). Prior to its translation to protein, mRNA may be spliced, edited, excised, transported, or even degraded. These processes may be dynamically influenced by environmental factors (Pleiss et al., 2007; Whangbo and Hunter, 2008). Due to this nature, RNA may capture some of the interaction between genetic and environmental factors that contribute to diseases.

Early RNA profiling was performed using polymerase chain reaction (PCR)-based technologies, which allows examination of a few genes. Such genes were usually selected a priori based on evidence in literature. Hence, studies using this technology are confirmatory in nature. It was successfully used in several experiments (Nickenig et al., 1998; Dieterich et al., 2000). Using this technology, Nickenig et al. validated the role of estrogen on AT_1 receptor (now gene *AGTR1*, angiotensin II receptor type 1), which has been implicated in the pathogenesis of hypertension and atherosclerosis (Nickenig et al., 1998). Dieterich et al. validated the role of genes MnSOD (now *SOD2*, superoxide dismutase 2), CuZnSOD (now *SOD1*, superoxide dismutase 1), and GPX (now *GPX3*, glutathione peroxidase 3) on oxidative stress that eventually result in cardiomyopathy (Dieterich et al., 2000).

Subsequent development uses custom-built microarray-based technologies, which allows for investigation and more precise quantification of thousands of genes. Such technology involves labor-intensive library preparation and microarray building. Yet it was successfully used to query "global" gene expression at the time. Barrans et al. (2002) were able to query 10,848 transcripts in human genome across 12 samples and identified several genes that were differentially expressed, such as atrial natriuretic peptide (now gene *NPPA*, natriuretic peptide A) and TGF-Beta (now gene *TGFB1*, transforming growth factor beta 1). Another study by van den Bosch et al. (2006) queried up to 6881 gene transcripts in mice in relation to cardiac hypertrophy and found gene Anf (homolog to gene *NPPA* in human), Myhc-b (now Myh7, homolog to *MYH7*, myosin heavy chain 7 in human), Pln (homolog to *PLN*, phospholamban in human), among others that are differentially expressed. The number of significantly differentially expressed genes increases proportional to the number of queried genes. Thus, studies also group such genes into "pathways" or "processes" to explain the roles of such genes. For example, van den Bosch et al. (2006) identified acetyl-CoA metabolism, fatty acid metabolisms, and other processes represented by the significant genes they have found.

These early technologies also had several challenges. They are labor intensive and costly, limiting the number of samples to assay. There was lack of standardized protocol, standardized quality control, or standardized gene name or location (Brazma et al., 2001; Pruitt et al., 2002). In addition, as the number of queried genes increases and statistical methods at the time being underdeveloped to cope with such technological development, the number of false positives or false negatives could be high. Nonetheless, there was some coherence in the results, such as gene *NPPA*.

The next development of the technology was the prefabricated microarray technology, which allows the examination of whole genome transcriptome with better precision. Combined with better standardization of protocols (Shi et al., 2006), quality controls (Shi et al., 2010), gene name and location (Pruitt et al., 2005, 2011, 2014), and much reduced labor requirement (Auburn et al., 2005), this technology brought down the cost significantly. This allowed the assay of many more samples, increasing the power of detection of significantly differentially expressed genes. Statistical methods also progressed (Benjamini and Hochberg, 1995; Storey and Tibshirani, 2003; Johnson et al., 2007; Leek and Storey, 2007) to reduce the number of false positives or false negatives.

A flurry of studies took advantage of this newer technology. Taurino et al. (2010) used the Illumina Sentrix humanref-6 to assay 24 samples in relation to coronary artery disease (CAD) and found 365 differentially expressed genes. In addition, Taurino et al. used quantitative real-time PCR (qRT-PCR) technology (Freeman et al., 1999), an improvement of the PCR technology, to assay

microRNAs (Bartel, 2004), a short noncoding RNA (ncRNA) of 16 to 26 nucleotides, in relation to CAD. Sinnaeve et al. (2009) used the Affymetrix microarray HGU133A technology to assay 241 samples in relation to CAD and found 160 differentially expressed genes, which in aggregate yield 0.776 partial least square. Szmit et al. (2010) used ScanArray technology to assay 12 patients in relation to heart failure and found 275 differentially expressed genes. Wingrove et al. (2008) used Agilent 41 K technology to assay 41 samples in relation to CAD and found 526 differentially expressed genes. There are many more studies using such technology in relation to CAD (Calverley et al., 2010; Rosenberg et al., 2010; Healy et al., 2006; Kiliszek et al., 2012). Lin et al. (2014) associated gene *PBX1*, among others, with atrial fibrillation on 2126 participants of Framingham Heart Study. It is worth noting that despite the increasing number of significantly differentially expressed genes, very few number of genes are in common across multiple studies. Nonetheless, these results all seem to point to processes commonly associated with CAD, such as oxidative stress, apoptosis, immune response, and inflammatory response.

The lack of replicability across studies highlights several important points: the necessity of better experiment design, heterogeneity of disease definition (Joehanes et al., 2013), variability across different expression platforms, tissue specificity of gene expression (Joehanes et al., 2012), and the importance of quality control procedures. Joehanes et al. (2013) to some degree resolved some of these issues but were unable to completely overcome the lack of replicability across study results. Chen and Stewart recently summarized replicable results (Chen and Stewart, 2016) across gene expression studies. Nonetheless, the pathways pointed by disparate sets of genes seem to be in common, as noted earlier.

Another avenue afforded by the new technology is to examine the coexpression patterns across genes in relation to CAD. Huan et al. (2012) investigated such patterns and confirmed the multiple pathways involved in CAD. Huan et al. also integrated findings from GWASes to reveal "key drivers," genes that are coexpressed with many other genes of CAD. These key drivers include *TNFRSF13C*, *SPIB*, *TSPAN13*, *CD79B*, *PLEKHG1*, and *CELSR1*, some of which were also identified in previous study (Joehanes et al., 2013).

Several studies also combine multiple high-throughput datasets to paint a more coherent picture of CAD pathophysiology. In addition to the study of Huan et al. (2012), several other studies integrate genetic findings with gene expression findings (Zhang et al., 2014a; Yao et al., 2015; Huan et al., 2015a) in relation to CAD. Such studies highlight two important points. First, genetic variance associated with CAD may manifest in gene expression changes. Second, there are similarities of differential expression patterns across several conventional CAD risk factors, such as low density lipoprotein, blood pressure, diabetes mellitus, and smoking.

Integration of multiple high-throughput evidence has the potential to point to the pathophysiology or etiology of CAD or its risk factors. In fact, the support of multiple human genetic evidence significantly improves the rate of clinical trial success of a drug targeted to a certain gene (Nelson et al., 2015). A study of Sen et al. (2014). integrated evidence from DNA, RNA, and protein that implicates gene *TREML4* in CAC. Burkhardt et al. (2015) and Yao et al. (2015) highlighted apparent pleiotropic genetic variants across multiple CAD risk factors and found some concordance in gene expression. Smith et al. (2016) used gene expression and DNA methylation evidence to follow up findings of GWAS and implicated single nucleotide polymorphism (SNP) rs9885413 to heart failure. The SNP variation eventually leads to lower expression of a chemokine gene *TSLP*, which is a key gene in inflammation response (Isaksen et al., 1999; Ziegler et al., 2013). Joehanes et al. (2017) were able to follow up GWAS results from CARDIoGRAMplusC4D consortium (CARDIoGRAMplusC4D Consortium et al., 2013) using expression quantitative trait locus dataset and identified potential causal variants to those results.

The primary limitation of probe-based microarray technology is the inability to detect novel isoforms of transcripts. Isoforms of known genes are sometimes vital to the pathophysiology of heart disease. For example, δ isoform of gene *CAMKII* (now *CAMK2B*, calcium/calmodulin dependent protein kinase 2B) has been implicated in failure of human myocardium (Hoch et al., 1999). Another classic example is the isoform of α_1 subunit of the voltage-dependent calcium channel (now gene *CACNA1C*) (Slish et al., 1989). There are some microarray technologies that partially overcome such limitation by incorporating known or putative isoforms in the array, such as Affymetrix Human Exon Array ST 1.0. Such platform has been used to detect putative isoform in relation to myocardial infarction (MI) in gene *PTGS1*, which may be modulated by genetic variance (Zhang et al., 2015a). Using the same platform, Joehanes et al. (2013) also detected potential alternative splicing of genes *GUK1* and *TMEM56* that may be associated with MI. There is also a growing evidence that alternative isoforms may play an important role in CAD etiology (Park et al., 2011).

The second important limitation of probe-based microarray technology is the relative inability to detect short transcripts. Microarray probes are usually 25 nucleotides or longer and rely on a few nucleotides of mismatch in the transcript sequence for their measurement precision (Draghici et al., 2006). However, multiple studies show the increasing importance of such short transcripts in the regulation of genome organization and gene expression (Morris and Mattick, 2014). They also have been implicated in cardiovascular development and diseases (Ono et al., 2011). Some microarray technologies (Liu et al., 2004; Okoniewski and Miller, 2008) also incorporated assays of short transcripts. However, for measuring the expression of such transcripts, microarray platform generally suffers from lower intensity, limiting its usefulness on less commonly expressed transcripts (Git et al., 2010). During this time, for assaying short transcripts, ncRNA, which includes a broad range of short molecules such as microRNA, piwi-interacting RNA, or short-interfering RNA, qRT-PCR was a technology of choice. Huan et al. implicated 15 microRNA in relation to CAD (Huan et al., 2015a). The significantly differentially expressed microRNAs are involved in intracellular transports, cell cycles,

protein localization, and gene silencing. MicroRNAs, such as mir-208a and mir-1, also have the potential for diagnosing acute MI (Wang et al., 2010).

Prefabricated microarray technologies were then superseded by sequence-based RNA profiling, called the RNA-seq technology (Wang et al., 2009), which is the newest to date. In this technology, the RNAs are sequenced directly and then quantified (Conesa et al., 2016). In general, RNA-seq has been shown to be superior to microarray technology, having a much better resolution (Black et al., 2014; Zhao et al., 2014; Zhang et al., 2015b). However, results from microarray are highly correlated with those of RNA-seq for a subset of genes for which microarray has little to no limitation of detecting (Nookaew et al., 2012; Xiong et al., 2012). Currently, RNA-seq technology is costlier than microarray technology and thus current RNA-seq experiments have low sample size. Yet, as the cost of sequencing declines, RNA-seq experiments with higher number of samples are expected to rise (Sboner et al., 2011; Muir et al., 2016).

A study of Liu et al. (2015) identified up to 492 genes differentially expressed in relation to heart failure ($n=6$). The findings were then followed up using a microarray experiment on a larger cohort ($n=313$) and could be used to classify disease status. A bigger case-control study ($n=90$) (Muehlschlegel et al., 2015) identified 1241 genes in relation to myocardial ischemia. None of the featured genes are in common to previous microarray-based results (Huan et al., 2012; Joehanes et al., 2013), however. As in microarray results, these genes point to a common set of processes, such as immune response and B-cell immunity (Huan et al., 2012).

RNA-seq technology has also been exploited to identify short RNA sequences in relation to heart diseases. ncRNA also plays important molecular regulatory roles, such as epigenetic imprinting, guide for transcription factors, and activation of enhancers (Mattick, 2006). Several ncRNAs have been implicated in heart diseases, such as *Novlnc6* (Ounzain et al., 2014) or *Mhrt* (Han et al., 2014). An excellent review of the role of ncRNA in CVD can be found in Uchida and Dimmeler (2015).

Bottom Line: Can Transcriptomic Biomarkers Be Used for Clinical Applications?

The lack of a common set of significantly differentially expressed genes in current findings highlights the need to overcome many challenges, such as appropriate experimental design, heterogeneity of disease definition, and, most importantly, sample size. On the other side, the common set of pathways pointed by the disparate sets of results mean that results of gene expression, regardless of the underlying technology, are in some way coherent. However, due to the lack of proper longitudinal study design, it is indeed not clear whether gene expression captures signals that may be causal to heart disease or signals that are consequence of heart disease.

Transcriptome-based prognostic biomarkers may still be achievable by incorporating biomarkers from CAD risk factors, such as diabetes (Patti, 2004), blood pressure (Huan et al., 2015b), cigarette smoking (Huan et al., 2016), age (Peters et al., 2015), or body mass index (BMI) (Mendelson et al., 2017). Indeed, transcripts of several genes are associated with multiple of these risk factors. For example McManus et al. (2017) showed that four genes, *FAM13A*, *CSF2RB*, *HIST1H2AC*, and *WNK1*, are significantly differentially expressed with six cardiometabolic factors, triglyceride, BMI, systolic and diastolic blood pressure, high density lipoprotein, and fasting glucose and four microRNAs, miR-505-5p, miR-197-3p, miR-145-5p, and miR-328, are significantly differentially expressed with the first four factors. These findings were then followed up with the integration of coexpression network to reveal transcriptomic regulatory architecture underlying CHD. Also, in many cases, dose–response relationship between the risk factor and the biomarkers is available (Huan et al., 2016), which may be useful to monitor disease progression even prior to symptoms manifestation. Combining these biomarkers with genetic biomarkers, which may help identify individuals predisposed to the disease, may be the future for clinical application of transcriptome.

Epigenome

Epigenome is a set of modifications to the DNA that are, in some cases, heritable (Jaenisch and Bird, 2003). Epigenetic modifications may affect gene expression (Romanoski et al., 2015; Attwood et al., 2002) by modulating the accessibility of surrounding promoter or enhancer of the gene (Greco and Condorelli, 2015). Such modifications include DNA methylation and histone modification (Allis and Jenuwein, 2016). Epigenetics modification has been documented to reflect the effects of environmental and dietary influences (Feil and Fraga, 2012; Aguilera et al., 2010). For example, air pollution has been documented to affect the methylation of certain genes (Bind et al., 2014). Gut microbiota have also been implicated as epigenetic regulator in the body of the host (Kumar et al., 2014). In addition, epigenetic modifications have also been associated with cardiac development (Gilsbach et al., 2014). Therefore, epigenetics hold an excellent potential to serve as biomarkers to CHD (Ordovás and Smith, 2010; Baccarelli et al., 2010).

DNA methylation (Moore et al., 2013), being the discovered first (Avery et al., 1994), is perhaps the most studied form of epigenome (Weinhold, 2006). It is a process where a methyl group (CH3) is added to the fifth position of cytosine, resulting in 5-methylcytosine. In mammals, such methylation occurs predominantly in cytosine-phosphate-guanine (CpG) sequence

(Jaenisch and Bird, 2003). The most common effect of such methylation is long-term gene expression silencing (Jaenisch and Bird, 2003). DNA methylation is also shown to be tissue specific (Gutierrez-Arcelus et al., 2015).

Early technology for DNA methylation detection is also based on PCR using bisulfite treatment of DNA, which selectively converts cytosine to uracil, but not 5-methylcytosine (Clark et al., 1994). Dong et al. (2002) reviewed studies using such technology and highlighted several genes in relation to atherosclerosis, such as estrogen receptor alpha (*ESR1*) and tumor protein 53 (*TP53*). Kim et al. (1772) showed that epigenetic changes in estrogen receptor beta (*ESR2*) are associated with atherosclerosis. Although initially the technology was gene-specific, a later breakthrough enabled global DNA methylation profiling (Yang et al., 2004), which will be the basis of later technologies.

After PCR-based technology, microarray is used to assay DNA methylation profile. A review by Muka et al. (2016) combined the results of early microarray technology and the PCR technology, and highlighted a few genes in relation to cardiovascular disease, such as *LINE1*, *ABCA1*, *KCNQ1*, and *C1QL4*. Haas et al. (2013) highlighted the role of genes *LY75* and *ADORA2A* in relation to dilated cardiomyopathy. Rask-Andersen et al. (2016) highlighted the methylation of a few genes in relation to MI, such as *IL6R*, *ABCG5-ABCG8*, and *HDAC9*. A preliminary result of a study of ten cohorts spanning 9725 individuals (Agha et al., 2016) identified 16 CpG sites differentially methylated in relation to both MI and incident heart disease (IHD), such as *IGF1R*, *GARNL3*, *ATP6V1H*, *FAM113B*, and *AHRR*. If examined separately, the study found 72 CpG sites significantly associated with MI and 149 CpG sites significantly associated with IHD. In addition, Kim et al. (2010) explored associations of DNA methylation with cardiometabolic risk factors across 286 individuals in an attempt to create a set of biomarkers for CHD.

The current technology to assay the DNA methylation profile is based on next generation sequencing (Masser et al., 2015). There are several techniques associated with such technology, such as whole-genome bisulfite sequencing, MeDIP-seq, Methyl Cap-seq, reduced representation bisulfite sequencing, and SureSelect Methyl-seq (Soto et al., 2016). Some of these sequencing technologies, such as MeDIP-seq and Methyl Cap-seq, overcome the primary limitation of bisulfite sequencing technology: inability to distinguish 5-hydroxymethylcytosine from 5-methylcytosine. The former promotes gene expression, while the latter represses it (Branco et al., 2011). However, as of this writing, no experiments on cardiovascular disease have been performed on the latest technology.

Histone modification is a class of covalent posttranslation modification to histones that may affect chromatin structure, which in turn affect transcription regulation (Bannister and Kouzarides, 2011). Tingare et al. (2013) discusses a role of histone modification in relation to cardiac remodeling and highlighted how the methylation of H3K9 governed cardiac biology. Montgomery et al. (2007) showed that histone deacetylases regulate cardiac morphogenesis, growth, and contractility, which leads to arrhythmias and dilated cardiomyopathy. Histone acetylation and deacetylation affect multiple pathways that lead to cardiac remodeling, such as inflammation, apoptosis, angiogenesis, oxidative stress, and fibrosis, which in turn affect multiple cardiovascular diseases (Wang et al., 2014). Kaneda et al. (2009) reported that tri-methylated histones H3H4 and H3K9 are associated with heart failure. Multiple histone modifications can be a mechanism that explains renal failure connection to cardiomyopathy in type 2 diabetes (Gaikwad et al., 2010). Mahmoud and Poizat summarized multiple epigenetic modifications in relation to cardiomyopathy (Mahmoud and Poizat, 2013).

Bottom Line: Can Epigenomic Biomarkers Be Used for Clinical Applications?

Although there are several epigenomic marks that are in common across several studies, most notably *LINE1*, *ABCA1*, *KCNQ1*, *C1QL4*, and *IGF1R*, more studies are needed (Aslibekyan et al., 2015). As the majority of such replicable signals came from microarray-based technology, at least replication based on a different technology is needed to avoid false positives. As in transcriptome, integration of biomarkers across multiple CHD risk factors is needed. Kim et al. (2010) has a proof of concept that it is possible. However, larger study is needed to bring in more statistical power.

Discussion and Future Direction

Despite the enormous progress in transcriptome and epigenome research on biomarkers for CHD, few biomarkers are replicable across multiple studies. Nevertheless, as indicated earlier, the findings so far seem to point to common set of pathways. Further research is needed to understand the variability in such findings. In addition, better, more precise technology is certainly needed to partially overcome this challenge.

The lack of replicability may be caused by several confounding factors. One of such factors is the heterogeneity of phenotypic definition of heart diseases. Such heterogeneity substantially affects GWAS results (Kitsios et al., 2011) and manifests in gene expression levels (Joehanes et al., 2013). Another contributing factor is the technical variability in transcriptome and epigenome that typically outweighs biological variability (Bryant et al., 2011). Such technical variability exists even in the latest technology (McIntyre et al., 2011; Meyer and Liu, 2014). This underscores the importance of standardized laboratory protocol, technical and biological replication, experimental design, and techniques to identify, account, and mitigate such variability. The next factor is the specificity of gene expression and epigenomic modifications (Maruyama et al., 2011), which underscores the importance of tissue

selection in CHD research. The question of tissue selection is dependent on the scientific question of the research. For purposes of finding biomarkers, blood-based biomarkers would be most desirable because of affordability, expediency, and relative noninvasiveness. However, caution must still be exercised since variability in expression levels (Joehanes et al., 2012) and DNA methylation levels (Thompson et al., 2013) does exist among different blood-derived samples.

Once these confounding factors have been overcome, the obvious next question is whether transcriptome or epigenome biomarkers provide better prognostic power for heart diseases, whether independent from or in conjunction to known risk factors (van Holten et al., 2013). For transcriptome-based biomarkers, caution needs to be exercised since the expression of thousands of genes tends to fluctuate due to circadian and ultradian rhythm (Zhang et al., 2014b; Ono et al., 2015; van der Veen and Gerkema, 2017), which diminishes their utility as stable biomarkers (Ramachandran, 2006). On the other hand, epigenome-based biomarkers tend to be more stable (Sarkies and Sale, 2012). Given that CHD is a multifactorial disease and preliminary evidence points to multiple biomarkers with low effects, if such biomarkers were found and validated, there will be dozens of them combined into a score. Wingrove et al. (2008) and Rosenberg et al. (2010) gave a proof of concept that it could be done. Although models using multiple biomarkers to predict cardiovascular events or cardiovascular death have been developed (Wang et al., 2006; Zethelius et al., 2008), using multiple biomarkers may lead to conflicting results and thereby confusion (Wang, 2010).

Another next question is whether these biomarkers can help dissect the genetic and genomic architecture of CHD. Given there are cross-talks (Ritchie et al., 2015) between genetic variants and both gene expression (Joehanes et al., 2017; Westra et al., 2013; Liang et al., 2013) and epigenomic modifications (Gaunt et al., 2016; Banovich et al., 2014; Gutierrez-Arcelus et al., 2013), biomarkers from disparate molecular datasets assembled together in a network can help dissect the intricacies of the architecture. Ritchie et al. (2015) described methods to dissect such architecture. Another method to uncover such architecture is to find common sets of genes and pathways across multiple CHD risk factors using one or more molecular datasets. An example of this is the study of McManus et al. that has been discussed in the previous section.

In summary, this article chronicles transcriptome and epigenome technologies. It surveys their findings in relation to cardiovascular diseases. It discusses its challenges of lack of replicability and potential solutions. Although transcriptomic and epigenomic technologies present enormous potential for clinical applications for CHD, further studies are needed.

Introduction

Organ transplantation is a life-prolonging procedure for many people with end-stage organ failure but almost all grafts eventually fail. Transplant arteriosclerosis (TA; also called cardiac allograft vasculopathy, transplant vasculopathy, or transplant vascular disease) is a vascular condition characterized by concentric intimal thickening and vasomotor dysfunction of arteries that develops in all solid organ transplants (Mitchell and Libby, 2007; Radio et al., 1996). It is widely established to be a main cause of heart transplant failure after the first postoperative year. The development of TA has diminished only minimally over the past 30 years despite advances in immunosuppressive drug formulation and delivery that have considerably reduced acute rejection (Stehlik et al., 2010). This differential effect of immunosuppressive drugs on TA and acute rejection highlights the therapeutic challenge of TA and may reflect uniqueness in its pathology. In this article, we will discuss the immunologic and vascular processes that cause TA.

Immune Mechanisms in Vascular Rejection and TA

T cells recognize peptides bound in the context of major histocompatibility complex (MHC) proteins, also called human leukocyte antigens (HLAs) in humans, through the T cell receptor. In addition to recognition of peptide-MHC, activation of T cells also requires the expression of costimulatory molecules and inflammatory cytokines that bind to partner molecules and receptors on T cells. These three signals act together to drive T cell activation and differentiation into specific effector lineages (Janeway and Medzhitov, 2002). The ability to activate resting T cells through the provision of these signals is restricted to certain cell types, collectively termed antigen-presenting cells. Dendritic cells, macrophages, and B cells are the main antigen-presenting cells that potently induce T cell activation. Dendritic cells and macrophages reside within or circulate through peripheral tissues where they acquire antigen and then interact with T cells in lymphoid organs and sometimes directly within nonlymphoid tissues. In addition to these cells, human vascular endothelial cells are also capable of presenting antigen and activating resting memory T cells (Pober and Tellides, 2012).

Depending on the strength of antigen stimulation and type of costimulation and inflammatory cytokines present, activated T cells differentiate into distinct effector cell types that migrate to peripheral tissues. CD8 T cells mostly differentiate into cytotoxic effectors that kill target cells and secrete interferon-γ (IFNγ). Killing occurs mainly through the secretion of granzymes, a family of serine proteases, and perforin, a pore-forming protein needed to deliver granzymes into target cells, that are stored in the granules of activated CD8 T cells (Choy, 2010). The expression of FasL on the surface of CD8 T cells can also induce cell death in some cell types by activating the death receptor Fas (Guicciardi and Gores, 2009). CD4 T cells differentiate into Th1, Th2, or Th17 cells that migrate to sites of inflammation. Th1 cells secrete IFNγ; Th2 cells secrete IL-4, 5, and 13; Th17 cells secrete IL-17. Each CD4 effector T cell type has distinct roles in protective immunity against pathogens and the cytokine profile secreted by each has specific immunopathological effects (Sallusto, 2016).

Immunologic responses toward organ grafts are a result of genetic differences between the donor and recipient. This is called alloreactivity. T cells recognize and are activated by foreign MHC-peptides on donor cells and by foreign peptides that are acquired from the graft and that are presented in the context of self-MHC molecules on antigen-presenting cells of the graft recipient. The majority of T cells that infiltrate grafts are cytotoxic CD8 T cells and Th1 cells, although experimental models have implicated Th2

 https://doi.org/10.1016/B978-0-12-809657-4.99563-2

and Th17 cells in some forms of graft rejection (van Besouw et al., 1995; Chan et al., 1995; Yuan et al., 2008). B cells are also activated to produce antibodies that bind foreign MHC and some non-MHC proteins (Djamali et al., 2014).

Immune-mediated damage to arteries causes the development of TA because this vascular condition does not occur in arteries outside the graft and it does not develop in experiments where grafts are performed between genetically identical animals or into recipients that lack adaptive immune cells (Shi et al., 1996). CD4 and CD8 T cells are present in the intima and adventitia of arteries with TA, and are normally absent from the media (Salomon et al., 1991). The T cell population is predominated by Th1 cells that secrete IFNγ and vascular cells in these arteries respond to this cytokine as is evident by their expression MHC class II, an IFNγ-induced gene (Burns et al., 2005; van Loosdregt et al., 2006; Salomon et al., 1991). Experimental models have established that T cells play a causative role in TA. Specifically, this vascular condition does not develop in grafts transplanted into animals that lack T cells (Shi et al., 1996). Depending on the model utilized, both CD4 and CD8 T cells have been shown to be important (Shi et al., 1996; Vessie et al., 2005). Further, the activation of Th1 cells is needed for the development of TA because intimal thickening is reduced in graft recipients that lack STAT4, a transcription factor needed to induce the development of Th1 cells (Koglin et al., 2000). In addition to Th1 cells, IL-17 expression is observed to a varying degree in TA and animal models have determined that Th17 cells can contribute to the development of this vascular condition, although these experiments were performed using graft recipients that cannot mount Th1 responses (Liu et al., 2012; Yuan et al., 2008). Amplification of Th2 responses in graft recipients does not affect intimal thickening but results in expansive medial damage and rupture that is reminiscent of aneurysms, a feature not observed in clinical cases of TA (Shimizu et al., 2004).

Antigens presented by dendritic cells, macrophages, B cells, and endothelial cells initiate immune responses toward allograft arteries. Arteries normally house populations of dendritic cells that reside primarily in the adventitia and intima (Ma-Krupa et al., 2004; Pryshchep et al., 2008; Millonig et al., 2001). Under physiological conditions, artery-associated dendritic cells impose tolerance toward arterial antigens and disruption of these dendritic cells can increase immunopathological responses in atherosclerosis (Choi et al., 2011). Activation of artery-associated dendritic cells with inflammatory toll-like receptor signals upregulates their expression of costimulatory signals and results in T cell activation that can drive immune activation in the arterial wall (Ma-Krupa et al., 2004). It is clear that antigen-presenting cells from the graft migrate into lymph nodes and spleen of graft recipients within days after transplantation and activate T cells that migrate back to the graft and cause rejection (Larsen et al., 1990). Dendritic cells that reside within arteries are also capable of activating T cells locally in these blood vessels (Ma-Krupa et al., 2004). Human vascular endothelial cells also express HLA class I and II and can activate resting memory CD8 and CD4 T cells (Pober et al., 1983; Page et al., 1994; Epperson and Pober, 1994). The pattern of costimulatory molecules expressed by human endothelial cells is partially distinct than that expressed by dendritic cells because these vascular cells do not express CD80/86 but instead express primarily LFA-3, 4-1BB ligand, ICOS ligand, and OX40 ligand (Hughes et al., 1990; Shiao et al., 2005). This may result in differences in the activation of certain T cell subsets by endothelial cells as compared to dendritic cells. For instance, human endothelial cells stimulate alloreactive memory T cells and poorly stimulate naïve T cells (Dengler and Pober, 2000; Ma and Pober, 1998). The phenotype of T cells activated by human endothelial cells is also different from those activated by professional antigen-presenting cells, and this may define a chronic and smoldering immune response in arteries that is a feature of TA (Lorber et al., 1999). Specifically, endothelial cells activate CD8 T cells to differentiate into a relatively immature phenotype (characterized by sustained expression of CD69, CD25, and CD62L) as compared to other antigen-presenting cells (Dengler and Pober, 2000). This effect on T cell activation is dominant over other antigen-presenting cells and may define the unique quality of local T cell activation in TA. Activation of T cells by allogeneic endothelial cells is sufficient to cause vascular rejection and intimal thickening reflective of TA in humanized mouse models (Murray et al., 1994; Lorber et al., 1999). Endothelial cells also have immune regulatory properties. They can induce the differentiation of T regs when IL-6 activity is prevented, support the differentiation of suppressive CD8 T cells, and can be induced to express the immune-inhibitory cell surface protein PD-L1 that opposes the development of TA (Fogal et al., 2011; Manavalan et al., 2004; Bolinger et al., 2010).

B cells can serve as effectors of immune responses by producing antibodies and can also activate immune responses by acting as antigen-presenting cells that stimulate T cells. Antibody-mediated rejection of grafts is vascular in nature, with endothelial changes observed in biopsies being a foundation for its clinical diagnosis (Berry et al., 2011). The development of antidonor antibodies and the incidence of antibody-mediated rejection are associated with the development of TA (Petrossian et al., 1989). The transfer of antidonor antibodies into graft recipients that lack T and B cells is sufficient to induce intimal thickening of allograft arteries in mice, indicating that antidonor antibodies are capable of inducing TA (Galvani et al., 2009). Due to their polymorphic nature, MHC molecules are main targets of antidonor antibodies. Studies have shown that antibody binding to MHC class I triggers the activation of Rho kinase, ERK, and mechanistic target of rapamycin (mTOR) signaling pathways in vascular cells (Ziegler et al., 2012; Jindra et al., 2008). This causes phenotypic alterations in endothelial cells including increased proliferation, survival, and migration (Jin et al., 2005). Antibody binding to MHC class I also results in inflammatory activation of the endothelium by increasing P-selectin and increasing secretion of von Willebrand factor (Valenzuela et al., 2013). These effects increase leukocyte transendothelial migration. Antibodies toward non-MHC molecules are also detected in patients with TA, correlate with poor graft outcome, and are sufficient to induce the development of TA in animal models. These antigens include vimentin, a fragment of the extracellular matrix protein perlecan, and angiotensin type II receptor (Jurcevic et al., 2001; Mahesh et al., 2007, 2010; Soulez et al., 2012; Dragun et al., 2005). These antibodies likely develop due to immune activation in the context of large-scale inflammation, which overrides tolerance mechanisms that are usually dominant in preventing activation against these antigens. Although the production of antibodies usually occurs in B cells activated within secondary lymphoid tissues, recent studies suggest that some antidonor antibodies can be generated within tertiary lymphoid structures that develop locally in allograft arteries (Huibers et al., 2015,

2016). This may reflect chronic immune activation in the setting of TA. In addition to producing antibodies, B cells also cause TA through antibody-independent mechanisms that involve the activation of alloreactive T cells through antigen presentation. TA and associated T cell responses are not affected in mice that contain B cells but cannot produce antibodies, but both are reduced in mice containing B cells that cannot present antigens to T cells (Zeng et al., 2014).

The role of NK cells in rejection of organ transplants is multifactorial and complex. Activation of these cells is determined by the combinatorial strength of inhibitory and activating signals presented by target cells. Self-MHC class I proteins are inhibitory NK cell ligands and the absence of self-MHC class I on target cells triggers NK cell activation (Sun and Lanier, 2011). As such, the absence of self-MHC class I on organ transplants may lead to NK cell activation. Experimental studies have shown a role for these innate immune cells not only in causing acute heart transplant rejection in immunosuppressed recipients but also in opposing rejection by killing donor antigen-presenting cells and competing with effector T cells for cytokines (McNerney et al., 2006; Laffont et al., 2008; Yu et al., 2006; Zecher et al., 2010). NK cells may contribute to the development of TA. Transplantation of hearts into recipients that express MHC class I proteins not present in the donor results in the development of TA that is dependent on NK cell activation (Uehara et al., 2005). Interestingly, T cells are needed for NK cell-mediated development of TA although the mechanism is currently not clear. NK cells may also contribute to vascular inflammatory changes and resultant development of TA induced by antidonor antibodies (Hirohashi et al., 2012).

Vascular Changes That Cause Arteriosclerotic Thickening in TA

Immunological effects on vascular cells cause structural and functional changes in TA. Structurally, arteriosclerotic thickening of the intima results from immune-mediated death of endothelial cells that line the arterial lumen as well as from cytokine-induced phenotypic alterations in endothelial and smooth muscle cells. Blood vessels also control blood flow by dilating or constricting. This vasomotor function is abnormal in TA, which further compromises blood flow through affected arteries and contributes to ischemic damage of grafts.

Immune-Mediated Vascular Cell Injury

The integrity of vascular endothelial and smooth muscle cells is essential for maintenance of arterial structure. Studies in the 1970s and 1980s that examined the effects of mechanical injury on arteries determined that endothelial injury resulted in a "response-to-injury" process in the artery wall that culminated in intimal thickening (Ross et al., 1977; Lindner et al., 1990; Ferns et al., 1991; Fingerle et al., 1989). Lesions consisted mostly of smooth muscle cells that migrated from the media into the intima and proliferated locally as well as of macrophages that infiltrated from the circulation. Intimal thickening was caused by the action of growth factors, such as fibroblast growth factor and platelet-derived growth factor, that were produced by injured vascular cells and infiltrating leukocytes (Ross et al., 1977; Lindner and Reidy, 1991). Although this early work focused mainly on mechanical injury to the arterial wall, the findings suggested that other pathological processes that lead to disruption of the luminal endothelium of arteries could have a similar effect.

Cytotoxic CD8 T cells infiltrate and kill target cells within transplanted organs. Cultured endothelial cells are sensitive to killing by alloreactive CD8 T cells mainly through the granzyme B/perforin pathway and may normally be resistant to FasL-mediated killing (Zheng et al., 2002; Krupnick et al., 2002; Choy et al., 2005; Sata et al., 2000). However, endothelial cells become sensitized to FasL-mediated killing by exposure to IFNγ or modified forms of low-density lipoproteins that are present in TA lesions (Stefanescu et al., 2008; Sata and Walsh, 1998). In TA, CD8 T cells that express perforin are observed to accumulate underneath the luminal endothelium (Fox et al., 1993). This is associated with histological features of endothelial injury, suggesting that endothelial killing through this mechanism could be a triggering event for the development of intimal thickening (Hruban et al., 1990). Indeed, increased apoptosis of luminal endothelial cells is observed in allograft arteries in early stages of TA development but not at later stages, suggesting that endothelial regeneration occurs after early endothelial injury (Dong et al., 1996). The expression of granzyme B is abundant in the intima of arteries with TA and is spatially correlated with cells undergoing apoptosis (Choy et al., 2003). Also, endothelial cell apoptosis in TA is spatially correlated with expression of the death receptor Fas, implicating a role of this cytotoxic mechanism in early endothelial injury (Dong et al., 1996) (**Fig. 1**).

Consistent with clinical observations that early endothelial cell death in allograft arteries may be a triggering event in the development of TA, early loss of luminal endothelial cells is observed in animal models of this vascular condition and this is reduced by administration of immunosuppressive drugs (Lai et al., 2003). The immune response toward transplanted organs is multifactorial, with several processes potentially having overlapping effects on the general outcome of graft failure or arteriosclerotic thickening in the case of TA. In animal models of TA in which grafts are transplanted across a complete MHC mismatch, intimal thickening is not affected by elimination of CD8 T cells. CD4 T cells and B cells play nonredundant roles in this model (Shi et al., 1996). However, T cell-mediated rejection in the absence of antibodies is prevalent in clinical organ transplantation. In models of TA that do not involve appreciable antibody responses, TA develops as a result of CD8 T cell killing of luminal endothelial cells through a perforin and granzyme B mechanism (Schnickel et al., 2004; Choy et al., 2004b, 2005).

Medial smooth muscle cell injury may also trigger the development of arteriosclerotic thickening of arteries (Fingerle et al., 1990; Yu et al., 2011a). Although medial damage and immune infiltration is normally minimal in clinical specimens of TA, this analysis of arterial changes at late stages of disease may not entirely reflect early transient events that are important in the pathogenic process.

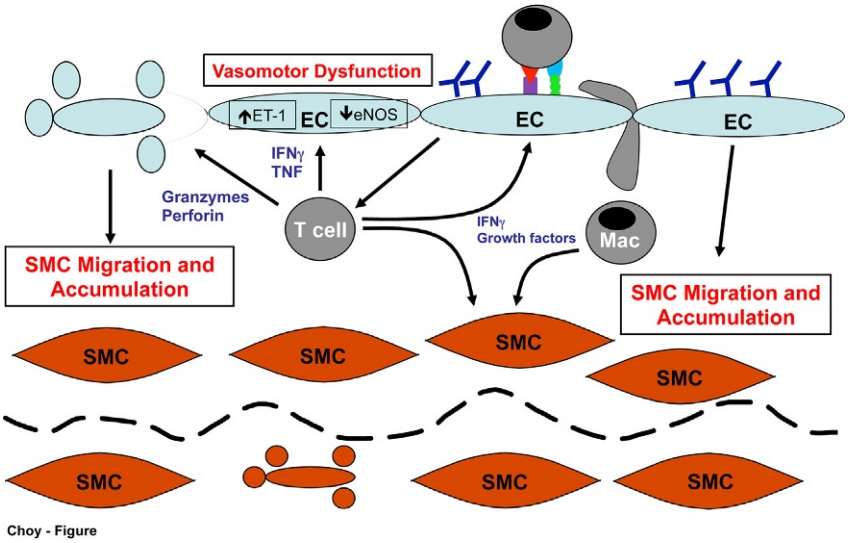

Fig. 1 Immunological causes of TA. Effector T cells within allograft arteries injure and cause dysfunction of vascular cells. Cytotoxic T cells induce endothelial cell death through granzyme B/perforin and potentially FasL pathways, which triggers a response to injury process in which smooth muscle cells (SMCs) migrate into the intima and proliferate. Effector T cells also secrete cytokines that increase inflammatory activation of the endothelium to amplify T cell and macrophage infiltration into the intima. Cytokines and growth factors produced by T cells and macrophages stimulate the intimal migration and proliferation of SMCs. IFNγ and TNF secreted by effector T cells also cause vasomotor dysfunction, characterized by reduced vasodilation and increased vasoconstriction, by reducing eNOS and increasing ET-1 expression. Antidonor antibodies contribute to TA by binding foreign MHC and non-MHC antigens on the surface of endothelial cells.

Medial smooth muscle cell death occurs in animal models of vascular rejection and TA, and injury of this vascular cell type depends on CD8 T cells and FasL (Legare et al., 2000; Hart-Matyas et al., 2010). Smooth muscle cells are normally resistant to FasL-mediated cell death but IFNγ can sensitize this vascular cell type to FasL by relocating Fas to the cell surface (Chan et al., 2000). Vascular smooth muscle cells can also be killed by granzyme B and this can occur through the extracellular proteolysis of matrix proteins (Choy et al., 2004a). In addition to CD8 T cells, neutrophils infiltrate allograft arteries early after transplantation and may also contribute to smooth muscle cell death (King et al., 2010; So et al., 2013). One mechanism by which smooth muscle cell death causes intimal thickening in TA involves the release of the chemokine CXCL12, also called stromal cell-derived factor-1, from injured cells, which triggers the migration and proliferation of mesenchymal stem cells into the intima (Li et al., 2012).

Cytokine-Mediated Vascular Cell Dysfunction

Activated T cells infiltrate allograft arteries and secrete effector cytokines. Most CD4 T cells in TA are Th1 cells that secrete IFNγ and vascular cells express IFNγ-induced proteins, indicating that they are responding to this cytokine (Burns et al., 2005). One of the main effects of IFNγ is the induction of MHC class I and II. This enables endothelial cells to activate resting memory CD8 and CD4 T cells as well as to trigger effector responses from infiltrating T cells that have been previously activated in lymphoid organs (Collins et al., 1984). The secretion of IFNγ from T cells causes intimal thickening through effects on smooth muscle cells (see later). IFNγ also induces the expression of proteins that support leukocyte infiltration into allograft grafts. This includes the chemokine IFN-inducible protein-10 and the upregulation of cell adhesion molecules, the latter occurring in cooperation with TNF (Burns et al., 2005; Pober et al., 1987). These effects contribute to arteriosclerotic thickening by exacerbating inflammation in the arterial wall.

Effector T cells also secrete TNF, which has potent inflammatory effects on the endothelium. TNF upregulates the surface expression of cell adhesion molecules, such as Intercellular adhesion molecule (ICAM) and Vascular cell adhesion molecule (VCAM), which are required for infiltration of all leukocytes into transplanted organs (Pober et al., 1987). In allograft arteries, TNF secretion by T cells likely acts as a positive feedback mechanism to amplify the infiltration of effector T cells and monocytes. Monocytes differentiate into macrophages, which can contribute to intimal thickening by secreting growth factors. Th17 cells are also present in TA and secrete IL-17. This cytokine induces similar signaling pathways as TNF. However, the level of inflammatory activation in endothelial cells induced by IL-17 alone is minimal although this cytokine can act cooperatively with TNF to synergistically upregulate cell adhesion molecules and leukocyte recruitment (Griffin et al., 2012). A main effect of IL-17 may be on the induction of cytokine production by pericytes that supports neutrophil infiltration and activation within inflamed tissues (Liu et al., 2016). The role of vascular effects of IL-17 in TA remains poorly understood because neutralization of its activity in a humanized mouse model of vascular rejection does not affect intimal thickening although a mouse model of TA using graft recipients that cannot mount Th1 responses showed that it contributes to the development of this vascular condition (Rao et al., 2008; Yuan et al., 2008).

T cell effector cytokines also change the phenotype of vascular smooth muscle cells. IFNγ upregulates the expression of MHC class II in these cells (Jonasson et al., 1988). Unlike endothelial cells, antigen presentation by smooth muscle cells does not lead to

activation of resting T cells (Murray et al., 1995). This is a result of a relative paucity of costimulatory molecules, expression of PD-L1, expression of the immune-inhibitory enzyme indoleamine 2,3-dioxygenase that depletes tryptophan and synthesizes the inhibitory metabolite kynurenine, and the secretion of the antiinflammatory molecule TGFβ (Zhang et al., 2010; Cuffy et al., 2007; Lebastchi et al., 2011; Koga et al., 2004). However, recognition of peptide-MHC on intimal smooth muscle cells by activated T cells elicits effector cytokine secretion. IFNγ and IL-17 induce expression of inflammatory cytokines and chemokines by vascular smooth muscle cells and, in this way, increases leukocyte infiltration into the arterial intima (Eid et al., 2009). Finally, IFNγ induces proliferation of vascular smooth muscle cells and this is sufficient for driving intimal proliferation in a humanized mouse model of arteriosclerosis (Tellides et al., 2000). The mitogenic effects of IFNγ are mediated through the activation of PI3K and mTOR signaling pathways, and can be inhibited by the RAS GTPase-activating protein ASK-1 interacting protein 1 (Yu et al., 2011b).

Antibody-Mediated Alterations in Vascular Cells

The development of antidonor antibodies and incidence of antibody-mediated rejection episodes correlate with the development of TA, suggesting a pathogenic role for antibodies (Petrossian et al., 1989; Cherry et al., 1992). Animal models have also established that anti-MHC antibodies can induce the development of TA (Galvani et al., 2009). Most antidonor antibodies bind to MHC molecules and cause cellular changes in endothelial cells that include increased proliferation, migration, and expression of inflammatory molecules (Jindra et al., 2008; Valenzuela et al., 2013). Increased endothelial proliferation and migration may disrupt the homeostatic properties of the luminal endothelium. This could increase vascular permeability that results from morphological changes associated with these cellular processes, which may contribute to intimal thickening (Choy et al., 2001). Antibodies also induce the expression of cell adhesion molecules that support leukocyte transendothelial migration and inflammation within the arterial wall (Valenzuela et al., 2013). In addition to having direct effects on endothelial cells, antibodies activate complement and this has immune activating properties. Complement activation by antidonor antibodies leads to the formation of membrane attack complexes, which is the terminal outcome of the complement cascade, on the surface of endothelial cells. Cell lysis does not occur but the membrane attack complex induces activation of inflammatory signaling pathways in endothelial cells that increases T cell activation (Jane-Wit et al., 2013). Overall, antibodies are likely to contribute to the development of TA by directly activating inflammatory signaling pathways in endothelial cells that pathologically alter endothelial cell phenotype and inflammatory gene expression as well as by indirectly stimulating endothelial cells through complement activation, which increases the activation of T cells by the graft endothelium.

Vasomotor Dysfunction in TA

There is also defective vasodilation and increased vasoconstriction of allograft arteries in TA, which further compromises blood flow to transplanted organs and contributes to ischemic graft damage. The endothelium is essential in regulating vasomotor function of arteries by producing vasodilatory and vasoconstrictive factors (Vanhoutte et al., 2016; Vanhoutte, 2011). Reduced agonist-induced vasodilation is observed early after heart transplantation in some patients and this precedes the development of intimal thickening (Pethig et al., 1998; Hollenberg et al., 1998, 2001).

Dysregulation of Vasodilation

One of the main mechanisms that controls the dilation of arteries is the production of the bioactive gas, nitric oxide (NO), by the endothelium (Palmer et al., 1987). NO is synthesized in endothelial cells by endothelial NO synthase (eNOS) where it diffuses into the arterial media and relaxes smooth muscle cells through the activation of soluble guanylate cyclase and downstream dephosphorylation of the cellular contractile apparatus (Janssens et al., 1992; Pollock et al., 1991; Rapoport and Murad, 1983). eNOS is basally expressed in the endothelium, and its expression and activity can be modified during immune responses to affect NO output. Agonist-induced vasodilation mediated by eNOS-derived NO is compromised in allograft arteries (Pethig et al., 1998; Hollenberg et al., 1998, 2001). Inflammatory cytokines alter the expression and function of eNOS. IFNγ and TNF secreted by effector T cells inhibit eNOS expression in endothelial cells and this contributes to pathological vasoconstriction in allograft arteries (Koh et al., 2004). Further, prolonged exposure to abnormally high levels of NO can desensitize blood vessels to NO-mediated vasodilation. In TA, NO is also produced by inducible NOS (iNOS) in infiltrating macrophages and T cells, and iNOS-derived NO can compromise vasodilation by desensitizing smooth muscle cells to this vasodilatory stimulus in allograft arteries (Koh et al., 2004; Choy et al., 2008). The regulation of eNOS by TNF and IFNγ also extends to effects on enzyme activity. Interestingly, both these cytokines increase eNOS activity and NO output by inducing the synthesis of cofactors needed for eNOS activity (Rosenkranz-Weiss et al., 1994; Katusic et al., 1998). Activated T cells also synthesize similar cofactors (Chen et al., 2011). Increased eNOS activity caused by cytokines may support acute vasodilation during inflammatory responses while decreased eNOS expression has chronic effects that are important in TA.

IL-17 also regulates eNOS expression and activity. This cytokine increases expression of eNOS, and resultant NO output, in cultured human endothelial cells through NF-κB, MAPK, and JNK signaling pathways. The level of IL-17 in human arteries with TA is positively correlated with increased eNOS protein levels and greater lumen size, suggesting that this cytokine may support increased blood flow into heart transplants by promoting outward expansion of arteries (Liu et al., 2012). However, IL-17 has been shown to inhibit eNOS activity in rat endothelial cells and contribute to hypertension in mouse models (Nguyen et al., 2013;

Madhur et al., 2010). The mechanisms controlling the context-specific effects of IL-17 on vasodilatory properties of endothelial cells are not clear and require further study.

Dysregulation of Vasoconstriction

The endothelium also produces vasoconstrictive molecules, with endothelin-1 (ET-1) being the most potent and having clear pathological indications in humans (Virdis et al., 2010). ET-1 levels are increased in TA and this factor increases pathological constriction inherent in allograft arteries (Ravalli et al., 1996; Weis et al., 1999; Larose et al., 2009). Expression of ET-1 is induced in endothelial cells by TNF, IL-1, IFNγ, and IL-6 (Lamas et al., 1992; Kahaleh and Fan, 1997). Also, the immunosuppressive drug cyclosporine may have the unintended consequence of increasing arterial vasoconstriction by increasing ET-1 levels while tacrolimus does not (Petrakopoulou et al., 2006). In addition to endothelial-dependent effects on vasoconstriction, vascular smooth muscle cells in the media have inherent myogenic constriction in response to outward flow-mediated pressure on the arterial wall. This is needed to maintain proper arterial diameter and blood flow. Myogenic constriction may be compromised by immune-mediated smooth muscle cell death during vascular rejection, which could pathologically increase intravascular hydrostatic pressure and concomitant fluid leakage into the interstitial space (Moien-Afshari et al., 2004). The resultant edema could lead to loss of ventricular compliance and heart transplant failure. Immunosuppressive drugs prevent medial damage and preserve myogenic constriction (Moien-Afshari et al., 2004).

Nonimmune Factors in TA

In addition to the immunological foundation that drives the development of TA, some nonimmune factors also contribute. Given the vascular nature of TA, risk factors associated with atherosclerotic coronary artery disease are also associated with TA. This includes age, male sex, hyperlipidemia, obesity, hypertension, hyperglycemia, and hyperhomocysteinemia (Caforio et al., 2004; Escobar et al., 1994; Valantine et al., 2001; Mehra et al., 1995; Gupta et al., 1998). These factors likely act in a similar manner as they do in coronary artery disease to increase arteriosclerotic thickening in TA. Increased and altered lipid deposition is observed in human TA (McManus et al., 1995; Lin et al., 1996). Hyperlipidemia, glucose, and homocysteine are proinflammatory and increase arterial inflammation (Gauthier et al., 1995; Kim et al., 1994; Postea et al., 2006). All of the mentioned factors activate vascular endothelial cells to increase expression of cell adhesion molecules that support leukocyte infiltration. They also promote inflammatory cytokine and chemokine secretion from vascular cells and leukocytes. This may amplify the immunologic response toward allograft arteries and/or increase endothelial dysfunction. Finally, viral infection with cytomegalovirus (CMV) is a risk factor for development of TA and prophylactic prevention of this infection reduces development of TA (Valantine et al., 1999). Most individuals exist in a state of chronic infection with CMV that is maintained in a latent state. Reactivation of the virus can occur as a result of immunosuppression and this likely contributes to the development of TA by increasing inflammation in the arterial wall, as a result of increased systemic inflammation and/or direct infection of vascular cells (La Rosa and Diamond, 2012).

Therapeutic Management of TA

The rate of late graft loss associated with TA has diminished only minimally over the past 30 years despite improvements in the formulation and delivery of calcineurin inhibitors that prevent acute rejection, thereby highlighting the therapeutic challenge of this vascular condition (Stehlik et al., 2010). Prevention of TA likely requires approaches that are able to inhibit both the chronic immune response and vascular reactions that cause arterial remodeling. Repurposing of existing drugs, such as mTOR inhibitors and statins, is promising. Experimental approaches that specifically inhibit immune responses, such as T reg therapy and B cell depletion, are being investigated in clinical trials.

Calcineurin inhibitors block calcium signaling pathways that are essential for T and B cell activation. Cyclosporine and tacrolimus are the main members of this drug class and act through a similar mechanism, although with different direct binding partners (Azzi et al., 2013). The majority of heart transplant recipients are given tacrolimus, which may have a slightly better effect at preventing the development of TA as compared to cyclosporine (Stehlik et al., 2010). The mechanism is not clear, although could be due to greater freedom from acute rejection or reduced adverse effects on lipid levels.

Proliferation signal inhibitors include everolimus and sirolimus. Both inhibit the signaling protein mTOR, a kinase that induces cellular processes needed to support cell growth and division (Fine and Kushwaha, 2016). Everolimus and sirolimus effectively inhibit lymphocyte proliferation so, in this way, are immunosuppressive. They also prevent proliferation of vascular smooth muscle cells and were initially used to prevent arteriosclerotic thickening caused by implantation of coronary artery stents (Grube and Buellesfeld, 2004). Seminal trials examining proliferation signal inhibitors in heart transplantation showed that administration of everolimus or sirolimus beginning early after transplantation reduces the development of TA (Eisen et al., 2003, 2013; Keogh et al., 2004; Andreassen et al., 2014). However, most reports do not show a clear survival benefit potentially because of complications associated with mTOR inhibition. Importantly, the therapeutic effect of these drugs on TA depends on early administration within the first year after transplant, suggesting that the pathogenic nature of TA involves targetable processes that occur early during development.

Statins have been a mainstay drug for the treatment of cardiovascular disease for several decades. This class of drugs reduces circulating cholesterol levels by inhibiting HMG CoA reductase. This effect on circulating cholesterol levels is a main mechanism of

its therapeutic effect in cardiovascular disease. Increased circulating lipid levels are a nonimmune risk factor for TA and TA lesions contain aberrant lipid accumulation. Treatment of adult heart transplant recipients with statins reduces the progression of TA and mortality (Kobashigawa et al., 1995). Potential effects of statins on TA in pediatric heart transplant recipients are less clear (Mahle et al., 2005; Greenway et al., 2016). The therapeutic effect of statins appears to be minimally related to reduction of circulating lipid levels, suggesting that other effects of these drugs are beneficial. Indeed, use of statins is related to less acute rejection and these drugs have antiinflammatory effects. Statins inhibit activation of proinflammatory signaling pathways in endothelial cells, which reduces the expression of cell adhesion molecules and prevents leukocyte transendothelial migration. These drugs may also inhibit T cell and macrophage activation (Li et al., 2002; Seljeflot et al., 2002; Forrester and Libby, 2007). The mentioned effects are established to contribute to the therapeutic effect of statins in cardiovascular disease and likely contribute to their effects in TA.

The drugs above have immune and/or vascular effects that oppose the development of TA. However, all lack specificity for immune reactions toward the graft and have undesirable side effects. Specific modulation of the immune response to prevent rejection while maintaining protective immunity, termed tolerance, is the "holy-grail" of transplantation. T regs are an essential tolerance component of the immune system that prevents immunopathological responses by inhibiting the activation and function of effector T cells (Josefowicz et al., 2012). Many experimental models have established a role for endogenous T regs in opposing immunologic rejection of many types of organ grafts as well as the potential effectiveness of administering large numbers of T regs to prevent rejection in the absence of immunosuppressive drugs (Lee et al., 2005; Joffre et al., 2008). Given the promise of these preclinical studies, phase 1/2 clinical trials are being conducted to examine the utility of this cell therapy in humans (Juvet et al., 2014). Although the majority of studies have focused on the prevention of acute transplant rejection, injection of T regs prevents the development of TA in preclinical studies using humanized mice (Nadig et al., 2010). Considerations that need to be addressed for the clinical application of T regs include optimization of protocols for expanding antigen-specific cells, precision of bulk-activated cells that are not specific for transplantation antigens, and the phenotypic stability of the injected T regs (MacDonald et al., 2012; Ezzelarab et al., 2016).

B cell depletion with rituximab has shown remarkable efficacy for the management of many immunopathological conditions. The beneficial effects of rituximab appear related to effects on antibody production and also to inhibition of T cell activation that is dependent on antigen presentation by B cells. Early stage clinical trials are underway to examine B cell depletion as an induction therapy in kidney transplant recipients (van den Hoogen et al., 2015; Tyden et al., 2009). Experimental studies have established that B cells contribute to the development of TA through antibody-dependent and independent mechanisms (Colvin et al., 2015; Zeng et al., 2014). Moreover, B cell depletion significantly reduces the severity of TA in nonhuman primate studies of heart transplantation when done in combination with costimulatory blockade for immunosuppression (Azimzadeh et al., 2016).

Conclusions

The pathogenesis of TA involves immunological processes that have distinct effects on vascular cells. This involves injury of vascular cells by T cells and antibodies that lead to altered reparative responses that drive arteriosclerotic thickening. Alterations in the phenotype of vascular cells by cytokines and antibodies also contribute to arteriosclerotic thickening by promoting inflammation and proliferation of smooth muscle cells. Vascular cells also have immunomodulatory properties that may influence the nature of immune activation locally within arteries and, in this way, define the unique pathogenesis of TA. Understanding these processes will be necessary for advancements that are able to specifically prevent immune activation toward allograft blood vessels and the arteriosclerotic response of vascular cells in order to prevent solid organ transplant failure. Similar processes may also be involved in other immune-mediated vascular diseases, such as giant cell arteritis and atherosclerosis, so knowledge of the pathogenesis of TA may contribute to further understanding of these diseases.

Cardiovascular disease (CVD), including coronary heart disease (CHD) and stroke, is one of the leading causes of death in developed countries. Advances in medical technology and changes in lifestyle during the past several decades have likely affected the prevalence of cardiovascular risk factors and thereby the incidence and mortality of CVD.

Fig. 1 shows the secular trends in mortality rates of CHD and stroke based on the data from vital statistics in three major developed countries in the world. Because the age distributions have differed among the countries and have changed with time, the mortality rates shown in these graphs were adjusted for age using the World Standard Population. In 1968, age-standardized mortality rates of CHD per 100,000 were 295 in the United States, 195 in the United Kingdom (England and Wales), and 43 in Japan. The corresponding rates in 1997 were 107, 119, and 30, respectively. During this period of three decades, the mortality rate of CHD in Japan had been much lower than in Western countries. While the mortality rates of CHD decreased greatly with time in the United States and in the United Kingdom, the decreasing trend in the CHD mortality in Japan was much smaller. On the other hand, age-standardized mortality rates of stroke per 100,000 in 1966 were 93 in the United States, 113 in the United Kingdom, and 223 in Japan, and the corresponding rates in 1997 were 35, 50, and 57, respectively. The mortality rate of stroke in Japan was much higher than in Western countries in the 1960s and decreased greatly with time during the next three decades.

Secular trends in CVD mortality during the period from 1979 to 2013 were recently published using the data from national statistics in the United Kingdom (Bhatnagar et al., 2016). Age-standardized mortality rate of total CVD in the United Kingdom declined by 70% during this period. Similar decreases were seen for both CHD and stroke (72% and 71%, respectively).

These statistics indicate that the mortality risks of CVD in developed countries have decreased with time in general, probably as a result of the improvement in medical technology and the management of cardiovascular risk factors. However, the patterns in the secular trends in CVD mortality in Japan have been completely different from those in Western countries, probably because of the different genetic and lifestyle backgrounds.

Vital statistics based on death certificates cannot determine whether the changes in mortality rates reflected a change in the incidence of CVD or the prevalence of its risk factors, or an improvement in case fatality. In addition, the diagnoses on death certificates are not always accurate and are not generally based on standardized diagnostic criteria. Accordingly, to examine accurate trends in the incidence and mortality rates of CVD and in the prevalence of risk factors, population-based studies with standardized criteria of CVD diagnosis are more useful. In the first two sections of this article, two population-based prospective studies that examined the secular trends in the incidence and mortality rates of CVD and the prevalence of its risk factors, the Framingham Heart Study (FHS) in the United States and the Hisayama Study in Japan, are introduced. The meta-analysis data from the Global Burden of Disease (GBD) studies are also introduced briefly in the last section.

The Framingham Heart Study

The FHS is a prospective epidemiological study of CVD following a two-third population sample of the residents of Framingham, Massachusetts, the United States (Sytkowski et al., 1996). The original cohort of this study consisting of 5209 participants aged 28–62 years was established in 1948. Information on newly developed CVD and its risk factors was collected through biennial health examinations including a medical interview, physical examination, and laboratory tests. Information on CVD events and deaths was collected through daily hospital and death surveillance. In the FHS, CHD was defined as myocardial infarction, angina pectoris, sudden and nonsudden coronary death, and coronary insufficiency. Stroke included both ischemic and hemorrhagic symptomatic stroke. All CVD events were diagnosed and adjudicated using standard criteria at regular meetings of a panel of physicians.

Using the prospective follow-up data from the FHS original cohort, three successive cohorts of residents aged 50–59 years without a history of CVD were established in 1950 ($n=1375$), 1960 ($n=1402$), and 1970 ($n=1432$) (Sytkowski et al., 1996).

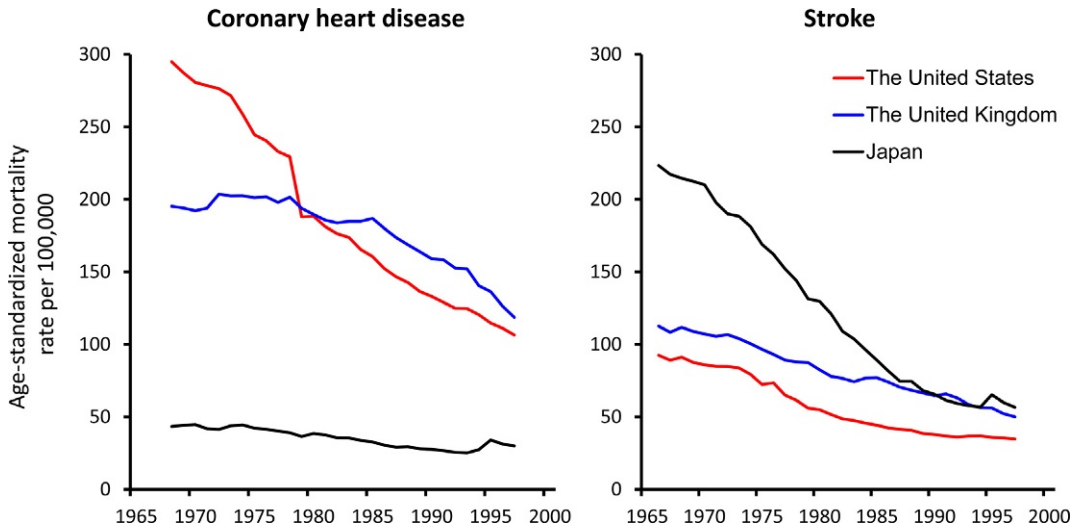

Fig. 1 Age-standardized mortality rates of coronary heart disease and stroke per 100,000 in the United States, the United Kingdom (England and Wales), and Japan, from the vital statistics (World Health Statistics Annual).

Then, the prevalence of risk factors at baseline and the incidence and mortality of CVD during the next 20 years were compared among the three cohorts established at different time points.

Prevalence of Risk Factors in Framingham

Prevalence or mean values of risk factors at the baseline examinations in 1950, 1960, and 1970 in the FHS are summarized in Table 1 (Sytkowski et al., 1996). In both men and women, mean levels of systolic and diastolic blood pressure decreased significantly with time as a result of the spread of antihypertensive medication over the years from 1950 to 1970. During this 20-year period, the prevalence of diabetes increased significantly with time in both sexes. The mean values of total cholesterol decreased significantly with time in women, but did not show a clear change in men. The mean values of body mass index increased significantly and the smoking rates decreased significantly in men. In contrast, the mean values of body mass index decreased significantly and the smoking rates increased significantly in women.

CVD Incidence and Mortality in Framingham

For each cohort, the participants were followed up for 20 years from the baseline examination (Sytkowski et al., 1996). Fig. 2 shows the secular trends in the 20-year cumulative incidence and mortality of CHD and stroke in the FHS cohorts. In both men and women, the risks of CHD incidence were much higher than those of stroke incidence. In men, the cumulative incidence of CHD and stroke showed no clear change, probably because the benefits from the improved blood pressure control and decreased smoking rates were negated by the increased prevalence of diabetes and obesity. In women, the cumulative incidence of CHD and stroke decreased significantly with time, probably as a result of the decreased levels of blood pressure, total cholesterol, and body mass

Table 1 Prevalence or mean values of risk factors at baseline of each cohort, the Framingham Heart Study

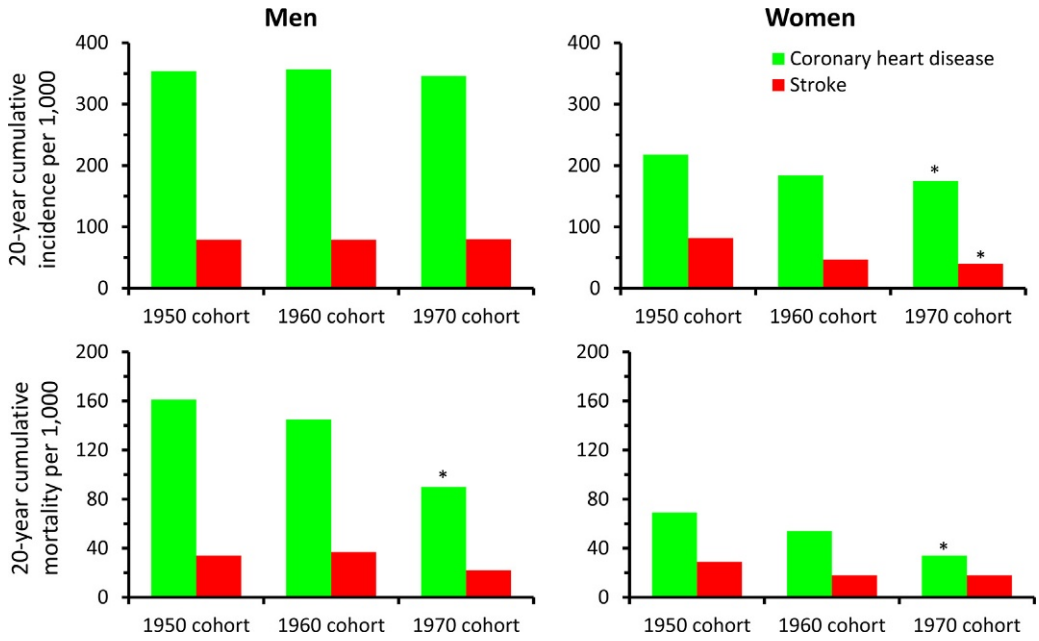

Fig. 2 Cumulative incidence (upper graphs) and mortality (lower graphs) of coronary heart disease and stroke per 1000 during 20 years of follow-up of each cohort, the Framingham Heart Study. $^{*}P$ for trend <0.05. Adapted from Sytkowski, P. A., D'Agostino, R. B., Belanger, A. and Kannel, W. B. (1996). Sex and time trends in cardiovascular disease incidence and mortality: the Framingham Heart Study, 1950–1989. *American Journal of Epidemiology* **143**, 338–350.

index, although the increased prevalence of diabetes and smoking rates might have influenced the CVD risk to some degree. The mortality risks of CHD in both sexes decreased significantly with time probably as a result of the improvement in medical management and reduction in case fatality after CHD, as well as a decreased incidence of CHD in women.

The Hisayama Study

The Hisayama Study is a population-based prospective study for CVD in Japan. The town of Hisayama is located in the eastern suburb of the Fukuoka metropolitan area on Kyushu Island, Japan. According to the national census, the age and occupational distributions in the town were very similar to those in the country of Japan as a whole (Hata et al., 2013). Since 1961, health examinations for residents of Hisayama aged ≥ 40 years have been repeated annually. To compare the incidence and mortality rates of CVD and the prevalence of its risk factors, five cohorts, consisting of residents aged ≥ 40 years without a history of CVD, established in 1961 ($n=1618$), 1974 ($n=2038$), 1983 ($n=2459$), 1993 ($n=1983$), and 2002 ($n=3108$), were used (Hata et al., 2013). Then, the prevalence of risk factors and the incidence and mortality of CVD during the next 7 years were compared among the cohorts. To compare the proportion of ischemic stroke subtypes or the location of intracerebral hematoma, three cohorts consisting of CVD-free residents aged ≥ 40 years established in 1961 ($n=1618$), 1974 ($n=2038$), and 1988 ($n=2637$) were followed up prospectively over the next 13 years, respectively (Kubo et al., 2008; Gotoh et al., 2014). Information on newly developed CVD was collected through annual health examinations and mail or telephone interviews, and a daily monitoring system organized by the study team, local physicians, and town government. All CVD events were diagnosed, classified, and adjudicated by a panel discussion of study physicians including cardiologists and stroke neurologists according to the standardized diagnostic criteria.

Prevalence of Risk Factors in Hisayama

Table 2 summarizes the age-adjusted prevalence rates or mean values of cardiovascular risk factors at baseline examination in the five Hisayama cohorts (Hata et al., 2013). The prevalence of hypertension increased slightly during the earlier period from 1961 to 1983 and then decreased slightly during the more recent period from 1983 to 2002, but these changes were not drastic. However, the mean values of systolic blood pressure among participants with hypertension decreased significantly as a result of the spread of antihypertensive treatment over the study period. In contrast, the prevalence of metabolic risk factors, namely, glucose intolerance (including diabetes mellitus and prediabetes), hypercholesterolemia, and obesity, increased significantly with time in both sexes, probably due to the westernization of dietary habits and physical inactivity as a result of motorization. The smoking rates in men and women decreased significantly from 1961 to 1993.

Table 2 Age-adjusted prevalence or mean values of risk factors at baseline of each cohort, the Hisayama Study

	1961	*1974*	*1983*	*1993*	*2002*

CVD Incidence and Mortality in Hisayama

For each of the five cohorts, the participants were followed up for 7 years from the baseline examination. Fig. 3 shows the secular trends in the age-adjusted incidence rates of acute myocardial infarction (AMI), total stroke, and each stroke subtype in the Hisayama cohorts (Hata et al., 2013). In both men and women, the incidence rates of AMI were much lower than those of stroke over the past half century. The incidence rates of AMI did not show a clear change during the study period. In contrast, the incidence rates of total stroke and ischemic stroke decreased greatly in the earlier period from the 1960s to the 1970s, but these decreasing trends slowed down in the subsequent period in both sexes. While the incidence rate of intracerebral hemorrhage in men decreased

consistently from the 1960s to the 1990s, the incidence of intracerebral hemorrhage in women did not show a clear change over the study period.

In this study, the incidence rates of total and ischemic stroke decreased mainly in the earlier period, probably because of the improvement in hypertension management resulting from the increased use of antihypertensive agents, reduction in salt consumption, and decreasing trends in smoking rates. However, the decreasing trends in the incidence of total and ischemic stroke slowed down in recent years, and there was no clear change in the incidence of AMI over the study period, probably because the benefits of hypertension control and smoking cessation were negated by the increasing prevalence of metabolic risk factors such as glucose intolerance, hypercholesterolemia, and obesity. While the decreased incidence of intracerebral hemorrhage in men was likely attributable to the improvement in hypertension management, a comparable trend of decrease was not seen in women, probably because of the small number of events. In addition, the Hisayama Study previously reported that alcohol consumption and hypertension synergistically increased the risk of intracerebral hemorrhage (Kiyohara et al., 1995). Thus the impact of hypertension on the development of intracerebral hemorrhage may have been smaller in women because the drinking rate in women was much lower than that in men.

Then, the participants who developed stroke or AMI during each 7-year period were further followed up for the subsequent 5 years. **Fig. 4** shows the age- and sex-adjusted survival curves after the onset of stroke or AMI in each cohort (Hata et al., 2013). The estimated 5-year survival rates after stroke and AMI improved greatly from the 1960s cohort to the 2000s cohort as a result of an improvement in medical management in the acute and chronic phases of CVD.

Fig. 5 shows the secular trends in the mortality rates from AMI and stroke in the same Hisayama cohorts during each 7-year period (Hata et al., 2013). The mortality rates from stroke in both sexes decreased significantly as a result of the decreased incidence and improved survival rates.

Ischemic Stroke Subtypes in Hisayama

Ischemic stroke was further classified into subtypes according to the size of affected arteries and the mechanisms of ischemia, namely, lacunar infarction, atherothrombotic infarction, and cardioembolic stroke. In the Hisayama Study, three cohorts without a history of CVD were established in 1961, 1974, and 1988 and followed up for 13 years each. During the follow-up periods, ischemic stroke events were observed in 134 subjects in the 1961 cohort, 142 subjects in the 1974 cohort, and 154 subjects in the 1988 cohort (Kubo et al., 2008). **Fig. 6** shows the secular trends in the proportion of ischemic stroke subtypes in each cohort. The proportion of lacunar infarction, the most common subtype of ischemic stroke in Japan, decreased with time from 62% in the 1961 cohort to 48% in the 1988 cohort. In contrast, the proportion of the other two subtypes, namely, atherothrombotic and cardioembolic infarction, increased with time. Lacunar infarction develops by the occlusion of small perforating arteries in deep parts of the brain, such as the basal ganglia, thalamus, and brainstem, as a result of lipohyalinosis or microatheroma mainly caused by hypertension. The decreased proportion of lacunar infarction in the Hisayama Study may be explained by an improvement in hypertension control during the study period. Atherothrombotic infarction is developed by atherosclerosis of large intracerebral or extracerebral arteries and its risk factors include metabolic disorders such as hypercholesterolemia and diabetes. Cardioembolic infarction is developed by thromboembolism from the heart in patients with atrial fibrillation or other cardiac diseases. The proportions of

atherothrombotic and cardioembolic infarction increased with time probably as a result of increased prevalence of metabolic risk factors and increased number of patients with atrial fibrillation as a result of the super-aged society in Japan (Ohsawa et al., 2005).

Location of Intracerebral Hemorrhage in Hisayama

In the same 13-year cohorts started in 1961, 1974, and 1988, intracerebral hemorrhage events were observed in 43, 33, and 53 subjects, respectively (Gotoh et al., 2014). Fig. 6 shows the secular trends in the distribution of hematoma location among

patients with intracerebral hemorrhage. In the 1961 cohort, the most common location of hematoma was the putamen. While the proportion of putaminal hemorrhage decreased steadily, the proportion of thalamic hemorrhage increased with time. In this study, the incidence of putaminal hemorrhage decreased with time mainly in the relatively young age group (60–69 years) and the incidence of thalamic hemorrhage increased especially in the very old subjects ($\geq$80 years) (Gotoh et al., 2014). The precise reasons for these findings are not clear, but the influence of aging and hypertension, the most powerful risk factors for hemorrhagic stroke, may differ among the locations studied.

The GBD Studies

The GBD studies (GBD 2010 and GBD 2013) have estimated country-specific and global incidence and mortality of stroke using the meta-analysis data from published studies in the world. The detailed country-specific data from the GBD 2010, which examined the secular trends in stroke burden during 1990–2010, are available elsewhere (Krishnamurthi et al., 2013). In this two decades, incidence rates of ischemic and hemorrhagic stroke decreased in high-income countries (13% for ischemic stroke and 19% for hemorrhagic stroke), probably due to improved prevention strategies and better health care. In contrast, in low- and middle-income countries, incidence rates of ischemic and hemorrhagic stroke increased in the same period (6% for ischemic stroke and 22% for hemorrhagic stroke). In these countries, diseases related to infection and undernutrition have been replaced with more chronic diseases such as stroke and other CVD as a result of changes in lifestyles, industrialization, and urbanization. During the same period, mortality rates of ischemic and hemorrhagic stroke showed decreasing trends in high-income countries (37% for ischemic stroke and 38% for hemorrhagic stroke) and in low- and middle-income countries (14% for ischemic stroke and 23% for hemorrhagic stroke) as a result of improved acute and chronic treatment of stroke.

Sex difference in stroke incidence is also an important issue. In the GBD 2013 study, incidence rates of ischemic and hemorrhagic stroke in 1990 and 2013 were compared between men and women (Barker-Collo et al., 2015). Age-adjusted incidence rates of ischemic stroke per 100,000 showed a nonsignificant decrease in men (147.40 in 1990 and 132.77 in 2013) and a significant decrease in women (113.31 in 1990 and 98.85 in 2013). For hemorrhagic stroke, there was little change detected in incidence over time (65.31 in 1990 and 64.89 in 2013 for men; 44.25 in 1990 and 45.48 in 2013 for women). Men had a higher incidence of ischemic stroke than women probably because cardiovascular risk factors are more frequent and severe in men than in women.

The risk of stroke in young adults is generally lower than that of older adults, but the societal impact is high due to the greater number of years of life lost and the resulting loss in productivity. The GBD 2013 study examined the mortality rates of stroke in young adults aged 20–64 years in 1990 and 2013 (Krishnamurthi et al., 2015). During this period, mortality rates of stroke per 100,000 young adults declined in both developing countries (47 in 1990 and 39 in 2013) and developed countries (33.3 in 1990 and 23.5 in 2013) as a result of improved treatment of stroke. However, mortality rate of stroke in developing countries was higher than in developed countries, suggesting that a more aggressive approach toward primary prevention and adequate healthcare services is required to narrow these disparities.

Introduction

Heart failure (HF) is a syndrome that affects over 5 million people in the United States and countless additional people across the world (Mozaffarian et al., 2016). A significant feature of HF is the episodic worsening of congestive symptoms, often referred to as acutely decompensated HF (ADHF), which often leads to a hospitalization. The major hallmark of most ADHF hospitalizations is retention of fluid leading, which is the cause of characteristics HF symptoms such dyspnea, orthopnea, and edema (Ambrosy et al., 2014). As such, the main focus of most HF hospitalizations is delivery of therapies aimed at adequately removing excess volume in order to improve symptoms of congestion.

Despite this seemingly straightforward strategy, historical data suggests inadequate volume removal during many ADHF hospitalizations (Fonarow and Horwich, 2003). Incomplete or inadequate therapies can lead to subsequent worsening outcomes including recurrent hospitalizations and decline in overall functional status (Setoguchi et al., 2007; Crespo-Leiro et al., 2016). Therefore, it is paramount to understand methods aimed to facilitate volume removal during an ADHF hospitalization. One such method is extracorporeal removal of fluid, otherwise known as ultrafiltration (UF) or aquapheresis.

Historical Background

The utilization of an extracorporeal circuit to manipulate physiologic volume status can trace its roots back to early attempts to treat acute renal failure. These early attempts were focused on the removal of unwanted metabolic by-products due to inadequate filtration by failing kidneys using a dialysis membrane as part of an "artificial kidney" (Kolff et al., 1944). Subsequent evolution led to the use of intermittent hemodialysis to treat renal failure (Scribner et al., 1960). The modern experience with hemodialysis focuses on the appropriate removal of metabolic by-products unable to be filtered by the failing kidney as well as control of volume status, which is also controlled by the hemodialysis circuit (Flythe and Brookhart, 2014; Weiner et al., 2014).

In the setting of ADHF, however, filtration of metabolic by-products is not necessarily required. Although renal function is known to be impaired in many HF scenarios, there is typically not a complete loss of native renal clearance (Patel et al., 2010). In many instances, appropriate removal of excess volume can result in restoration of renal function (Mullens et al., 2009). Therefore, specifically targeting the excess fluid retention that occurs in ADHF by using extracorporeal means could be an effective strategy. Indeed, early exploratory studies utilized variations of traditional dialysis circuits to treat HF with some degree of efficacy. These early results led to the development of specific UF filters, designed to remove plasma water alone, to be used in HF patients (Costanzo et al., 2017).

Alternative Therapies

The major accepted alternate therapy for volume removal during an ADHF event has been intravenous loop diuretics such as furosemide. Robust clinical data supporting the use of diuretic therapies in the settings as well as data guiding dosing strategies is somewhat sparse. Diuretic therapies earned their place in the treatment of HF prior to the advent of clinical testing, and as such have always been considered "gold standard" against which other therapies have been compared.

 https://doi.org/10.1016/B978-0-12-809657-4.99661-3

Generally, intravenous loop diuretics are recommended for patients presenting with worsening signs of congestion at a dose equivalent to or greater than their baseline dosing (Yancy et al., 2013). Although typically effective in improving symptoms and volume overload, the use of intravenous loops diuretics may incur some physiologic cost. First, the mechanism of action of loop diuretics results in hypotonic urine, implying less total sodium loss per volume of fluid removed compared to the plasma sodium concentration of the patient. This effect may counteract the intended goal of removing both sodium and water in volume overloaded patients (Costanzo et al., 2017). Additionally, the use of loop diuretics activates neurohormonal pathways that are considered to be detrimental in the setting of HF. One consequence of such activation is diminished response to the same loop diuretics being utilized for therapy (Braam et al., 2012). Historically, utilization of diuretic-based strategies has not resulted in significant improvement in the overall treatment of ADHF (Gheorghiade and Filippatos, 2005).

Some of the difficulties in demonstrating improved outcomes with the use of diuretic therapies may lie in the lack of clarity currently available guiding dosing strategies. This issue was addressed in the Diuretic Optimization Strategies Evaluation (DOSE) Trial. In this trial, 308 patients presenting with ADHF for randomized and a 2×2 factorial designed to receive either low- or high-dose furosemide as either a continuous infusion or via bolus dosing. Patients were followed for the primary endpoint of a change in their own global assessment of symptoms and changes in renal function within the initial 72 h of therapy. Secondary endpoints measured included worsening kidney function. Ultimately, no difference was demonstrated between bolus and continuous infusions, and no statistical difference was found between low- and high-dose strategies (Felker et al., 2011). At present, the prompt administration of diuretic therapy for ADHF remains a Class I recommendation; however adjustments in therapy due to inadequate response, including increasing diuretic dosing or adding a second diuretic agent, carry Class IIa recommendations (Yancy et al., 2013). Specific recommendations on dosing strategies are still lacking.

Tolvaptan, an arginine vasopressin antagonist, can be used to facilitate volume removal. By utilizing a mechanism unique compared to loop diuretics, tolvaptan aims to facilitate free water excretion without activating the neurohormonal pathways seen with loop diuretics. When used in the treatment of an acute decompensation event, tolvaptan was initially shown to improve markers of dyspnea and fluid loss, along with serum sodium levels. However, the effect of tolvaptan was no better than placebo when added to standard HF therapies when assessing long-term outcomes (Konstam et al., 2007). In a follow-up investigation, the Targeting Acute Congestion with Tolvaptan in Congestive Heart Failure (TACTICS-HF) trial, tolvaptan was not associated with improvements in dyspnea but did show greater weight loss and fluid loss (Felker et al., 2017). Currently approved uses for tolvaptan are limited to those patients with hyponatremia and ADHF, which is a Class IIb recommendation (Yancy et al., 2013). The routine use of tolvaptan for ADHF, though, is not supported (Starling and Young, 2017).

Description of UF

UF is an extracorporeal circuit that passes blood through a semipermeable membrane. The creation of a pressure gradient across the membrane allows passage of an iso-osmotic and isonatremic filtrate that is removed from circulation. Hematologic components and other larger molecules, namely potassium, do not pass through the membrane and are returned to the patient. The resultant loss of fluid is achieved without the need to administer loop diuretics and hence can be considered a "diuretic holiday" during therapy (Ronco et al., 2001; Costanzo et al., 2017).

Selection of the membrane to determine which molecules are filtered distinguishes UF from other forms of hemofiltration. Both goals can be achieved through the use of traditional hemodialysis machines if adjusted to the desired effect (Sharma et al., 2001). For situations where only UF is required, such as volume overload in ADHF, two smaller, specialized UF machines exist. These devices allow the use of temporary peripheral, and not central, vascular access to connect a patient with the circuit (Jaski et al., 2003). Depictions of the circuits are shown in **Fig. 1** (Costanzo et al., 2017).

During a treatment course, the rate of fluid removal occurs at a rate set by the user. This rate is adjustable and should be set at a level to allow adequate volume removal without excessively depleting vascular volume, which can lead to hypotension or hypoperfusion (Costanzo, 2008). Theoretically, the removal rate should be set a level equal to the plasma refill rate to allow refilling of the vascular volume by "third spaced" fluid (Marenzi et al., 2001). Although conceptually relatively simple, matching this rate is clinically challenging since it is currently immeasurable in clinical situations. Once the patient's volume status has reached an optimal level, the circuit is discontinued and standard therapies can be resumed.

Clinical Evidence Regarding UF

Several clinical trials have been conducted to examine the efficacy of UF in the treatment of ADHF. Selected studies are described below:

1. Early Ultrafiltration in Patients With Decompensated Heart Failure and Observed Resistance to Intervention with Diuretic Agents (EUPHORIA) trial

   Nonrandomized trial enrolling 20 patients, all of which were treated with UF early in the presentation of ADHF (prior to initiation of IV diuretics). UF resulted in short length of stays with adequate volume removal. Rehospitalizations rates were low following therapy (Costanzo et al., 2005).

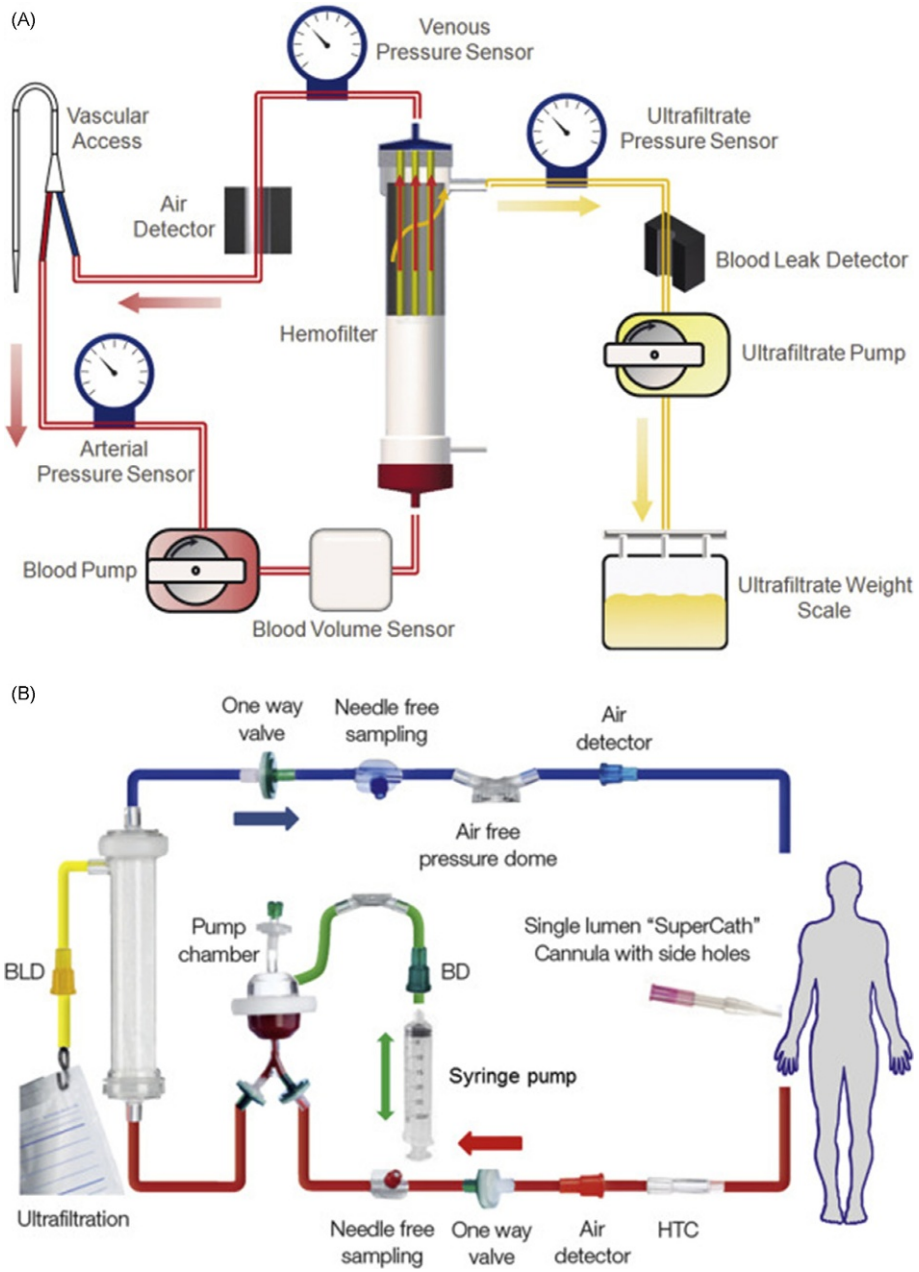

Fig. 1 (A) UF circuit using a multi-lumen venous access catheter allowing blood to pass through a hemofilter to extract ultrafiltrate prior to return into the patient. (B) UF circuit using a single-lumen, multihole peripheral access point. Two one-way valves guide blood flow through a syringe pump-controlled chamber and across a filter from which the ultrafiltrate is removed (Costanzo et al., 2017).

2. Ultrafiltration Versus IV Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure (UNLOAD) trial
   Randomized controlled trial enrolling 200 patients, treated with either early UF or standard diuretic therapy when presenting with ADHF. Greater weight loss and fluid loss was seen in the UF arm, with suggested lasting benefits after discharge. UF patients had lower diuretic regimens postdischarged compared to IV diuretic patients (Costanzo et al., 2007).
3. Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS-HF) trial
   Randomized controlled trial intended to enroll 200 patients but halted after 188 enrollments due to worsening renal function in the UF arm. UF was compared to stepped pharmacologic therapy (IV diuretics) for the bivariate endpoint of weight change and kidney function change. In the endpoint analysis, UF fared worse than IV therapies (Bart et al., 2012).
4. Continuous Ultrafiltration for Congestive Heart Failure (CUORE) trial
   Randomized controlled trial comparing adjustable-rate ultrafiltration (AUF) to standard IV therapies for ADHF. A total of 64 patients were enrolled, with those treated by AUF were less likely to be rehospitalized for ADHF within the first year (Marenzi et al., 2014).

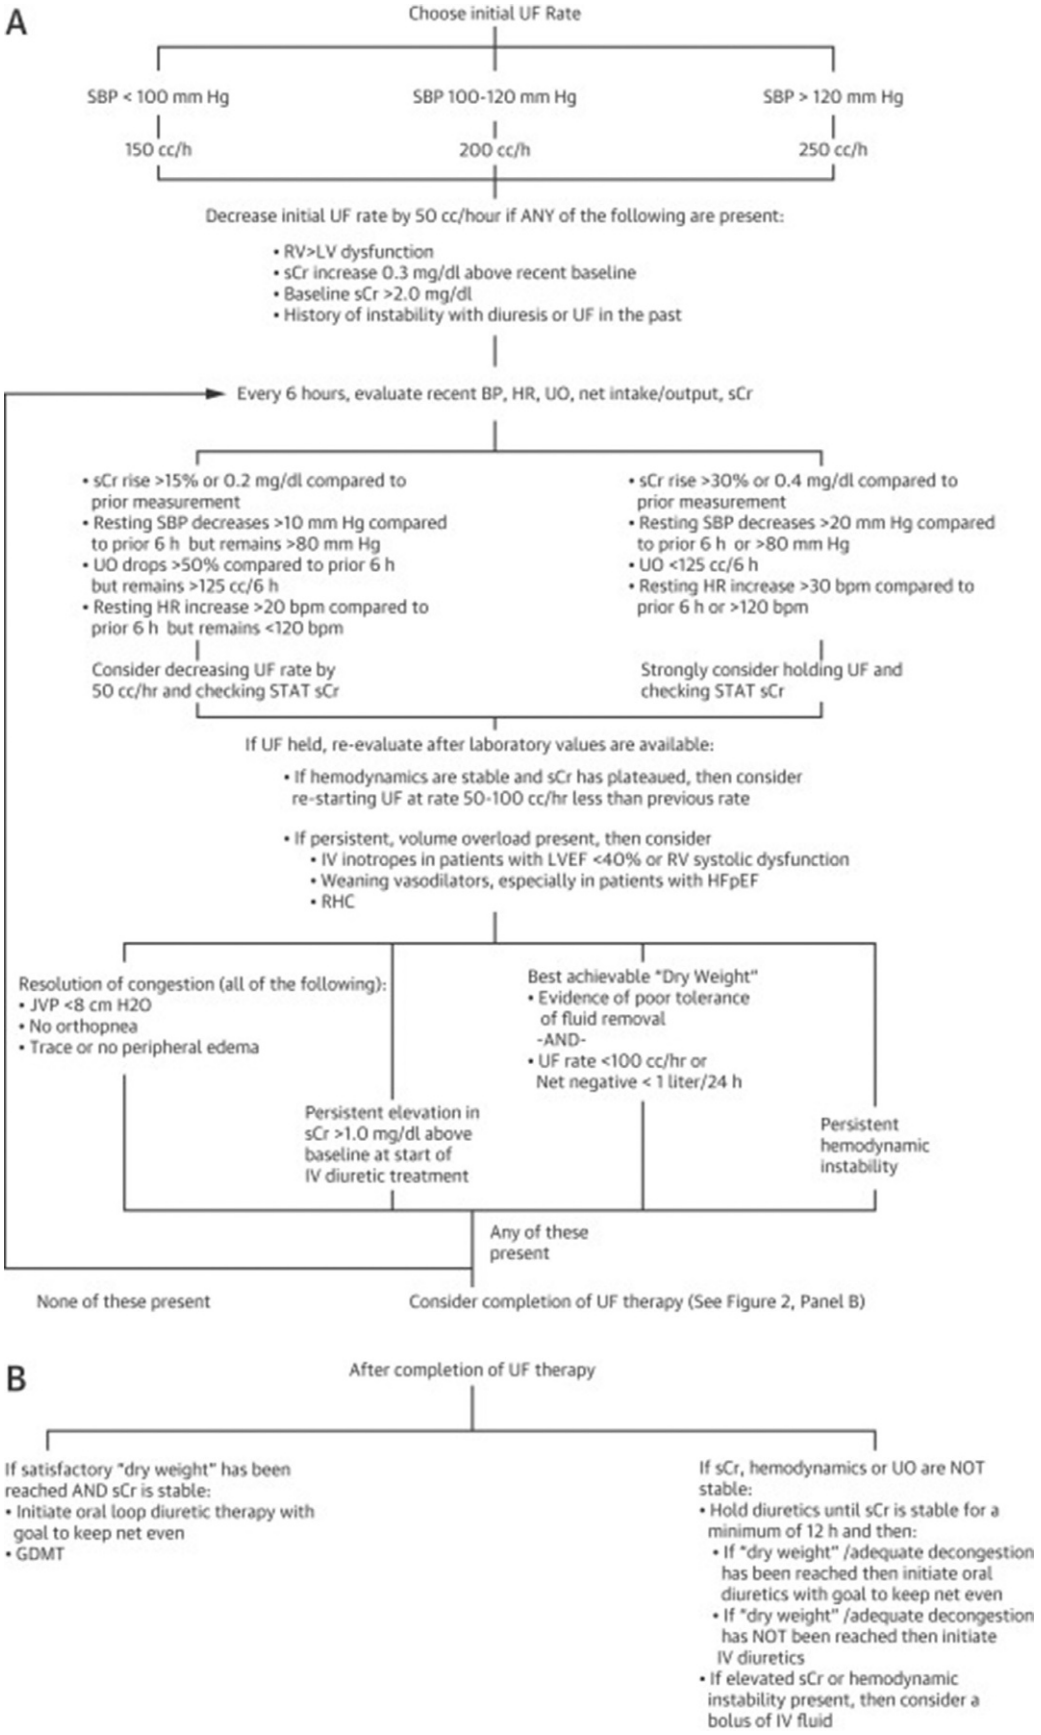

Fig. 2 Suggested algorithm for UF management in treating ADHF. (Costanzo MR, et al, 2017)

5. Aquapharesis Versus Intravenous Diuretics and Hospitalizations for Heart Failure (AVOID-HF) trial

   Randomized controlled trial intended to compare AUF to stepped pharmacologic therapy for the treatment of ADHF. The trial designed called for 810 patients to be enrolled in order to detect a difference in 90-day readmissions for HF. The trial was discontinued after 224 patients following withdrawal of sponsor support. No safety or efficacy concerns were identified, but the trial was underpowered to demonstrate the primary endpoint. Improved outcomes with AUF were suggested but did not meet prespecified criteria for significance (Costanzo et al., 2016).

With the exception of CARRESS-HF, the remaining trials suggest efficacy of UF in the treatment of ADHF. Although enrollment was small in most trials, there exists a fairly consistent signal of improved outcomes beyond the hospitalization when using UF for fluid removal compared to IV diuretics. Nonetheless, the safety concerns and worsening renal function noted in CARRESS-HF must be considered. In evaluating the result of CARRESS-HF further, two specific considerations are noteworthy. First, the signal for worsening renal function in the trial was noted to be an increase of serum creatinine by 0.23 mg/dL when using UF compared to IV diuretics (Bart et al., 2012). This small incremental increase was statistically significant, but the clinical relevance of this change is debatable. A more widely used definition of worsening renal function is a change in serum creatinine of $\geq$0.3 mg/dL (Mehta et al., 2007). If this more standardized definition of kidney injury were to be applied, the true magnitude of worsening kidney function seen in CARRESS-HF may be diminished.

Second, the protocol-specified use of UF was universally set at 200 mL/h of fluid removal (Bart et al., 2012). The use of the same rate for all patients goes against the need to match the needed volume removal rate, either by estimating the plasma refill rate or by individualizing for blood pressure and total excess volume present. The efficacy as well as the safety profile of UF may have been affected the chosen approach. These concerns would have been better addressed by the AVOID-HF trial, which was designed to compare adjustable-rate UF to adjusted medical therapy. The aforementioned early termination of the trial, unfortunately, leaves the question of AUF versus adjustable diuretic therapy unanswered.

Current Status of UF

At present, UF carries a Class IIb recommendation for use in ADHF for both patients in whom response to standard therapy is suboptimal and in patients who have significant signs and symptoms of volume overload (Yancy et al., 2013). UF can be considered as an alternative to intravenous diuretics to treat ADHF, especially when high doses of diuretics may be anticipated. Specific guidelines on the management of UF have not yet been conclusively been proven, but suggested algorithms exist to guide clinicians (**Fig. 2**). UF can be delivered at the bedside using compact machines and may provide lasting benefits beyond the acute treatment phase. Ongoing investigations will help determine the validity of the proposed benefits, as well as better inform the patient selection and management portions of the knowledge base.

Introduction

Coronary artery disease (CAD) is characterized by stable or dynamic atherosclerotic obstructions of the coronary vasculature that may result in myocardial ischemia or infarction. CAD itself is a broad descriptor that encompasses several syndromes that may be broadly divided into two categories: the acute coronary syndromes (ACS) and stable ischemic heart disease (SIHD).

The acute coronary syndromes may be further divided into three subcategories: ST-segment elevation myocardial infarction (STEMI), non-ST-segment elevation myocardial infarction (NSTEMI), and unstable angina (UA). In patients with STEMI (also referred to as STE-ACS), plaque instability occurs, typically with components of ulceration, plaque rupture, vasospasm and thrombosis. This results in complete occlusion of the affected coronary artery and necrosis of the subtended myocardium if coronary revascularization is not rapidly achieved. In contrast, NSTEMI and UA are typically the result of subtotal, non-occlusive coronary obstruction resulting in either reversible ischemia (UA) or myocardial necrosis (NSTEMI).

As such, NSTEMI and UA represent different points on the same pathophysiologic continuum of subtotal dynamic coronary artery occlusion, with the distinguishing feature being the presence of elevated cardiac biomarkers in patients with NSTEMI. Furthermore, at presentation these two entities may be indistinguishable owing to initially normal cardiac biomarkers in both settings, and, thus, the initial management of NSTEMI and UA is similar. Given their pathophysiologic similarities, the most recent ACC/AHA guidelines and others have combined these entities into a single group termed the non-ST elevation acute coronary syndromes (NSTE-ACS) (Amsterdam et al., 2014; Roffi et al., 2015). With the advent of ultra-high-sensitive cardiac biomarker assays, very low levels of biomarkers can now be detected, thereby making a biomarker-negative category of ACS increasingly less common (Braunwald and Morrow, 2013). However, for the present time the traditional framework continues to have clinical utility. This chapter will review the current clinical understanding of unstable angina, focusing on its presentation, diagnosis, and management.

Presentation and Diagnosis of Unstable Angina

Presentation

The clinical hallmark of coronary artery disease is that of anginal chest pain, which was originally described by Heberden in 1772. This description has stood the test of time, and is worth revisiting: "They who are afflicted with it, are seized while they are walking (more especially if it be up hill, and soon after eating), with a painful and most disagreeable sensation in the breast, which seems as if it would extinguish life, if it were to increase or continue; but the moment they stand still, all this uneasiness vanishes" (Heberden, 1772). The contemporary description of classic angina is that of a pressure-like discomfort that is deep substernal in location but not precisely localized, that builds over minutes rather than achieving maximum intensity at its onset, that is provoked by exertion or by

Table 1 Performance of selected clinical findings in ACS

Clinical finding	*LR*	*CI*	*Sens. (%)*	*Spec. (%)*
Chest pain radiating to both arms	2.6	(1.8–3.7)	11	96
Pain similar to prior ischemia	2.2	(2.0–2.6)	47	79
Change in pattern over 24 h	2.0	(1.6–2.5)	27	86
Typical chest pain	1.9	(0.9–2.9)	66	66
Radiation to neck/jaw	1.5	(1.3–1.8)	24	84

Modified from Fanaroff, A. C., Rymer, J. A., Goldstein, S. A., Simel, D. L., Newby, L. K. (2015). Does this patient with chest pain have acute coronary syndrome?: The rational clinical examination systematic review. *JAMA* **314** (18), 1955–1965. https://doi.org/10.1001/jama.2015.12735.

emotional stress, and is relieved with rest or the administration of nitroglycerin. When added to age and gender, the extent to which a patient's symptoms are typical of angina is predictive of the presence of coronary artery disease at angiography (Diamond and Forrester, 1979; Fihn et al., 2012).

While this description of typical angina remains useful, atypical symptoms are present in many patients, particularly in the elderly, diabetics, and females. A review of national myocardial infarction databases demonstrated heterogeneity in symptoms at presentation, and warned against the expectation of typical symptoms in all patients suspected of having ACS (Canto et al., 2000). Dyspnea in isolation is the most commonly noted atypical anginal symptom; other less frequent "angina equivalents" include nausea, epigastric pain, and fatigue.

The pattern of anginal symptoms defines the stability of the coronary syndrome. Chronic stable angina is that which occurs on exertion, usually after a predictable or reproducible amount of effort. In contrast, the symptoms of unstable angina/ACS may occur in several patterns including the presence of symptoms at rest, symptoms that occur with less exertion than previously required, or symptoms occurring for a longer duration (generally greater than 20 min) or with more intensity than usual. The new appearance of angina is also compatible with the presentation of an acute coronary syndrome. It should be noted that the symptoms of UA may be indistinguishable from those of MI, although the later tends to be more intense and prolonged. A classification scheme of different subtypes of UA based on the clinical phenotype has been proposed in the past, but is not routinely used in clinical practice (Braunwald, 1989; Hamm and Braunwald, 2000).

The variety of potential symptoms makes the clinical evaluation of patients suspected of having unstable angina challenging. A recent systematic review and meta-analysis examined the test performance of symptoms in patients presenting with suspected acute coronary syndromes (**Table 1**) (Fanaroff et al., 2015). Pooling from multiple studies, the investigators calculated the test performance characteristics of various presenting symptoms in terms of their sensitivity, specificity, and positive and negative likelihood ratios (LR). From this data, symptoms that were strong predictors of acute coronary syndrome included pain that radiated to both arms (LR 2.6), pain similar to prior episodes of ischemia (LR 2.2), a change in symptom pattern over the preceding 24 h (LR 2.0), pain that is worse with exertion (LR 1.5–1.8) and pain that radiates to the jaw or neck (LR 1.5). "Typical" chest pain had modest sensitivity and specificity (0.66 for both) and while a positive likelihood ratio was noted (LR 1.9) the confidence interval crossed 1 and did not meet statistical significance. Other symptoms that were associated with a low likelihood ratio included pleuritic pain (LR 0.35–0.36) and associated syncope (LR 0.55).

Physical Examination

The physical examination in acute coronary syndrome may be unremarkable; however, important clinical features may be present and may be prognostically important and useful in determining the timing of revascularization and in triage of the patient to the appropriate level of care. A general inspection provides information about the overall comfort of the patient, and may identify associated findings such as diaphoresis, dyspnea, or postures such as Levine's sign (fist clutched over the left chest) suggesting ischemic chest discomfort. Cardiac auscultation may reveal a new murmur suggestive of ischemic mitral regurgitation, a third heart sound suggestive of ventricular volume overload, or a fourth heart sound consistent with impaired diastolic filling. The physical examination may also identify evidence of an alternative diagnosis including musculoskeletal pain (often reproducible on examination), aortic dissection (asymmetric pulses and discrepant BP in upper extremities), pericarditis (friction rub, pulsus paradoxus), pneumothorax (unilateral diminished breath sounds), and pneumonia (rhonchi or pleural rub).

The evidence base for the utility of these physical findings in the setting of UA is rather sparse. A recent systematic review found only one high quality study on physical examination findings in 700 patients with suspected ACS. None of the physical signs studied had a positive likelihood ratio. The physical exam finding with the highest positive LR was hypotension with an LR of 3.9 (95% CI 0.98–15). The sign with the lowest LR was chest pain that was reproduced with palpation, with an LR of 0.28 (95% CI 0.14–0.54) (Fanaroff et al., 2015).

A particular focus at the time of presentation should be the identification of heart failure, as this portends a worse prognosis in all forms of ACS. The Killip classification scheme was originally developed in the 1960s, and provides a prognostic framework for the patient with ACS based entirely on clinical examination findings compatible with heart failure (see **Table 2**). While this classification was originally developed in patients with acute MI, its prognostic value in unstable angina has been validated. In the GRACE

Table 2 Killip classification

	Defining clinical features
Class I	Absence of evidence of heart failure on examination
Class II	Mild to moderate heart failure, evidenced by rales less than halfway up the posterior lung fields, presence of S3, or JVP elevation
Class III	Overt pulmonary edema
Class IV	Cardiogenic shock

Modified from Killip, T., Kimball, J. T. (1967). Treatment of myocardial infarction in a coronary care unit. A two year experience with 250 patients. *American Journal of Cardiology* **20**, 457–464.

registry, patients with unstable angina who developed heart failure during admission had a 15.9% case fatality rate, whereas those who did not develop signs of heart failure had a 1% case fatality rate (Steg et al., 2004).

Diagnostic Evaluation

The clinical diagnosis of unstable angina depends on the presence of ischemic symptoms, which may or may not be accompanied by changes in the electrocardiogram (ECG), and which occur without a detectable increase in cardiac enzymes. As such, UA is the subset of acute coronary syndrome whose diagnosis depends nearly entirely upon clinical history. The discussion above regarding the limited test performance of chest pain characteristics speaks to the difficulty in making the diagnosis of UA, especially at the initial presentation. Without the ability to rely on laboratory testing for diagnosis, unstable angina may be difficult to distinguish from noncardiac, or nonischemic, causes of chest pain, or from myocardial infarction.

The ECG may provide supportive evidence of the diagnosis of UA but is frequently normal (Lev et al., 2003; Slater et al., 1987). Common findings on ECG during an episode of UA that support the diagnosis include ST depression, T wave inversions, or transient ST segment elevations. These abnormal ECG findings in a patient with anginal symptoms have relatively low sensitivity for diagnosing UA, but are fairly specific. A contemporary systematic review of 7 studies examining the performance of the ECG in the diagnosis of any acute coronary syndrome found a positive LR of 5.2 (95% CI 2.8–8.6) for ST depressions, and positive LR of 1.8 (95% CI 1.3–2.7) for T wave inversions (Fanaroff et al., 2015). Serial EKGs should be checked in the initial stages of suspected UA to monitor for dynamic or evolutionary changes suggestive of ACS.

The third universal definition for myocardial infarction is useful in providing a framework by exclusion for distinguishing NSTEMI and STEMI from unstable angina, driven largely by the presence or absence of elevations in cardiac biomarkers (Thygesen et al., 2012). The diagnosis of myocardial infarction requires the typical rise and fall of cardiac biomarkers with at least one value above the 99th percentile upper reference limit, along with at least one of the following: symptoms of ischemia, changes in electrocardiogram (Q waves, ST segment elevation or depression, new left bundle branch block), imaging evidence of loss of viable myocardium, or demonstration of coronary thrombus during angiography or at autopsy. At initial presentation with ACS, it may be unclear if a patient has MI or UA; thus, serial assessment of cardiac biomarkers is necessary. Biomarkers should be checked at presentation and 3–6 h later. The vast majority of patients with MI will develop elevated biomarkers within 6 h of symptom onset.

The development of high sensitivity troponin assays has increased the ability to detect very low-level elevations of troponin in plasma. This increased sensitivity of contemporary troponin assays to detect myocardial necrosis far exceeds that of other cardiac biomarkers. As a result, current guidelines state that CKMB and myoglobin are not useful in the diagnosis of ACS (Amsterdam et al., 2014). The increased sensitivity in laboratory testing may reduce the frequency of the diagnosis of unstable angina, as troponin positivity at lower levels could recategorize many patients with unstable angina as having NSTEMI (Braunwald and Morrow, 2013). Furthermore, while false negatives will be decreased substantially by the use of high-sensitivity troponin assays, detectable elevations in troponin may be found in a sizeable portion of the population not clinically suspected of having an acute coronary syndrome (Deckers, 2013). Some single centers have already reported declines in the rates of diagnosis of unstable angina with current troponin assays (D'Souza et al., 2015), and other studies have demonstrated that detectable troponin levels in asymptomatic individuals correlate with the risk of future coronary events (Ford et al., 2016).

Management of Unstable Angina

Risk Stratification

After the initial evaluation and diagnosis, a critical step in the management of all patients diagnosed with unstable angina is the performance of risk stratification. The identification of patients who are at higher risk provides important prognostic information and allows for triage decisions to be made, especially as related to the decision to pursue an invasive approach with early coronary angiography. While contemporary practices have favored cardiac catheterization for most patients with ACS, risk stratification tools continue to provide a useful framework by which to guide therapeutic decisions.

There are several validated risk stratification tools for use in patients with NSTEMI/UA; two of the most commonly used are the TIMI (Thrombolysis In Myocardial Infarction) and GRACE (Global Registry of Acute Coronary Events) scores. The TIMI risk score was derived from the pooled data of two randomized, controlled trials (RCTs) examining anticoagulation in selected patients

Table 3 TIMI risk score and prognosis

TIMI risk factor	*Comment*	*Points*
Age >65		1
≥3 traditional CAD risk factors	Family history CAD, HTN, HLD, DM, current smoking	1
Known prior coronary stenosis	≥1 known stenosis of >50% on coronary angiography	1
ST segment deviation on EKG		1
Severe anginal episodes	≥2 episodes in 24 h	1
Use of aspirin in last 7 days		1
Elevated cardiac enzymes	Not applicable in unstable angina	1

TIMI Score	*Risk of 14d all-cause mortality, new or recurrent MI, or severe recurrent ischemia requiring revascularization*
≤1	4.7%
2	8.3%
3	13.2%
4	19.9%
5	26.2%
≥6	40.9%

Adapted from Antman, E., Cohen, M., Bernink, P. J. L. M. et al. (2000). The TIMI risk score for unstable angina/non—ST elevation MI. *JAMA* **284** (7) 835–842. https://doi.org/10.1001/jama.284.7.835.

presenting with chest pain, including those with unstable angina (**Table 3**) (Antman et al., 2000). From a regression analysis, seven variables were identified that were predictors of the primary outcome, a composite of 14-day all-cause mortality, MI, or urgent revascularization. The TIMI scoring system has been validated in additional cohorts of patients, and higher TIMI scores correlate with a higher risk of coronary events (Mega et al., 2005). Patients with elevated TIMI scores (e.g., ≥3) derive greater benefit from aggressive antiplatelet therapies and early invasive therapy than do their lower risk counterparts.

The GRACE score was similarly devised to provide prognostic information about patients presenting with ACS, but incorporates more data points than does the TIMI score (Granger et al., 2003). The GRACE score was derived from the international registry of the same name, and the scoring system was subsequently validated among separate patient subsets. The original model estimated the risk of in-hospital mortality with high predictive accuracy (c-statistic value: 0.84). Studies have since demonstrated that the GRACE score not only provides prognostic data during the acute hospitalization for ACS but also predicts outcomes at 6 months, 12 months, and 3 years after ACS (Fox et al., 2014). The GRACE scoring system is not reproduced in this chapter owing to the numerous variables that it takes into consideration; however, several on-line calculators and smartphone applications are available for the calculation of GRACE scores.

Regardless of the exact scoring system used, the prognostic information provided helps guide decision-making in regard to the use of further diagnostic or therapeutic measures. This decision-making process is discussed in more detail below, under invasive therapies.

Medical Therapies

Overview

The medical management of unstable angina involves therapies aimed at the relief of angina, and the inhibition of platelet aggregation (**Table 4**) and of thrombosis (**Table 5**), and consideration of catheterization and revascularization of culprit vessel stenosis.

Antiplatelet therapies

Aspirin

The use of aspirin as a cornerstone of platelet inhibition in ACS has been well established. Aspirin is an irreversible inhibitor of the COX-1 enzyme resulting in a reduction in the synthesis of thromboxane A2, a potent stimulus for platelet aggregation (Brunton, 2006). The data supporting the use of aspirin in unstable angina comes from early trials that were performed prior to the widespread use of early interventional approaches to ACS, and showed a substantial 46% relative risk reduction in major vascular events compared to placebo (Antithrombotic Trialists' Collaboration, 2002). Aspirin has since been a routine part of standard medical therapy in ACS trials, and should be administered to all patients who are suspected of having unstable angina. In aspirin-naïve patients, it should be given as an initial loading dose of 162–325 mg (Amsterdam et al., 2014). The optimal long-term aspirin dosing has been studied in several trials in the NSTEMI and STEMI population, and may be extrapolated to UA. The CURRENT-OASIS trial was designed as a 2×2 factorial trial examining optimal dosing of clopidogrel and aspirin, and the primary endpoint was a composite of death, MI, or stroke at 30 days. When the aspirin dosing subgroups were examined, there were no significant

[c]Adapted from Roffi, M., Valgimigli, M., Bax, J. J. et al. (2015) ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation. *European Heart Journal* **32**, 2999–3054. https://doi.org/10.1093/eurheartj/ehv320.

differences in ischemic outcomes between low dose (75–100 mg) and high dose (300–325 mg) groups (Mehta et al., 2010). A similar result was found in the TRANSLATE-ACS study, which examined a registry of more than 10,000 patients with STEMI or NSTEMI who underwent percutaneous coronary intervention (PCI) and found no difference in cardiovascular events between high (325 mg) and low dose (81 mg) aspirin (Xian et al., 2015).

Based on these data, aspirin is recommended for all patients with suspected unstable angina without contraindications at the time of presentation. It should be administered as an initial loading dose of 162–325 mg and a maintenance dose of 75–100 mg daily thereafter (Amsterdam et al., 2014).

P2Y12 Inhibitors

The diversity of stimuli that lead to platelet aggregation and contribute to thrombosis has resulted in considerable interest in the development of additional platelet inhibitors for use in patients with ACS. The P2Y12 receptor is a platelet surface receptor that, when activated, results in activation and aggregation of platelets. Inhibitors of this receptor currently available and in use include clopidogrel, prasugrel, and ticagrelor. Older agents, such as ticlodipine, have fallen out of use as a result of their side effect profile.

Clopidogrel

The efficacy of clopidogrel was established in the landmark CURE trial, examining the benefit of clopidogrel when added to aspirin therapy in >12,000 patients with NSTEMI-ACS, approximately 75% of whom were diagnosed with unstable angina at study entry (Yusuf, 2001). This study found a significant reduction in the composite cardiovascular endpoint of death from cardiovascular causes, nonfatal myocardial infarction, or stroke at both 30 days and 1 year. Clopidogrel is absorbed as a prodrug and requires activation to an active form in the liver. Polymorphisms in the CYP system required to metabolize the prodrug have been identified, resulting in variations in the amount of active drug in circulation. Some of these polymorphisms have been associated with higher rates of death from any cause, nonfatal stroke, or myocardial infarction during 1 year of follow-up in those taking clopidogrel (Simon et al., 2009). High rates of these polymorphisms have been identified in patients of Asian heritage and warrant consideration when administering this medication to this patient group (Jang et al., 2012). Despite these considerations, the routine genetic testing for these polymorphisms in patients taking clopidogrel continues to be debated and is not routinely recommended (Aradi et al., 2014; Levine et al., 2011).

Prasugrel

Prasugrel is another P2Y12 inhibitor and is also absorbed as a prodrug. However, it is more rapidly and reliably converted to the active metabolite than is clopidogrel and, therefore, also produces more rapid inhibition of platelet function (Wiviott et al., 2007a). The use of prasugrel was studied in the TRITON-TIMI 38 trial randomizing over 13,000 patients with ACS (of whom 10,000 had either NSTEMI or unstable angina) and who were scheduled for percutaneous coronary revascularization, to treatment with prasugrel or clopidogrel (Wiviott et al., 2007b). The results of the trial showed a statistically significant reduction in the primary composite endpoint of cardiovascular death, nonfatal myocardial infarction, or nonfatal stroke in those patients treated with prasugrel. A retrospective analysis of the NSTEMI-ACS patients enrolled in TRITON was performed and confirmed the benefit of prasugrel over clopidogrel in this population (De Servi et al., 2014). However, prasugrel was also associated with an increased risk of major bleeding that was particularly problematic in patients who were elderly (age >75 years), had low body weight (<60 kg), or had a prior stroke. As a result, the use of prasugrel should be avoided in these subgroups. Whereas prasugrel has benefit in patients with ACS who are undergoing PCI, a large RCT revealed that it was not superior to clopidogrel in patients who did not undergo revascularization (Roe et al., 2012). As such, in the setting of UA, prasugrel is currently only indicated for those patients planned to undergo PCI (Amsterdam et al., 2014).

Ticagrelor

Ticagrelor is among the newest of the P2Y12 inhibitors. Unlike clopidogrel and prasugrel, it is neither a prodrug nor a thienopyridine, and it functions as a reversible P2Y12 inhibitor. Its efficacy was evaluated in the PLATO trial, which studied over 18,000 patients with ACS (17% of patients with UA) who were randomized to receive either clopidogrel or ticagrelor in addition to aspirin (Wallentin et al., 2009). The trial showed a 16% reduction in the composite primary endpoint of cardiovascular death, myocardial infarction, or stroke in patients treated with ticagrelor. While there were no differences in overall major bleeding between the ticagrelor and clopidogrel groups, there was an increase in nonprocedure-related major bleeding including fatal intracranial bleeding in the ticagrelor treated group.

Current guidelines suggest the addition of clopidogrel or ticagrelor to aspirin for patients with NSTEMI-ACS; however, there is no compelling data to favor one over the other. The upstream use of P2Y12 inhibitors in patients with unstable angina who ultimately undergo CABG for revascularization is potentially problematic due to the persistence of the medication, and a higher risk of operative bleeding. Thus, the possibility of the need for surgical revascularization should be considered prior to starting dual antiplatelet therapy in patients with UA. It is currently recommended to discontinue clopidogrel or ticagrelor for 5 days prior to surgery and prasugrel for 7 days prior to surgery (Amsterdam et al., 2014; Roffi et al., 2015).

GpIIb/IIIa Inhibitors

Inhibition of the GpIIb/IIIa platelet surface complex produces significant inhibition of platelet function, and may be useful in the treatment of unstable angina. The currently available GpIIb/IIIa inhibitors are tirofiban and eptifibatide (both small molecule inhibitors), and abciximab (a monoclonal antibody). Previously, the use of GpIIb/IIIa inhibitors was common in the setting of ACS; however, since the advent of oral P2Y12 inhibitors the use of GpIIb/IIIa inhibitors has declined and their routine use in the management of ACS is no longer recommended (Amsterdam et al., 2014; Roffi et al., 2015).

Antithrombotic therapies

Unfractionated heparin

Unfractionated heparin (UFH) is a polymeric inhibitor of the coagulation cascade. Its pharmacologic effect relates to the inactivation of thrombin and factor Xa in a manner dependent on interaction with the molecule antithrombin (Halperin, 2001). The original efficacy of heparin was established in addition to aspirin, with reduction in cardiovascular events in patients with unstable angina (Theroux et al., 1988). In the setting of UA, the administration of UFH for 48 h decreases the risk of recurrent ischemic events. There is, however, wide variability in pharmacokinetics and patients require weight-based dosing and frequent dose adjustments to ensure that the anticoagulant effect remains within a relatively narrow therapeutic window. Despite these limitations, UFH has the advantage of being able to turn on or off a continuous infusion and to rapidly reverse its effects with protamine, rather than await the longer half-lives of alternative antithrombotic agents. It is in this regard that heparin may have an advantage for those imminently planned for catheterization. Given its practicality, UFH persists as a reasonable antithrombotic choice albeit with justifiable concerns about its narrow therapeutic window and variability of pharmacokinetics.

Low-molecular-weight heparin

The low-molecular-weight heparins (LMWHs), of which enoxaparin is the most commonly used, are glycosaminoglycan chains similar to unfractionated heparin but synthesized at a much lower and more uniform weight (mean molecular weight of 5000) (Weitz, 1997). As a result, LMWH has greater specificity for the inhibition of Factor Xa than does UFH, and has been found to have a more reliable dose response and more stable pharmacokinetics. LMHW is dosed in a weight-based fashion and requires adjustments for reduced GFR due to its renal clearance.

Several studies have established the efficacy of LMWH in acute coronary syndromes. The ESSENCE trial was performed in patients with NSTEMI or unstable angina, who were randomized to receive either UFH or LMWH (Cohen et al., 1997). The results of

the trial showed a reduction in the composite endpoint of death, myocardial infarction, or recurrent angina at 30 days in the LMWH group (16.6% vs 19.8%). There was no difference in major bleeding noted between the agents; however, LMWH was associated with an overall increased risk of bleeding compared with UFH, primarily resulting from ecchymoses at injection sites. Importantly, this trial was performed in patients being treated primarily with medical therapy, and was performed prior to the widespread use of P2Y12 inhibitors. Examination of the difference between LMWH and UFH in more contemporary cohorts with higher rates of P2Y12 inhibitor use, and higher rates of coronary angiography and interventions, has yielded more equivocal results with noninferiority seen in some trials and meta-analyses (SYNERGY Investigators, 2004; Silvain et al., 2012).

The use of enoxaparin as an initial therapy in patients with unstable angina should continue until PCI, or for a period of at least 48 h for those managed noninvasively. In the patient who is given enoxaparin as initial therapy and is then taken for percutaneous intervention, enoxaparin should be continued as the antithrombotic agent of choice during the procedure, given an observed increase in significant bleeding in patients who cross over to UFH at the time of catheterization (Petersen et al., 2004).

Fondaparinux

Fondaparinux is a pentasaccharide molecule that results in selective inhibition of factor Xa, has high bioavailability and a reliable dose response. The medication is administered subcutaneously, and can be given once a day. Its efficacy in the management of acute coronary syndromes was established in the OASIS trial, which compared the use of fondaparinux to enoxaparin in more than 20,000 patients, 45% of whom had a diagnosis of unstable angina. The overall results of the trial demonstrated noninferiority of fondaparinux with regard to the primary composite endpoint of death, myocardial infarction, or refractory ischemia (Anon, 2006). There was a strong trend toward reduced bleeding events, including procedural bleeding, in the group treated with fondaparinux. Importantly, patients undergoing catheterization were noted to have increased rates of catheter thrombosis. Subsequent analyses have demonstrated that this effect was minimized with the use of a bolus of UFH at the time of catheterization.

Bivalirudin

Bivalirudin is an intravenous direct thrombin inhibitor that is a congener of hirudin, an anticoagulant first identified in leeches. It is a reversible inhibitor of thrombin and requires dose adjustment to maintain anticoagulation parameters within an acceptable therapeutic window. The use of bivalirudin in ACS including unstable angina has been studied extensively in comparison to other antithrombotic regimens. The early studies were somewhat confounded by the co-administration of GpIIb/IIIa inhibitors with heparin and a variable use of P2Y12 inhibitors (Stone et al., 2006). A meta-analysis of these early trials included a subgroup analysis of the use of bivalirudin compared to heparin alone (not in combination with GpIIb/IIIa inhibitors) and demonstrated similar rates of mortality and MI, and reduced bleeding with bivalirudin (Navarese et al., 2015). There was notably a significant increase in acute stent thrombosis appreciated when bivalirudin was compared to heparin alone in this meta-analysis. However, a recent randomized control study comparing heparin and bivalirudin in patients with NSTE-ACS being managed with a planned invasive strategy demonstrated similar rates of cardiovascular events (Valgimigli et al., 2015). Bivalirudin is a reasonable option for antithrombotic therapy in patients with UA who are planned for coronary angiography and intervention.

Antianginal therapies

An important goal in the early management of unstable angina is the relief of ischemic symptoms, which is usually achieved by correcting the oxygen supply–demand mismatch that is present in ischemic myocardium. Given that oxygen extraction in resting myocardium is already near maximal, restoring oxygen balance to the myocardium can only be accomplished in one of two ways: reduction in myocardial demand or increase in coronary oxygen delivery. The therapies used to achieve these goals are described below.

Oxygen

Supplemental oxygen may increase the oxygen content of blood and thereby deliver more oxygen to ischemic myocardium. However, given the sigmoidal curve of the oxygen–hemoglobin dissociation curve, the oxygen-carrying capacity of hemoglobin is generally saturated at ambient levels of oxygen unless an additional process is ongoing (Hall and Guyton, 2011). The use of oxygen by nasal cannula had been a routine measure taken for patients presenting with unstable angina; however, an increased awareness of oxygen toxicity, including adverse effects of hyperoxia on coronary hemodynamics, has led to a reduction in the routine use of supplemental O2. The potential for adverse effects is supported by the results of randomized studies in patients with STEMI, in which no benefit, and some markers of harm, were reported in patients without hypoxemia who were treated with supplemental oxygen (Stub et al., 2015). In unstable angina, the use of supplemental oxygen should be restricted to the hypoxemic patient.

Beta-blockers

Beta-blockers work to slow heart rate, decrease myocardial contractility, lower blood pressure (and ventricular wall stress), and thereby reduce the oxygen consumption of myocardial cells in unstable angina. While there is no defined goal for heart rate reduction to guide titration, initiation of beta-blockers at a low dose to ensure tolerance is recommended (Amsterdam et al., 2014). The evidence for the efficacy of beta-blockers in unstable angina is extrapolated from studies in acute coronary syndrome in general, but a trend toward reduced cardiovascular events (reinfarction, ventricular arrhythmias, and long-term mortality) has been seen in several meta-analyses (Kontos et al., 2011; Chatterjee et al., 2013). However, beta-blockers must be used with caution in patients at risk for cardiogenic shock including those >70 years of age, and those with hemodynamic abnormalities including a heart rate

greater than 110 beats/min, and systolic blood pressure below 120 mmHg. Similarly, the use of beta-blockers in patients with suspected or known left ventricular dysfunction must be judiciously considered. Nonetheless, beta-blockers should be administered to all patients with ACS who do not have a contraindication.

Calcium channel blockers

Similar to beta-blockers, the non-dihydropyridine calcium channel blocking agents produce a decrease in heart rate, contractility, and wall stress, thereby reducing the myocardial oxygen demand. They are generally considered as second line to beta-blockers, as the evidence supporting their use is generally less robust. Early trials in unstable angina showed reduction in the rates of recurrent infarction with the use of diltiazem or verapamil; however, these agents must be used with caution in patients with depressed left ventricular systolic function or with overt heart failure (Smith et al., 1998).

Nitrates

Nitroglycerin preparations produce endothelium-dependent veno- and vasodilation resulting in decreases in preload and afterload as well as coronary vasodilation. These effects help to decrease myocardial oxygen demand and increase coronary blood flow, thus reducing myocardial ischemia. The primary utility of nitrates has been for the relief of ischemic symptoms, as the use of these agents has not translated into a reduction in hard clinical events in the limited trials that have addressed this question in the setting of NSTE-ACS. Sublingual nitroglycerin should be administered acutely to patients with angina symptoms and can be repeated every 5 min until relief of symptoms, or the medication is no longer tolerated. Patients with persistent angina should be started on an intravenous infusion of nitroglycerin, which can be up-titrated to achieve angina relief. Intravenous nitroglycerin may also be useful for the management of hypertension or heart failure during NSTE-ACS. Nitrates may produce hypotension in patients with aortic stenosis, right ventricular dysfunction/infarct, or volume depletion, and should be avoided in these settings. In addition, nitrates are contraindicated in patients who have recently used phosphodiesterase inhibitors such as sildenafil and tadalafil, owing to the risk of hemodynamic compromise.

Morphine

Morphine has several potential beneficial effects in patients with unstable angina, including the relief of pain and anxiety, factors which may increase myocardial oxygen demand through increased heart rate and blood pressure. There have been no definitive trials to define the role of morphine in UA; rather, its use is supported by clinical experience. Nonetheless, caution should be used when administering morphine to ACS patients with acute heart failure as observational studies suggest an increase in adverse events in this setting. There is some data to suggest that morphine decreases absorption of P2Y12 receptor inhibitors such as clopidogrel resulting in decreased circulating active metabolites; however, there is currently no data to suggest an increase in ischemic events in patients receiving both agents (Hobl et al., 2014). Thus, at present, morphine remains the analgesic of choice in patients with UA and ongoing chest pain.

Cholesterol Lowering Therapies

Cholesterol lowering therapy, primarily achieved with statin medications, is well established in the secondary prevention of coronary artery disease. Meta-analyses of statin therapy in patients with CAD have demonstrated a reduction in the risk of mortality on the order of 16% (Wilt et al., 2004). A complete discussion of statin therapy is beyond the scope of this chapter; however, given the beneficial effects of these agents in the setting of ACS and stable CAD, all patients presenting with unstable angina should receive high-intensity statin therapy in the absence of contraindications (Amsterdam et al., 2014; Roffi et al., 2015). A high-intensity statin therapy has been defined by the ACC/AHA as therapy known to reduce LDL cholesterol by 50% or more, and includes atorvastatin 40–80 mg daily and rosuvastatin 20–40 mg daily (Stone et al., 2014). The use of statin therapy in patients with established CAD and age >75 is not well studied, and a moderate intensity strategy may be reasonable in this older population.

Invasive Strategies for Unstable Angina

As an important early step in the management of unstable angina, all patients should undergo risk stratification to estimate their short- and medium-term risk of adverse events. The TIMI and GRACE scoring systems are described above, and help to identify patients who are at increased risk for complications such as death, recurrent MI, and the need for repeat revascularization.

An understanding of this risk is necessary to inform decision-making in regard to the timing and necessity of coronary angiography and PCI. There have been multiple studies comparing a conservative approach of optimized medical therapy with an invasive strategy in patients with NSTE-ACS, including in patients with unstable angina. These studies have taken place over several decades, during which medical therapies and invasive techniques have changed significantly, and the outcomes of the studies have varied. Nonetheless, several meta-analyses of routine invasive strategies for patients with NSTE-ACS have shown a reduction in future adverse cardiovascular events when an invasive approach is pursued. One such meta-analysis revealed a relative risk reduction in cardiovascular death or nonfatal MI of 19% at 5 years of follow-up in patients receiving invasive therapies compared with conservative management (Fox et al., 2010).

In general, patients with high-risk features derive more benefit from an early invasive approach than do low-risk patients. Patients with persistent or recurrent angina despite optimal medical therapy should undergo urgent catheterization with the goal of revascularization if feasible, as should patients in whom UA is accompanied by heart failure, hemodynamic instability, or sustained ventricular arrhythmias. An invasive approach should also be considered for patients with UA who have elevated risk scores (e.g., TIMI score >2, GRACE score >109), depressed LVEF, diabetes, prior coronary revascularization, or evolutionary ischemic changes on serial electrocardiograms. Patients without high-risk clinical markers and with low-risk scores (e.g., TIMI score 0–1, GRACE score <109) can often be managed with an ischemia-guided strategy. With this strategy, optimal medical therapy is the primary therapeutic approach with invasive evaluation reserved for those patients who have refractory angina despite medical therapy or have objective evidence of ischemia on predischarge noninvasive stress testing.

A discussion of invasive procedural considerations and decisions regarding revascularization strategies (i.e., PCI versus CABG) is beyond the scope of this chapter, and is described elsewhere. Patient comorbidities and preference should be taken into consideration when making decisions regarding the invasive evaluation of patients with unstable angina and their subsequent revascularization.

Conclusions

The acute coronary syndromes represent a critical instability in coronary atherosclerotic disease. The diagnosis of unstable angina remains a clinical challenge but is supported by historical features and findings on physical examination. Unstable angina reflects one end of the spectrum of ACS, and is distinguished from myocardial infarction by the presence of elevated cardiac biomarkers in the latter setting. The prevalence of UA may decrease in the future as emerging biomarkers with greater sensitivity are able to identify minimal elevation in cardiac enzymes and, thereby, reclassify patients previously diagnosed with UA as having NSTEMI. Aggressive medical therapy should be initiated early in patients with UA with a combination of antiplatelet, antithrombotic, and antianginal agents, as well as cholesterol lowering therapies. Early risk stratification should be performed to both inform prognosis and guide the consideration of invasive evaluation with catheterization and subsequent coronary revascularization. With the advances in therapies described above, there has been substantial improvement in the natural history of this ominous condition.

The functioning of essentially all organs and tissues of vertebrates relies on the circulation of blood, which provides the necessary nutrients and removes harmful waste products, and on the conveyance of biochemical and electrical signals that control and coordinate the execution of tissue and organ tasks (Standring, 2016). These complex functions are, respectively, under the control of two pervasive and ubiquitous anatomic systems, namely, the vascular and the nervous system, which physically interacts and ramifies in architecturally similar patterns (Standring, 2016). Altogether, these observations would imply some degree of functional interdependence, such as the requirement for oxygen and nutrients by nerves, as well as the responsiveness to the same guidance cue (s) by the two systems during embryonic development, when vascular endothelial cells (ECs), neurons, and neuronal growth cones travel over long distances to achieve their final destinations.

In 1989, Paul Martin and Julian Lewis (Martin and Lewis, 1989) provided the first experimental evidences supporting the hypothesis that nerves and blood vessels frequently navigate along the same route because they likely respond to the same steering cues whose molecular nature and signaling mechanisms were, at that time, still unknown. Over the last two decades, several laboratories contributed in developing a wide and detailed knowledge about the different guidance cues and signaling pathways that control both nervous and vascular guidance emerged (Blockus and Chédotal, 2016; Kania and Klein, 2016; Mehlen et al., 2011; Worzfeld and Offermanns, 2014). It emerges that ECs and neuron growth cones are guided in their journey throughout by the same families of plasma membrane-associated or secreted proteins that elicits either attractive or repulsive cytosolic pathways that impact on cytoskeletal, trafficking, and adhesive dynamics. Here, we will review the literature describing how the major vascular guidance cues were first identified and their signaling mechanisms and function were then thoroughly characterized.

Ephrins and Eph Receptors

The first Eph receptor was isolated in a screening aimed at identifying new tyrosine kinases endowed with tumorigenic function (Hirai et al., 1987). The name Eph derives from erythropoietin-producing hepatocellular carcinoma cell line, from which its cDNA was initially cloned. Since then, additional Eph receptors were discovered and divided in categories based on their sequence homology (Kania and Klein, 2016). Fourteen Eph receptors members exist and are classified into two subfamilies: type A (EphA1-8 and EphA10), which bind to their cognate ligand type A ephrins (ephrin-A1-5) and type B (EphB1-4 and EphB6), which bind to type B ephrins (ephrin-B1-3) (Kania and Klein, 2016). However, this sort division is somehow arbitrary since some EphB receptors can bind ephrin-A ligands and EphA receptors can bind ephrin-B ligands (Taylor et al., 2017).

EphA and EphB receptors share a similar structure (Kania and Klein, 2016). They have a ligand-binding domain and a cysteine-rich region (Cys domain) followed by two FNIII domains in the extracellular portion, a single transmembrane domain and an intracellular juxtamembrane domain (important for receptor activation), a kinase domain, a sterile alpha motif (required for receptor oligomerization), and a PDZ domain-binding motif (Kania and Klein, 2016). Ephrins are ligands tethered to the cell

 https://doi.org/10.1016/B978-0-12-809657-4.99546-2

surface, and the two subfamilies are very different from each other (Kania and Klein, 2016). Class B ephrins have an extracellular receptor-binding domain, a transmembrane domain, and a short cytoplasmic tail, containing conserved tyrosine residues and a PDZ-binding site. On the contrary, class A ephrins are smaller, being composed only by a receptor-binding domain tethered to the membrane through a glycosylphosphatidylinositol (GPI) anchor. The fact that Eph ligands are linked to cell surface implies that the repulsive or attractive signaling through these receptors depends on cell-to-cell contacts. Moreover, the ephrin-Eph signaling can occur bidirectionally, and the interaction takes place between ligand and receptor on two neighboring cells or on the same cell (Kania and Klein, 2016). Another order of complexity is achieved thanks to the fact that, to be efficiently activated, both ephrins and Eph receptors aggregate into homotypic or heterotypic clusters (Taylor et al., 2017).

The development of the vascular system largely relays on the specific ephrin-B2/EphB4 ligand-receptor pair although some findings highlighted functional redundancies involving other ephrins and Eph receptors (Adams et al., 1999). From the onset of embryonic angiogenesis, Ephrin-B2 and its cognate receptor EphB4 are expressed by arterial and venous ECs, respectively, and serve to establish the identities of each vascular compartment (Wang et al., 1998). Moreover, ephrin-B2 and EphB4 reciprocal interaction promotes the structural and functional cooperation between arteries and veins that is essential for their effective angiogenic remodeling. Indeed, due to severe embryonic and yolk sack defects in both arterial and venous vessels growth and remodeling, ephrin-B2 or EphB4 knockdown causes the death of mouse embryos at midgestation (Gerety et al., 1999; Wang et al., 1998). Ephrin-B2 and EphB4 participate in the formation of arteries and veins acting downstream of the transcription factors Notch and chicken ovalbumin upstream promoter–transcription factor II (Coup-TFII). While Notch signaling promotes arterial and suppresses venous fates by upregulating ephrin-B2 and downregulating EphB4, Coup-TFII represses Notch signaling in venous ECs (You et al., 2005). Ephrin-B2 and EphB4 repulsive signaling is required for the formation of the two major embryonic blood vessels, the dorsal aorta and the cardinal vein. First in the zebrafish and more recently in mouse models, it has been demonstrated that the dorsal aorta assembles first and contains venous precursors. This mixed population of ECs in dorsal aorta is characterized by the presence of two different signatures: arterial precursors expressing ephrin-B2 and venous ones expressing EphB4. Ephrin-B2–EphB4 repulsive signaling promotes the relocation of venous ECs and the ensuing assembly into cardinal vein (Herbert et al., 2009; Lindskog et al., 2014).

The Ephrin-B2–EphB4 interaction is also an important regulator of sprouting angiogenesis, as extensively studied in postnatal mouse retina and in pathological tumor vascularization mouse models, wherein it cooperates with and controls VEGF signaling. VEGF gradients promote the migration of tip cells of vascular sprouts, promoting internalization of their receptors, which is necessary to foster downstream signaling and induce filopodia extension (Sawamiphak et al., 2010; Wang et al., 2010). In this context, ephrin-B2 and its intracellular interactors, the clathrin-associated protein disabled 2 (Dab2) and the cell polarity regulator PAR-3, enable clathrin-dependent VEGFR2 internalization and downstream signaling, being both negatively regulated by atypical protein kinase C (Nakayama et al., 2013b; Sawamiphak et al., 2010; Wang et al., 2010).

Upon EphB binding, ephrin-B reverse signaling is activated thanks to the phosphorylation of its cytoplasmic domain by Src family kinases. Once phosphorylated, ephrin-B recruits the PDZ containing phosphatase PTP-BL that switches off the signaling of ephrin-B itself (Palmer et al., 2002). Recently, ephrin-B2 was shown to control EC survival and death, which in turn regulate hyaloid and retinal vessel pruning in the eye, in a VEGF-independent manner (Salvucci et al., 2015). Ephrin-B2 is phosphorylated in the remodeling vasculature during eye development, wound healing, and tumor growth (Salvucci et al., 2015). At sites of blood vessel pruning, signals that induce ephrin-B2 dephosphorylation promote JAK2/STAT1 activation and the ensuing c-Jun N-terminal kinase 3-mediated EC apoptosis and vascular degeneration (Salvucci et al., 2015). Interestingly, mature quiescent blood vessels do not depend on ephrin-B2 phosphorylation for their integrity, suggesting that other mechanisms are involved in the stabilization and maintenance of the nonangiogenic vasculature. Ephrin-B2 was also found in venous valves, and the induction of its expression in venous ECs is one of the first events during valve development (Bazigou et al., 2011). Continuous ephrin-B2 signaling is also required for valve maintenance, albeit the precise underlying mechanism of action remains to be clarified (Bazigou et al., 2011).

Ephrin-B2 is also expressed in pericytes and vascular smooth muscle cells (VSMCs) and regulates their migration and adhesion during the assembly of the blood vessel wall. A conditional gene targeting approach, aimed to selectively disrupt the expression of ephrin-B2 in mural cells, revealed that knockout pericytes and VSMCs failed to develop mature contacts with ECs, causing alterations in blood vessel architecture and hemorrhages. A complex formed by the adaptor proteins Crk and p130Cas is involved in the ephrin-B2 signaling that promotes mural cell spreading and motility (Foo et al., 2006). In addition, a more recent study revealed that in mural cells ephrin-B2 interacts with PDGF receptor β (PDGFRβ) to control its localization, internalization, and signaling (Nakayama et al., 2013a). In the absence of ephrin-B2, PDGFRβ internalization and the ensuing Tiam1–Rac1 activation is impaired, while mitogen-activated protein kinase and JNK signalings are instead increased (Nakayama et al., 2013a). As a result, mural cells migrate and proliferate less, finally resulting into blood vessel wall defects and aortic aneurysms (Nakayama et al., 2013a).

Semaphorins, Neuropilins, and Plexins

Semaphorins (Semas) are a large family of secreted or membrane-associated glycoproteins that elicits repulsive or attractive signals on migrating cells. Originally identified as axon guidance molecules in the developing nervous system (Kolodkin et al., 1993; Luo et al., 1993), Semas were later involved in many physiological and pathological processes, such as vascular EC motility, cardiovascular development, lymphocyte activation, bone and lung morphogenesis, cancer angiogenesis, and metastatic dissemination

(Epstein et al., 2015; Kruger et al., 2005; Neufeld et al., 2012; Serini et al., 2013). The Sema family consists of a large number of phylogenetically conserved proteins characterized by an extracellular amino-terminal homodimeric "sema" domain consisting of two β-propellers that bind and elicit the dimerization of Sema receptors (Siebold and Jones, 2013). Based on the carboxyl-terminal domains and phylogenetic analyses, eight Sema classes have been identified: class 1 and 2 are encoded by invertebrates, classes 3–7 are from vertebrates, and class V Sema are found in viruses. The seven vertebrate class 3 Semas (Sema3A–G) are produced as secreted proteins by cells of multiple lineages, including ECs and epithelial cells, neurons, and tumor cells. From the N-terminus to the C-terminus, Sema3 contains a sema domain followed by a plexin–semaphorin–integrin (PSI) domain, an immunoglobulin (Ig)-like domain, and a basic domain. Sema3 holoreceptor complexes belong to the families of plexins and neuropilins (Nrps).

Plexins are a family of nine transmembrane proteins subdivided into four (A to D) classes. Their intracellular region contains a guanosine triphosphatase (GTPase)-activating protein (GAP) domain (Wang et al., 2012, 2013; Worzfeld and Offermanns, 2014; Worzfeld et al., 2014), whereas their N-terminal Sema-PSI domain combination mediates the binding to Sema homodimers (Janssen et al., 2010, 2012; Liu et al., 2010; Nogi et al., 2010; Olsson et al., 2006; Siebold and Jones, 2013). Compared to membrane-associated Semas, secreted Sema3 proteins display a less hydrophobic dimeric interface that need to be stabilized by disulphide bonds between Ig domains, which are negatively regulated by the proteolytic activity of furins (Adams et al., 1997; Koppel and Raper, 1998). Electrostatic interactions mediate a head-to-head interface between each sema domain of a Sema dimer and the sema domain of a monomeric plexin, giving rise to a 2:2 Sema–plexin heterotetramer (Janssen et al., 2010; Liu et al., 2010; Nogi et al., 2010; Siebold and Jones, 2013). The same head-to-head interface is probably employed by Sema3A to bind to and signal through plexin receptors (Nogi et al., 2010). Nevertheless, since no high-affinity binding has been revealed so far (Janssen et al., 2012), the interaction between the sema domains of Sema3A and plexins must be extremely weak and the involvement of coreceptors, such as Nrp1 (Janssen et al., 2012) or proteoglycans (Casazza et al., 2013; Pang et al., 2015), is likely needed. The intracellular region of plexins is highly conserved and contains two large portions that are highly homologous to Ras GAP domains (Hu et al., 2001; Rohm et al., 2000). These domains were reported to exert their enzymatic activity on two Ras-related small GTPase proteins: R-Ras (Oinuma et al., 2004) and M-Ras (Saito et al., 2009). However, subsequent studies did not confirm that Plexins exert GAP activity toward R-Ras or M-Ras (Sakurai et al., 2010; Tong et al., 2009; Wang et al., 2012). Similarly, analyses of knock-in mice carrying inactivating mutations in the GAP domain of Plexin D1 or B2 unveiled an R-Ras and M-Ras independent function for those domains in the control of embryonic development (Worzfeld et al., 2014). Wang and colleagues provided instead evidence that purified cytoplasmic regions of different Plexins exert their GAP activity on the small GTPase Rap1 and that this function was required for Plexin-mediated neuronal growth cone collapse (Delcommenne et al., 1998). The same laboratory also described the crystal structures of zebrafish Plexin C1 cytoplasmic region in complex with Rap1 (Wang et al., 2013). Of note, the small GTPase Rap1 effectively controls vascular morphogenesis (Chrzanowska-Wodnicka, 2013) and promotes the conformational activation of integrins via talin and the adhesion of different cell types to the extracellular matrix (Calderwood et al., 2013; Chrzanowska-Wodnicka, 2013).

In vertebrates, Nrp1 and Nrp2 act as Sema3 coreceptors (Guo and Vander Kooi, 2015). The extracellular parts of both Nrps contain two complement binding domains (a1/a2), two coagulation factor V/VIII homology domains (b1/b2), and a MAM domain (c); while the short cytoplasmic domain is about 40 amino acids long and contains a C-terminal PDZ-binding SEA motif. In addition to Sema3, Nrp1 and Nrp2 are coreceptors also for vascular endothelial growth factor-A (VEGF-A) and -C (VEGF-C) family members, respectively (Guo and Vander Kooi, 2015; Parker Matthew et al., 2015; Soker et al., 1998). The b1 domain of Nrp1 mediates the high-affinity binding to the basic domain of VEGF-A and Sema3 proteins (Giger et al., 1998; Nakamura et al., 1998; Parker et al., 2012b,c; Renzi et al., 1999; Siebold and Jones, 2013), in which a C-terminal arginine is naturally present or exposed upon furin-dependent cleavage, respectively (Adams et al., 1997; Guo et al., 2013; Guo and Vander Kooi, 2015; Parker et al., 2010, 2012b,c). The a1 domain of Nrp1 does not directly bind with high affinity the sema domain of Sema3A (Janssen et al., 2012) but favors its attachment to the sema domain of type A plexins, such as Plexin A2 (Janssen et al., 2012; Parker et al., 2012a; Siebold and Jones, 2013).

Sema3A

Sema3A is required for the appropriate pattern establishment of trunk intersegmental blood vessels in the developing zebrafish embryo (Torres-Vázquez et al., 2004; Zygmunt et al., 2011). Sema3A1 and Sema3A2 proteins keep the vascular sprouts budding from trunk large blood vessels within the intersomitic boundaries (Torres-Vázquez et al., 2004). Indeed, *sema3a1*/*sema3a2* and *plxnd1* morphants, along with the *plxnd1* knock-out mutant *out-of-bounds* (*obd*) present patterning anomalies of intersegmental blood vessels that invade somites (Torres-Vázquez et al., 2004). In addition, in quiescent aortic ECs adjacent to somites, Sema3A/PlexinD1 signaling was found to promote the autocrine secretion of soluble VEGFR1 that, sequestering VEGF, decreases blood vessel sprouting in somite boundaries (Zygmunt et al., 2011). Moreover, the implantation of anti-Sema3A antibody-soaked beads substantially alters the vascular pattern in the developing forelimb of chick embryos (Neufeld and Kessler, 2008). Similarly, retrovirus-mediated delivery of dominant negative constructs of Sema3A holoreceptor impairs vascular remodeling in the developing chick embryo (Serini et al., 2003). *Sema3a* knockout embryos present severe abnormalities in the remodeling of both cephalic plexus and dorsal longitudinal anastomotical vessel (Serini et al., 2003). Furthermore, *Sema3a*$^{-/-}$ pups that survive until the adulthood exhibit an aberrantly increased number of glomerular ECs together with defects of renal blood vessels (Reidy et al., 2009). The reported lack of vascular abnormalities in one study on *Sema3a* null mice (Vieira et al., 2007) may be due to the comparison between wild-type and *Sema3a* null embryos by using an age-and-stage matching strategy that inherently misses growth

retardation phenotypes (Hamada et al., 2005), such as that of *Sema3a* null mice (Serini et al., 2003). Endothelial tip cells of murine retinal vascular spouts were also found to express much more *Sema3a* mRNA than stalk ECs (Strasser et al., 2010) and EC-specific *Sema3a* knockout mice exhibit a significantly increased number and length of endothelial tip cell filopodia in retinal vascular sprouts (Ochsenbein et al., 2016).

The role of Nrp1 in Sema3A signaling in ECs incompletely understood. A $Nrp1^{Sema-}$ mouse strain carrying mutations in a1 domain of Nrp1 that impair Sema3 signaling was previously generated (Foo et al., 2006). Differently from *Nrp1* null mice, which die by E12.5, 60% of $Nrp1^{Sema-}$ mouse were found to survive until P7 and to exhibit cardiac, but not vascular abnormalities (Foo et al., 2006). However, two subsequent reports (Joza et al., 2012, 2013) showed that only 18% of $Nrp1^{Sema-}$ mice survive until P4 and exhibit lung alveolar capillary dysplasia. The lack of angiogenic remodeling defects in major head and trunk blood vessels in $Nrp1^{Sema-}$ mice (Gu et al., 2003) and the severity of the vascular phenotype in both Sema3A (Serini et al., 2003) and Nrp1 (Kawasaki et al., 1999) knockout mice support the possibility that the reduced responsivity of ECs to Sema3A in mutant $Nrp1^{Sema-}$ may be due to additional Sema3A coreceptors, such as proteoglycans (Casazza et al., 2013; Pang et al., 2015). Indeed, *Plxna4* null mice display several misprojected axon bundles that are not present in *Nrp1* (Kitsukawa et al., 1997) or $Nrp1^{Sema-}$ (Gu et al., 2003) mutant animals, implying that Plexin A4 may elicit Nrp1-independent Sema3A signals (Yaron et al., 2005). Hence, similar to membrane-associated Semas, Sema3A might bind at very low affinity and signal *via* plexins (Nogi et al., 2010).

Sema3A can signal through Plexin A1 (Takahashi et al., 1999), Plexin A2 (Janssen et al., 2012; Takahashi and Strittmatter, 2001), Plexin A4 (Kigel et al., 2011; Yaron et al., 2005), and Plexin D1 (Zhang et al., 2009), the latter being significantly more efficient that type A plexins in forming high-affinity Nrp-dependent holoreceptor complexes for Sema3A and Sema3C (Gitler et al., 2004). Sema3A-elicited EC collapse depends on both Plexin A1 and Plexin A4 (Kigel et al., 2011), and Sema3A inhibits the sprouting of aortic blood vessels or the migration of primary ECs isolated from $Plxnd1^{-/-}$ less efficiently than wild-type animals (Zhang et al., 2009). Therefore, Sema3A may control in vivo vascular morphogenesis by binding with high affinity to coreceptors, such as Nrp1 or proteoglycans, and signal through low-affinity receptors, for example, Plexin A1, Plexin A2, Plexin A4, and Plexin D1.

Sema3E

Independently from Nrp1, Sema3E binds to Plexin D1 with high affinity (Nakayama et al., 2013a). Both in *Sema3e* and *Plxnd1* knockout embryos, blood vessels invade somites resulting in the loss of the typical stereotyped intersomitic vascular pattern (Nakayama et al., 2013a). However, while *Plxnd1* knockout pups become cyanotic sudden after birth and die within 24 h (Gitler et al., 2004), $Sema3e^{-/-}$ mice are alive, fertile, and survive throughout adulthood although displaying initially severe vascular defects (Meadows et al., 2012; Nakayama et al., 2013a). This suggests that Plexin D1 likely transduces signals of Sema3 proteins other than Sema3E, such as Sema3A (Zhang et al., 2009) and Sema3C (Gitler et al., 2004). Interestingly, both Sema3A (Behar et al., 1996) and Plexin-D1 (Kanda et al., 2007) null mice share common axial skeletal defects. Moreover, endothelial *Plxnd1* gene inactivation in mice induces myocardial defects and skeletal malformations, associated witho a strong reduction of the bone microvasculature (Zhang et al., 2009).

Sema3E protein produced by the lateral plate mesoderm is required for dorsal aortae patterning and to generate the avascular zones laterally to the dorsal aortae and along the midline (Meadows et al., 2012, 2013). In this regard, $Sema3e^{-/-}$ embryos develop highly branched plexiform vessels that convert into single, unbranched dorsal aortae between E8.25 and E8.75 (Meadows et al., 2013), due to unidentified repulsive cues originating from the lateral plate mesoderm (Nakayama et al., 2013a). Furthermore, differently from zebrafish *sema3a1*/*sema3a2* and *plexind1* morphants as well as *obd* mutants (Torres-Vázquez et al., 2004) (Lamont et, al., 2009), *sema3e* zebrafish morphants do not display any overshooting of intersomitic sprouts.

Other Sema3 Proteins

Sema3B inhibits angiogenesis through its binding to Nrp1 (Varshavsky et al., 2008). Sema3B knockout mice are alive and fertile (Falk et al., 2005). An unbiased transcriptomic analysis revealed that SEMA3B is upregulated in severe forms of human preeclampsia and inhibits the differentiation of placental cytotrophoblasts; SEMA3B derived from the cytotrophoblast acts in a paracrine way to impair uterine microvascular EC functions (Zhou et al., 2013).

Sema3C protein binds with high affinity to Nrp1–Plexin D1 and to Nrp2–PlexinD1 complexes with lower affinity (Gitler et al., 2004). Accordingly, Sema3C was reported to inhibit angiogenesis by signaling *via* Nrp1 and Plexin D1 (Yang et al., 2015a). Deletion of *Sema3c* (Feiner et al., 2001), *Nrp1* (Kawasaki et al., 1999), or *Plxnd1* (Gitler et al., 2004) genes causes postnatal lethality due to cardiovascular defects, for example, the improper septation of the cardiac outflow tract, resembling the persistent truncus arteriosus observed in humans (Crupi et al., 1977). A recent study proposed that neural crest cell-derived Sema3C elicits both the Nrp1-dependent endothelial-to-mesenchymal transition in the endocardial cushions and the myocardialization of septum (Plein et al., 2015).

Sema3D inhibits EC spreading and migration through a Nrp1 and PI3K/Akt-dependent pathway (Aghajanian et al., 2014). In the developing embryo, Sema3D is expressed in a subpopulation of proepicardial cells, which will form the sinus venosus and the coronary endothelium (Dunah et al., 2005), and in the mesocardial reflections located between the splanchnic mesoderm and the venous pole of the heart, where Sema3D exerts a Nrp1-dependent repulsive effect to direct pulmonary venous EC migration toward the left atrium (Degenhardt et al., 2013). Consistently, *Sema3d* null mice exhibit anomalous pulmonary venous connection (Degenhardt et al., 2013). In venous ECs, Sema3D inhibitory signals are also conveyed through a Nrp1–ErbB2 signaling complex (Aghajanian et al., 2016).

Unc5, Netrins, and FLRTs

Netrin 1 (Ntn1) was first identified as an axon guidance molecule secreted by floor plate cells and capable of promoting the growth of commissural axons in the embryonic spinal cord (Kennedy ,et al., 1994; Serafini e,t al., 1994). It belongs to a family of laminin-related factors, which includes other two secreted Netrins (Ntn3 and Ntn4) and two GPI-anchored membrane proteins, netrin G1 and netrin G2 (Mehlen and Guenebeaud, 2010). Ntn1 and Ntn3 are structurally similar to the short arms of laminin-γ chains and contain a laminin VI domain, three epidermal growth factor (EGF)-like repeats related to the laminin V domain (V-1, V-2, and V-3), and a positively charged heparin-binding COOH-terminal motif termed domain C. In contrast, Ntn4 is more related to laminin-β chains and shares little homology with Ntn1 and Ntn3. Ntn4 regulates the assembly of the basement membrane in the vasculature and other organs, affecting branching morphogenesis (Koch et al., 2000; Schneiders et al., 2007).

Through its laminin VI domain, Ntn1 interacts with and activates several receptors, including Down's syndrome cell adhesion molecule, neogenin, deleted in colorectal cancer (DCC), adenosine A2b receptor, and uncoordinated-5 (UNC5) homologue family members (UNC5A, UNC5B, UNC5C, and UNC5D in humans, and Unc5h1, Unc5h2, Unc5h3, and Unc5h4 in rodents) (Mehlen et al., 2011). Unc5b is so far retained the only Netrin 1 receptor expressed in murine embryonic ECs (Lu et al., 2004), whereas putative expression of the other receptor remains unclear. However, adult aortic ECs express DCC and the receptor is required for Netrin 1-induced ERK1/2 activation and the ensuing nitric oxide production (Nguyen and Cai, 2006).

Strong genetic evidences indicate that Netrin 1 and its receptor play a critical role in angiogenesis; however, conflicting data about their function during vascular development appear to reveal the complexity of the mechanisms of action. Lu and colleagues demonstrated that inactivation of Unc5b gene in mice and targeting by means of morpholinos *unc5b* or *ntn1a* in zebrafish leaded to aberrant blood vessels navigation and branching, hence suggesting a possible antiangiogenic role for Netrin 1. Mice lacking *Unc5b* died of heart failure at embryonic day E10.5 or E12, depending on the genetic background, and the vascular branching defects were ascribed to the loss of Ntn1 inhibition of EC filopodia extension and migration (Lu et al., 2004). In a follow-up study, authors demonstrated that Unc5b is downregulated in adult quiescent blood vessels and expressed in sprouting vasculature of tumor implants, thus defining an inhibitory role for Ntn1 in sprouting angiogenesis (Larrivée et al., 2007). On the contrary, a series of data from other *in vivo* and *in vitro* studies reported a proangiogenic function for Ntn1 (Epting et al., 2010; Navankasattusas et al., 2008; Park et al., 2004; Wilson et al., 2006). In 2004, Park et al. found that Ntn1 promotes EC migration and proliferation (Park et al., 2004), while a follow-up study revealed that *ntn1a* silencing in zebrafish embryos impair the formation of parachordal vessels, that are precursors of lymphatic vessels, and that Netrins promote the revascularization of ischemic tissues in murine models (Wilson et al., 2006). In 2008, Navankasattusas and colleagues generated endothelial-specific *Unc5b* knock-out mice in which they observed a decrease in the density in placental labyrinth arterioles, finally resulting in embryonic death between E12 and E13.5 (Navankasattusas et al., 2008). Recently, Netrin 1a and its receptor Unc5b were found to be upstream activators of a signaling cascade involving the ELMO1–DOCK180-dependent activation of Rac1 in cultured ECs and blood vessel formation in the zebrafish embryo (Epting et al., 2010). Moreover, adeno-associated viral overexpression of Ntn1 induced in vitro EC proliferation and migration and elicited the formation of new artery-like blood vessels in the adult rodent brain (Fan et al., 2008).

In an alternative model, it was proposed that Ntn1 may function as prosurvival factor, blocking cell death induced by its unbound Unc5b that in ECs also functions as a dependence receptor (Castets et al., 2009). Authors proposed that, in the absence of Netrin 1, Unc5b activates the serine/threonine death-associated protein kinase (DAPK), which in turn leads to cell apoptosis, through the action of caspases (Castets et al., 2009). On the contrary, in the presence of Ntn1 the proapoptotic caspase signaling cascade is blocked, thus promoting EC survival and proliferation (Castets et al., 2009).

More recently, Yung and colleagues generated a *Ntn1* null mouse, by inserting *loxP* sites around the second exon of *Ntn1* and crossing animals with a germline-specific *Cre* line. In these mice, in which no Ntn1 protein was expressed, phenotypic analysis confirmed a Ntn1 primary function during midline guidance of commissural axons, but not in other Unc5b-mediated effects such as repulsion, neuronal survival, or blood vessel branching. The authors proposed that Ntn1 may not be the primary ligand for Unc5 receptors *in vivo*, thus suggesting that other Unc5 ligands might play key roles in the control of EC survival and angiogenesis (Yung et al., 2015). In this regard, the fibronectin leucine-rich transmembrane proteins (FLRTs) have been found to interact with Unc5 receptors and act as repulsive guidance cues (Yamagishi et al., 2011). FLRT1–3 are the three members of the FLRT family of ligands that mediate both homophilic and heterophilic cell-to-cell adhesive interactions (Seiradake et al., 2014). Moreover, transmembrane FLRT proteins can be shed and act as soluble Unc5 ligands (Seiradake et al., 2016). FLRTs are regulators of early embryonic cardiovascular and neural development and are characterized by the presence of an N-terminal LRR domain followed by a linker region, a type 3 fibronectin domain (FN) and a juxtamembrane linker, containing a metalloprotease cleavage site (Seiradake et al., 2016). During development, upon proteolytic cleavage and shedding from the cell surface, FLRT2 and FLRT3 extracellular domains may function as repulsive guidance cues for Unc5-positive neurons (Yamagishi et al., 2011). Yet, the homophilic interaction among FLRT molecules on neighbor cells may promote instead cell-to-cell adhesion, thus indicating that FLRT can trigger both adhesive and repulsive signals in the same cell (Karaulanov et al., 2006). Recently, FLRT3 was found to be expressed by primary human artery ECs together with its receptor UNC5B and to control retinal vascularization in mouse models. In both cases FLRT–UNC5B interaction exerts a repulsive function toward ECs (Seiradake et al., 2014).

Ntn4, the most divergent member of the Ntn family, is a secreted protein which functions in axon guidance and regulates both mammary and lung morphogenesis in addition to blood vascular development. Some reports showed an inhibitory role for Ntn4 specifically in pathological angiogenesis (Lejmi et al., 2008; Nacht et al., 2009). Ntn4 was found to be upregulated by VEGF

stimulation and to inhibit EC migration and angiogenesis in laser-induced choroidal neovascularization and tumor xenograft models in mice (Lejmi et al., 2008). Ntn4 exerts its function by binding to its receptor neogenin and promoting its association with Unc5b, both receptors being necessary for downstream signaling (Lejmi et al., 2008). Hypoxia was found to increase Ntn4 expression in the retina (Lange et al., 2012) and in an oxygen-induced model of retinopathy neovascularization was significantly increased in *Ntn4*$^{-/-}$ mice (Kociok et al., 2016). Ntn4 was also found to promote in vivo lymphangiogenesis and to contribute to tumor metastatic dissemination (Larrieu-Lahargue et al., 2010). Indeed, the high-affinity binding of Ntn4 to α6β1 integrin, which is expressed on lymphatic ECs, leads to the activation of Src signaling and to the formation of cell-to-matrix contacts (Larrieu-Lahargue et al., 2011). The role of Ntn4i n the control of developmental angiogenesis is instead less clearly understood. Despite a low *Ntn4* gene transcription during embryonic zebrafish development, Lambert and colleagues showed that Ntn4 plays a crucial role for *in vivo* blood vessel formation (Park et al., 2005). Authors showed that Ntn4 induced EC survival, proliferation, and migration through the activation of different kinase pathways, that is, ERK1/2, Akt, JNK, and FAK, and that these signaling cascades finally lead to sprouting angiogenesis in zebrafish embryos (Lambert et al., 2012).

A recent structural study revealed that Ntn4 inhibits axonal growth, angiogenesis, and tumor progression by blocking laminin polymerization and disrupting preexisting laminin network in a nonenzymatic manner, independently from its binding to canonical Ntn receptors (Reuten et al., 2016). In particular the high-affinity binding of Ntn4 to laminin γ1 would cause the disruption of the basement membrane lying between ECs and pericytes, thus inhibiting the stabilization of capillaries and finally resulting in a collapse of the whole vascular network (Reuten et al., 2016).

Slits and Robos

Signaling by the Slit–Roundabout (Robo) ligand/receptor pair was first discovered to be implicated in the control of axon guidance (Carmeliet and Tessier-Lavigne, 2005), and more recently this interaction has been shown to be involved in vascular injury (Yuen and Robinson, 2013) as well as in physiological (Yadav and Narayan, 2014) and tumor angiogenesis (Wang et al., 2003). The Robo receptor family is composed of four known members, named Robo 1–4. While Robo2 and 3 are mainly neuronal, Robo1 is expressed in both nervous and vascular systems. Robo1–3 transmembrane receptors share a common molecular structure, consisting of five Ig-like and three fibronectin type III (FNIII) domains in the extracellular portion and four cytoplasmic conserved motifs (CC0, CC1, CC2, and CC3) (Kidd et al., 1998). The most newly discovered member of the family Robo4, also known as magic Roundabout, is an endothelial-specific protein that was identified independently by using bioinformatics data mining (Huminiecki et al., 2002) and in a study aimed at finding genes perturbed in mice with altered developmental angiogenesis (Park et al., 2003). Robo4 displays significant structural differences form the other family members, since it contains in the extracellular portion only two Ig and two FN repeats and in the intracellular domain only is variants of CC0 and CC2 motifs.

Slit proteins are the cognate ligand for the Robo receptors. Slits are a family of secreted glycoproteins composed of three members in vertebrates (Slit 1–3), *D. Melanogaster* and *C. Elegans* expressing instead only one single Slit protein. All mammalian Slits are expressed in the nervous system, but Slit2 and 3 can also be found in other organs. Slits are large proteins containing a stretch of four LRR, seven to nine EGF-like domains, a domain named Agrin, Laminin, Perlecan, and SLIT (ALPS) or laminin G-like module, and a C-terminal cysteine knot (Brose et al., 1999). Structural studies conducted in *Drosophila* showed that a site located in the second LRR domain of slit binds to the Ig region of robo1-3 and transduces cellular signaling (Howitt et al., 2004). Moreover, *Drosophila* slit binding to robo is enhanced by the high-affinity interaction of the C-terminal portion of slit with the heparan–sulfate (HS) proteoglycan syndecan, which probably acts by concentrating slit on the cell surface (Hohenester et al., 2006). Later, a corresponding HS/heparin-binding site was identified in the Ig1 and Ig2 domains of robo1, suggesting the importance of ternary complex formation to foster the stabilization of the signaling unit (Fukuhara et al., 2008). Of note, mammalian Robo3 and Robo4 lack the key amino acid residues required for Slit and heparin binding (Morlot et al., 2007; Zelina et al., 2014), and cell-based assays failed so far to demonstrate a direct Slit2–Robo4 interaction (Koch et al., 2011).

Despite the importance of Slit and Robo in the regulation of angiogenesis, the exact effect of Slit2 on ECs remains to be investigated due to the controversial reports on its attractive or repulsive signaling. Wang and colleagues were the first to investigate the role of Slit2 and Robo1 in vascular guidance. In particular, they demonstrated that Slit2 produced by tumor cells was able to attract Robo1-expressing ECs and promote angiogenic sprouting in a PI3K-dependent manner (Wang et al., 2003). Once the endothelial-specific Robo4 was discovered, different groups supported the hypothesis of an inhibitory effect of Slit2 on EC migration (Jones et al., 2008; Kaur et al., 2008; Park et al., 2003; Seth et al., 2005). In particular, *Robo4*-null mice are viable and fertile and have normal vessel patterning in multiple organs but exhibit increased basal and VEGF-induced retinal vascular permeability and show an increased experimentally induced pathological neovascularization. Robo4 is expressed by the endothelium of various vascular beds of embryonic and adult mice, but it is absent from tip ECs of retinal blood vessels, suggesting a possible role of Robo4 in the maintenance of vascular stability. Accordingly, Slit2 exerts a Robo4-dependent inhibitory function respect to VEGF-A165-induced migration and permeability by blocking the activation of Src kinase family proteins (Jones et al., 2008). This study was confirmed by a genetic dissection analysis, which revealed that Slit2 and Slit3 produced by mural cells inhibit VEGF-induced blood vessel growth in mammary gland, in a Robo4-dependent manner (Marlow et al., 2010). The clinical implication of these findings was further highlighted in multiple murine models of inflammation-induced endothelial permeability, wherein administration of the exogenous active N-terminal fragment of Slit2 (Slit2N) enhances the endothelial barrier function

and reduces cytokine storm-dependent vascular leakage by acting through Robo4 (London et al., 2010). The molecular mechanisms underlying the maintenance of vascular stability by Robo4 were dissected and a yeast two-hybrid screening identified paxillin and its paralog Hic-5 as Robo4 interactors. Accordingly, the formation of the Robo4/paxillin/Hic-5 complex was enhanced by Slit2. Moreover, upon Robo4 binding, paxillin recruits the ADP-ribosylation factor GTPase-activating proteins (Arf-GAP) GIT1 and inhibits VEGF-induced Arf6 GTP loading and the downstream activation of Rac (Jones et al., 2009). Since it has been demonstrated that Slit2 enhances vascular barrier function by stabilizing VE-cadherin at the EC surface (Jones et al., 2009), this may depend on the inhibition of the Arf6-induced internalization of VE-cadherin.

In a protein–protein interaction screening, the extracellular portion of Robo4 was found to interact with Ntn receptor UNC5B, another vascular specific axon-guidance receptor. In the model conceived by Koch and colleagues, Robo4 acts as a ligand that binds and signals through Unc5B receptor. This hypothesis is corroborated by the finding that soluble Robo4 treatment rescued vessel barrier function in Robo4$^{-/-}$ mice and blocked VEGF-induced vascular permeability in wild-type animals, but not in mice treated with an Unc5B inhibitory antibody. The suggested mechanism of action is that Robo4-activated Unc5B could associate with phosphorylated Src and prevent it from binding to VEGFR2 upon VEGF stimulation. Blocking Robo4–Unc5B interaction increases Src association with VEGFR2 and VE-cadherin phosphorylation. Moreover, since Robo4 knockdown leaves developing retinal vessels unaffected, it has been hypothesized that the absence of Robo4 may be compensated by alternative Unc5B ligands, such as netrins or FLRTs (Koch et al., 2011).

A possible explanation for ROBO4 responsiveness to SLIT2 in absence of direct binding comes from a study conducted on HUVECs by Sheldon and colleagues. Authors found that ROBO1 and ROBO4 can form heterodimers and, upon SLIT2 binding to ROBO1, ROBO4 acts as a signaling unit that recruits Wiskott–Aldrich syndrome protein (WASP), neural WASP (NWASP), and their regulatory proteins WASP-interacting protein (WIP) and syndapin. The formation of this signaling complex would promote local actin polymerization, filopodia formation, and directional EC migration toward the source of SLIT2 (Sheldon et al., 2009).

Other studies described a promigratory role for Slit2 in postnatal retina and in mouse models of pathological ocular neovascularization. In blood vessels of the mouse retina, Slit2, signaling *via* Robo1 and Robo2, cooperates with VEGF to induce the establishment of EC front-to-rear polarity and motility. Slit2 binding to Robo leads to the recruitment of the scaffolding protein Nck1/2 and the ensuing activation of Cdc42 and Pak2, which in turn promote cytoskeletal remodeling and directional migration (Dubrac et al., 2016; Rama et al., 2015). On note, compared to its wild-type counterpart, the Slit2-ΔE15 alternative splicing variant, which lacks the exon 15-encoded C-terminus of the second LLR responsible for the direct binding to the first and second Ig domains of Robo1, exhibits a stronger and Robo-independent ability of inhibiting EC motility and stabilizing blood vessel integrity (Yang et al., 2015b). Notably, Slit2-ΔE15 expression is lost in many cancers (Yang et al., 2015b).

Slit–Robo can also signal to influence the behavior of other cell types, which contribute to the formation of the blood vessels wall. Two recent studies described the expression of Slit2, Robo1, and Robo4 in VSMCs and pericytes that surround medium/large diameter blood vessels and capillaries, respectively. In both studies, Slit2 inhibited platelet-derived growth factor-induced in vitro cell migration (Guijarro-Muñoz et al., 2012; Liu et al., 2006). These results suggest the existence of autocrine and paracrine circuits among cells localized within different layers of blood vessel walls, which may be involved in vascular guidance and remodeling.

Introduction

Vascular repair in the cardiovascular system is a complex biological process involving orchestrated responses among and between the endothelium, smooth muscle cells, cardiac fibroblasts, and myocytes. The endothelium serves as a nexus for molecular signaling events that contribute to postinjury tissue remodeling. While cardiac tissue remodeling plays an initially protective role in response to injury, excessive activation of fibroblasts leads to adverse remodeling and fibrosis that exacerbates heart failure. Endothelial cell-derived factors can both facilitate and inhibit vascular tissue repair, the balance of which ultimately determines the extent of fibrosis and cardiac dysfunction.

One of the first endothelium-mediated responses to myocardial infarction (MI) is the generation of thrombin that promotes a cascade of cellular effects to facilitate vascular repair. Thrombin-mediated cellular signaling occurs via classical G protein-coupled protease-activated receptors (PARs), which initially facilitate vascular repair but also contribute significantly to the pathological consequences of cardiac remodeling. PARs are the most abundant GPCR expressed on fibroblasts, which upon ligand-binding promote detrimental vascular remodeling and fibrosis.

Vascular injury also induces endothelial cell-mediated production of cardioprotective factors, such as neuregulin-1 (NRG-1), a growth and survival factor critical for heart development and cardiac repair. Similar to PARs, NRG-1 receptors are expressed throughout the cardiovascular system, but in contrast to PARs elicit mainly positive signaling events that contribute to attenuation of inflammation and fibrosis.

A detailed description of all the known molecular factors of vascular injury and repair is beyond the scope of this article. Rather, a novel perspective is provided in which the roles of PARs and NRG-1 in vascular repair are compared and contrasted, which is especially relevant given that both PARs and NRGs are promising therapeutic targets.

Role of Fibrosis in Vascular Repair After MI

MI is a major cause of heart failure, in part due to the limited capacity of the adult heart to regenerate after injury. Following an MI, cardiomyocyte death and loss of architectural integrity, together with specific hormones, growth factors, and cytokines induces infiltration of circulating immune and stromal cells to the injured area, proliferation of resident fibroblasts, and transdifferentiation of fibroblasts into a profibrotic phenotype (i.e., myofibroblasts). In concert with a multiphase inflammatory reaction, MI prompts myofibroblast-mediated replacement of the affected tissue with a fibrotic scar (van den Borne et al., 2010). This replacement fibrosis (i.e., scar formation) is a pivotal process in preventing ventricular wall rupture after an ischemic insult (van den Borne et al., 2010; Shinde and Frangogiannis, 2014). Impairment of cardiac function with subsequent heart failure may result from remodeling of the uninjured myocardium and in the infarct border zone due to exaggerated fibrotic response and reactive fibrosis (Talman and Ruskoaho, 2016; Sutton and Sharpe, 2000). This eventually leads to increased ventricular thickening (cardiomyocyte hypertrophy), ventricular stiffness, and altered chamber compliance with subsequent heart failure (Weber et al., 2013). Therefore, therapies for post-MI treatment that reduce pathological cardiac remodeling and fibrosis represent an attractive target for therapeutic intervention.

The Role of PARs in Vascular Repair

PARs are classical G protein-coupled receptors, but they are uniquely activated by proteases, resulting in release of a tethered ligand (Coughlin, 2000; Patterson et al., 2001). The PAR family, which consists of PAR-1, PAR-2, PAR-3, and PAR-4, can be activated by numerous serine proteases, including trypsin, plasmin, activated protein C, cathespsin G, kallikreins, tryptase, and matriptase. Most notably, all PAR family members, with the exception of PAR-2, can also be activated by the potent hemostatic protein thrombin. PARs reside in vascular cells, including vascular smooth muscle cells (VSMCs), endothelial cells, platelets, fibroblasts, and cardiac myocytes, and are intimately involved in vascular repair (Fig. 1). PAR-1 activation in endothelial cells leads to endothelial cell proliferation, attachment of polymorphonuclear cells, and increased permeability, steps that are important in the inflammatory cascade and hence intimately associated with vascular repair (Coughlin, 2000; Cleator and Vaughan, 2008).

PAR Activation by Thrombin

Thrombin stimulates PAR-1 and PAR-4 on human platelets and is the most potent activator of platelets. Moreover, thrombin-mediated PAR-1 stimulation on VSMCs causes contraction (Alberelli and De Candia, 2014). In addition, PAR-1 mediates the proliferation, migration, and hypertrophy of VSMCs in the setting of endothelial dysfunction, which contributes to the pathophysiology of atherosclerosis. Counteracting these deleterious effects, thrombin mediates activation of endothelial nitric oxide synthase (eNOS) to generate nitric oxide, which causes vasodilation in VSMCs and inhibits platelet activation (Alberelli and De Candia, 2014) which has been referred to as the thrombin paradox.

Thrombin induces an increase in thrombosponsdin-1 (TSP-1) gene expression in human microvascular endothelial cells as demonstrated by microarray analysis, which also corresponds to an increase in TSP-1 protein expression (McLaughlin et al., 2005). TSP-1 is an "adhesion-modulating" component of the extracellular matrix (ECM) (Mosher and Adams, 2012) that contributes to wound healing, in part via activation of latent transforming growth factor-β (TGF-β) (Murphy-Ullrich and Poczatek, 2000), a potent profibrotic cytokine important for fibroblast activation and secretion of ECM components, such as collagen. Thrombin-induced

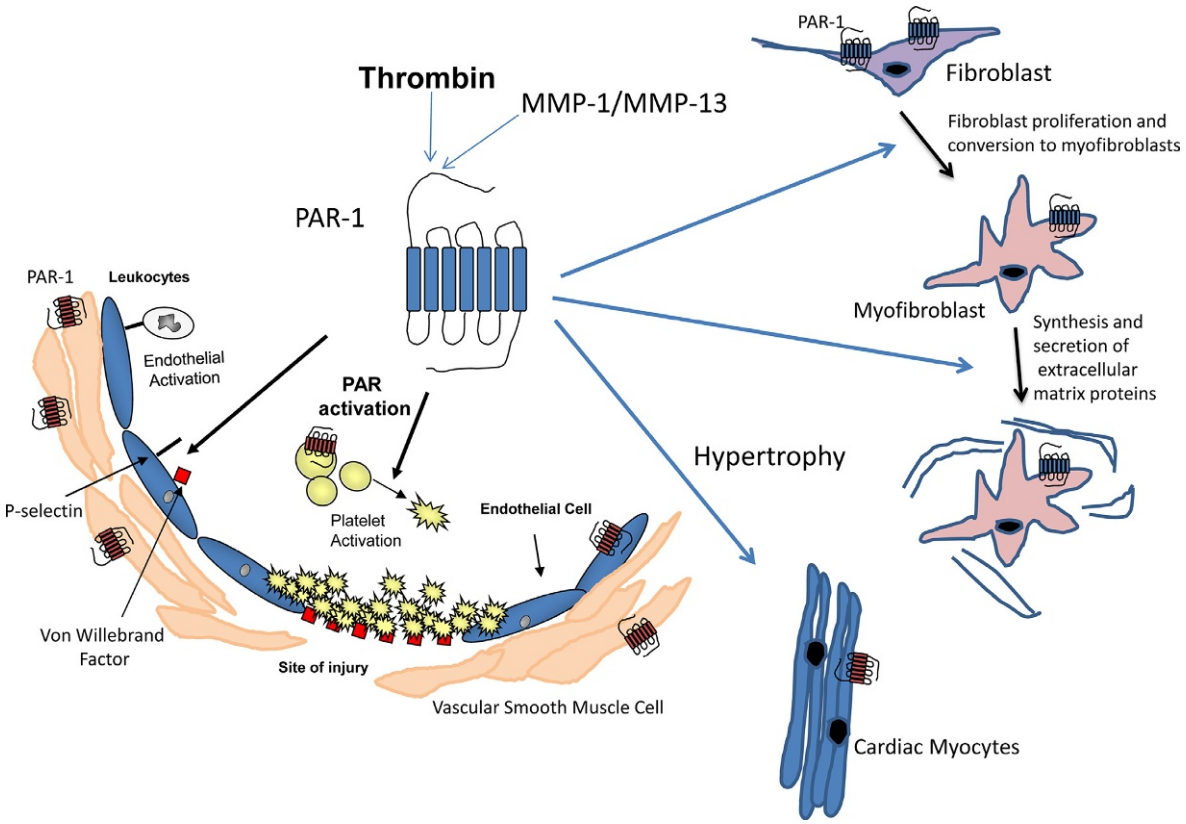

Fig. 1 PAR-1 mediation of vascular effects that influence vascular repair. Depicted centrally is the main thrombin receptor, PAR-1 which is activated when thrombin cleaves the N-terminal domain, unmasking a tethered ligand. PAR-1 activation leads to platelet activation and endothelial cell activation with exocytosis of Von Willebrand factor and P-selectin, which are critical steps in thrombosis and inflammation. PAR-1 activation also leads to fibroblast proliferation and conversion to myofibroblasts, partly through increased expression of TGF-β. In addition, PAR-1 is also expressed on cardiac myocytes, and PAR-1 activation leads to cardiac hypertrophy.

cleavage of PAR-1 also causes the proliferation and migration of VSMCs and inhibits angiogenesis (Krishna and Golledge, 2013). TSP-1 has also been implicated in wound-healing "gone awry," enhancing profibrotic signaling, matrix synthesis, and endothelial dysfunction (Krishna and Golledge, 2013). TSP-1 was shown to localize to calcified atherosclerotic lesions (Hansen et al., 2009) and to promote the formation of platelet–monocyte rosettes in patients with severe coronary artery stenosis and atherothrombotic cerebral ischemia (Jurk et al., 2010).

PAR Activation by Matrix Metalloproteinases

In addition to thrombin, PAR-1 can be activated by matrix metalloprotease 1 (MMP-1) and MMP-13, which results in biased activation, as opposed to classical canonical G protein signaling mediated by thrombin. MMP-1 and MMP-13 cleave the N-terminal domain of PAR-1 at a different site than thrombin resulting in distinct signaling that may be leveraged for therapeutic gain in vascular repair (Austin et al., 2013). MMPs are zinc-dependent endopeptidases, which are interstitial collagenases that play a pivotal role in vascular repair and development (Shoulders and Raines, 2009). Within the vasculature, MMPs affect the proliferation, migration, and apoptosis of VSMCs, endothelial cells, and inflammatory cells. Targeting of MMPs has long been investigated in treating vascular disease ranging from inhibition of MMP-1 in treating tissue accumulation after balloon injury (i.e., restenosis) to attenuating vascular remodeling after MI.

PAR Activation in Cardiac Cells

PAR-1 is also expressed on cardiomyocytes, as well as on fibroblasts that mediate cardiac remodeling (Sabri et al., 2000, 2002). In fact, PAR-1 is the most highly expressed GPCR present on cardiac fibroblasts and when stimulated leads to increased proliferation, conversion to the profibrinogenic myofibroblast phenotype, and increased production of TGF-β (Sabri et al., 2002; Snead and Insel, 2012). PAR-1 activation in cardiac fibroblasts also causes a significant increase in the expressions of MMP-1 and MMP-13 (Sonin et al., 2013). At the level of the cardiomyocyte, PAR-1 activation leads to hypertrophy, as demonstrated in a rat neonatal model (Glembotski et al., 1993). Furthermore, PAR-1 expression is increased in the hearts of patients with cardiomyopathy (CM) (both ischemic and nonischemic) (Moshal et al., 2005a), which correlates with basic science studies demonstrating increased PAR-1 expression in mice with experimentally induced chronic heart failure (Moshal et al., 2005b). Multiple groups have reported that inhibition of PAR-1 decreases cardiac remodeling and also limits myocardial ischemia reperfusion injury (**Table 1**).

Table 1 Studies of effects of PARs on vascular repair

Author	*Vascular model*	*Intervention*	*Outcome*
Rajput et al. (2014)	Rat middle cerebral artery occlusion	Knockdown of PAR-1	Decreased infarction and vascular disruption
Mao et al. (2010)	Mouse transient middle cerebral artery occlusion	PAR-4 knockout	Decreased infarction with attenuation of microvascular inflammation and inhibition of platelet activation
Xie et al. (2015)	Rat middle cerebral artery occlusion	Ginsenoside-Rg administration correlated with downregulation of PAR-1 expression	Reduced infarct volume, permeability, and neurobehavioral function score
Olson et al. (2004)	Mouse combined cerebral hypoxia/ischemia model	PAR-1 knockout and PAR-1 antagonist studies	Reduced infarct volume, cellular death, and motor behavior impairment
Junge et al. (2003)	Transient focal middle cerebral artery occlusion	PAR-1 knockout and PAR-1 antagonist studies	Reduced infarct volume
Strande et al. (2007)	Rat left coronary artery occlusion	Selective PAR1 antagonist SCH79797	Reduced infract size and increased ventricular recovery
Strande et al. (2008)	Rat left coronary artery occlusion	PAR4 antagonists (tc-y-NH2 and P2pal10)	Reduced infarct size and increased ventricular recovery
Kolpakov et al. (2016)	Mouse LAD artery occlusion	PAR-4 knockout	Reduced infarct size and cardiomyocyte apoptosis
Pawlinski et al. (2007)	Mouse LAD artery occlusion	PAR-1 knockout	Reduced remodeling but not infarction. Cardiomyocyte overexpression of PAR-1 induced adverse remodeling
Gu et al. (2015)	Rat left coronary artery ligation	Hirudin (a direct thrombin inhibitor)	Increased cardiac function which was reversed by PAR-1 agonist peptides
Baker et al. (2009)	Total body irradiation	Bone marrow transplantation	Increased PAR-1 expression correlated with adverse cardiac remodeling

Also, knockdown of either PAR-1 or PAR-4 confers a protective effect, with less cerebral infarction after stroke (middle cerebral artery infarct model, **Table 1**). This expands the potential therapeutic role of PARs in vascular repair to the cerebral vasculature, which shares a postischemic thromboinflammatory injury pattern with the cardiac vasculature (Bai and Lyden, 2015; De Meyer et al., 2016). Interestingly, it has become increasingly evident that paradoxically low levels of thrombin might by cytoprotective in the central nervous system (Krenzlin et al., 2016).

Therapeutic Applications of PAR Antagonists

Recently, multiple large randomized trials have investigated the effects of vorapaxar, a PAR-1 antagonist, in preventing adverse major cardiovascular events in patients with coronary artery disease. In patients presenting with acute coronary syndrome undergoing percutaneous coronary intervention, administration of vorapaxar failed to reduce the primary endpoint of ischemic events and increased the rates of severe bleeding (Tricoci et al., 2012; Morrow et al., 2009). However, a larger secondary prevention trial utilizing vorapaxar in patients with either a history of MI, history of ischemic stroke, or peripheral artery disease (TRA2 TIMI 50) demonstrated favorable results (Morrow, 2012). In a subgroup analysis, patients with a history of MI benefitted from addition of vorapaxar with a decrease in recurrent ischemic events (Scirica et al., 2012). It has been opined that off-target effects of PAR-1 antagonism on nonplatelet vascular cells may attenuate adverse remodeling contributing to beneficial effects.

Unintended deleterious side effects of vorapaxar, such as intracranial bleeding, have led to the development of alternative antithrombotic inhibitors that might block platelet aggregation while retaining beneficial PAR-mediated effects on cardiovascular endothelial cells. A small anatagonist peptide was recently reported to successfully elicit these cellular effects, including inhibition of thrombin-triggered clot formation in rodents (Ramachandran et al., 2017). Antibody blockage of PAR-4 in an arterial thrombosis monkey model was similarly efficacious, with minimal bleeding and the added advantage of oral administration (Wong et al., 2017).

NRG-1 Signaling in the Cardiovascular System

NRG-1 is encoded by one of four NRG genes belonging to the epidermal growth factor (EGF) superfamily of potent growth factors, which are potent modulators of cellular development, differentiation, and survival in multiple cell types and organ systems (Buonanno and Fischbach, 2001; Falls et al., 1993; Talmage and Role, 2004). NRG transduces signaling via erythroblastic leukemia viral oncogene homolog (ErbB) receptors (ErbB2, ErbB3, and ErbB4) (Yarden and Sliwkowski, 2001), which are tyrosine kinases that function similarly to the founding member (ErbB1, also called EGFR).

NRG-1 signaling is initiated upon engagement of its EGF-like domain to the extracellular binding region of either ErbB3 or ErbB4, which leads to receptor auto-phosphorylation of its cytosolic kinase region, dimerization with a second subsequently phosphorylated ErbB receptor, and recruitment and phosphorylation of one of several cytosolic adaptor proteins. ErbB3 is virtually kinase-dead, and thus NRG-1/ErbB3-mediated signaling requires recruitment and activation of ErbB2, which exhibits strong tyrosine kinase activity but lacks an extracellular ligand-binding domain. As is the case for ErbB1/EGFR, ErbB4 possesses both the ligand-binding and kinase domains and can therefore transduce growth factor-mediated signaling via homo- or hetero-dimerization.

Some of the specificity of NRG-1 signaling is achieved by variable expression and surface presentation cycling of ErbB receptors, which is highly dependent upon spatial and temporal context. NRG-1 and its receptors are widely expressed throughout the body, but the most prevalent source of NRG-1 in the cardiovascular system is the microvascular endothelium (Galindo et al., 2014a; Rupert and Coulombe, 2015). Endothelial cell-derived NRG-1β induces both autocrine and paracrine signaling within the myocardium (Kuramochi et al., 2004a; Noireaud and Andriantsitohaina, 2014; Lemmens et al., 2006; Kalinowski et al., 2010; Iivanainen et al., 2007). NRG-1 also acts distally to modulate adult heart homeostasis, most notably the control of heart rate and blood pressure via sympathetic vasomotor neurons in the rostral ventrolateral medulla (**Fig. 2**) (Matsukawa et al., 2011).

The Indispensability of NRG-1 in Cardiovascular Development and Repair

It is widely appreciated that NRG-1/ErbB signaling is critical for embryological development of the heart. Genetically altered mice with disruption in NRG-1, ErbB2, ErbB3, or ErbB4 die in utero due to defects in development of cardiac trabeculation and/or endocardial cushion formation (Meyer and Birchmeier, 1995; Gassmann et al., 1995; Lee et al., 1995). NRG-1/ErbB signaling also plays a crucial role in adult cardiovascular homeostasis and repair (**Fig. 2**), as evidenced by conditional knockout studies in mice and in human breast cancer patients. In mice, disrupted expression of ErbB2 or ErbB4 in the postnatal heart results in the development of dilated CM. More importantly, a higher incidence of heart failure was observed in women who received anthracyclines in combination with trastuzamab treatment (Slamon et al., 2001). Trastuzamab is a monoclonal antibody that was developed to specifically target ErbB2 (more often called HER2 in the arena of tumor biology), which is inappropriately activated (in the absence of ligand-bound dimerization partners) in some highly invasive and metastatic breast cancers.

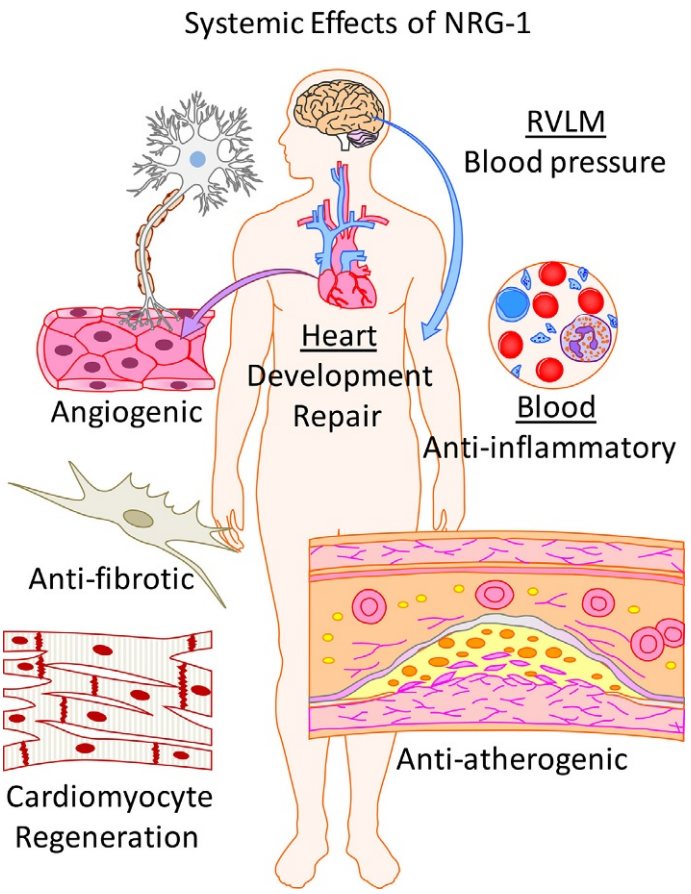

Fig. 2 Systemic effects of neuregulin-1 (NRG-1). NRG-1 plays a role in the development of the heart and in postnatal maintenance of the cardiovascular system, including regulation of heart rate and blood pressure via sympathetic vasomotor neurons in the rostral ventrolateral medulla (RVLM). NRG-1 is regenerative in response to cardiac injury, with direct effects on the endothelium, fibroblasts, and myocytes. NRG-1 might also inhibit atherosclerosis, as depicted.

In a reciprocal fashion, ErbB2 inhibition is detrimental for cardiovascular and nervous systems that require this receptor for homeostatic and stress-induced responses to NRG-1.

Ischemia/reperfusion injury is a potent activator of NRG-1/ErbB signaling in the intact heart, and selective disruption of endothelial NRG-1 expression impairs recovery of cardiac contractile function after an ischemic insult (Hedhli et al., 2011). Endothelial-derived NRG-1 is important for adaptive cardiomyocyte hypertrophy and cell lengthening, as indicated by genetically altered mice with conditional knockout of ErbB2 or ErbB4, which develop severe dilated CM characterized by chamber dilation, wall thinning, and decreased contractility (Ozcelik et al., 2002; Crone et al., 2002; Garcia-Rivello et al., 2005). ErbB2 expression is significantly decreased in a dog model of ischemic heart disease, as well as in human ischemic CM (Gordon et al., 2009). With ErbB2 blockade, however, in animals with chronic hypertrophy secondary to aortic stenosis, expressions of ErbB2 and ErbB4 are maintained during the compensatory stage of the disease and decline during the transition to failure (Rohrbach et al., 1999). A similar situation is observed in humans. Although ErbB2 is upregulated following ventricular unloading in heart failure patients (Uray et al., 2002), ErbB2 and ErbB4 expressions and activities are reduced in patients with advanced heart failure (Rohrbach et al., 2005). NRG-1/ErbB signaling might also play a role in the normal physiological adaptation of the heart to pregnancy (Lemmens et al., 2011), and its perturbation might therefore contribute to postpartum CM.

Cellular Effects of NRG-1/ErbB Signaling in the Heart

In vascular endothelial cells, NRG-1 induces proliferation and angiogenesis (Kalinowski et al., 2010; Russell et al., 1999; Bagheri-Yarmand et al., 2000), prevents endothelial dysfunction (Wang et al., 2017; Hedhli et al., 2012), and contributes to eNOS-dependent cardioprotection (Matsukawa et al., 2011; Ebner et al., 2013). NRG-1/ErbB signaling in the vasculature also prevents intimal thickening (Clement et al., 2007; Hintsanen et al., 2007), smooth muscle hyperplasia (Clement et al., 2007), and rarefaction of capillaries (Russell et al., 1999; Hedhli et al., 2012; Safa et al., 2011; Lok et al., 2009). In addition to autocrine signaling in microvascular endothelial cells (Kalinowski et al., 2010), NRG-1 induces paracrine signaling in cardiomyocytes (Pentassuglia et al., 2007, 2009; Baliga et al., 1999; Giraud et al., 1985; Sawyer et al., 2002; Matsui et al., 1999; Miao et al., 2000; Fujio et al., 2000;

Timolati et al., 2006; Cote et al., 2005; Fukazawa et al., 2003; Zhao et al., 1998; Kuramochi et al., 2004b, 2006; Okoshi et al., 2004; Jamnicki-Abegg et al., 2005; Lemmens et al., 2004; Mansour et al., 2004; Boateng et al., 2005; Kuppuswamy, 2002; Pfister et al., 2007; Peng et al., 2006, 2008), aortic smooth muscle cells (Yoshizumi et al., 2001), cardiac fibroblasts (Galindo et al., 2014b; Kirabo et al., 2017), resident and circulating stem cells (Liang et al., 2015; Polizzotti et al., 2015; Sun et al., 2011; Wang et al., 2008, 2009; Zhu et al., 2010; Hao et al., 2014), and monocytes (Ryzhov et al., 2017) (**Fig. 2**). NRG-1/ErbB signaling is strongly induced in myocytes in response to stress or injury, resulting in cellular proliferation (Polizzotti et al., 2015; Bersell et al., 2009; Ganapathy et al., 2016; Wadugu and Kuhn, 2012; Parodi and Kuhn, 2014; D'Uva et al., 2015) and survival (Kuramochi et al., 2004a; Rohrbach et al., 2005; Pentassuglia et al., 2007; Giraud et al., 1985; Matsui et al., 1999; Fujio et al., 2000; Fukazawa et al., 2003; Zhao et al., 1998; Belmonte et al., 2015; Liu et al., 2006; Jie et al., 2012; Li et al., 2007a; Fang et al., 2017), preserved excitation-coupling (Timolati et al., 2006), reduced oxidative stress (Timolati et al., 2006; Belmonte et al., 2015), reduced endoplasmic reticulum stress (Fang et al., 2017), and mitochondrial dysfunction (Guo et al., 2012), increased glucose uptake and protein synthesis (Baliga et al., 1999; Cote et al., 2005), and enhancement of sarcomere organization (Baliga et al., 1999; Sawyer et al., 2002; Cote et al., 2005; Mansour et al., 2004; Liu et al., 2006).

In addition to its mitogenic and protective effects on vascular cells and cardiomyocytes, NRG-1 alters the cardiac interstitium and associated cell populations (Galindo et al., 2014a). NRG-1 inhibits cardiac fibrosis (Gui et al., 2012; Li et al., 2011), presumably via decreased production of ECM structural and regulatory proteins (Galindo et al., 2014b; Li et al., 2011), alterations in MMPs (Yuan et al., 2008a,b; Li et al., 2009; Momeny et al., 2015; Asrani et al., 2013; Kim et al., 2012; Sigala et al., 2006), and fewer ventricular myofibroblasts (Galindo et al., 2014b). Paradoxically, NRG-1 enhances proliferation and survival of normal human cardiac ventricular fibroblasts when cultured in vitro (Kirabo et al., 2017), which could point to a pro-wound-healing effect if these functional results are recapitulated in the intact heart in conjunction with cardiovascular injury.

Circulating monocytes express ErbBs and respond to NRG-1, which reduces production of inflammatory mediators (Ryzhov et al., 2017; Marballi et al., 2010; Zhou et al., 2017). In animal models of vascular disease, NRG-1 inhibits stress and ischemia-induced accumulation of leukocytes (Hedhli et al., 2011; Lok et al., 2009; Liu et al., 2006; Li et al., 2009; Marballi et al., 2010; Xu et al., 2005; Panutsopulos et al., 2005). In monocytes acquired from heart failure subjects, higher surface expression of ErbB3 was found to be correlated with lower levels of the inflammatory cytokine tumor necrosis factor α (TNFα) (Ryzhov et al., 2017). Surprisingly, an inverse relationship between TNFα and ErbB3 was not observed in this same subpopulation of monocytes obtained from healthy individuals (Ryzhov et al., 2017), which underscores the highly contextual nature of NRG-1/ErbB signaling and the need for further investigation of this phenomenon. Recent evidence also supports a role for NRG-1 in the alteration of macrophages from a proinflammatory to a regenerative phenotype in the postinfarct setting (Diaz-Herraez et al., 2017).

Distant NRG-1 signaling can also impact cardiovascular function and homeostasis (**Fig. 2**). Recent evidence suggests that NRG-1 stimulation of resident cardiac fibroblasts might contribute to a multicellular, intersystemic signaling network (Kirabo et al., 2017). It is possible that NRG-1-induced production of cytokines modulates the inflammatory response during wound healing and pathological cardiac remodeling. Additionally, NRG-1-induced secretions from activated cardiac fibroblasts might stimulate influx of circulating monocytes, pericytes, endothelial progenitors, resident stem cells, bone marrow-derived stem cells, or pluripotent mesenchymal cells. Consistent with this theory, NRG-1 enhances embryonic stem cell cardiomyogenesis (Sun et al., 2011; Wang et al., 2008, 2009; Hao et al., 2014; Chen et al., 2013; Kim et al., 2007), regulates cardiac subtype specification (Zhu et al., 2010; Ruhparwar et al., 2007), and may also stimulate new cardiomyocyte production from endogenous cardiac progenitor cells in response to workload (Polizzotti et al., 2015; Waring et al., 2014). Given the importance of NRG-1 in normal physiological and pathophysiological responses to stress and tangential stem cell studies for cardiac regeneration, these intersecting research areas are ripe for investigation.

NRG-1 as a Potential Therapy for Cardiovascular Disease and Injury

Preclinical data support the efficacy of NRG-1 as a therapeutic candidate in multiple areas of cardiovascular medicine (**Fig. 2**), including vasculopathy. Endogenous NRG-1 is required for angiogenesis and arteriogenesis following ischemic injury, and administration of exogenous NRG-1 enhances this process (Hedhli et al., 2012). Plasma levels of NRG-1 were shown to be significantly lower in patients with coronary artery syndrome and angina, compared to those with mild hypertension and normal individuals (Wang et al., 2009). NRG-1 expression is amplified in atherosclerotic lesions in coronary artery disease (Sigala et al., 2006; Panutsopulos et al., 2005). Administration of exogenous NRG-1 suppressed macrophage foam cell formation in primary human monocyte cultures (Wang et al., 2009). Further, in apolipoprotein E-deficient mice, NRG-1 was shown to inhibit atherogenesis (Wang et al., 2009). In a rat model of carotid vascular injury, NRG-1 injection reduced lesion size by 50% compared with vehicle-treated control animals and prevented mitogen-stimulated VSMC proliferation and migration (Clement et al., 2007). These findings suggest that NRG-1 may be a novel therapeutic candidate for the treatment of atherosclerosis. Local administration of NRG-1 could also mitigate restenosis following endovascular therapy, which might possibly reduce re-intervention and increase vessel preservation for future treatment options.

Multiple in vivo studies have established the therapeutic potential for NRG-1 for the treatment of heart failure (**Tables 2** and **3**). The EGF-domain fragment of recombinant human NRG-1β2a (rhNRG) was used in a series of small and large animal models of systolic heart failure to demonstrate a positive effect on heart function and survival (**Table 2**). For example, rhNRG administration to myocardial-infarcted rodents improved LV remodeling and cardiac function, induced angiogenesis, activated the cell cycle in

Table 2 Studies of effects of recombinant NRG-1 on heart failure (animal studies)

Animal model	*Species*	*NRG-1 formulation*	*Treatment*	*Outcome*
Carotid vascular injury (Clement et al., 2007)	Rat	rhNRG	2.5 ng/kg, before balloon injury then every 2 days, for 14 days	Attenuated neointima formation, 50% reduction in lesion size
MI (Liu et al., 2006)	Rat	rhNRG	10 μg/kg i.v. daily, for 5 days, 10 days, 1 week, or 2 months after LAD	Attenuated dysfunction and improvements in cardiac performance. Increased capillary abundance in the fibrotic peri-infarct area (angiogenesis)
MI (Bersell et al., 2009)	Mouse	rhNRG	2.5 μg/mouse i.p. daily for 12 weeks, 1 week after LAD	Induced cell cycle in cardiac myocytes and improved cardiac function and structure
MI (Gu et al., 2010)	Rat	rhNRG	5 μg/kg/h at 10 μL/h osmotic pump, for 7 days, 8 weeks after LAD	Upregulated cardiac myosin light chain kinase associated with improved cardiac function
MI (Guo et al., 2012)	Rat	rhNRG	10 μg/kg i.v. daily, for 5 days, 10 days, 1 week, or 2 months after LAD	Improved LV remodeling and cardiac function, reduced mitochondrial dysfunction, myocyte apoptosis, and oxidative stress
MI (Xiao et al., 2012)	Rat	rhNRG	rhNRG-carrying lentivirus injected in infarcted area	Improved LV function, decreased apoptosis, promotion of neovascularization and angiogenesis
MI (Hill et al., 2013)	Rat	rhGGF2	0.625 or 3.25 mg/kg, with or without high fat diet, twice weekly for 4 weeks, 7 days post-MI	Improved LV contractile function, corrected gene expression alterations, beneficial effects independent of dietary fat content
MI (Galindo et al., 2014b)	Swine	rhGGF2	0.67 mg/kg or 2 mg/mL i.v. twice weekly, for 4 weeks, 1 week post-MI	Improved LV contractive function, decreased fibrosis
MI (Hill et al., 2013)	Rat	rhGGF2	0.65, 2.6, or 3.25 mg/kg at variable freq. and durations	Sustained improvement of LV function and morphology
I/R	Rat	rhNRG	1, 2, 4, or 8 μg/kg i.v. for 20 min prior to I/R	Improved LV structure, reduced infarct size, decreased apoptosis
I/R (Fang et al., 2017)	Rat	rhNRG	4 μg/kg i.v. for 20 min prior to I/R	Decreased myocardial infarct size, inhibited ER stress
Viral myocarditis (Liu et al., 2006)	Mouse	rhNRG	30 μg/kg i.v. daily, for 5 days	Improved echocardiographic parameters and survival
Dox-induced CM (Liu et al., 2006)	Mouse	rhNRG	20 μg/kg i.v. daily, for 5 days, 4 weeks post-Dox treatment	Prevented cardiac dysfunction and improved survival
Dox-induced CM (Bian et al., 2009)	Mouse	rhGGF2	0.75 mg/kg *sub.q* 1 day prior to Dox, daily thereafter, 5 days	Improved survival and cardiac function
Dox-induced CM (Jay et al., 2013)	Mouse	NN	20 μg/mouse i.p. daily for 1 week, 16 weeks post-Dox	Improved LV function, increased posterior wall thickness, decreased end-systolic diameter
Diabetic CM (Li et al., 2011)	Rat	rhNRG	10 μg/kg i.v. daily, every 2 days for 2 weeks, 12 weeks post-STZ injection	Improved LV structure and dysfunction, decreased apoptosis, decreased fibrosis
Diabetic CM + atherosclerosis (Vandekerckhove et al., 2016)	Mouse	rhNRG	20 μg/kg i.p. 5 days/week for 14 weeks	Prevented LV dilatation, improved LV contractile function, reduced atherosclerotic plaque size, attenuated nephropathy
Cardiac cryoinjury (Polizzotti et al., 2015)	Mouse	rhNRG	100 ng/g sub-q. daily, for the first 34 days of life	Improved myocardial function, reduced prevalence of transmural scars
Cardiac cryoinjury (Ganapathy et al., 2016)	Mouse	rhNRG	100 ng/g *sub-q.* daily, for first month of life	Cardiac regeneration in absence of neoplasia
Pacing-induced CM (Liu et al., 2006)	Dog	rhNRG	5 μg/kg *i.v.* daily, 5 days with continuous pacing, 3 weeks after start of pacing	Improved LVEDP and LVESP, improved cardiac contractility and relaxation
Pacing-induced CM (Li et al., 2007b; Li and Qiang, 2007)	Rhesus monkey	rhNRG	3 μg/kg *i.v.* daily, for 10 days	Improved LV function, increased MHCα

LV, left ventricular; *LVEDP*, left ventricular end-diastolic pressure; *LVESP*, left ventricular end-systolic pressure; *MI*, myocardial infarction; *I/R*, ischemia/reperfusion; *NRG*, neuregulin-1; *rhNRG*, recombinant human neuregulin-1; *rhGGF2*, recombinant human glial growth factor 2; *NN*, bivalent NRG-1.

cardiomyocytes, and reduced mitochondrial dysfunction, myocyte apoptosis, and oxidative stress I (Liu et al., 2006; Guo et al., 2012; Gu et al., 2010; Xiao et al., 2012). In rat models of ischemia reperfusion, pretreatment with rhNRG improved LV structure, reduced infarct size, and inhibited endoplasmic reticulum stress and apoptosis (Fang et al., 2010, 2017). Treatment with rhNRG similarly increased cell survival and myocardial function in a mouse model of viral myocarditis (Liu et al., 2006), in mice with doxorubicin-induced CM (Liu et al., 2006; Bian et al., 2009), in Type I diabetic CM rodent models with and without atherosclerosis

Table 3 Human studies of effects of recombinant NRG-1 on heart failure

Trial	*Description*	*Formulation of NRG-1*	*Dose*	*Effect*
ACTRN12607000330448[a] Completed (Gao et al., 2010)	Phase II, randomized, double-blind, multicenter, background-therapy-based, placebo-controlled, parallel group study	rhNRG	0.3, 0.6, or 1.2 μg/kg 10 h intravenous infusion, daily for 10 days	Improved and sustained LVEF % and decreased LVEDV and LVESV at 30 and 90 days after treatment
ACTRN12607000330448[a] Completed (Jabbour et al., 2011)	Single-center, prospective, nonrandomized, open label study	rhNRG	Initial dose of 1.2 μg/kg for 6 h; followed by 0.6, 1.2, or 2.4 μg/kg for 12 h intravenous infusion, daily for 10 days	Acute increase in CO and improvement in LVEF
NCT01258387[b] Completed (Lenihan et al., 2016)	Phase I, single ascending dose study of cimaglermin alfa (neuregulin 1β3) in patients with systolic dysfunction and heart failure	rhGGF2	0.007, 0.021, 0.063, 0.189, 0.378, 0.756, or 1.512 mg/kg for 30 m, single intravenous infusion	Persistent (90 day) increase in LVEF, with minimal side effects for 0.189 mg/kg and higher doses

LVEF %, % left ventricle ejection fraction; *LVEDV*, left ventricle end-diastolic volume; *LVESV*, left ventricle end-systolic volume; *CO*, cardiac output; *rhNRG*, recombinant human neuregulin-1; *rhGGF2*, recombinant human glial growth factor 2.

(Li et al., 2011; Vandekerckhove et al., 2016), cryo-injured mice (Polizzotti et al., 2015; Ganapathy et al., 2016), and in two large animal models of pacing-induced CM (Liu et al., 2006; Li et al., 2007b; Li and Qiang, 2007).

Another version of NRG-1, representing the full-length NRG-1β3 isoform (rhGGF2), was also developed and likewise shown to be efficacious in the failing myocardium (**Table 2**). Most interestingly, rhGGF2 has been demonstrated to prevent adverse remodeling after injury, in part via antifibrotic effects in the heart. In post-MI swine, rhGGF2-treated pigs exhibited less fibrosis, improved ECM structure, and reduced myofibroblast percentages in myocardial tissue remote from the infarct (Galindo et al., 2014b). More recently, Parry et al (Parry et al., 2017). directly compared the kinetics and pharmacological effects of the two different recombinant NRG-1 formulations in vitro and in post-MI rats and concluded that (1) rhGGF2 has higher ErbB4 receptor binding affinity than rhNRG, (2) better protects doxorubicin-challenged cardiomyocytes, and (3) provides sustained improvements in post-MI cardiac function with relatively infrequent dosing compared to a daily dosage regimen with rhNRG.

These promising preclinical animal studies have led to ongoing clinical trials examining whether these NRG-1βs have similar effects in humans (**Table 3**).

Developing Novel Methods for Target-Specific NRG-1 Therapies

Cooperative intercellular signaling via NRG-1/ErbB has been demonstrated for cardiomyocytes and endothelial cells (Lemmens et al., 2006) and likely occurs among other cell types. NRG-1-mediated activation of other EGFR family members provides further complexity, enhancing feed-forward signaling cascades that tend to confound disease-specific therapeutic applications. Off-target effects are of prime concern, given the strong associations of both ErbB2 and ErbB3 in tumor development and progression. Two recent advances provide potential solutions to these issues: bivalent ErbB receptor agonists (Jay et al., 2011, 2013), and conjunctive therapies using microparticles or stem cells.

Diaz-Herraez et al. (2017) recently demonstrated synergistic, vasculogenic, and cardioreparative effects of NRG-1 combined with adipose-derived stem cells in post-MI rats, when administered in microparticles coated with collagen and poly-D-lysine. This combinatorial treatment approach induced significant heart regeneration, including a reduction of ~36% in infarct size, stimulation of cardiomyocyte proliferation, and formation of both arterioles and capillaries (Diaz-Herraez et al., 2017). Similarly, controlled delivery of a combination of NRG-1 and fibroblast growth factor, encapsulated in biodegradable microparticles, promoted cardiac regeneration in post-MI rats (Formiga et al., 2014). Transplantation of ErbB4-overexpressing mesenchymal stem cells was also efficacious in post-MI mice, which exhibited a greater reduction in infarct size and better preserved cardiac function than in mice treated with the corresponding wild-type stem cells (Liang et al., 2015). This therapeutic strategy was also superior to post-MI mice treated with recombinant NRG-1 alone (Liang et al., 2015), implying endogenously produced NRG-1 was sufficient to activate the cells once administered, or possibly that other ErbB4 ligands contributed to the observed improvement in cardiac regeneration and performance.

A Possible Link Between PAR-1 and NRG-1

A simplified view of thrombin/PAR-1 and NRG-1/ErbB signaling is that they respectively act negatively and positively on the vasculature. This "inverse functional relationship" is not entirely unrealistic, because there is some evidence to support

NRG-1-mediated inhibition of thrombin activities via increased production of inhibitory factors in the postinfarct setting (Galindo et al., 2014b). Most notably, NRG-1 administration to pigs, beginning 1 week after MI and continuing twice weekly for 4 weeks, resulted in a significant increase in thrombomodulin (THBD) mRNA in myocardium remote from the infarct (Galindo et al., 2014b).

THBD is the other major cofactor/receptor for thrombin. Although the level of thrombin is a result of the net balance between its synthesis and degradation, its physiological effects are determined primarily by availability of PAR-1 and THBD. THBD alters vascular remodeling and decreases neointima formation in animal models of vascular injury. In a mouse carotid ligation model, binding of THBD to thrombin inhibited thrombin-induced PAR-1 activity, which resulted in significantly attenuated atherosclerosis and neointima formation (Wei et al., 2011). In a separate study, THBD was likewise shown to decrease the severity of neointima formation and reduce arterial remodeling via thrombin-mediated PKC activation. In this same study, THBD inhibited leukocyte adhesion to the vessel wall after carotid ligation (Li et al., 2006). NRG-1-mediated alterations in the coagulation cascade via upregulation in THBD transcription might therefore contribute to its proreparative effects in response to vascular injury.

Summary and Conclusions

PARs and NRG-1 are indispensable in the response of the vasculature to ischemia and other injurious insults. The complex balance between vascular repair and maladaptive remodeling leading to fibrosis, atherosclerotic plaque formation, or thrombosis has complicated efforts to harness NRG or inhibit PAR. Nonetheless, clinically translatable progress has provided insights into the underlying mechanisms associated with these two inducible signaling cascades. Novel, selective therapies continue to evolve as we improve our basic understanding of vascular injury and repair, in keeping with the general trend of modern medicine toward more personalized, context-driven solutions.

Introduction

The vascular system is one of the earliest functional organ systems to develop in all vertebrate embryos. Comprising a highly complex and intricate network of arteries, veins, capillaries, and lymph vessels, the circulatory system transports gases, nutrients, and metabolites throughout the body and plays important physiological roles in regulating homeostasis in the developing embryo as well as in the adult. The vascular system retains morphogenetic plasticity in the adult, which is important in normal physiological processes like the oestrous cycle and wound healing. Furthermore, vascular anomalies have been implicated in the pathology of several diseases including cancer (Carmeliet, 2003). Thus, the establishment of a proper vascular network is imperative for the normal development and functioning of all organ systems in the body.

The development of the vascular system involves two distinct processes known as vasculogenesis and angiogenesis (Poole and Coffin, 1989; Risau et al., 1988). Vasculogenesis, which is the de novo differentiation and assembly of endothelial cells into primary blood vessels, is the process by which the first major axial vessels, the dorsal aorta (DA) and cardinal vein (CV), are formed in most vertebrates (Coffin and Poole, 1988; Poole and Coffin, 1989). Following the formation of a primitive vascular plexus and the major axial vessels, elaboration of the primary vasculature by coordinated sprouting of blood vessels occurs by angiogenesis (Poole and Coffin, 1989). While these two processes are equally important in the establishment of the vascular network, this review will focus on the mechanisms underlying vasculogenesis. Vasculogenesis is initiated during late gastrulation when a subset of cells in the lateral plate mesoderm (LPM) is specified as vascular endothelial progenitor cells (EPCs), also known as angioblasts. Angioblasts migrate toward the midline, differentiate into vascular endothelial cells, and coalesce to form solid tubes (Kimmel et al., 1995; Stainier et al., 1995). In response to extracellular cues, the endothelial cells acquire either an arterial or venous identity. The final step in vasculogenesis is the process of lumenization of the vessels into hollow tubes, which allows blood cells to circulate through the primitive vessels. The current review aims to summarize the key events during vasculogenesis together with models used to describe these events.

Sites of Vasculogenesis

In amniotes, the earliest vasculogenesis occurs in the blood islands of the yolk sac which give rise to the extraembryonic primitive vascular plexus. In mouse, yolk sac vasculature forms at around E7.5. This is followed by the intraembryonic vasculogenesis which takes place within the LPM and gives rise to the major axial vessels, such as the DA and the CV (Drake and Fleming, 2000). Early studies have suggested that the vasculature in many organs is derived from vascular endothelial progenitors which originate de novo and are not derived from the existing vascular network (Gouysse et al., 2002). However, in most cases, lineage tracing has not been performed to confirm these observations. More recent studies showed that many organ-specific vessels are derived from existing vasculature through a combination of vasculogenesis and angiogenesis. For example, intestinal vasculature in zebrafish is formed from vascular endothelial progenitors that originate from the posterior CV (PCV) and migrate as individual cells and subsequently coalesce into the subintestinal artery and subintestinal vein (Goi and Childs, 2016; Hen et al., 2015; Koenig et al., 2016). Genetic lineage tracing studies have demonstrated that the murine hepatic plexus is derived from the endocardium and shares a common developmental origin with coronary arteries (Zhang et al., 2016). A substantial portion of murine coronary vasculature is formed by de novo vasculogenesis from endocardial progenitors (Tian et al., 2014), which themselves originate from the LPM. In addition to

the LPM, cell-tracking experiments have demonstrated that some vascular endothelial cells are derived from somites in chick embryos (Ambler et al., 2001; Wilting et al., 1995). It is somewhat controversial whether any endothelial cells are derived from somites in nonamniote embryos although recent experiments in zebrafish have suggested this possibility (Nguyen et al., 2014).

Hemangioblast—The Common Precursor of Vascular Endothelial and Blood Cells

Based on multiple observations including the spatial proximity of endothelial and hematopoietic cell development in avian and mammalian embryos, it has been speculated that a common precursor cell known as the hemangioblast gives rise to both blood cells and endothelial cells (Detrich et al., 1995; Haar and Ackerman, 1971; Moore and Owen, 1965). The concept of a common progenitor of both cell types arose from initial observations made nearly a century ago by Sabin and Murray, who described the close proximity of hematopoietic and endothelial cells in the developing chick embryo (Murray, 1932; Sabin, 1920). The support for the existence of such a common progenitor comes from studies of in vitro-differentiated embryonic stem (ES) cells or mouse posterior primitive streak regions, which were shown to harbor a vascular endothelial growth factor (VEGF)-responsive progenitor, which expresses VEGFR2/FLK1 and has a potential of generating both blood and endothelial cells in culture at a single cell level (Choi et al., 1998; Faloon et al., 2000; Huber et al., 2004). Studies on human ES cell differentiation in vitro have identified a progenitor which has the potential to give rise to both endothelial and hematopoietic cells (Choi et al., 1998; Kennedy et al., 1997; Zambidis et al., 2005). Moreover, cell lineage tracing studies using *Flk1-Cre* and Rosa-stop–EYFP or Rosa-stop–LacZ reporter mice also supported the notion that blood and endothelial cells originate from the Flk1-expressing progenitors (Lugus et al., 2009; Motoike et al., 2003). Single-cell fate mapping experiments and retrospective clonal analysis in zebrafish embryos have shown that while the majority of cells at the blastula and gastrula stages give rise to either endothelial or blood cells and that these two types of cells differentiate through different paths, a small fraction of cells gave rise to both endothelial and blood cells, suggesting that only a subset of mesodermal cells could give rise to hemangioblasts (Vogeli et al., 2006).

The recent identification of the zebrafish *cloche* mutant gene *npas4l* will likely add to our understanding of hemangioblast as *cloche* mutants lack nearly all hematopoietic and endothelial cells (Reischauer et al., 2016; Stainier et al., 1995). While it is tempting to postulate that the earliest cells which express *npas4l* could be the presumptive hemangioblasts which give rise to both endothelial and primitive erythroid cells, accumulating evidence points to other possibilities. Some endothelial progenitors which express *npas4l* could form a specialized intermediate hemogenic endothelium which gives rise to primitive erythroid cells in addition to giving rise to vascular endothelial cells (Lancrin et al., 2009). Another possible explanation is that *npas4l* is expressed only in endothelial progenitors which go on to form endothelial cells (Parker and Stainier, 1999). These endothelial cells then provide essential signals and the appropriate microenvironment for the differentiation of hematopoietic progenitors into primitive erythroid cells. In both scenarios, the loss of *npas4l* leads to loss of both endothelial cells and primitive blood cells.

The Role of Etv2 in Vascular Endothelial Specification

One of the earliest transcription factors expressed in vascular endothelial progenitors and/or hemangioblast cells is an ETS transcription factor Etv2/ER71/Etsrp which functions (Lee et al., 2008; Sumanas and Lin, 2006). In the developing mouse embryo, *Etv2* is expressed in the primitive streak, embryonic mesoderm, amnion, allantois, and yolk sac blood islands at around E7.5 (Lee et al., 2008). Its expression becomes rapidly downregulated as the embryo develops and becomes restricted to major vessels, including the DA and branchial arches, at around E8.25–E9.5 (Lee et al., 2008). *Etv2* expression in the adult is mainly observed in the testis (Brown and McKnight, 1992). Similarly, *Etv2* expression in differentiating ES cells, embryoid bodies (EBs), is initiated around the same time as *Brachyury* expression. *Etv2* expression within EBs is also transient and becomes undetectable once hemangiogenic progenitors have been generated (Lee et al., 2008). Consistently, transgenic reporter expression driven by the *Etv2* promoter/enhancer region or the endogenous *Etv2* locus can be detected in the extraembryonic mesoderm, lateral mesoderm, and vascular structures in the embryo proper and yolk sac. However, the *Etv2*-reporter is no longer expressed at later stages of development (Kataoka et al., 2011; Rasmussen et al., 2011; Wareing et al., 2012).

Similarly, in zebrafish embryos, *etv2* expression is initiated in the anterior LPM (ALPM) as early as the 1-somite stage. *npas4l* function is required for *etv2* expression (Reischauer et al., 2016). *etv2*-expressing cells in the ALPM give rise to the endocardium, cranial vasculature, and myeloid progenitors (Proulx et al., 2010). Shortly afterward, at the 2–3 somite stage, *etv2* expression is observed in endothelial progenitors in the posterior LPM (PLPM). Similarly, in *Xenopus* embryos, *etv2* expression is observed in the dorsal LPM which gives rise to the DA and hematopoietic stem cells, in the ventral blood island where primitive hematopoietic cells originate, and in the vascular endothelial progenitors that correspond to the vascular plexus and PCV (Ciau-Uitz et al., 2013; Salanga et al., 2010).

Transient *Etv2* expression pattern is manifested by its transient requirement in hematopoietic and vascular development. In particular, *Etv2*-deficient mice display a complete block in blood, endothelial cell and endocardial formation, which indicates that ETV2 performs a nonredundant and indispensable function in hematopoietic and vessel development (Ferdous et al., 2009; Lee et al., 2008). Similarly, *Etv2* functional knockdown in zebrafish using morpholinos, as well as genetic mutant data demonstrate the critical role of *Etv2* during embryonic vasculogenesis and hematopoiesis. Specifically, vascular endothelial cells fail to differentiate, and the expression of multiple vascular endothelial markers is lost or downregulated in *etv2* morpholino (MO) knockdown

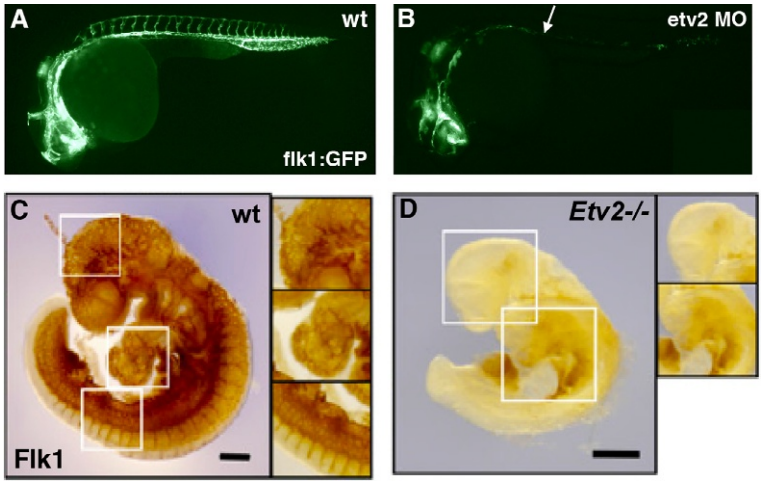

Fig. 1 Etv2 is required for specification of vascular endothelial cells in vertebrates. (A and B) Vascular endothelial specific *flk1:GFP* (*kdrl:GFP*) expression is greatly reduced in Etv2 MO-injected embryos at 24 hpf. (C and D) Flk1 immunostaining is absent in mouse *Etv2* knockout embryos at E9.5.

zebrafish embryos (morphants) and *etv2* mutants during early and mid-somitogenesis stages (**Fig. 1**) (Pham et al., 2007; Sumanas and Lin, 2006). Etv2 directly activates the transcription of many vascular endothelial specific genes by binding to vascular enhancers in combination with other transcription activators such as FOXC family members (De Val et al., 2008; Liu et al., 2015). *etv2*-expressing EPCs in Etv2 translation blocking MO-injected zebrafish embryos fail to migrate to the midline, remain positioned bilaterally, and do not coalesce into blood vessels due to their failure to form junctions between adjacent cells (Sumanas and Lin, 2006). In striking contrast to a complete block in hematopoietic and vascular formation seen in *Etv2* knockout mouse embryos, *Etv2* deletion after the hemangiogenic program commitment leads to normal development. Specifically, *Etv2* deletion using *Tie2-Cre* (hematopoietic and endothelial cell specific), *Vav-Cre* (hematopoietic specific), or *VEcadherin-Cre* (endothelial cell specific) systems do not lead to any defects in hematopoietic or endothelial cell development (Park et al., 2016; Xu et al., 2017). However, in zebrafish Etv2 plays a redundant role with other ETS factors such as Fli1b during later vascular development (Craig et al., 2015). It is also important for vascular regeneration during mouse hindlimb ischemia and during tumor angiogenesis in the zebrafish model (Baltrunaite et al., 2017; Park et al., 2016). This suggests that while *Etv2* is not essential in homeostatic hematopoietic and vascular functions, it plays an important role during vascular regeneration and pathological angiogenesis.

VEGF Signaling During Vasculogenesis

VEGF-VEGFR2/Flk1 signaling plays a critical role in vasculogenesis. In primitive streak stage mouse embryos, VEGF receptor tyrosine kinase *Flk1* is first detected in the extraembryonic mesoderm and the LPM (Dumont et al., 1995; Ema et al., 2006; Yamaguchi et al., 1993). Subsequently, its expression becomes downregulated in hematopoietic cells (Kabrun et al., 1997) and confined to endothelial cells of the yolk sac and embryo proper, and the developing endocardial tube. *Flk1*-deficient mice display similar defects to *Etv2*-deficient mice in the formation of yolk sac blood islands, blood vessels, and endocardium (Shalaby et al., 1995, 1997). VEGFA has been identified as an exclusive ligand for FLK1 in the formation of hematopoietic and vascular systems, as *Vegfa* deficiency results in similar defects observed in *Flk1* knockout mice. Importantly, $Vegfa^{+/-}$ embryos display similar blood and vessel defects that are observed in $Flk1^{-/-}$ embryos (Carmeliet et al., 1996; Ferrara et al., 1996). This indicates that VEGFA dosage is critical for properly forming hematopoietic and vascular systems. Consistent with this idea, mice homozygous for the *Vegfa* hypomorphic allele, *Vegfa*(*lo*), die around E9.0 with severe yolk sac vasculature abnormalities and dorsal aortae defects (Damert et al., 2002). Conversely, overexpression of *Vegfa* also leads to an embryonic lethality (Miquerol et al., 2000). These studies clearly demonstrate that VEGFA levels and the optimal FLK1 signaling are critical for proper hematopoietic and vascular development and embryogenesis.

Cell lineage tracing studies have revealed that Flk1-expressing progenitors contribute to blood, endothelial cells, cardiomyocytes, and skeletal muscle cells (Lugus et al., 2009; Motoike et al., 2003). By examining *LacZ* expression from the *Flk1-LacZ* knock-in targeted allele, hemangiogenic progenitors were shown to have high expression levels of *Flk1*, while cardiac and somite progenitors have low *Flk1* expression levels. Thus, it was suggested that while FLK1 mesoderm can contribute to blood, endothelial cell, skeletal muscle cells and cardiomyocytes, FLK1 expression levels, presumably reflecting VEGF signaling strength, might determine the cell lineage outcome of the $FLK1^{+}$ cells in the embryo (Ema et al., 2006). As such, while blood and endothelial cells are generated from hemangiogenic progenitors expressing high levels of FLK1 ($FLK1^{high}$), cardiac or muscle cells would be generated from $FLK1^{low}$ progenitors (Ema et al., 2006). Consistent with this idea, $FLK1^{+}$ hemangiogenic progenitors can be readily detected around embryonic day (E) 7.5, which progressively expand during E7.5–E8.5. Similar to the *LacZ* reporter expression pattern in *Flk1-LacZ* knock-in mice, the mean fluorescence intensity of FLK1 expression within a subset of the $FLK1^{+}$ cell population becomes

greater as the embryo develops, suggesting an elevated FLK1 signaling activity within a subset of FLK1^{+} cells. Remarkably, the FLK1^{high} cell population is exclusively missing in *Etv2*$^{-/-}$ embryos. This cell population represents a small fraction of the embryo, suggesting that hematopoietic and endothelial cells develop from a small pool of FLK1^{high} progenitors (Liu et al., 2015). Thus, ETV2 function is to generate FLK1^{high} hemangiogenic progenitors to ensure proper hematopoietic and vascular development.

Recently, a reporter ES cell line expressing tdTomato and GFP from the *Etv2* and *Scl* loci, respectively (named as SGET cells), has been generated to track molecular and cellular events leading to hemangiogenic cell lineage specification (Zhao and Choi, 2017). *Scl* is a direct target of ETV2 and is expressed shortly after *Etv2* (Liu et al., 2015). Flow cytometry analysis of tdTomato and GFP expression confirmed that the onset of Scl-GFP expression was later than that of Etv2-tdTomato. Importantly, emerging Scl-GFP expressing cells were mainly observed within cells expressing high levels of Etv2-tdTomato (Etv2^{high}). RNA-seq analysis of Etv2^{high} and Etv2$^{low/intermediate}$ cells has revealed that previously identified ETV2 targets (Liu et al., 2015) were activated within Etv2^{high} cells, which suggests that the hemangiogenic lineage program becomes activated after the threshold of *Etv2* expression has been achieved. Thus, it appears that *Etv2* directly specifies the hemangiogenic fate in a threshold-dependent manner. Importantly, VEGF is required for generating Etv2^{high} cells. *Flk1*$^{-/-}$ ES cells fail to generate Etv2^{high}, not Etv2^{low}, cells. As such, VEGF plays an instructive role in the hemangiogenic cell lineage specification (**Fig. 2**). Consistent with this idea, *Etv2* inactivation using the *Flk1-Cre* system results in embryonic lethality, apparently showing decreased generation of the FLK1^{high} cell population (Liu et al., 2015). This suggests that any perturbation of *Etv2*, VEGF, and FLK1 balance causing insufficient generation of Etv2^{high} and FLK1^{high} cells might lead to defects in hematopoietic and endothelial cell development.

In zebrafish, two homologues of VEGFA are present—*vegfaa* and *vegfab* (Bahary et al., 2007). While fish heterozygous for *vegfaa* do not exhibit a phenotype, homozygous *vegfaa*$^{-/-}$ mutants display defects in vasculogenesis and angiogenesis (Casie Chetty et al., 2017; Rossi et al., 2016). Although *flk1/kdrl*$^{+}$ endothelial cells are present in *vegfaa* mutants, the embryos form only a single vessel instead of a separate DA and PCV (Casie Chetty et al., 2017; Rossi et al., 2016). Previous studies have demonstrated that chemical inhibitors blocking Vegf signaling leads to a reduction in the expression levels of endothelial genes, suggesting an impairment in endothelial cell differentiation (Chan et al., 2002). In contrast, a study using Vegfaa morpholinos reported an increase in venous gene expression but a decrease in arterial gene expression in the morphants (Lawson et al., 2002). These data point to separate functional roles of Vegfa in promoting endothelial differentiation and inducing arteriovenous specification. In an attempt to elucidate these different functional roles of Vegfa, a recent study analyzing endothelial gene expression in both *vegfaa* mutants and Vegf signaling-inhibited embryos (by chemical treatment) pointed to a dose- and time-dependent role of Vegfa in promoting endothelial cell differentiation (Casie Chetty et al., 2017). Similar to mice, Vegfa in zebrafish during early vasculogenesis appears to promote endothelial differentiation and survival by enhancing the expression of the ETS transcription factor *etv2*, which in turn activates the expression of multiple endothelial genes (Casie Chetty et al., 2017; Sumanas and Lin, 2006).

Signaling Pathways That Induce Specification of Vascular Endothelial Progenitors and Hemangioblasts

While FLK1 has served as an excellent marker for hemangiogenic progenitors, FLK1^{+} progenitors are heterogeneous and include cardiac progenitors (Kattman et al., 2006; Moretti et al., 2006). Recently, PDGFRα expression was used to further segregate FLK1^{+} progenitors. As such, FLK1+PDGFRα-progenitors are enriched for hemangiogenic progenitors (Kattman et al., 2011; Liu et al., 2012). Additional markers including Brachyury (T), a pan-mesoderm marker, and Scl, an ETV2 direct target, were used to track hemangiogenic lineage development. These studies revealed that hemangiogenic progenitors develop through a distinct developmental route (Zhao and Choi, submitted). In particular, as previously reported, both FLK1^{+} and PDGFRα^{+} cells were found mainly within T-GFP^{+} cells in early EBs, confirming their primitive streak origin. Initially arising FLK1^{+} cells were also positive for PDGFRα, suggesting that PDGFRα expression precedes that of FLK1. Importantly, Etv2-tdTomato^{high} cells were found mainly within FLK1^{+} cells. Comparison of RNA-seq data of T-GFP^{+}PDGFRα^{-}FLK1^{-}, T-GFP^{+}PDGFRα^{+}FLK1^{-}, T-GFP^{+}PDGFRα^{+}FLK1^{+}, and Etv2-tdTomato^{high} as well as Etv2-tdTomato^{int}, Etv2-tdTomato^{high}Scl-GFP^{-} Etv2-tdTomato^{high}Scl-GFP^{int}, and Scl-GFP^{high} cell populations to those published RNA-Seq of undifferentiated ES cells, ES cell-derived epiblast-derived stem cells (EpiSCs), endoderm, and cardiac progenitors (Choi et al., 2012; Factor et al., 2014; Wamstad et al., 2012) has revealed that while genes expressed in the primitive streak/early mesoderm such as *T*, *Mesp1*, *Gsc*, *Pdgfra*, *Tbx6*, and *Mesp2* were enriched in T-GFP^{+}PDGFRα^{+}FLK1^{-} cells, genes enriched in hemangiogenic or cardiac progenitors still remained low in these cells. This suggests that T-GFP^{+}PDGFRα^{+}FLK1^{-} cells represent primitive streak/nascent/early mesoderm. Consistently, T-GFP^{+}PDGFRα^{+}FLK1^{-} transcriptome was more similar to the proximal regions of the primitive streak of the E7.0 gastrulating embryo (Zhao and Choi, submitted), where nascent mesoderm emerges, than to the distal regions, which form definitive endoderm (Peng et al., 2016). From these studies, hemangiogenic progenitors (ETV2^{high}SCL^{+}) develop from the pluripotency stage through the following developmental path: gastrulating mesendoderm (T-GFP^{+}), nascent/early mesoderm (PDGFRα^{+}), and LPM (FLK1^{+}) (**Fig. 2**).

Previous in vitro and in vivo experiments have shown the involvement of bone morphogenetic protein (BMP), fibroblast growth factor (FGF), Wnt and Indian hedgehog (IHH) signaling pathways in the generation of hemangioblast, and/or vascular EPCs (Marcelo et al., 2013). BMP4 has been shown to be sufficient for the induction of mesoderm in vitro, and its ablation results in embryonic lethality in mice due to a failure in the generation of mesoderm (Park et al., 2004; Pearson et al., 2008; Winnier et al., 1995). Similarly, loss of the downstream effector of BMP4, *Smad5*, leads to a severe disruption of yolk sac vasculature, similar to *Bmp4*$^{-/-}$ mutant mice (Chang et al., 1999). Along the same lines, genetic deletion studies have shown that FGF2 signaling via the FGF receptor type I is a key player in the induction of the mesoderm (Flamme and Risau, 1992; Saxton and Pawson, 1999;

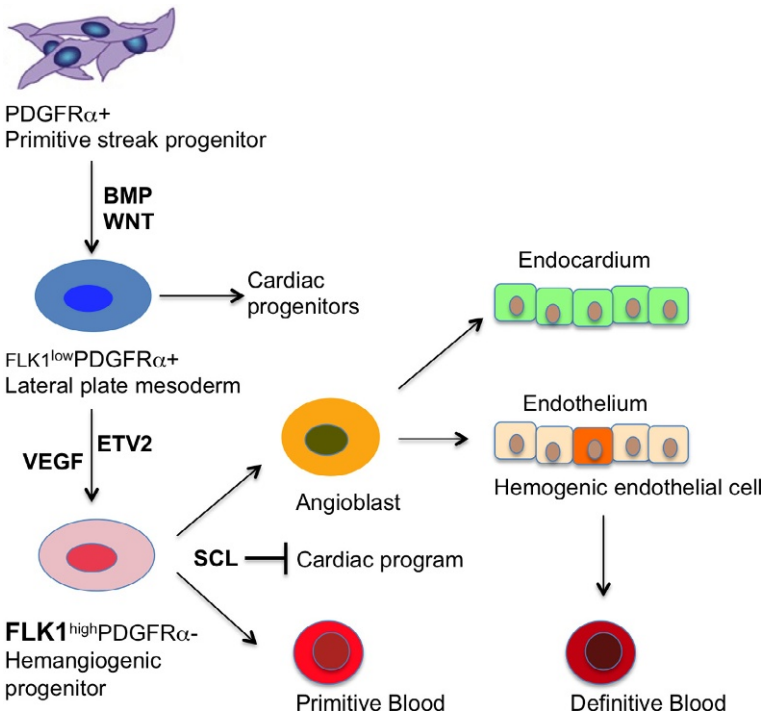

Fig. 2 A model showing the developmental route and factors involved in the generation of hematopoietic and endothelial cells.

Yamaguchi et al., 1994). The disruption of these pathways generally causes a defect in mesoderm formation, which in turn could result in the failure of endothelial and hematopoietic cell fate specification. Additionally, the IHH signaling pathway has been demonstrated to play a critical role in the differentiation of endothelial cells during development in mice. IHH, which is secreted by the yolk sac visceral endoderm, binds to its receptors expressed in the underlying mesoderm in developing mouse embryos. Experiments from mouse embryo explant cultures that lack endoderm have revealed that IHH is sufficient to promote the formation of both endothelial and hematopoietic cells (Kelly and Hirschi, 2009). However, loss of IHH or its receptor Smoothened does not completely inhibit endothelial cell differentiation, indicating the contribution of multiple signaling pathways in this process (Byrd et al., 2002). More recent in vitro studies have demonstrated the combined roles of the BMP, Notch, and Wnt pathways in generating FLK1^{+} mesoderm (Lee et al., 2008). Although the hierarchy of these signaling pathways in specifying hemangioblasts in the mesoderm is still not well understood, BMP4 and Wnt are likely to be involved in the generation of FLK1^{low}PDGFRα^{+} LPM, while VEGF further plays an instructive role in the generation of the FLK1^{high}PDGFRα^{-} hemangioblast by promoting Etv2 threshold expression (Fig. 2, Zhao and Choi, submitted). In the future, further in-depth experiments looking at the direct signaling pathways governing hemangioblast formation would be necessary to better understand the mechanisms of hemangioblast specification in the mesoderm.

Assembly of the Major Embryonic Vessels

Following the specification of angioblasts in the PLPM, the angioblasts coalesce to form the major axial vessels—the DA and CV—in the trunk. In many vertebrates, including zebrafish and frog Xenopus laevis, this involves migration of angioblast progenitors toward the midline. In zebrafish embryos, the first bilateral lines of angioblasts can be observed by *npas4l* expression as early as the tailbud stage and by both *etv2* and *npas4l* expression at the 2-somite stage (Reischauer et al., 2016). At the 10-somite stage, the second set of bilateral lines of angioblasts located laterally to the medial angioblasts can be observed by *etv2* expression. The two medial lines of angioblasts begin to migrate between the somites to the midline starting at around the 9–10 somite stage and continue to migrate till around the 15-somite stage when all the medial angioblasts congregate at the midline (Kohli et al., 2013). The angioblasts migrate as individual cells and subsequently coalesce after they have reached the midline (Jin et al., 2005). It is interesting to note here that this migration occurs in a wave-like manner, beginning with the more anteriorly located angioblasts and then progressing posteriorly. It is unclear what spatiotemporal cues coordinate this pattern of migration of angioblasts. Starting at around the 16-somite stage, the lateral lines of angioblasts begin to migrate toward the midline and largely complete their migration by the 22-somite stage although individual migrating angioblasts can be seen even at later stages. Lineage tracing and cell labeling experiments have demonstrated that the first wave of medial angioblasts gives rise to the DA and the second wave of lateral angioblasts contributes to the PCV (Kohli et al., 2013). Thus, DA and PCV in zebrafish originate at distinct locations and different time points; arterial progenitors originate earlier and closer to the midline than venous progenitors (Fig. 3A and B).

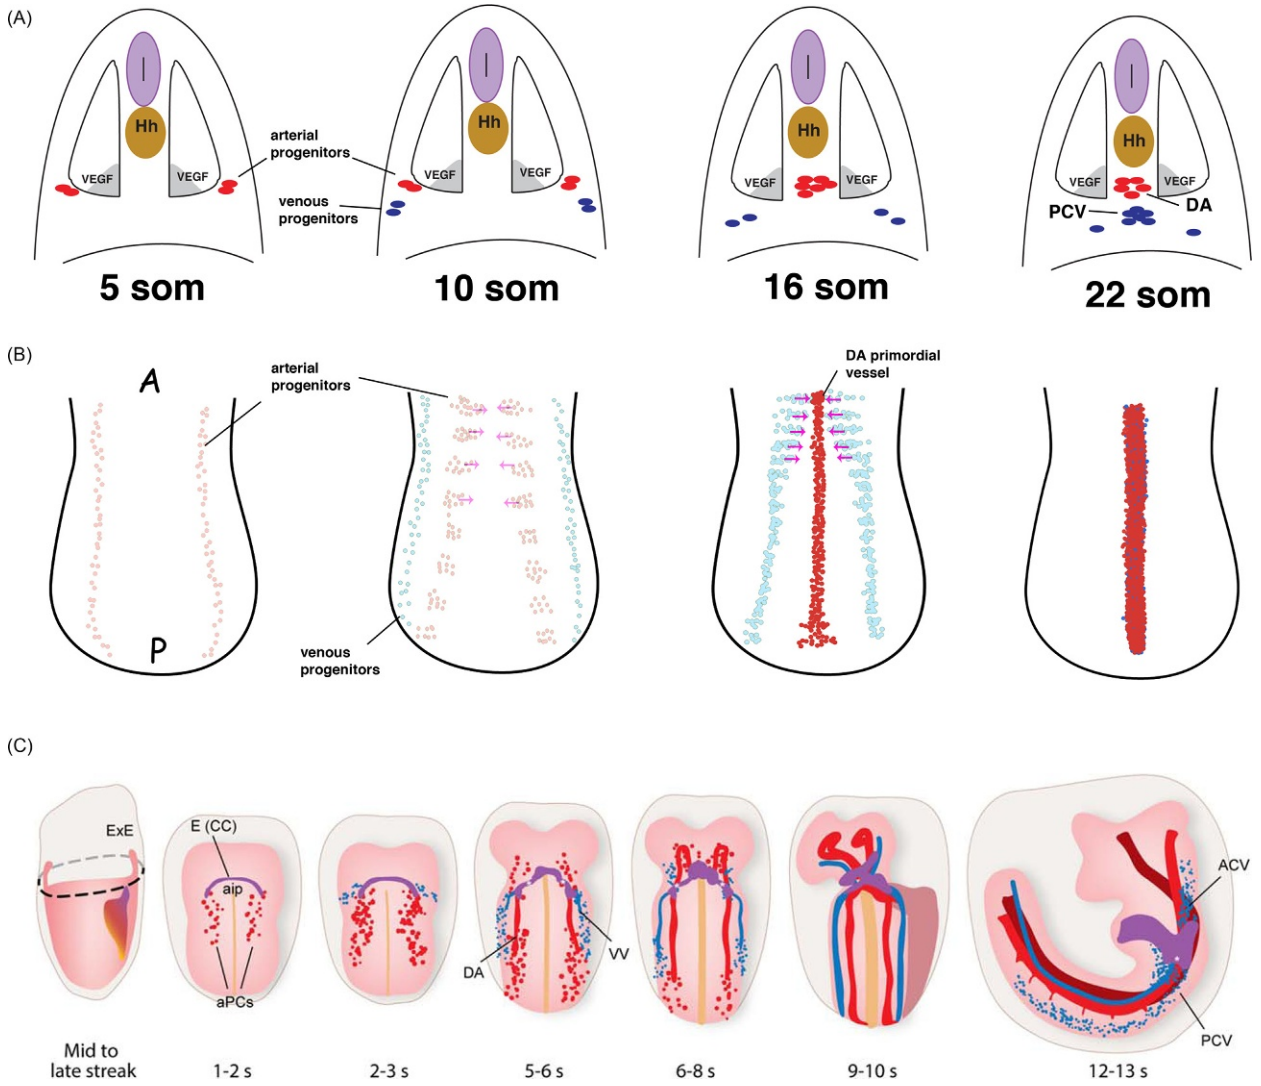

Fig. 3 Assembly of the major axial vessels in zebrafish (A and B) and mouse (C) embryos. (A and B) Transverse cross-sectional (A) and dorsal views of vascular endothelial progenitors in the trunk region. The first group of endothelial progenitors appears as a pair of bilateral lines (*light-red colored cells*) at around the 5 somite stage. At approximately the 10 somite stage, a second pair of bilateral lines are observed (*light-blue cells*), located laterally to the initial lines of endothelial progenitors. At around the same time, the more medially located lines of angioblasts begin to migrate toward the midline (indicated by *pink arrows*) between the somites (at the somite boundaries), beginning at the anterior end of the embryo. This initial migration is completed at approximately the 16ss, and at this point the second population of angioblasts commences their migration toward the midline. Angioblasts in this second wave of migration congregate at a position more ventral to the first group of cells. By around the 22ss, nearly all the angioblasts have completed their migration to the midline. Hedgehog (Hh) secreted by the notochord induces the secretion of VegfA from the somites. The first group of endothelial cells has a more dorsal location and is thus closer in proximity to the source of Vegf. In response to the high concentration of Vegf ligand, these cells differentiate into arterial cells (*red*) and form the DA. The more ventrally located group of endothelial cells experience a lower concentration of Vegf and are specified as venous cells (*blue*) which form the PCV. Adapted from Kohli, V., Schumacher, J. A., Desai, S. P., Rehn, K. and Sumanas, S. (2013). Arterial and venous progenitors of the major axial vessels originate at distinct locations. *Developmental Cell* **25**, 196–206. (C) In mouse embryo, Flk1 + angioblasts are apparent in the LPM starting at the 1–2-somite stage, posterior to the endocardial cells underlying the cardiac crescent (E(CC), *purple*). Aortic progenitor cells (aPCs) coalesce to form paired dorsal aortae (DA). Venous progenitors coalesce into viteline veins (VV) by 5–8-somite stage. The embryo turns between 9–12-somites. Anterior (ACV) and posterior cardinal veins (PCV) are apparent by the 12–13-somites. Reprinted from Fish, J. E. and Wythe, J. D. (2015). The molecular regulation of arteriovenous specification and maintenance. *Developmental Dynamics* **244**, 391–409, with permission from John Wiley and Sons.

In contrast, a different mechanism of DA and PCV formation, termed ventral sprouting has been proposed by Herbert and colleagues. According to it, both the medial and lateral lines of angioblasts migrate to the same location at the midline, to form a common precursor vessel (Herbert et al., 2009). Subsequently, venous progenitors begin to migrate ventrally out of the precursor vessel to give rise to the PCV. Both models can be reconciled if the majority of the cells form the PCV by direct migration while some venous progenitors contribute to PCV through ventral sprouting. Intriguingly, studies in mouse embryos also showed that some

venous progenitors are initially present within the DA. Ephrin B2/EphB4 signaling was implicated in clearing venous-fated ECs from the DA (Lindskog et al., 2014). Additional studies will need to resolve the remaining discrepancies and clarify the details of DA and PCV assembly.

Similar to zebrafish, arterial cells which give rise to the paired dorsal aortae in mammalian embryos originate earlier and closer to the midline compared to the venous progenitors. As early as the 1–2-somite stage Flk1 + positive angioblasts align bilaterally and start coalescing to the paired aortae at the 5–6-somite stage (Chong et al., 2011). Because aortae are initially paired in mouse embryos, differently from fish or frogs, angioblasts do not need to migrate to the midline. Arterial progenitors are thought to spread in the anterior and posterior direction as they coalesce into the dorsal aortae. Scattered venous progenitors appear first near the endocardium and sinus venosus at the 2–3-somite stage. They migrate laterally and posteriorly and coalesce into the vitelline veins. After the embryo completes turning at 13-somites, anterior and PCVs begin to appear (**Fig. 3C**) (Chong et al., 2011). It is currently not clear if the mechanisms involved in the midline migration of angioblasts in zebrafish and frog embryos are equivalent to guiding migration in mammalian embryos.

Several guidance cues have been implicated in the guiding the migration of angioblasts from the LPM to the midline. In *Xenopus*, VegfA was demonstrated to play an important role in guiding the migrating angioblasts to the midline (Cleaver and Krieg, 1998). It was suggested that a similar function of VegfA as an angioblast chemoattractant would be present in zebrafish as well (Coultas et al., 2005; Gore et al., 2012; Verma et al., 2010). However, since then, many studies have revealed that VegfA signaling is not required for this process in zebrafish. The knock down of Vegf or its downstream signaling molecule *plcγ1* did not affect angioblast migration (Helker et al., 2015). Additionally, the *vegfaa* mutant does not appear to have a clear defect in migration (Rossi et al., 2016).

Upstream of Vegf signaling, Sonic Hedgehog (Shh) signaling from the notochord is known to be important for proper angioblast migration in zebrafish (Lawson et al., 2002). Previous studies have shown that either chemical inhibition of Hh signaling (Gering and Patient, 2005) or a lack of a notochord (*noto/floating head* mutants) or defective notochord (*ta/no tail* mutants) in zebrafish leads to an impairment in angioblast migration (Fouquet et al., 1997; Sumoy et al., 1997). As mentioned earlier, it has been well established that there are two waves of angioblasts that migrate to the midline and that the DA forms before the PCV in both mouse and zebrafish (Herbert et al., 2009; Kohli et al., 2013; Lindskog et al., 2014; Torres-Vazquez et al., 2003). In embryos lacking Hedgehog signaling, the first wave of angioblast migration appears to be absent and all the angioblasts migrate in the second wave, giving rise to the PCV (Williams et al., 2010). Despite the lack of Vegf signaling in these Hedgehog-deficient zebrafish embryos, the angioblasts are still able to migrate to the midline, suggesting that neither Vegf nor Hedgehog signaling is required for angioblast migration (Helker et al., 2015). Intriguingly, studies in chick embryos have shown that the notochord produces BMP inhibitors Noggin and Chordin which prevent endothelial cells from entering the midline regions resulting in the bilateral position of dorsal aortae (Bressan et al., 2009; Reese et al., 2004).

Relatively recent studies have identified a novel signaling mechanism which guides angioblast migration in zebrafish (Helker et al., 2015). Apelin, which is a short peptide encoded by the *apln* gene, is secreted by the notochord and has been shown to be involved in regulating heart field development (Zeng et al., 2007). Apelin is secreted by the notochord at around the same time that its corresponding receptors *apelin receptor a* (*aplnra*) and *apelin receptor b* (*aplnrb*) are expressed by angioblasts, prior to their migration. While knocking down either receptor caused a reduction in the efficiency of migration of angioblasts to the midline, migration was completely abolished in double knock-down embryos. This was confirmed in double-mutant embryos for the *aplnra* and *aplnrb* genes, emphasizing the necessity of apln receptor signaling during the migration of angioblasts to the midline during early vasculogenesis (Helker et al., 2015). Surprisingly, the depletion of the Apln ligand by MO and genetic knockout revealed no defects in migration and vasculogenesis, suggesting that another ligand might be involved in the process. The recently identified novel peptide hormone, Elabela, has been shown to bind and activate apln receptors (Chng et al., 2013; Pauli et al., 2014). Homozygous ela mutants exhibited a strong defect in angioblast migration although it was not as severe as that seen in the apln receptor double mutants. However, homozygous double mutants for *apln* and ela ($apln^{-/-};ela^{-/-}$) have a severe migration defect, similar to that seen in the apln receptor double mutants. These results suggest that Ela, which is also secreted by the notochord, plays a central role angioblast migration to the midline, while Apln plays a minor role in the process. Understanding the downstream signaling cascades of Apln signaling will provide essential insight into one of the earliest and most important steps in vasculogenesis.

Although defects are observed in the axial vasculature in *vegfaa* and *shh* mutants, the anterior vasculature remains unaffected, suggesting that different mechanisms regulate the formation of vessels from the angioblasts in the ALPM. Time-lapse videos using *etv2:GFP* reporter showed that the majority of cranial vascular endothelial progenitors come from two distinct regions. The most anterior region, the rostral organizing center (ROC) gives rise to the most rostral cranial vasculature while the rest of the cranial vasculature comes from the MOC region, which is located within the LPM ventral from the midbrain (Proulx et al., 2010). While the ROC and MOC angioblast clusters are derived by vasculogenesis, the majority of the cranial vasculature including the lateral DA (LDA) forms by angiogenesis when angioblasts coalesce into cord-like structures and extend angiogenic sprouts. In addition to endothelial progenitors of the cranial vasculature, MOC also gives rise to the primitive macrophages as well as the endocardial progenitors (Proulx et al., 2010). Interestingly, all myeloid progenitors originate in the MOC region and not the more rostral region. Therefore clearly not all EPCs go through the hemangioblast stage. Similar to the formation of the LDA, at around 17hpf a group of more laterally located angioblasts in the ALPM and in the anterior region of the PLPM begin to migrate toward each other and eventually form the posterior hindbrain channel which is the largest vein in the head region (Bussmann et al., 2011; Siekmann et al., 2009). This migration event has been shown to be mediated by the chemokine Cxcl12b, expressed in the endoderm underlying the

lateral aortae and its receptor Cxcr4a (Siekmann et al., 2009) which is restricted to endothelial cells. The knockdown of *cxcr4a* or Cxcl12b leads to impaired fusion of the angioblasts and results in the disrupted formation of the LDA.

Several studies have pointed to a critical requirement of the endoderm during vasculogenesis (Bielinska et al., 1996; Palis et al., 1995; Vokes and Krieg, 2002). Experiments on *Xenopus* embryos have indicated a requirement of the endoderm for proper angioblast migration and vessel formation during vasculogenesis (Vokes and Krieg, 2002). Loss of the endoderm by surgical removal resulted in an impairment in the formation of functional vascular tubes in avian and frog embryos (Vokes and Krieg, 2002). Similarly, angioblasts were shown to be in close association with the endoderm during their migration in mouse and quail embryos, further underscoring the significance of the endoderm during early stages of vascular development (Vokes et al., 2004). However, a more recent study on zebrafish embryos indicated that the endoderm, while necessary for the proper temporal regulation of angioblast migration, was not essential for the formation of functional vascular tubes. In zebrafish mutant embryos showing either a complete lack of endoderm (*casanova*) or a strong reduction in endoderm (*bonnie and clyde*), migration of the angioblasts to the midline was severely delayed and the angioblasts appeared to migrate in aggregates by forming cell–cell junctions with each other, as opposed to migrating as individual cells (Jin et al., 2005). Despite their abnormal migration, the angioblasts appeared to form two normal axial vessels at the midline. Thus, though the endoderm plays an important role in the temporal regulation of angioblast migration, it does not affect the overall formation of the axial vessels.

Arteriovenous Specification

A functional vascular system consists of arteries and veins, which are both formed by angioblasts, but have distinct molecular and structural properties. Classical models of vasculogenesis have attributed these differences between arteries and veins to hemodynamic forces exerted on the walls of the vessels during circulation (Gonzalez-Crussi, 1971). Indeed, blood flow can regulate arterial-venous identity in some cases (le Noble et al., 2004). However, growing evidence over the past twenty years has demonstrated that cells acquire distinct arteriovenous fates at early stages prior to the initiation of circulation (Wang et al., 1998; Zhong et al., 2000, 2001). During the early stages of vascular development, endothelial cells acquire either an arterial or venous fate, and this step is critical for the correct architecture of the vascular network. Early cell labeling experiments demonstrated that a single endothelial progenitor can give rise to either arterial or venous cells but not to both lineages (Zhong et al., 2001). However, this does not necessarily demonstrate that each progenitor is committed to a specific lineage. Although it is unclear as to exactly when an endothelial cell makes the decision to become either arterial or venous, the signaling pathways and downstream effectors that govern this decision-making process have been fairly well described.

Several initial studies in zebrafish delineated a Shh–Vegf–Notch signaling axis for promoting arterial specification and repressing venous identity (Lawson et al., 2001, 2002, 2003). Sonic hedgehog, which is secreted by the notochord, induces the secretion of VegfA from the somites (Lawson et al., 2001, 2002). VegfA then binds to Vegfr2/*kdrl* present on the surface of endothelial progenitors and activates notch signaling which, in turn, promotes arterial fate (Lawson et al., 2001, 2002). However, it has been recently shown that Shh can also act directly on endothelial cells and promote arterial fate in a Vegf-independent manner via a calcitonin receptor-like receptor (Wilkinson et al., 2012). Vegf role in arterial specification appears evolutionarily conserved. High concentrations of Vegf promote arterial differentiation ES cell culture (Lanner et al., 2007). Mouse VegfA mutants display loss of arterial development (Carmeliet et al., 1996; Ferrara et al., 1996). Vegf signaling through VegfR2 has been shown to promote arterial fate by inducing the expression of several arterial-specific genes. In zebrafish it has been proposed that the first population of angioblasts that arise in a more medial location in the LPM and migrate to the midline to form the DA experience a higher concentration of VegfA ligand secreted from the somites than the second wave of lateral angioblasts that form the PCV, which is located ventrally to the DA (Kohli et al., 2013). This higher concentration of VegfA experienced by the more dorsally located endothelial cells results in the suppression of venous genes and the induction of arterial genes (**Fig. 3A**) (Kohli et al., 2013). A recent study demonstrates separate roles of Vegfa signaling during initial endothelial cell differentiation and subsequent arteriovenous specification. While low levels of Vegfa signaling at early stages appears to promote endothelial cell differentiation through the induction of *etv2* expression, high levels of Vegf signaling at subsequent stages appear to repress venous gene expression and promote the expression of arterial genes (Casie Chetty et al., 2017). High level of Vegf results in the higher expression of *etv2* in the arterial progenitors, which in turn upregulates *dll4* and *notch* expression. Subsequently, Dll4–Notch signaling promotes arterial and inhibits venous differentiation. While several studies have shown that VegfA signaling promotes arteriogenesis, there is some controversy surrounding the downstream effectors that are activated in this process. The identification of a mutant with defective artery formation revealed a critical role of phospholipase C gamma-1 (plcg1) downstream of Vegf signaling, in regulating arterial specification (Lawson et al., 2003). Several studies have shown that the activation of extracellular signal-regulated kinase (ERK) drives arterial gene expression downstream of plcg1, through a complex cross talk with PI3K (Deng et al., 2013; Hong et al., 2006, 2008; Ren et al., 2010). However, a more recent study demonstrated that VegfA signaling via ERK does not promote arterial specification but instead is responsible for the initiation of angiogenesis (Shin et al., 2016).

According to the current model of arteriovenous specification, which is based on the Shh–Vegf–Notch axis, Notch signaling is activated downstream of Vegf signaling (Gore et al., 2012). In zebrafish, similar to the mammalian embryos, both the receptors (Notch1b, Notch5) and ligands (Delta homolog Dll4, Jagged) of Notch signaling are expressed exclusively in arterial endothelial cells. The upregulation of the Notch ligand Dll4 in response to Vegf signaling results in high Notch signaling activity within the developing aorta (Quillien et al., 2014). This increase in Notch activity appears to be a critical event in the repression of venous

genes, which allows cells to take on an arterial identity (Quillien et al., 2014). A deficiency in Notch signaling resulted in the expansion of venous markers into arterial domains and the loss of arterial marker expression, while overactivation of Notch leads to enhanced arterial gene expression and a suppression of venous genes in the PCV (Lawson et al., 2001, 2002, 2003). Similar to zebrafish, Dll4–Notch signaling is required for arterial specification in mouse embryos (Duarte et al., 2004; Gale et al., 2004; Kim et al., 2008). With regard to the regulation of Notch activity, multiple ETS transcription factors including Etv2 have been shown to bind to the promoters of several endothelial genes, including that of *dll4* (De Val et al., 2008; Lee et al., 2008; Liu et al., 2015; Wythe et al., 2013). It has been proposed that Vegf-MAPK-dependent induction of ETS factors including Erg and Fli1 regulates the expression of *Dll4* and *Notch4* and thus promotes arterial fate in mouse embryos (Wythe et al., 2013).

Apart from the well-established Shh–Vegf–Notch signaling pathway, additional signals and transcription factors are important for arteriovenous specification. COUP-TFII/Nr2f2 transcription factors are required in mouse embryos to establish venous identity by suppressing Notch signaling (You et al., 2005). The SRY-related HMG box (Sox) group of transcription factors has also been implicated in the regulation of arteriovenous specification. Loss-of-function studies have demonstrated that Sox7 and Sox18 (which are expressed in the artery and vein) are important in ensuring proper arteriovenous morphogenesis (Cermenati et al., 2008; Herpers et al., 2008; Pendeville et al., 2008). Sox factors promote arterial differentiation by directly binding together with RBPJ/Notch Intracellular domain to an enhancer that regulates Dll4 expression (Sacilotto et al., 2013). Murine Sox17 is selectively expressed in arteries, and endothelial-specific inactivation of Sox17 in the mouse embryo results in the absence of arterial differentiation (Corada et al., 2013). In addition, Wnt/beta-catenin pathway has been implicated in murine vascular development and arterial differentiation by upregulating Dll4/Notch signaling (Corada et al., 2010). In vitro experiments also support a combined role of Notch and beta-catenin in arterial differentiation (Yamamizu et al., 2010).

Vessel Lumenization

The formation of a hollow tube is one of the final steps in vasculogenesis and is critical for ensuring proper circulation in the developing embryo. Tubulogenesis can occur by several mechanisms and varies between different types of tubes (Baer et al., 2009; Lubarsky and Krasnow, 2003). During the formation of the vascular network, the two waves of endothelial progenitors which migrate to the midline as individual cells form aggregates which represent a vascular cord-like structure (Jin et al., 2005). The now-differentiated endothelial cells then undergo different morphogenetic processes to form a tubular structure. This can occur by several mechanisms including (a) cell hollowing—vacuoles form within cells and then fuse between cells to create a contiguous intracellular luminal space; (b) cord hollowing—cells within the cord acquire apicobasal polarity resulting in membrane separation and the formation of a lumen between cells; (c) wrapping—cells become polarized and migrate to form a lumen; (d) cavitation—cells within the center of the cord undergo apoptosis and leave a luminal space (Hogan and Kolodziej, 2002; Kucera et al., 2007; Lubarsky and Krasnow, 2003). In zebrafish embryos, the DA and PCV are fully lumenized by around the 28–30hpf, while mouse aortae are lumenized at 3–5 s (around E8.0) (Chong et al., 2011; Isogai et al., 2001).

When endothelial cells aggregate at the midline to form a vascular cord in zebrafish, they do not appear to form cell–cell junctions and instead remain as clusters of cells (Jin et al., 2005). At about 17hpf, the cells begin to form tight junctions between each other as seen by zona occluding-1 staining. Beginning at ~18hpf, the DA begins to lumenize by a "hollowing out" mechanism (Jin et al., 2005). Similar observations were reported by Parker et al. who identified an EC-derived secreted factor EGF-like domain 7 (*EGFL7*) which appears to regulate vessel lumenization (Parker et al., 2004). Following the formation of the solid vascular cord, angioblasts undergo spatial separation and rearrangement to form a lumen within the center of the nascent vessel. This involves the breakdown of tight junctions between angioblasts within the center of the tube—a process controlled by EGFL7. Loss of EGFL7 function results in a failure of the angioblasts to separate and form a lumen in the center of the vascular cord, indicating that EGFL7 is required for the downregulation of tight junctions during tubulogenesis (Parker et al., 2004). It has been proposed that the DA and PCV lumenize by different mechanisms: while the DA appears to lumenize by a cord hollowing-out mechanism, the PCV is formed by ventrally sprouting venous cells that coalesce around blood cells (Herbert et al., 2009). Subsequently, intersegmental vessels lumenize by the fusion of intracellular vacuoles (Kamei et al., 2006).

Similar to zebrafish, aortic lumenization in the mouse also appears to occur by a cord-hollowing mechanism. Studies examining the molecular mechanisms of lumen formation in the paired aortae of mouse embryos revealed the formation of intercellular adherens junctions by VE-cadherin between endothelial cells followed by junctional remodeling and the polarization of endothelial cells (Dejana et al., 2009; Strilic et al., 2010). The initial establishment of apical–basal polarity in endothelial cells appears to rely on the presence of VE-cadherin without which the accumulation of antiadhesive molecules such as CD34-sialomucins and podocalyxin at cell–cell contact sites does not occur (Strilic et al., 2010). Both these molecules which contain negative charges accumulate at the future luminal surface of the ECs and cause repulsion between the cells, thus initiating the formation of a lumen. The establishment of EC polarity is also dependent upon proper GTPase signaling, which regulates structural changes in the cytoskeleton and overall cell shape and polarity. Mice which lack an endothelial-restricted Ras-interacting protein Rasip1 fail to form lumenized vessels due to dysregulation of GTPase signaling which leads to a defect in the establishment of cell polarity (Xu et al., 2011). Following polarization of ECs, Vegf induces the localization of myosin II to the apical surface of the cells, causing constriction of the apical membrane. Further cell shape changes occur by the recruitment of F-actin to the apical surface, a process dependent on CD-34 sialomucins and Moesin (Strilic et al., 2010; Wang et al., 2010). Together, these processes lead to the formation of a mature lumen (**Fig. 4**).

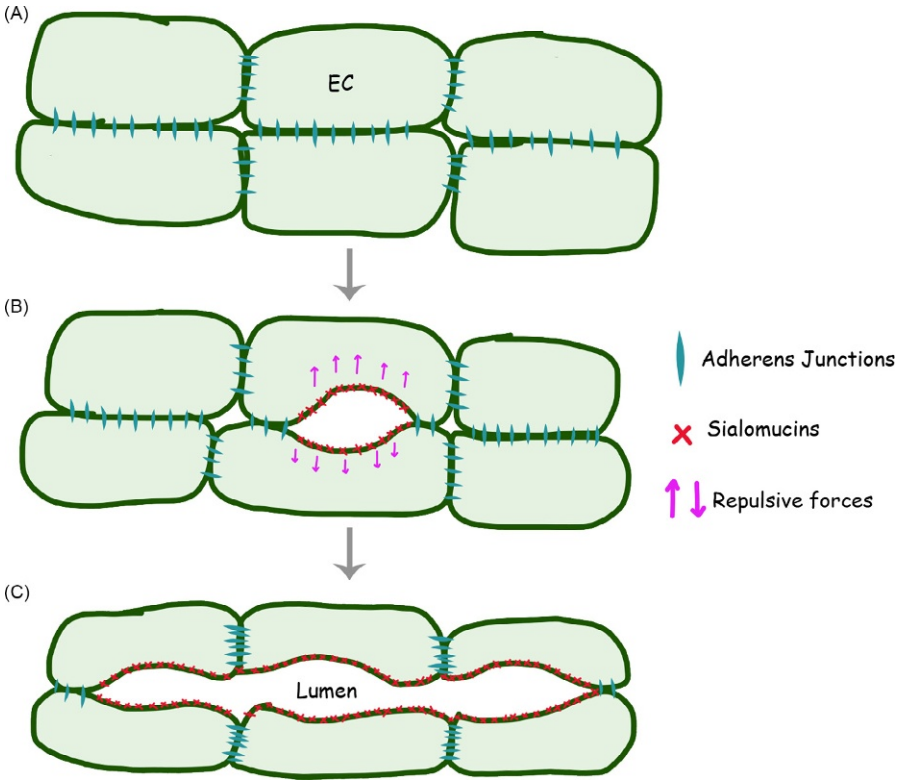

Fig. 4 Following the migration of endothelial progenitors, the cells form a vascular cord-like structure which consists of an aggregation of cells. The formation of adherens junctions by VE-cadherin between neighboring cells is important for the establishment of these aggregates (A) and also for the establishment of apicobasal polarity of the ECs. Negatively charged sialomucins become localized at the future-luminal surface of the ECs and cause repulsion between cells at the luminal surface (B). This is accompanied by a reorganization of adherens junctions and a change in cell shape (C). Repulsion between multiple cells along the length of the vascular cord results in the formation of a continuous lumen (C). Note that the lumen in smaller vessels forms by vacuole fusion (not shown).

Concluding Remarks

While this review focuses on the mechanisms of vasculogenesis during embryonic development, many of the described steps can be affected in vascular diseases. For example, mutations in Notch affect arteriovenous specification and can result in arterial–venous malformations (AVMs) (Delev et al., 2016). Furthermore, vasculature defects in AVMs can be alleviated in the mouse model by activating Notch (Murphy et al., 2012), which points to the potential future clinical therapies. Another example of potential therapeutic intervention is the ETS transcription factor Etv2, which is critical for embryonic endothelial specification. Overexpression of Etv2 can transdifferentiate fibroblasts into vascular endothelial progenitors and promotes recovery in the mouse hindlimb ischemia model (Lee et al., 2017; Morita et al., 2015; Park et al., 2016). Therefore, research on the molecular mechanisms related to embryonic vasculogenesis will ultimately greatly contribute toward the development of novel therapeutic approaches for numerous vascular disorders, wound healing, ischemia, and cancer.

Introduction

Hypertrophic cardiomyopathy (HCM) is an autosomal dominant disease caused by mutations in genes coding for cardiac sarcomeres. There are multiple genetic variants, but all phenotypic expressions display pathology characterized by myocardial hypertrophy and disarray. HCM is the most common inherited heart disease with a prevalence of 0.2% in the general population (Maron et al., 1995). Patients with HCM are at an increased risk of potentially lethal ventricular arrhythmias (Elliott et al., 2006a; Maron et al., 2000). Prevention of sudden cardiac death (SCD) is best accomplished by implantation of a cardioverter-defibrillator (ICD) in patients who are at risk of SCD due to ventricular arrhythmias (Maron et al., 2000; Russo et al., 2013). Selection of patients in whom ICD implantation is appropriate is guided by risk stratification using the presence or absence of specific clinical risk factors (Russo et al., 2013).

Ventricular Arrhythmias and SCD

Conventional Risk Factors

Patients with HCM are at an increased risk of the development of ventricular dysrhythmias, including ventricular tachycardia (VT) and ventricular fibrillation (VF). SCD is the most serious consequence of the development of ventricular dysrhythmias. The young are at particular risk for SCD, while those over 60 are less affected by SCD (Russo et al., 2013). Five risk factors have been found to be associated with SCD; these include family history of sudden death, personal history of unexplained syncope, massive left ventricular wall thickness, nonsustained VT, and an abnormal blood pressure response to exercise (Dimitrow et al., 2010; Maron et al., 2013a; Gersh et al., 2011). While these risk factors were derived from tertiary referred patients, the same risk factors were found to be important even in a community-based cohort (Anastasakis et al., 2013).

LV hypertrophy

The degree of left ventricular hypertrophy (LVH) directly correlates to the risk of SCD, increasing progressively in relation to the maximal wall thickness (Spirito et al., 2000). While the highest risk was observed in those with maximal wall thicknesses $\geq$30 mm, there was not a sudden increase in risk with this measurement but rather a linear increase in risk as wall thickness increased. The burden of VT also directly correlates with increasing LVH; in one study of patients with HCM in whom VT had been documented,

 https://doi.org/10.1016/B978-0-12-809657-4.99797-7

the extent of LV hypertrophy was compared with a control group of HCM patients without documented VT. The study found significantly more LV hypertrophy in patients with documented VT (53%) versus those without VT (21%) (Spirito et al., 1987).

A more recent study including 157 HCM patients evaluated the ventricular arrhythmia events over a median of 3.7 years (Puntmann et al., 2010a). Patients were evaluated with 2-D echocardiography for LV wall measurements at baseline and followed clinically thereafter. Maximal ventricular wall thickness and basal anterior thickness above 15 mm were associated with a 4.5 fold increase in relative risk of ventricular arrhythmias. Additionally, equatorial inferior thicknesses above 19 mm had a 5.9 fold increase in relative risk. The two regional measures (basal and equatorial) were independently associated with risk of ventricular arrhythmias.

Syncope

Syncope is present in approximately 14%–35% of patients with HCM. Unexplained syncope has been repeatedly identified as a predictor of SCD (Spirito et al., 2009; Fananapazir et al., 1992). A large cohort study of 1511 patients with HCM found 205 patients to have unexplained or neurally mediated syncope. Over a mean follow-up of 5.6 ± 5.2 years, 74 of the 1511 patients experienced sudden death (Spirito et al., 2009). The relative risk of sudden death was 1.78 (95% CI: 0.00–3.51, $P = 0.08$) in patients with unexplained syncope and 0.91 (95% CI 0.00–3.83, $P = 1.0$) in those with neurally mediated syncope compared with HCM patients without syncope. Additionally, the timing of unexplained syncope was independently associated with SCD; patients who had an episode of unexplained syncope within 6 months before initial evaluation had a 5-fold increase in risk compared with patients without syncope (HR 4.89%, 95% CI 2.19–10.94). A smaller but similar study of 174 consecutive patients with HCM and with a follow-up of 74 ± 22 months reported eight cardiovascular deaths. A history of syncope was noted in all eight patients (Kyriakidis et al., 1998).

Family history of sudden death

A family history of sudden death due to HCM has been identified as a significant risk factor for sudden death in patients with HCM. Alone, a positive family history has a 1.9 (95% CI 0.8–4.5, $P = 0.15$) risk ratio for sudden death. However, when combined with history of syncope, the risk ratio increases to 5.3 (95% CI 1.9–14.9, $P = 0.002$) (Elliott et al., 2000). In the 2011 ACC/AHA Guidelines a single family member with SCD qualifies as a risk factor, while in the 2006 European Guidelines it took two family members dying suddenly from HCM. Additionally, it is not clear how proximate the family member must be; whether 2nd degree relatives, who presumably carry the same gene confer as much risk as 1st degree relatives is not completely understood.

Nonsustained ventricular tachycardia

Nonsustained VT (NSVT) in patients with HCM has been independently associated with sudden death in multiple studies. In one study examining 1380 HCM patients during exercise testing, 24 had NSVT and 3 had VF (Gimeno et al., 2009). Eight of these 27 patients died or had a cardiac event requiring ICD implant or ICD firing, compared with 150 patients without exercise-induced NSVT/VF ($P = 0.008$). Patients with NSVT or VF had a 3.73 fold increase in risk of sudden death or ICD firing (HR 95% CI: 1.61–8.63, $P = 0.002$). Beyond arrhythmias in the setting of exercise, another study used Holter monitoring for arrhythmia detection. In this study, the estimated rate for sudden death was 1.8% per year in patients with NSVT compared with 0.8% in those without NSVT (Adabag et al., 2005). However, the presence of NSVT has some conflicting evidence as to its contribution to SCD. In one study of an unselected patient population with HCM, a history of NSVT was not associated with adverse prognosis (Cecchi et al., 1998). Evidence is accumulating that not all NSVT portends an equivalent risk. NSVT in the patient less than 30 years is more highly predictive of SCD than NSVT in individuals >30 years (Monserrat et al., 2003). Additionally, faster and longer NSVT is more predictive of SCD than slower and shorter NSVT (**Figs. 1** and **2**) (Wang et al., 2017).

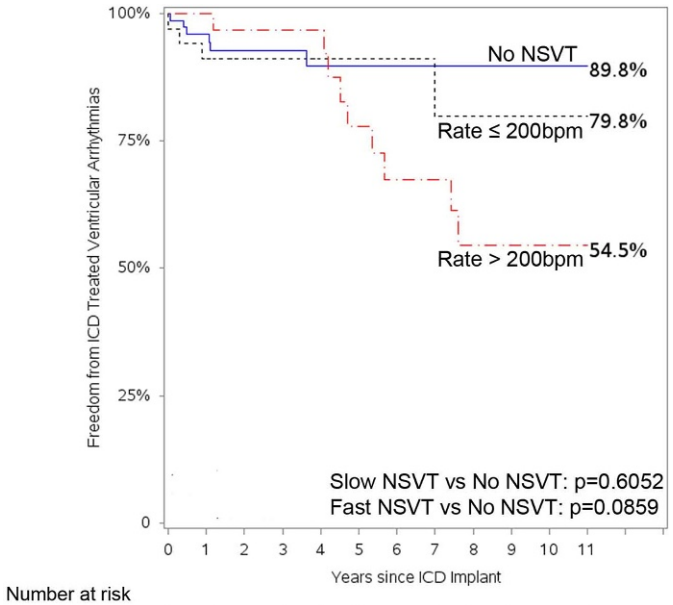
Abnormal blood pressure response to exercise

A hypotensive or normotensive response to exercise was initially proposed as a marker for increased disease-related mortality in a study of HCM patients by Olivotto. Of 126 patients, 19 had failure of blood pressure to rise and 9 had a hypotensive response (Olivotto et al., 1999). On follow-up of 4.7 ± 3.7 years, 9 patients had HCM-related deaths and 4 of them had abnormal blood pressure response to exercise. Additionally, survival analysis found that patients aged ≤50 years with abnormal blood pressure response had an increased risk for cardiovascular mortality. Although the positive predictive accuracy was low, the negative predictive accuracy was high, allowing for possible consideration of this test to be used in screening fashion to identify low-risk patients.

Emerging Risk Factors

Fibrosis

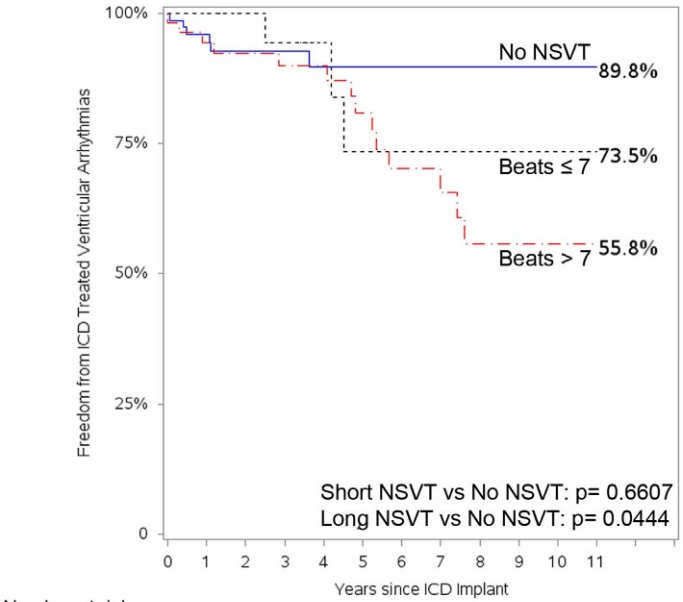
Myocardial fibrosis is a common finding in HCM patients. Late gadolinium enhancement (LGE) on cardiac magnetic resonance imaging (CMR) assesses for fibrosis. Multiple studies have found associations between the percentage of myocardial scar due to fibrosis, as measured by LGE on CMR, and ventricular tachyarrhythmias (Oka et al., 2008; Kwon et al., 2008; Adabag et al., 2008; Leonardi et al., 2009; Chan et al., 2014). The largest of these studies examined 1293 patients undergoing CMR, and fibrosis as



Number at risk

No NSVT	74	61	47	37	26	22	18	15	9	6	3	3
Rate ≤ 200bpm	34	30	24	20	15	13	10	6	5	4	1	1
Rate > 200bpm	32	31	28	23	22	16	13	11	6	5	3	1

Fig. 1 Survival probability for freedom from first ICD treated ventricular tachyarrhythmia stratified by the rate of nonsustained ventricular tachycardia (NSVT) ($\leq$200 bpm vs. $>$200 bpm) in 66 patients. Survival was estimated using Kaplan–Meier curves and compared using log-rank test.



Number at risk

No NSVT	74	61	47	37	26	22	18	15	9	6	3	3
Beats ≤ 7	25	24	19	15	11	7	7	5	2	2	1	0
Beats > 7	54	48	43	34	33	25	18	14	9	7	4	2

Fig. 2 Survival probability for freedom from first ICD-treated ventricular tachyarrhythmia stratified by length of nonsustained ventricular tachycardia (NSVT) ($\leq$7 vs. $>$7 beats) in 79 patients. Survival was estimated using Kaplan–Meier curves and compared using log-rank test.

quantified by LGE correlated linearly with risk of ventricular arrhythmias (Chan et al., 2014). A total burden of scar by LGE $\geq$15% of LV mass connoted a two-fold increase in SCD event risk. Additionally, certain locations of scarring may be at an increased likelihood of ventricular arrhythmias. The frequency of VT was several-fold higher in patients with basal septal scarring on CMR as compared to those patients without (27% vs. 5%, $P=0.03$) (Kwon et al., 2009). In a separate study, a higher number of scarred segments was shown to be a significant arrhythmogenic risk factor in patients with basal septal hypertrophy (Amano et al., 2014).

Additionally, signal intensity may be a useful tool to prognosticate arrhythmic risk. One study examining signal intensities of LGE found that intermediate signal intensity was a better predictor of ventricular tachyarrhythmias including NSVT, ventricular couplets, and PVCs, as compared to high intensity LGE (Appelbaum et al., 2012).

Left ventricular apical aneurysm

LV apical aneurysm has an estimated prevalence of approximately 2% in HCM patients (Maron et al., 2008). In a large cohort study, these patients experienced an adverse event rate of 10.5% per year, events including sudden death, aborted cardiac arrest, and appropriate ICD interventions for SCD. In this study, >40% of those with LV aneurysm who experienced cardiac arrest, SCD, or appropriate ICD interventions had no otherwise conventional risk factors (Maron et al., 2008). Apical aneurysms are typically ringed with scar and associated with additional transmural myocardial scarring and fibrosis. This degree and location of scarring likely serves as the arrhythmogenic substrate (Maron et al., 2008; Paul et al., 2006).

End-stage phase

The end-stage phase of HCM, characterized by LV systolic dysfunction and often dilatation, is associated with poor outcomes from clinical heart failure, and an increased risk for sudden death (Harris et al., 2006). In a large multicenter cohort of HCM patients, end-stage disease had a SCD prevalence of 3.5%, appropriate ICD interventions in 10% of patients annually, and an overall annual mortality rate of 11% per year (Harris et al., 2006). Although often occurring concomitantly with other traditional risk factors, given the high rate of severe and mortal events at least somewhat associated with ventricular arrhythmias, it is not unreasonable to consider end-stage HCM as an independent risk factor for SCD. Clinically, patients with end-stage HCM risk being overlooked, as they may not fulfill traditional criteria for ICD implantation in the nonischemic population (ejection fraction $\leq$35%). However, an ejection fraction below 50% in a patient with HCM, when systolic function is usually hyperdynamic, indicates significant myocardial dysfunction and elevated risk (Harris et al., 2006).

Left ventricular outflow tract obstruction

About 1/3 of HCM patients have left ventricular outflow tract obstruction at rest and another 1/3 only with exertion (Maron et al., 2003a; Elliott et al., 2006b; Autore et al., 2005). Obstructive patients are at a significantly higher risk of SCD than those without obstruction (Maron et al., 2003a; Elliott et al., 2006b; Maki et al., 1998). In one large cohort study, an LVOT basal gradient $\geq$30 mmHg was an independent predictor of sudden death or appropriate ICD discharge, and the severity of outflow tract obstruction positively correlated with a higher occurrence of sudden death and appropriate ICD discharges (Elliott et al., 2006b). Due to its high prevalence in patients with HCM, when considered as a lone risk factor, outflow tract obstruction has a high negative predictive value (95%–95.9%) but a low positive predictive value (7%–9.7%) (Maron et al., 2003a; Elliott et al., 2006b).

High risk genetic mutations

Early studies reported that patients with troponin T mutations were at a high risk of SCD at a young age (Fiset and Giles, 2008; Baudenbacher et al., 2008; Watkins et al., 1995; Tsoutsman et al., 2006). Additionally, recent studies have shown that double or compound sarcomere mutations may predispose patients to advanced disease progression and higher risk of sudden cardiac risk absent conventional risk factors. However, with over 1000 different mutations currently known in HCM, including many involving troponin T, and significant phenotypical heterogeneity, clinical risk stratification based on genetic testing has a very limited role in risk stratification (Alcalai et al., 2008; Maron, 2010; Maron et al., 2012). Further prospective observations of large genetic databases with clinical correlations will be required to further elucidate whether individual mutations or gene defects correlate with elevated risk, and to what degree.

Myocardial ischemia

Atherosclerotic coronary artery disease (CAD) compounds and elevates risk of SCD in patients with HCM. Patients with HCM and concomitant CAD have reduced survival free of SCD compared with HCM patients with no CAD (Sorajja et al., 2003). The rate of SCD in these patients is 2% annually and overall mortality is 6.6% per year, far exceeding historical rates seen otherwise in patients with CAD with normal left ventricular function. Independent of atherosclerosis, patients with HCM have poor coronary flow reserve, of which the resulting ischemia severity correlates negatively with long-term outcome (Maron et al., 2009). This microvascular dysfunction also may cause abnormal stress findings, and in some studies was an independent predictor of death from cardiovascular causes (Cecchi et al., 2003; Petersen et al., 2007).

EKG parameters

Heart rate

A recent study of 106 HCM patients evaluated cardiovascular event end points including arrhythmias (as measured by Holter monitoring) over a mean 10.1 year follow-up (Kawasaki et al., 2012). The study found no evidence of differences in heart rate variability and turbulence on Holter monitoring between patients with or without cardiovascular events; however, average heart rates were significantly lower in patients with cardiovascular events (64.7 ± 11.2 beats/min) versus patients without cardiovascular events (73.7 ± 10.2 beats/min). Further studies are needed to confirm the significance of heart rate and prognosis in HCM.

Fragmented QRS

Surface electrocardiogram (ECG) findings have been evaluated to assess risk for future arrhythmic events. Using appropriate ICD therapies as a surrogate, fragmented QRS (fQRS) as seen on surface ECG at ICD implant was found to predict arrhythmic events in HCM patients along with history of VT/VF. Lateral lead fQRS significantly increased the risk of appropriate ICD therapy ($P < 0.0001$) (Femenia et al., 2013).

QT intervals/dispersions

QT variables have also been evaluated as a part of noninvasive risk stratification (Uchiyama et al., 2009). A study of 479 HCM patients found the mean QTc to be 440 ± 28 ms and 13% of patients exceeded 480 ms (Johnson et al., 2011). Patients with QTc >480 ms were found to have greater obstructive, thicker ventricles, and be more symptomatic. The QT interval should be assessed as it may reflect the degree of hypertrophy and obstruction in addition to its pro-arrhythmic potential.

T-wave alternans

In one study from 2002, 27 of 53 evaluated patients with HCM were noted to have T-wave alternans (TWA). These 27 patients were found to have an increased maximal number of successive ventricular ectopic beats, NSVT, as well as histopathological disarray score (Kuroda et al., 2002). A similar study conducted years later found that TWA is not useful for predicting SCD in HCM; however, this study measured TWA while the patients were maintained on anti-arrhythmic medications, as opposed to the aforementioned study (Fuchs and Torjman, 2009). A recent third study performing TWA-exercise testing and follow-up found TWA to be associated with greater maximal and regional left ventricular wall thickness, an otherwise independent risk factor (Puntmann et al., 2010b).

Methods of Prevention of SCD

Medical Management

Medical management of HCM patients for the prevention of SCD has never been proven to be effective. Anti-arrhythmic agents (including amiodarone and Ia antiarrhythmic drugs), β-blockers, and calcium antagonists have been proposed as potentially useful for prevention of SCD (Maron et al., 2003b). While early reports suggested amiodarone as potentially protective (Cecchi et al., 1998; Maron et al., 2003b; McKenna et al., 1984, 1985), it is now clear that amiodarone does not provide absolute protection from sudden death in HCM patients (Maron et al., 2000; Spirito et al., 2000; Melacini et al., 2007). In addition, amiodarone is associated with significant cumulative toxicity, making it unsuitable for long-term use in young patients (Maron et al., 2003b).

Implantable Cardioverter Defibrillators

Defibrillator use for prevention of sudden cardiac death

Defibrillators are the only proven therapy for prevention of SCD in patients with HCM (**Figs. 3** and **4**) (Maron et al., 2003b, 2007, 2013a; Epstein et al., 2008; Zipes et al., 2006). Despite questions of whether ICDs could reliably terminate ventricular arrhythmia due to increased LV mass, ICDs have been shown to reliably terminate VT and VF (Maron et al., 2000; Alsheikh-Ali et al., 2013). High-risk patients with ICDs have annual appropriate discharge rates of 4%–7% per year, with appropriate treatment occurring more frequently when placed for secondary prevention (7%–11% per year) compared to primary prevention (3%–5% per year) (**Figs. 1–3**) (Maron et al., 2000, 2007, 2013a; Woo et al., 2007). Subcutaneous defibrillators also appear to be effective in patients with HCM, but the experience is more limited (Weinstock et al., 2016; Maurizi et al., 2017).

Patient selection and guideline recommendations

2011 ACC/AHA consensus guidelines

The most recent AHA/ACC/HRS consensus guidelines for the implantation of ICDs in patients with HCM was published in 2011 (**Fig. 5**) (Gersh et al., 2011). Recommendations for management are graded in this as well as the AHA/ACC/ESC guidelines into class I: recommended; class IIA: reasonable; class IIB: may be considered; and class III: not advisable or harmful. In addition the strength of evidence supporting the recommendations is graded into levels of evidence (LOE). In general, LOE A is supported by several randomized trials, LOE B is supported by prospective or retrospective data, and LOE C is supported by expert opinion. In HCM there are very few randomized trials; thus most recommendations are based on level B or C evidence.

According to these guidelines, patients with resuscitated SCD or sustained VT should have an ICD implanted (class I, LOE B). For primary prophylaxis, ICD implantation is recommended if any one of the following three risk factors is present: massively thick myocardium, family history of SCD, or personal history of syncope (class IIA, LOE C). For patients with NSVT or hypotensive response to exercise, the presence of additional risk modifiers (LVOT Obstruction, LGE on CMR, LV Apical Aneurysm, Genetic Mutations (especially multiple)) may be useful when making the decision for implantation of an ICD. The presence of one or more of these risk modifiers yields a recommendation for ICD implantation (class IIA, LOE C). However, the absence of these additional risk factors drops the recommendation class (class IIB, LOE C) (Gersh et al., 2011). More recent data on NSVT finds that NSVT at a younger age, and longer and faster NSVT are more predictive of SCD risk (Wang et al., 2017). An additional IIB recommendation (LOE C) is made for those individuals with class III or IV heart failure with an LVEF less than or equal to 50%. Implantation of an ICD is not recommended (class III, LOE C) solely to permit athletic participation, or solely

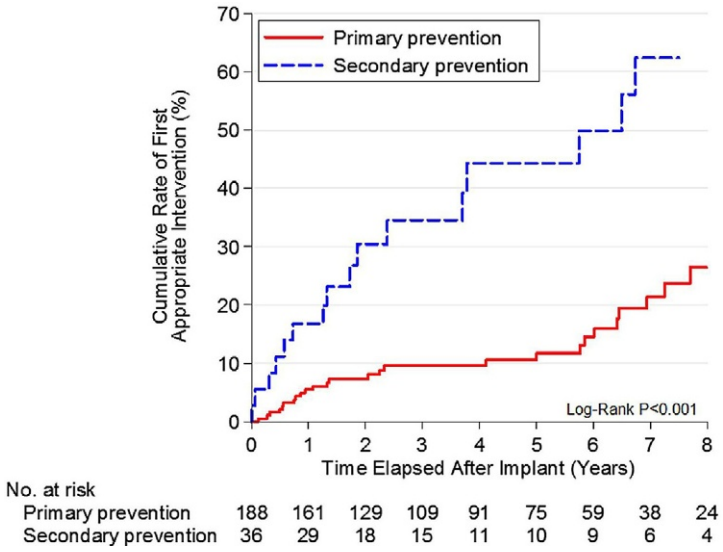


Fig. 3 ICD intervention rates. Cumulative rates for first appropriate implantable cardioverter-defibrillator (ICD) intervention, shown separately for patients who underwent implantation for primary ($n=188$) or secondary ($n=36$) prevention. The rate of first appropriate ICD shock for secondary prevention exceeded that for primary prevention by fourfold. From Maron BJ, Spirito P, Ackerman MJ, Casey SA, Semsarian C, Estes NA 3rd, Shannon KM, Ashley EA, Day SM, Pacileo G, Formisano F, Devoto E, Anastasakis A, Bos JM, Woo A, Autore C, Pass RH, Boriani G, Garberich RF, Almquist AK, Russell MW, Boni L, Berger S, Maron MS, and Link MS (2013a) Prevention of sudden cardiac death with implantable cardioverter-defibrillators in children and adolescents with hypertrophic cardiomyopathy. *Journal of the American College of Cardiology* **61**, 1527–1535, with permission.

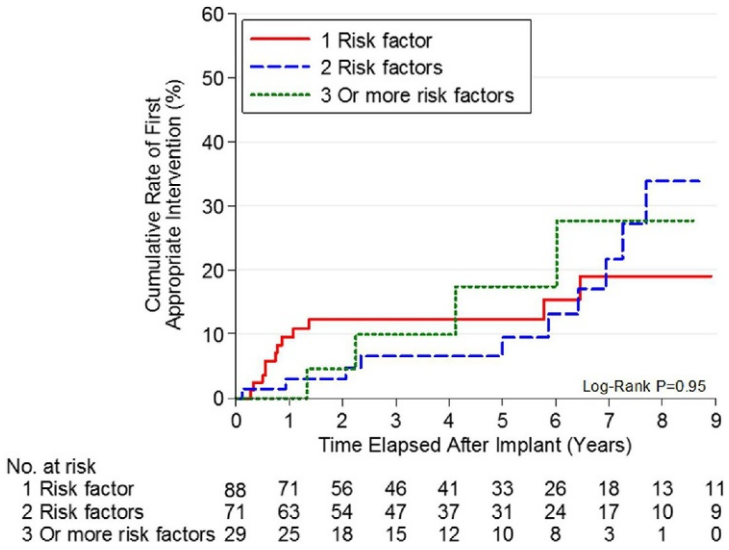

Fig. 4 Number of sudden death risk factors and ICD interventions. Cumulative rates for first appropriate implantable cardioverter-defibrillator (ICD) intervention in 188 patients who underwent implantation for primary prevention and 1, 2, or ≥ 3 risk markers. Event distribution was nonuniform during the follow-up period, with early interventions disproportionate ($P=0.023$). From Maron BJ, Spirito P, Ackerman MJ, Casey SA, Semsarian C, Estes NA 3rd, Shannon KM, Ashley EA, Day SM, Pacileo G, Formisano F, Devoto E, Anastasakis A, Bos JM, Woo A, Autore C, Pass RH, Boriani G, Garberich RF, Almquist AK, Russell MW, Boni L, Berger S, Maron MS, and Link MS (2013a) Prevention of sudden cardiac death with implantable cardioverter-defibrillators in children and adolescents with hypertrophic cardiomyopathy. *Journal of the American College of Cardiology* **61**, 1527–1535, with permission.

on the basis of prior alcohol septal ablation or need for permanent pacemaker. There is some data that these risk factors play less of a role for individuals greater than 60 years of age. In a study of 428 patients older than 60 years, only 16 (3.7%) died of HCM-related events (Maron et al., 2013b).

In addition, guidelines offer guidance on the type of ICD to be implanted. Single-chamber ICDs (class IIA) are recommended unless the need atrial pacing is anticipated (LOE C). Additionally, a dual chamber device is recommended in patients with sinus bradycardia or who have a history of atrial fibrillation (AF) (LOE C) or those with an LV outflow gradient >50 mmHg and clinical heart failure who may potentially benefit from RV pacing (LOE B) (Gersh et al., 2011).

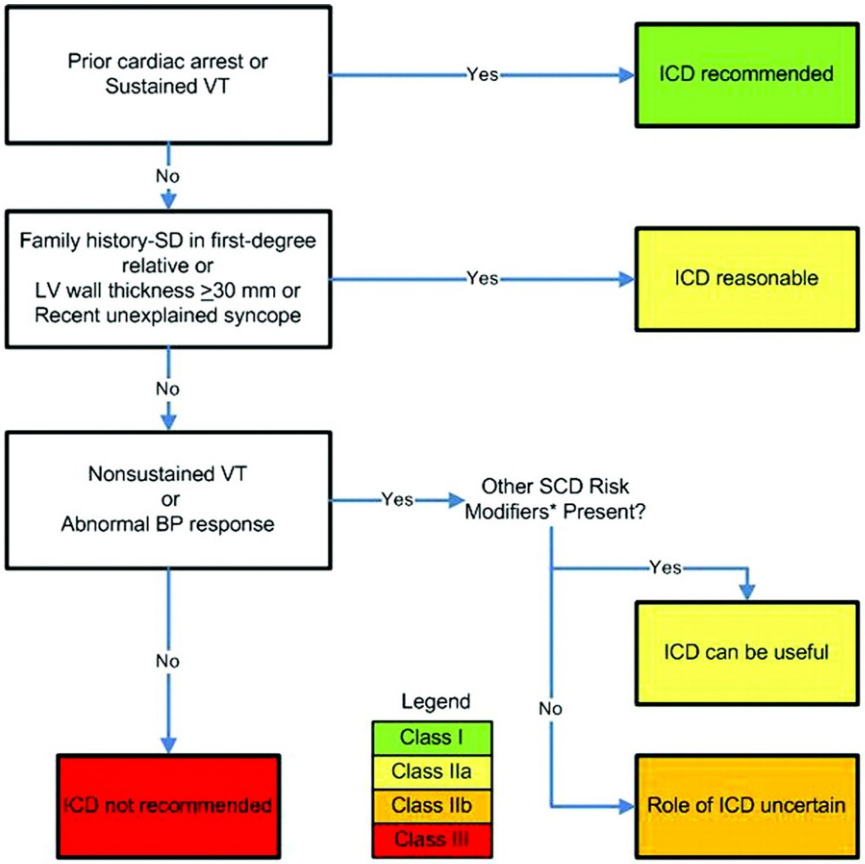

Fig. 5 Guidelines for implantation of implantable defibrillators (ICDs) in patients with HCM. From Gersh, B. J., Maron, B. J., Bonow, R. O., Dearani, J. A., Fifer, M. A., Link, M. S., Naidu, S. S., Nishimura, R. A., Ommen, S. R., Rakowski, H., Seidman, C. E., Towbin, J. A., Udelson, J. E. and Yancy, C. W. (2011). 2011 ACCF/AHA guideline for the diagnosis and treatment of hypertrophic cardiomyopathy: executive summary: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* **124**, 2761–2796, from Circulation with permission.

A balance of benefit must be weighed against potential for harm, however, when choosing to implant ICDs. Insertion of dual chamber ICDs is associated with a greater risk of lead complications, both in short-term and long-term follow-up. Due in large part to a high incidence of AF in patients with HCM, inappropriate discharges are also common in HCM patients, with up to 25% receiving inappropriate shocks (Maron et al., 2000, 2007, 2013a; Lin et al., 2009). Young age and AF have been shown to be associated with inappropriate ICD shocks (Maron et al., 2007, 2013a; Woo et al., 2007). Inappropriate discharge due to sinus tachycardia, AF, and lead malfunction are the most common ICD complications in HCM. Infection, hemorrhage, thrombosis, lead fracture, dislodgement, and T-wave oversensing are found at rates similar to the general population of patients with pacemakers and ICDs (Lin et al., 2009).

European guidelines

Data from Europe has also been published on the risk of SCD and included in the most recent European Society of Cardiology Guideline update in 2014 (Elliott et al., 2014). In a multicenter consortium 3675 patients were followed for a median of 5.7 years. Of prespecified predictors eight were associated with SCD or appropriate ICD shock, including age, maximal left ventricular wall thickness, left atrial diameter, left ventricular outflow tract gradient, family history of SCD, nonsustained VT, and unexplained syncope. A score based on these risk factors is calculated by a HCM-SCD calculator. This algorithm calculates an individual HCM patient's estimated risk of SCD at 5 years. Three tertiles of groups are delineated by 5-year risk estimations given as percentages; a low-risk estimation is denoted for patients whose risk is <4%, an intermediate-risk estimation is denoted for patients whose risk is

4%–6%, and a high-risk estimation is denoted for patients whose risk is $\geq$6%. A low-risk estimation carries a recommendation of "ICD generally not indicated," an intermediate risk recommendation is "ICD may be considered," and a high-risk recommendation is "ICD should be considered" (Elliott et al., 2014; O'Mahony et al., 2014).

Conclusion

SCD is a major cause of mortality in patients with HCM, especially in the young, but can occur at any age. The substrate of HCM is highly vulnerable to the development of ventricular arrhythmias, which are responsible for the elevated rate of SCD in this population. In patients with HCM, SCD is the predominant concern in young patients, while progressive heart failure, AF, and stroke become more significant causes of morbidity and mortality in the later years. Major risk factors for SCD include prior resuscitated SCD or sustained VT, a family history of SCD due to HCM, recent unexplained syncope, and marked cardiac hypertrophy over 3.0 cm. Other risk factors include NSVT, abnormal blood pressure response to exercise, and newer emerging risk factors including fibrosis burden on CMR, genetic mutations, and the presence of apical aneurysm. Medications may be palliative and reduce symptoms, but are ineffective at prevention of SCD. The only proven effective treatment for prevention of SCD is implantation of an ICD. Risk assessment schemes, performed at initial presentation and repeated annually or when new risk factors arise, are vital in the management of patients.

VAD Introduction

A ventricular assist device (VAD) is an implantable mechanical device which can partially or fully replace the function of a ventricle of a failing heart. The growing heart failure population and limited number of donor hearts available for transplantation (for survival posttransplant, see **Fig. 1**) have resulted in rapid technological advances and increased implantation of VADs. They may be classified into devices that support the left ventricle, right ventricle, or both ventricles. The decision to implant a specific type of device is based on the patients underlying diagnosis as well as assessment of left and right ventricular function. The patients are classified into those who are given a VAD as:

- Bridge to recovery (BTR)
- Bridge to candidacy (BTC)
- Bridge to transplant (BTT)
- Destination therapy (DT)

Notwithstanding these implant definitions, in the current era VADs are used to treat refractory heart failure and the ultimate disposition of the patients depends on the response to mechanical circulatory support.

The first clinical use of a VAD was in 1966 by Michael DeBakey. He successfully supported a 37-year-old woman for 10 days after complex cardiac surgery using a pneumatically driven VAD (DeBakey, 1971). The subsequent development of these devices initially focused on bridging patients to heart transplantation. The early generation Novacor and paracorporeal pneumatic VAD were followed by the implantable pneumatic Heartmate VAD in 1992. The REMATCH trial published in 2001 confirmed the superior survival for patients with implantable left VADs as compared with optimal medical management (Rose et al., 2001). This shifted the focus to long-term support of heart failure patients.

The dramatic evolution in VADs from large bulky pulsatile devices to miniature ventricular assist devices (MVAD) weighing less than 100 g is illustrated in **Fig. 2** (Moayedi and Ross, 2017).

The registry for mechanically assisted circulatory support (INTERMACS) keeps track of the volumes related to durable mechanical cardiac support. From 2006 to 2014, there were 15,745 patients (2500/year) who received a durable device (Kirklin et al., 2015). Over 90% of these patients received a continuous flow ventricular assist device (CF-LVAD). In 2014, almost half of the devices implanted were designed for DT. Patients who underwent implant were predominantly INTERMACS profile 2–3 (65%), less than 20% of patients were INTERMACS 4–7 (**Table 1**) (Kirklin et al., 2015).

Procedure of Implantation of VAD

Before implantation of a VAD, the patient should be medically optimized. This may require inotropic support, diuresis, clearing of infection, and removal of any unnecessary central lines. Intraoperatively they will require invasive monitoring as well as transesophageal echocardiogram (Slaughter, 2011).

Table 1 INTERMACS profiles (Kirklin et al., 2015)

Profile	*Profile description*
1	Critical cardiogenic shock (Crash and burn)
2	Progressive decline (Sliding fast on inotropes)
3	Stable but on inotrope dependent
4	Resting symptoms or oral therapy at home
5	Exertion intolerant (housebound)
6	Exertion limited (walking wounded)
7	Advanced NYHA class III

The most common method for the implantation of VADs utilizes cardiopulmonary bypass with the heart beating. They can also be inserted while stopping the heart using aortic cross clamping and cardioplegia. The inflow cannula is most commonly placed in the LV apex to ensure adequate decompression. First the LV apex is cored, 2 cm lateral to the left anterior descending artery, and then the inflow cannula is secured with either running or interrupted sutures. The use of pledgets is dependent on the surgeon's preference and the quality of the heart muscle. The inflow cannula is then attached to the pump as per the manufacturer's instructions (Whitson, 2015). It should be parallel to the septum and pointing toward the mitral valve.

The outflow cannula is attached to the ascending aorta as far distal as possible, with a beveled anastomosis, to the sinotubular junction, using a partial occlusion clamp. Commonly this is done using a 4-0 or 5-0 nonabsorbable monofilament suture. The outflow conduit should be away from the midline to ensure easier reopening should the patient be transplanted. If the conduit is too redundant there is a risk of turbulent blood flow at the aortic anastomosis which may predispose to pump thrombus.

The percutaneous driveline is tunneled through the subcutaneous tissues and exits in the midclavicular line 3–4 cm below the costal margin. This can be done before systemic heparinization to limit bleeding. Old scars should be avoided and the drive line (DL) should be in a location that is accessible to the patient for change of dressings. Consideration is given to the patient's preference for a left- or right-sided DL exit site. Adequate de-airing is confirmed using echocardiogram guidance before starting the device.

Once the VAD has been implanted and hemostasis achieved, the device should be wrapped in a pericardial patch or in Gortex fabric to reduce adhesions should the patient recover or be suitable for transplantation.

Traditionally VADs have been implanted using a full sternotomy. However, there is a move to use a left thoracotomy and hemimedian sternotomy. As the implantable devices get smaller and more surgeons are using minimally invasive approaches for their routine surgeries, this will become more common.

Indications for LVAD

The contemporary indications for VAD therapy for patients as a bridge and DT are listed in **Table 2** (Feldman et al., 2013).

Contraindications to VAD Therapy

Contraindications to VAD therapy include mechanical aortic valve without plan to replace or close, profound thrombocytopenia, coagulopathy, uncontrolled systemic infection, recent stroke, or cerebrovascular disease that increases risk for intraoperative stroke, contraindication to systemic anticoagulation or antiplatelet therapy, significant right heart failure, psychosocial instability (ongoing substance abuse, lack of care plan, noncompliance), or other medical conditions that limit survival to less than 24 months (Feldman et al., 2013). Center-specific contraindications such as body size (BSA) $<1.2\ m^2$, right ventricular (RV) failure such as an RV stroke work index (RVSWI) $<250\ mm\ Hg \times mL/m^2$, end organ renal failure with a creatinine >3 mg/dL, moderate to severe pulmonary dysfunction, BMI $>45\ kg/m^2$, restrictive cardiomyopathy, and hypertrophic cardiomyopathy (Mancini and Colombo, 2015).

Preoperative Assessment and Selection

Patients who are being investigated for a durable LVAD should also be assessed for heart transplantation eligibility (Mehra et al., 2016; Costanzo et al., 2010). To determine eligibility for LVAD, the following tests should be completed as per the most recent ISHLT guidelines (Feldman et al., 2013):

1. All patients require assessment of RV function with hemodynamic and echocardiographic measures.
2. Patients with a history of coronary bypass should have a chest computed tomography (CT) to provide the location of bypass graft(s).
3. Patients with a history of vascular and coronary artery disease should have preoperative assessment of the ascending aorta for dilatation and atherosclerotic burden.
4. All patients with a history of atherosclerotic vascular disease require screening for peripheral and carotid/vertebral vascular disease.
5. A recent echocardiography or contrast cardiac CT should rule out the presence of apical thrombus.
6. All patients should have psychosocial risk factors assessed and a screen for cognitive dysfunction.

Palliative Care Input Before VAD

Palliative care is a critical part of the multidisciplinary team management of patients with advanced heart failure. In this complex group of patients, advanced care planning focusing on goals of care and desired therapies is vital. In fact pilot studies have shown

Table 2 Indications for VAD therapy: inclusion criteria (Kirklin et al., 2015)

Indications for VAD therapy	
Bridge (BTR, BTC, BTT)	*Destination therapy*
Listed for heart transplantation Status 1A or 1B listing NYHA class IV	LVEF equal or less than 25% Peak oxygen consumption (VO_2) less than 14 mL/kg/min (50% age/sex predicted) And 1 of 3 following criteria: ● NYHA class IIIB–IV symptoms(Mehra et al., 2016) despite medical therapy for at least 45 days or the prior 60 days, or ● Dependence on IV inotropes for greater or equal to 14 days, or ● Dependence on IABP for greater than 7 days

VAD, Ventricular assist device; *LVEF*, left ventricular ejection fraction; *NYHA*, New York Heart Association; *IABP*, intraaortic balloon pump.

benefits in quality of life, depression, and symptom control (Luo et al., 2016). Patients with heart failure have episodic exacerbations requiring regular reassessment, making timing of referral for palliative care challenging. Results from the recent randomized control trial of Palliative Care in Heart Failure are awaited (Mentz et al., 2014).

The goals of palliative care input for mechanical support patients include:

- Supporting the family while deciding goals of care
- Discussing care preferences in the event of a complication or poor quality of life
- Engaging the patient, family, and their appointed decision maker
- Empowering the family to make decisions in the event of device deactivation
- Providing a better understanding of the patient's treatment plan
- Helping with caregiver stress

The Decide-Left VAD (LVAD) trial is currently in progress across six sites. This randomized controlled trial is assessing illustrated pamphlets as well as a video to aid patients and caregivers with decision-making. As more patients have mechanical circulatory support implanted as DT, it is important to plan for the long-term management of these patients.

Survival of Patients With LVAD

Research related to LVADs can be traced back to over 60 years ago; with the first case of an extracorporeal VAD described by Dr. Debakey for a 37-year-old woman with mitral stenosis and aortic regurgitation (DeBakey, 1971; Hetzer and Delmo Walter, 2017). The REMATCH trial was the first randomized trial that showed the use of durable LVAD resulted in a clinically meaningful survival benefit in patients ineligible for heart transplantation. The rate of survival at 1 year was 52% for those with the pulsatile flow device (PF-LVAD) heartmate XVE versus 25% with medical therapy (Rose et al., 2001). In the subsequent HeartMate II Bridge to transplant trial (HM BTT), was a prospective nonrandomized trial where 80% either underwent transplantation or were alive at 180 days still listed as status IA or IB (Miller et al., 2007). The HM II CF-LVAD has also been compared to the PF-LVAD HMXVE device in the HeartMate II DT trial which showed an improved survival free from debilitating stroke and need for pump repair. More recently, the centrifugal CF-LVAD Heartware (HVAD) device was shown to be noninferior to the axial CF HM2 counterpart for DT. The HVAD bridge to transplant study device also showed that the HVAD was noninferior to HMII (Aaronson et al., 2012). The third generation of CF-LVAD, HM3, a fully magnetically levitated pump, was compared to the second-generation HM2, where there were no significant differences in the rates of death or disabling stroke, but pump thrombosis was less frequent with HM3 (0.7% vs. 7.7%, $P=0.02$) (Mehra et al., 2017). The current 1- and 2-year survival of patients with continuous flow LVAD devices is 80% and 70%, respectively (Kirklin et al., 2015).

Care of the Patient With the LVAD

The care of the patient with an LVAD depends on a collaborative multidisciplinary staff involving the cardiovascular surgeon, the heart failure clinician, nursing staff, MCS coordinator, and other specialists such as gastroenterology and infectious disease when needed (Feldman et al., 2013). The frequency of visits depends on the institution and the clinical stability. For example, in our institution, patients are seen weekly for the first month post discharge and then monthly. Each clinic visit would include a clinical assessment, interrogation of the LVAD to evaluate pump parameters and alarm history and routine blood work including coagulation and hemolysis screening. In our program, we routinely complete an echocardiogram, a RAMP study in all our VAD patients up to 3 months post discharge. Additional testing such as repeat echocardiogram and/or hemodynamic assessment may be warranted in patients who are bridge to transplantation or in the presence of change in clinical parameters.

Complications of VADs

While mechanical circulatory support has revolutionized treatment of heart failure patients, they are associated with significant complications. These can be classified into:

- Short term (<3 months post implantation)
- Long term (>3 months post implantation)

The most reliable information on adverse events is published by the INTERMACS registry. **Table 3**, published in September 2016, summarizes the adverse events in patients receiving primary implants between June 23rd 2006 and September 30th 2016.

INTERMACS also reports the most common cause of death in this patient population. The table published in September 2016 summarizes the causes of death in patients receiving primary implants between June 23rd 2006 and September 30th 2016.

Figs. 3–7 demonstrate some common pathological complications of VADs (**Table 4**).

Table 3 Adverse events

Adverse event type	*Early <3 months (%)*	*Late >3 months (%)*
Arterial non-CNS thromboembolism	0.9	0.5
Bleeding	29.6	23.5
Cardiac arrhythmia	21.9	11.5
Device malfunction +/− pump thrombosis	8.1	19.1
Hepatic dysfunction	3.6	2.5
Infection	28.3	31.4
Myocardial infarction	0.3	0.4
Neurological event	10.1	14.2
Other serious adverse event	21.0	16.0
Pericardial drainage	4.5	0.2
Psychiatric episode	5.7	3.5
Rehospitalization	38.3	65.3
Renal dysfunction	9.7	5.6
Respiratory failure	16.0	6.2
Venous thromboembolism	3.7	0.9
Wound dehiscence	1.2	0.5

Fig. 3 Picture of an explanted (recipients) heart with an LVAD in place. The outflow cannula (*arrow*) which is connected to the aorta has been cut here at explantation. The white line (*white arrow*) is the drive line, comes out of the skin, and is connected to the power pack.

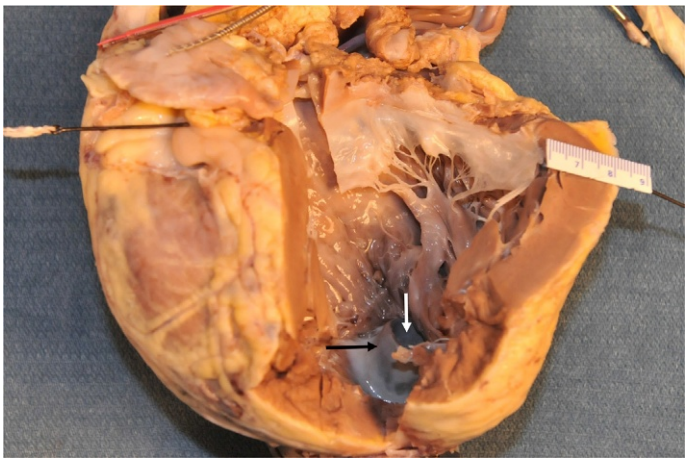

Fig. 4 This explanted (recipient) heart shows the inflow cannula (*black arrow*) and its orifice (*white arrow*). The cannula takes blood from the left ventricle to the LVAD. The cannula is covered with a layer of gray-white, shiny tissue called pannus or host tissue reaction. Among other things, pannus can help prevent thrombus deposition.

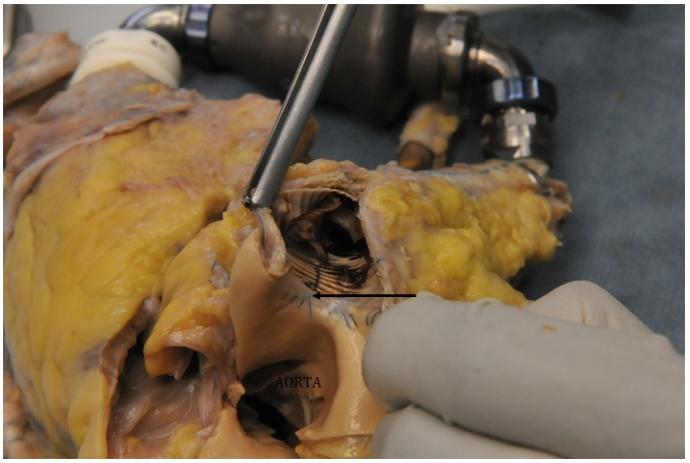

Fig. 5 This image shows the outflow graft at its junction with the aorta. At 5 years post implantation, there is a mild degree of tissue overgrowth (*arrow*) at the anastomosis. Dark gray-black, post mortem clot is seen in the synthetic (pleated dacron) graft.

Fig. 6 Explanted (recipients) heart shows a Heart Mate 2 LVAD. Device in place for over 5 years. There are extensive fibrous adhesions around the inflow cannula and the outflow cannula (*arrow*). A defibrillator pack is also seen.

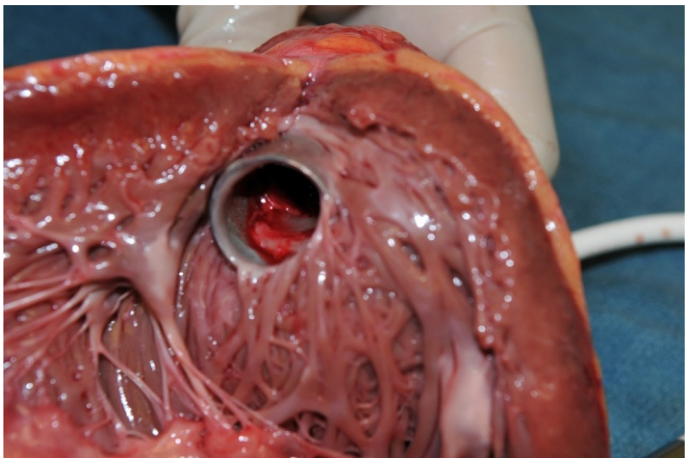

Fig. 7 This photograph of a left ventricle shows the LVAD inflow cannula in place. The cannula is adherent to the LV septal myocardium.

Table 4 Causes of death post VAD insertion

Cause of death	*Percentage (%)*
• Congestive heart failure	3.4
• Cardiac arrhythmia	2.6
• Major bleeding	2.8
• Right heart failure	4.1
• Sudden unexplained death	4.0
• Device malfunction	3.3
• Major infection	8.6
• Multisystem organ failure	16.1
• Neurological event	19.3
• Respiratory failure	5
• Withdrawal of support	9.3

The Future of VADs

It is estimated that 10 million people in the United States alone will be affected by heart failure by 2030 (Heidenreich et al., 2013). There is a significant discrepancy between donor heart availability and number of patients awaiting transplantation. VADs offer the option of bridge to heart transplantation or as DT.

Patients who had the devices implanted were in the advanced stages of heart failure and often inotrope dependent (Lima et al., 2015). The REVIVE-IT is an NIH-supported trial attempted to look outcomes of patients with less-advanced heart failure supported with durable LVAD (Baldwin and Mann, 2010; Pagani et al., 2016). The control group was noninotrope dependent, ambulating and only in moderately advanced heart failure. Unfortunately, this trial was discontinued early and failed to achieve its goal of widespread use of LVAD in less sick patients. The ROADMAP trial was a prospective trial which assessed the use of LVAD support as compared to optimized medical management in patients with INTERMACS profile 4 symptoms. In the as-treated analysis, the 12-month survival was significantly greater for LVAD than medically managed patients (Estep et al., 2015). With the evolving mechanical support technology mitigating significant adverse events, there the use of LVADs will perhaps be available to the less sick patient to further improve functional status and overall survival.

Introduction Heart Transplantation

Heart transplantation is the gold standard therapy for patients with advanced heart failure. It has resulted in an improved quality of life and survival in patients with stage D heart failure. As per the most recent ISHLT registry data, there have been an increasing number of heart transplantations since the 1980s, 4500 reported adult and pediatric heart transplantations occurred most recently in 2014; with a median recipient age of 53 years. The median survival is increasing and is currently 10.7 years with a median conditional on surviving the first year is 13.3 years (Lund et al., 2016).

Criteria for Heart Transplantation Listing

Patients with ACC/AHA Stage D heart failure comprise approximately 5% of all patients with heart failure. Such patients require several investigations to complete heart transplantation evaluation. Based on the updated 2016 ISHLT criteria for heart transplantation guidelines, **Table 3** describes some of the essential tests recommended to guide listing (Mehra et al., 2016).

Care of Patient Post Heart Transplant

The practice of care post heart transplantation is guided by clinical expertise and can be different from one institution to another (Costanzo et al., 2010). The core principles of care include monitoring for rejection, treating infection, and managing the late potential complications of heart transplantation such as chronic side effects of immunosuppression (IS) (e.g., hypertension, diabetes, renal dysfunction, cancer) and coronary allograft vasculopathy (CAV) (**Table 5**).

Patients post heart transplant require clinical assessment and surveillance endomyocardial biopsy frequently for the first 6–12 months after transplant for allograft rejection. The ISHLT guidelines recommend weekly biopsies for the first month, then bimonthly for the second month, monthly until 6 months, and then every few months until 18 months (Costanzo et al., 2010). An endomyocardial biopsy may be expedited if there are signs of rejection or a change in IS.

The standard maintenance therapy for IS includes calcineurin inhibitor, mycophenolate mofetil, and corticosteroids, which can be weaned or maintained at a low dose. Where there is clinical indication, there may be addition or a switch for a proliferative signal inhibitor such as everolimus or sirolimus.

Table 5 Criteria for heart transplant listing (Mehra et al., 2016)

Cardiopulmonary stress test	• Listing only based on peak VO_2 should not be performed • Respiratory exchange ratio (RER) >1.05 • When intolerant of beta-blocker peak VO_2 ≤14 mL/kg/min • In presence of B-blocker ≤12 mL/kg/min • In presence of submaximal stress test (RER <1.05) a ventilation equivalent of carbon dioxide slope ≥35
Role of diagnostic right heart catheterization	• Should be performed on all adult candidates • A vasodilatory challenge when pulmonary artery systolic pressure ≥50 mmHg and either transpulmonary gradient ≥15 and pulmonary vascular resistance >3 Wood units while maintaining a systolic blood pressure >85 mmHg
Age	• Carefully selected patients ≥70 years of age
Obesity	• Body mass index area <35 kg/m^2
Diabetes	• HbA1c <7.5%
Renal	• Estimated glomerular filtration rate if <30 mL/min/1.73 m^2 relative contraindication
Vascular	• Vascular Doppler and carotid Doppler to assess severity of peripheral vascular disease and cerebrovascular disease
Assessment of frailty	• Using modified frailty score where a score of 0 is nonfrail, 1–2 prefrail, and 3–5 frail (Fried et al., 2001)
Tobacco and substance use	• Cessation of smoking for 6 months • No active substance abuse including alcohol
Psychosocial evaluation	• Social supports need to be deemed sufficient

Complications of Heart Transplantation

The ISHLT registry provides information on patient profiles as well as morbidity and mortality after heart transplantation. The number of patients who are bridged to transplantation with mechanical circulatory support is steadily increasing. For causes of death posttransplant and significant risk factors for first year mortality, see **Tables 6** and **7**.

The most common morbidities post heart transplantation are listed in **Table 8**.

Among these complications, cardiac allograft vasculopathy (CAV) is the most notable as more than 50% of patients post heart transplantation have CAV by 10 years. It is a most common cause of death after the first year (Lund et al., 2016; Clerkin et al., 2017). CAV is characterized by intimal thickening and narrowing of the artery and results in flow limitation which results in restrictive remodeling (Clerkin et al., 2017). Causes of CAV can be associated with traditional cardiovascular risk factors, nonimmunological causes such as ischemic time, CMV infection, and immunological causes such as donor-specific antibodies, antibody, and cellular rejection (Clerkin et al., 2017). Patients require screening for CAV, most commonly with coronary angiography and a follow-up angiogram to assess disease progression. Although CAV does significantly limit posttransplant survival, there are limited therapies that can prevent or reverse progression. Of the immunosuppressive regimens, everolimus and sirolimus are associated with a decrease in a combined endpoint of death, CAV progression, or need for coronary intervention (Mancini et al., 2003).

Future of Heart Transplantation

Until a fully dependable artificial heart becomes available, the need for heart transplantation will continue. For monitoring graft hearts for rejection, the endomyocardial biopsy remains the gold standard, whether antibody mediated (AMR) or cell mediated (ACR). The biopsy is however associated with a 0.5%–1.5% risk of complications such as pericardial effusion, tricuspid regurgitation, and very rarely death (Crespo-Leiro et al., 2015). Based on the ISHLT guidelines, a patient will undergo 13 endomyocardial biopsies within the first year of transplantation. Gene expression profiling can be used to create a global picture of cellular function as an alternative to assessing cellular and antibody rejection. Currently, AlloMap, a proprietary algorithm based on 11 genes, is a

Cardiac graft vasculopathy	7.8	29.4	47.6
Malignancy	5.1	15.7	27.4

simple blood test being used clinically to assess for cellular rejection. The AlloMap score is associated with a negative predictive value that estimates the probability that a patient is not experiencing moderate (Grade 2R) rejection (Crespo-Leiro et al., 2015; Deng et al., 2006). It is hoped that these gene profiling scores will become an adequate substitute to endomyocardial biopsy for both cellular- and antibody-mediated rejection.

The future of heart transplantation rests on research that focuses on CAV and the need for immune tolerance to give, improve, and extend years of productive life for patients, post heart transplantation.

Introduction

Ventricular arrhythmias are an important cause of morbidity and sudden cardiac death (SCD) in almost all forms of heart disease. In North America and Europe the annual incidence of SCD ranges between 50 and 100 per 100,000 in the general population (Fishman et al., 2010). About half of these SCDs are caused by ventricular fibrillation (VF) or ventricular tachycardia (VT). VF is defined as "turbulent, disorganized electrical activity of the heart in such a way that the recorded electrocardiographic deflections continuously change in shape, magnitude, and direction" (Robles de Medina et al., 1978) (**Figs. 1–3**).

Mechanism of VF

As mentioned earlier, VF is defined as turbulent cardiac electrical activity, which implies a large amount of irregularity in the electrical waves that underlie ventricular excitation (Mandapati et al., 1998). Electrocardiography (ECG) during VF is characterized by chaotic, variable amplitude, morphology of deflection and which suggests complex and disorganized cardiac activation (**Fig. 1**).

Despite many decades of research, the underlying mechanism of VF is not fully understood. The electrical activity of the cardiac muscle during VF has been studied using extracellular and optical recordings in either vivo, or in perfused, isolated heart. Studies suggest that VF is unlikely to be one static mechanism but rather a dynamic process of electrical derangement that changes with duration (Tabereaux et al., 2009). The two major proposed mechanisms of VF are multiple wavelets theory and mother rotors theory, and whether VF is maintained by wandering wavelets or mother rotors remains controversial.

In 1930, Wiggers first proposed four progressive phases of VF based on epicardial movement using high-speed cinematography (Wiggers, 1930). Wiggers concluded that VF could not be adequately described as an asynchronous contraction of individual myocardial fibers. His observations suggested that the apparent lack of coordination and synchrony first involved relatively large areas of the myocardium, which seemed to gradually multiply and decrease in size as fibrillation evolved through its various stages (Jalife, 2000). Relatively recently Huang et al. investigated stages of VF using a high-density epicardial array during VF (**Fig. 4**) (Huang et al., 2004). Their classification was different from that of Wiggers'. They found that VF rapidly gained complexity in the first minute, followed by a recovery of organization over the next 10 min. In conclusion, they classified VF into five stages based on observation of the electrically mapped epicardial activation patterns during VF. According to their theory, stage 1, lasting the first 11 s after the onset of VF, demonstrates many wavefronts, a rapid frequency of activation, reentry, and a rapid propagation velocity. During stage 2 (12–62 s) these measures decrease, albeit with rapid dynamic fluctuations. During a brief stage 3 (63–86 s), many of these descriptors again increase consistent with a higher degree of organization, perhaps caused by a temporary decrease in extracellular potassium. Stage 4 (87–310 s) shows a steady decrease in most quantitative measures of VF organization, whereas during stage 5 (311–600 s), these measures all gradually toward zero, indicative of cell death and cessation of electrical activity.

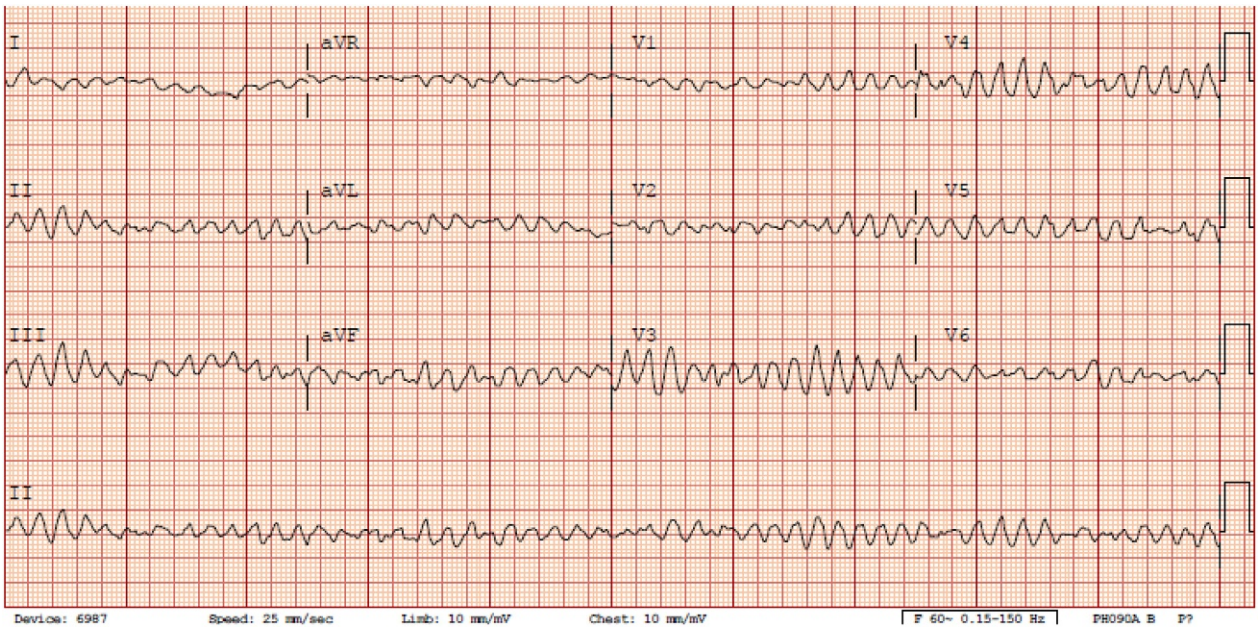

Fig. 1 Twelve lead ECG during ventricular fibrillation. Irregular deflections of varying amplitude and contour were seen in all 12 leads.

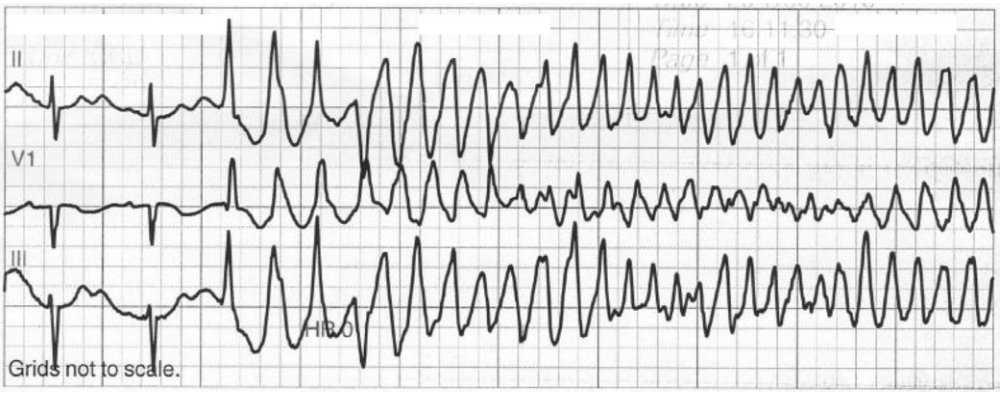

Fig. 2 Initiation of ventricular fibrillation on telemetry, VF was initiated by PVC on T wave.

Huizar et al. (2007) found three distinct phases of local VF dynamics during the first 10 min of VF: (1) a distinct increase in wavefront conduction velocity and organization during the brief third stage beginning ~1 min after VF induction and lasting ~30 s, (2) a high variation for most descriptors from second to second during VF, especially during the second stage, and (3) an increased incidence of reentry beginning ~40 s after VF induction and lasting for ~2 min. Although there are some differences among these theories, it seems that VF continues to change through different stages as it progresses. These different stages raise the possibility that the relative importance of different arrhythmogenic mechanisms changes as VF is initiated and then progresses through different stages (Wiggers, 1930; Huang et al., 2004; Huizar et al., 2007).

Initiation

Similar to the mechanisms of atrial fibrillation (AF), the mechanisms of VF can be divided into initiation by triggers and maintenance by substrate. The Purkinje system and premature ventricular contractions (PVCs) have been shown to be a trigger for VF in patients with no structural heart disease (Bänsch et al., 2003; Haïssaguerre et al., 2003; Marrouche et al., 2004). If a PVC occurs during the vulnerable period of the T wave, the impulse can propagate chaotically through the variably refractory myocardial cells and establish reentrant patterns that result in turbulent cardiac electrical activity. Computerized mapping techniques showed that reentrant wave fronts underlie the onset of VF in intact canine ventricles (Lee et al., 1996; Chen et al., 1986; Cha et al., 1994).

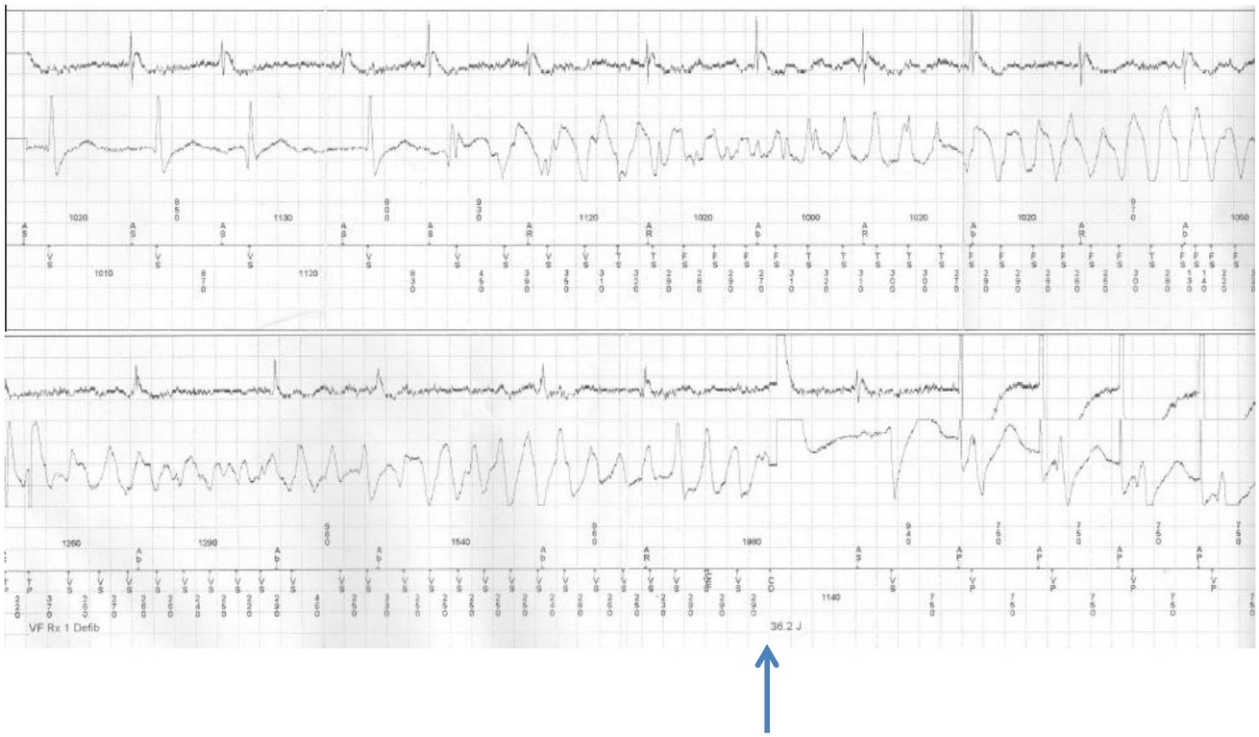

Fig. 3 Intracardiac ECG recorded on ICD. Ventricular fibrillation was detected and terminated by electrical shock of 36.2 J (*arrow*).

Clinical observations also indicate that VF is almost always preceded by VT, the duration of which can be a few beats to many beats (Kempf and Josephson, 1984).

Maintenance of VF "Wandering Wavelets" or "Mother Rotors"

Wandering Wavelets Theory

On the basis of a computer model of AF by Moe developed in 1962, fibrillation was hypothesized to be maintained by multiple small, wandering wavelets, in which the activation pattern is constantly changing (Moe, 1962). According to the wandering wavelet hypothesis, wavelets continue to change pathways and are short lived. Wandering wavelets terminate in two different mechanisms: (1) they are extinguished when they collide with another wavelet, strike a nonconducting boundary, or completely block; (2) they partially block and fractionate into two or more daughter wavelets. If the amount of tissue exceeds a critical mass, enough daughter wavelets that block and reenter are constantly being formed so that reentry circuits are constantly present to sustain fibrillation.

Mother Rotors Theory

Winfree introduced the term "rotor" to describe a source of rapid activation that creates a spiral wave in two dimensions and a scroll wave in three dimensions (Winfree, 1987). In his theory, although a spiral or scroll wave has a large rotating wavefront, the actual source of activation is the rotor in the center (Chen and Weiss, 2005). Animal study using Langendorff-perfused rabbit heart demonstrated that rotating spiral waves are most likely the underlying mechanism of VF and contribute to its frequency content (Mandapati et al., 1998). These electrical spiral waves or so called "rotors" have been observed on the endocardium and epicardium during VF in animal and human studies of VF (Cha et al., 1994; Zaitsev et al., 2000; Ohara et al., 2001; Masse et al., 2007; Krummen et al., 2014). Other studies have also documented the existence of rotors in the first few seconds of VF (Zipes and Jalife, 2013). Other studies however have failed to prove an existence of mother rotor at VF initiation (Choi et al., 2002) and several studies reported that two types of VF can occur, a type with "wandering wavelets" and another type consisting of a "mother rotor" with daughter wavelets (Choi et al., 2002; Liu et al., 2004; Nanthakumar et al., 2007).

The basic components of the rotor are a curved wave front, a curved wave tail, and a core around which the wave front and tail rotate (Zipes and Jalife, 2013) (Pandit and Jalife, 2013) (**Fig. 5**). The traditional view of a wave propagates in a fixed ring-like path, with an excitable gap separating the wave front from its tail of refractoriness (**Fig. 5A**). Functional reentry was initially described via the leading circle hypothesis (**Fig. 5B**) (Allessie et al., 1977). Different from leading circle hypothesis in a rotor, the curved

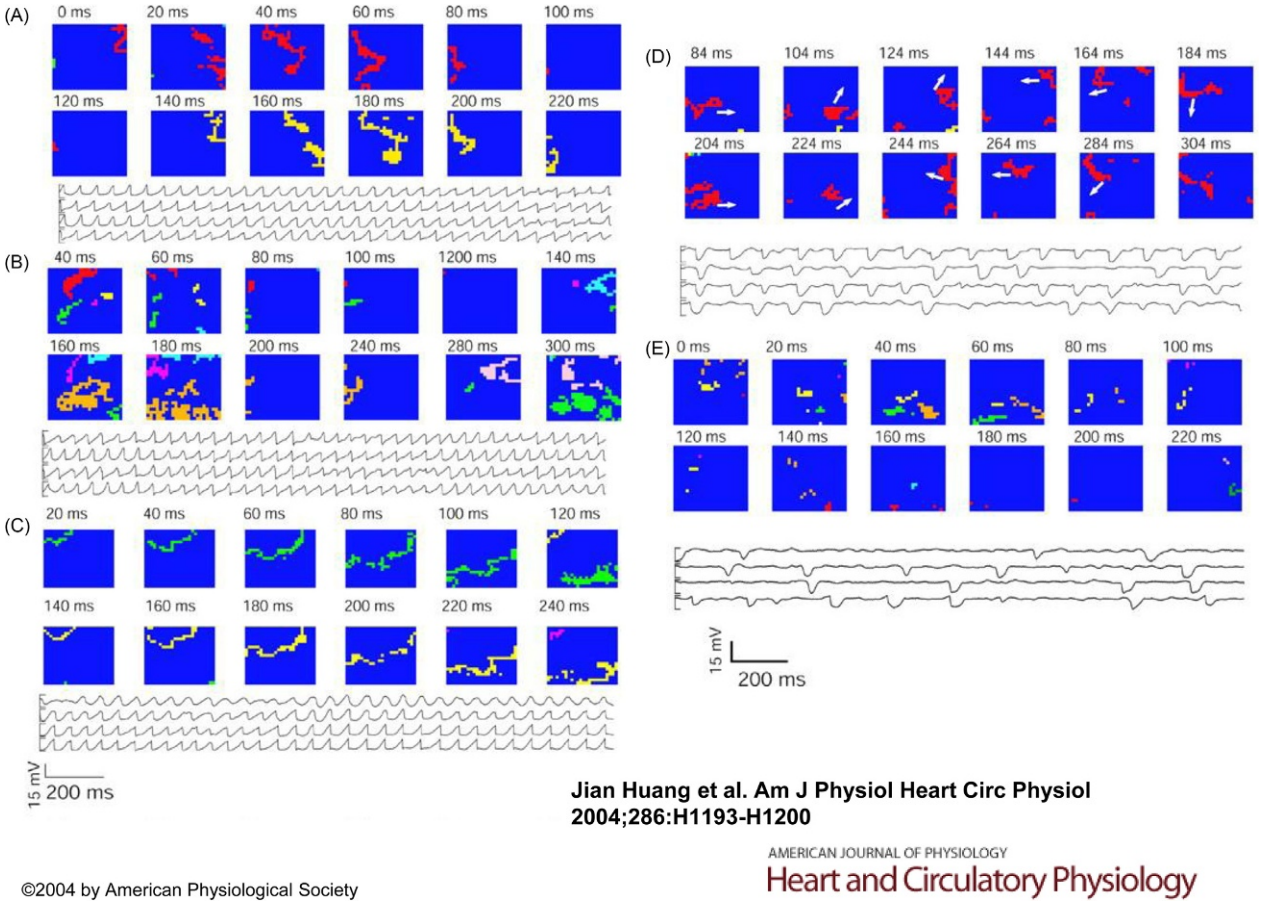

Fig. 4 Snapshots of activation during *stages i–v* of ventricular fibrillation (VF) in one dog. Each colored pixel is an electrode site at which the rate of voltage change (dV/dt) is less than or equal to −0.5 V/s sometime during the 5-ms interval represented by each frame. The numbers show the time from the beginning of each VF stage. Different-colored pixels indicate distinct isolated wavefronts. The arrows in *stage iv* indicate the direction of wavefront movement. Recordings from the same four electrodes are shown below the activation maps for each stage. (A) During *stage i*, the wavefronts are large and coherent and in this particular example repeatedly propagate from right to left. (B) During *stage ii*, there are large spatial and temporal variations in the number of wavefronts and extent of the area swept out by each wavefront. (C) During *stage iii*, the wavefronts become more regular. (D) A reentrant wavefront rotates counterclockwise in this particular example during *stage iv*. (E) There are few wavefronts in *stage v*, which is characterized by slow conduction and small wavefront areas.

wavefront and the wave tail meet each other, at a singularity (white asterisk, Fig. 5C), and the tissue at the center is not refractory (Pandit and Jalife, 2013). The waves might be highly stable and spiral periodically around their generating rotor to activate the ventricles at extremely high frequencies, or might breakup in the rotor peripherally and result in fibrillatory conduction. That can explain complex spatial and temporal pattern of ventricular activation in VF. A rotor is composed of a wave of excitation propagating around a topological defect, which is known as a phase singularity. Rotor termination occurred when rotors of opposite chirality merged or when a single rotor collided with a boundary (Gray et al., 1998).

Defibrillation

Over the last half century, electrical defibrillation has been used clinically as the principal effective treatment for VF (Beck et al., 1947; Zoll et al., 1956) and defibrillation is still the only known effective therapy for VF. ICDs (implantable cardioverter defibrillators) have been used widely for prevention of SCD and have become standard therapy for high-risk patients with cardiac disease. Previously, it was believed that to have a successful defibrillation, a shock must be strong enough to depolarize a large amount of the cardiac tissue. Then if a sufficient amount of the cardiac tissue were changed to unexcitable state by the shock, the wavefronts of VF would be eliminated (Zipes et al., 1975). Although this concept remains as the underlying principle of defibrillation, the process of defibrillation is likely to be much more complex.

In defibrillation, a shock is delivered to the cardiac tissue to uniformly and simultaneously depolarize a critical mass of the excitable myocardium. To defibrillate cardiac muscle, a shock must alter the transmembrane potential so that it terminates the VF

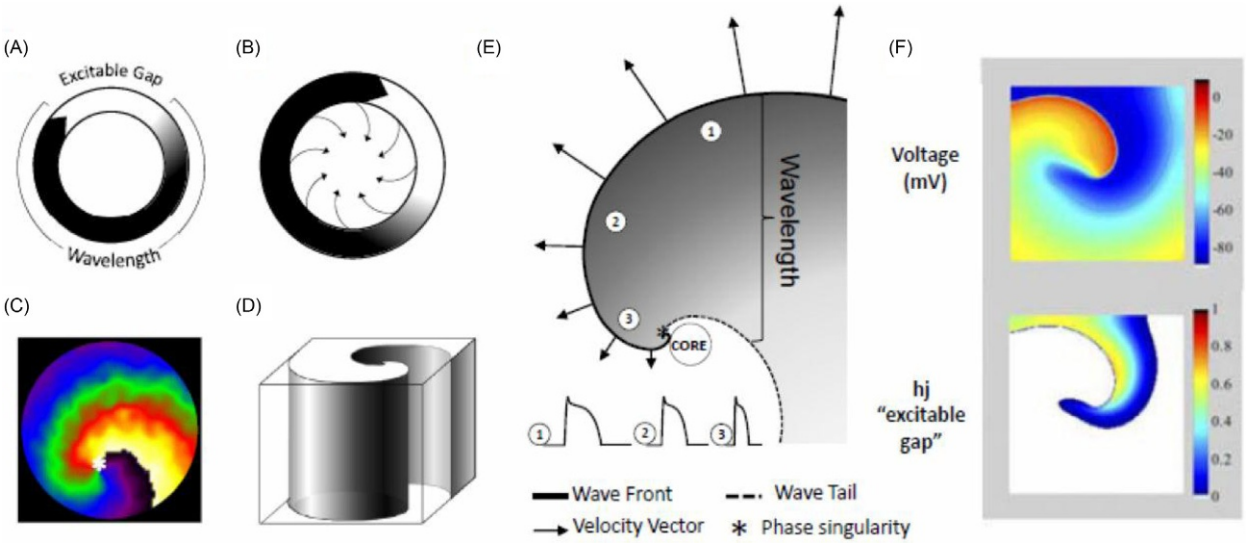

Fig. 5 Rotors and spirals, basic concepts. (A) Schematic representation of reentry around a ring-like anatomical obstacle where the wavelength (*black*) is shorter than the path length allowing for a fully excitable gap (*white*). (B) Leading circle reentry around a functional obstacle, with centripetal forces pointing inward toward a refractory center. (C) Two-dimensional spiral wave, along with the rotor tip at the center "*". (D) Schematic of a three dimensional scroll wave. (E) Snapshot of the spiral wave: electrotonic effects of the core decrease conduction velocity (*arrows*), action potential duration (representative examples shown from positions 1, 2, and 3) and wavelength (the distance from the wave front (*black line*) to the wave tail (*dashed line*)). Conduction velocity (CV) decreases and wavefront curvature becomes more pronounced, near the rotor, which is a phase singularity at the point where the wave front and the wave tail meet "*". (F) Computer simulation of reentry. Bottom panel: snapshot of inactivation variables of sodium current, "h.j"during reentry.

wave fronts but simultaneously must not reinitiate new wave fronts that lead to VF. Therefore, to fully understand the mechanism of defibrillation, it is essential to understand the mechanism of initiation and reinitiation of VF.

Mechanism of Defibrillation

The exact mechanism by which electrical energy defibrillates the cardiac tissue has not been completely elucidated. The electrical shock seem to be electrically synchronize cardiac cells by either activation or change cardiac cells into refractory state by extending refractoriness.

Computer simulations showed that areas close to shocking electrodes produce virtual electrodes that either hyperpolarize or depolarize the surrounding tissue (Roth, 1995; Wikswo et al., 1995; Dosdall et al., 2010).

Defibrillation Waveforms

The electrical shocks delivered from the defibrillator (either ICD or external defibrillator) discharge to the cardiac muscle through the high energy electrodes. The waveform typically shows a voltage that declines exponentially (Fig. 6).

Biphasic Versus Monophasic Wave

Two different types of waveforms are used clinically, monophasic and biphasic (Fig. 6). In monophasic waveforms, the polarity of the shock is unchanged at each duration of the electric shock, while in biphasic forms, the polarity of the shock reverses at each electrode pathway through the defibrillation waveforms. Contemporary ICDs incorporate biphasic waveforms because biphasic defibrillation is superior to monophasic defibrillation, requiring less energy and causing less cardiac damage with higher success rates.

The monophasic shock defibrillates most of the myocardial cells in the ventricle (at least 60%, can be 90%). Therefore, monophasic shocks may be strong enough to terminate the wavefronts of VF. However, the shocks would create virtual electrodes that can generate new wave fronts that can reinitiate VF. Recovered cells are stimulated and simultaneously the action potential will be extended to those cells that are activated already. The required voltage for monophasic shocks are higher and that is consistent with the fact the defibrillation threshold (DFT) with monophasic shock is higher than biphasic shock. Unnecessarily high-energy defibrillation shocks have since been shown to result in more postshock cardiac dysfunction as a result of a direct membrane-depressant effect and electroporation (Jones and Jones, 1984; Jones et al., 1987; Noujaim et al., 2007; Tang et al., 1999).

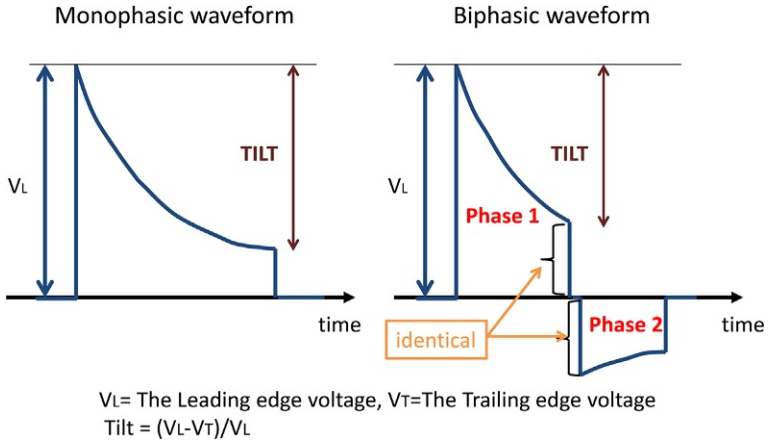

Fig. 6 Monophasic and biphasic waveform in defibrillation.

A biphasic shock has two phases of opposite polarity. After an initial pulse (phase 1), a second pulse with the opposite polarity (phase 2) is delivered after 2 or 3 ms in ICD (Stroobandt et al., 2009). In the middle of the shock, the waveform reverses direction rather than traveling in one direction only. Just as monophasic shock, phase 1 depolarizes and extends the refractory period of most ventricular cells, while phase 2 acts as a powerful catalyst to reduce significantly the electrical requirements of the first phase. Phase 2 removes the charge of cells that were not captured (capture means extending refractory periods of the cardiac cell). This phase 2 shock reduces the number of borderline stimulated cells that would exhibit delayed activation capable of desynchronizing the heart. In fact, as the effectiveness of the single capacitor biphasic waveform has been established, it has successfully been incorporated in clinical use in the ICD as well as the automated external defibrillator (AED) (Stroobandt et al., 2009; Bardy et al., 1996; Schneider et al., 2000).

Truncated Waveform

The waveform terminates prematurely before full capacitor discharge; thus it is called truncated biphasic waveform. Truncated biphasic waveform defibrillation has had a very favorable impact on ICD and AED energy requirements (Bardy et al., 1989, 1996; Schneider et al., 2000; Marks et al., 1994; Mittal et al., 1999; Swartz et al., 1993; Winkle et al., 1989). Mainly there are two merits for truncation. First, truncation can avoid the refibrillatory effects induced by the low-voltage tail of complete capacitor discharge. Secondly, an excessively long shock waveform wastes much energy. At maximum membrane voltage, the largest number of cells will be captured. Extension of the shock duration beyond this point results in the decreasing voltage that can reduce the success rate of defibrillation. It captures the largest number of cells, long before complete discharge of the high voltage capacitor. Unnecessary long shock duration can also cause shortening of the battery life of ICD.

Defibrillation Threshold

The goal of defibrillation is to use the minimum amount of energy required to overcome the threshold of defibrillation. Excessive energy can cause myocardial injury and cardiac arrhythmias. The DFT is the minimum amount of energy required to reliably defibrillate the heart when it is experiencing a hemodynamically unstable VF or VT.

To know the DFT allows the physicians to be sure that the ICD is programmed to deliver energy that is sufficient enough to defibrillate ventricular arrhythmias. Therefore DFT testing requires VF induction. Another reason for the test is to confirm reliable sensing, detection, and redetection of VF.

The DFT does not exhibit a constant value because defibrillation requirements vary as a result of many influencing factors. In fact, a clinical measurement of DFT has only fair reproducibility. In one study of 25 patients, the correlation coefficient between two successful determinations of the DFT was 0.64 (Swerdlow et al., 1996).

DFT Test in Clinical Practice

DFT Testing

DFT testing had been considered an integral part of ICD implantation for many years. This has traditionally been done by VF induction and termination through the device or, less commonly applied, through upper limit of vulnerability (ULV) testing. The DFT testing usually starts by programming a ventricular sensitivity of 1.2 mV, which is higher than nominal setting of 0.3 mv (less sensitive). Defibrillation from ICD might fail and external defibrillation pads are placed before the implantation procedure begins.

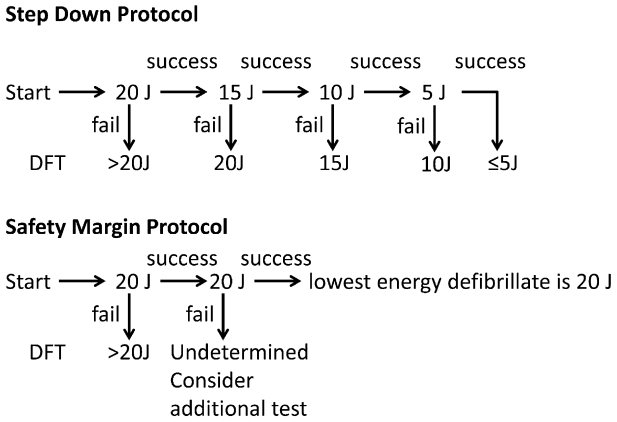

Fig. 7 Two common protocols of defibrillation threshold testing at implant of an ICD with a maximum shock strength of 30 J.

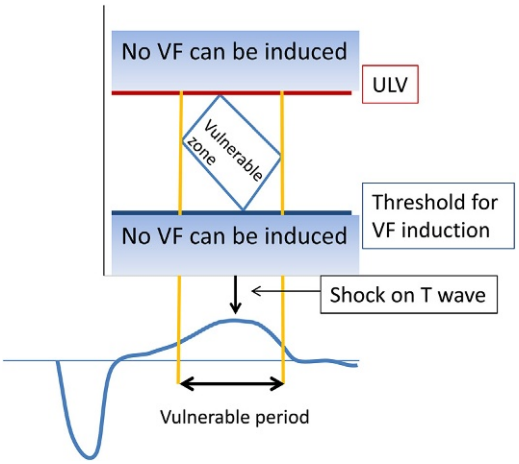

Fig. 8 Vulnerable period and upper limit of vulnerability (ULV).

Testing is done with the device in the surgical pocket and with leads connected. Electrical activity during VF is lower than that during VT and VF and not fast VT has to be induced for the testing. The method of VF induction depends upon the manufacturer, and the capabilities of the device and programmer. VF is induced by rapid pacing, direct current, or T-wave shocks. Given the probabilistic nature of DFT, DFT testing requires multiple shocks to determine with precision. During DFT testing, VF is induced one or more times, and each episode of VF is defibrillated at one or more shock energies. In patient-specific testing, the success or failure of the first test shock usually determines the programmed strength of the next test shock:

There are two common methods for DFT testing, "the safety margin protocol" and "the step down protocols" (**Fig. 7**). In both protocols, the first shock is programmed at least 10 J below the maximal output of the ICD. A safety-margin protocol is preferred when the principal goal is to minimize the risks of shocks, fibrillation and defibrillation testing. After the safety margin testing, the first shock usually is programmed to maximum output.

Upper Limit of Vulnerability

Testing the ULV has been used as an alternative to standard DFT testing as a way to estimate DFT without inducing VF. ULV testing provides an accurate estimate of the probability of defibrillation success and is more reproducible than the DFT testing (Swerdlow et al., 1996). If shock was applied during a certain period of time of a regular cardiac cycle, VF can be induced. This period is called as "vulnerable period." This period is simultaneous with the T wave in the ECG (**Fig. 8**). The ULV is the weakest shock that does not induce VF when delivered during the vulnerable period (Stroobandt et al., 2009; Swerdlow et al., 2003). To successfully defibrillate, the shock strength must reach or exceed the ULV. A shock on the vulnerable period of the T wave can only induce VF if the energy is smaller than a critical value. If a higher energy is delivered, VF will not be induced. It correlates closely with the minimum shock energy that defibrillates reliably (Chen et al., 1986; Swerdlow et al., 2003). The measurement of ULV is performed in regular rhythm (usually during right ventricular pacing at 120–150 beats per minute) providing an estimate of the minimum shock strength required for reliable defibrillation. A shock is delivered on top of the T wave. If VF is not induced, the next shock will be delivered

20 ms before or after the top of the T wave. If you only need to determine a safety margin, the shock strength should be 5–10 J below the maximum output of the device. For example, if VF is not induced by the 20 J shock, the ICD shock can be programmed at 30 J (more than 10 J safety margin). The ULV is more reproducible than the DFT and can provide an accurate patient-specific safety margin with fewer episodes of VF (Swerdlow et al., 1996, 1998). Thus, the ULV testing has been used as a surrogate for the DFT testing, especially patients with high risk for DFT.

The Future of DFT Testing

With developments in the technology of manufacturer of defibrillators, ICDs are now capable of delivering high energy (>35 J) shock and can be programmed to increase the efficacy of biphasic shock. The need for DFT testing has therefore become debatable, given that the incidence of an inadequate safety margin is infrequent. While complications during ICD implantation are also infrequent, many of these can be directly or indirectly related to DFT testing. Adverse effects related to DFT testing include myocardial injury, depression of ventricular systolic function, persistent hypotension, central nervous system injury, stroke, thromboembolic events, or respiratory depression (Mollerus and Naslund, 2007; Schlüter et al., 2001; Toh et al., 2012; Wilkoff et al., 2016a,b,c).

Recently large prospective randomized studies were conducted to evaluate the efficacy of DFT testing (Bänsch et al., 2003; Blatt et al., 2008; Brignole et al., 2012; Healey et al., 2015). Those studies revealed that routine defibrillation testing at the time of ICD implantation does not improve shock efficacy or reduce arrhythmic death in patients with left-sided pectoral implantation. Based on these results, the US guidelines was modified and now advocates that DFT testing can be reasonably omitted in patients undergoing a left pectoral transvenous ICD implantation with a right ventricular apical lead that is functioning appropriately (Wilkoff et al., 2016a,b,c).

Conclusions

VF is an important cause of morbidity and sudden death. Even after many decades of research, the mechanism of VF has not been fully understood. An electrical defibrillation is the only proven effective therapy for VF and ICD has become standard of care for patients with the risk of SCD. The efficacy of the ICD for the primary and secondary prevention of SCD has been well established. The goal of defibrillation is to use the minimum amount of energy required to overcome the threshold of defibrillation while minimizing myocardial injury and cardiac arrhythmias caused by excessive energy. Until recently, DFT testing has been considered the standard of care during ICD implantation procedure.ULV has also been used as alternative to DFT during ICD implantation to minimize the number of induction of VF and defibrillation. With the development of contemporary pectoral ICD systems with biphasic waveforms and higher output shocks, the risk of unsuccessful defibrillation becomes much lower, and DFT is not recommended routinely any more. Further studies are needed to elucidate the mechanism of VF and defibrillation and that would lead to improvement of prognosis of patients with the risk of SCD.

Introduction

Heart failure (HF) affects 5.7 million Americans, costs $30.7 billion annually, and is associated with a 50% 5-year mortality (Mozaffarian et al., 2015). The lifetime risk of HF in Americans is approximately 26% (Folsom et al., 2015). The prevalence and incidence of HF increases exponentially with age, disproportionately burdening the elderly who are projected to account for 20% of the U.S. population by 2030 (Ortman et al., 2014). Indeed, using the American College of Cardiology (ACC) and American Heart Association (AHA) HF staging system (Yancy et al., 2013), which emphasizes the continuum of risk for the HF syndrome, contemporary data from an elderly community-based cohort demonstrate that 52% had clinical risk factors for HF without overt structural heart disease (Stage A), 30% had evidence of cardiac structural and functional abnormalities (Stage B), with only 5% having neither (Shah et al., 2017a). These HF trends are partly related to advances in diagnosis and treatment of coronary artery atherosclerosis, including cardiac revascularization therapy, such that greater numbers of patients survive myocardial infarction (MI) and are at heightened risk for development of HF (Armstrong and Committee, 2006).

At the same time, the phenotypic profile of HF is changing, related to both the aging population and secular trends in the prevalence of cardiometabolic HF risk factors including obesity and diabetes. Data from community-based studies have established that HF with preserved ejection fraction (HFpEF) accounts for up to 50% of HF cases and is increasing in prevalence (Bhatia et al., 2006; Owan et al., 2006). HFpEF is associated with rates of HF rehospitalization and functional decline similar to HF with reduced ejection fraction (HFrEF) (Tsutsui et al., 2001; Smith et al., 2003), and carries a significantly higher risk of death compared to age-matched controls (Vasan et al., 1999; Davis et al., 2008). Although outcomes of patients with HFrEF remain poor, the clinician has several evidence-based pharmacologic and device interventions to reduce disease-associated morbidity and mortality. In contrast, no disease-specific therapy has been definitively shown to improve prognosis in HFpEF, despite multiple randomized controlled trials (Yusuf et al., 2003; Cleland et al., 2006; Massie et al., 2008; Pitt et al., 2014).

Left ventricular (LV) remodeling is the culmination of a complex series of transcriptional, signaling, structural, electrophysiological, and functional events occurring within the cardiac myocyte and other elements of the LV. The remodeling process encompasses cellular changes including both cellular and interstitial components of the myocardium. The alteration in ventricular architecture is driven at a cellular level by a combination of myocyte hypertrophy, necrosis (Tan et al., 1991), apoptosis (Sharov et al., 1996; Olivetti et al., 1997), fibrosis (Anderson et al., 1979), increased fibrillar collagen (Brilla et al., 1990), and fibroblastic proliferation (Villarreal et al., 1993). Pathophysiologic changes in myocyte function are related to decreased beta-adrenergic receptor density and signaling, abnormal excitation–contraction coupling, and myosin heavy chain isoform switching (Mann and Bristow, 2005). In addition, reorganization of intercellular matrix components, involving interstitial and perivascular fibrosis, and associated increases in LV stiffness and alterations in chamber geometry, characterize remodeling (Weber, 2000).

This review article will focus on patterns of structural LV remodeling in HF as assessed by noninvasive imaging techniques. Given the burden of HFpEF, and lack of clarity regarding pathophysiology of this heterogeneous syndrome, we will place particular emphasis on what is known—and not known—about ventricular remodeling in HFpEF.

Ventricular Remodeling: Describing LV Size and Shape

The term "ventricular remodeling" was first coined to describe the progressive cavity dilatation following MI (Pfeffer et al., 1985), but has come to be used more generally to refer to changes in LV structure in response to physiologic and pathologic hemodynamic stress. Indeed, alterations in cardiac structure and function have long been recognized as markers of heightened risk for cardiovascular events. Using pathologic samples, Linzbach described two distinct patterns of LVH, reflecting the impact of volume and pressure loading on LV muscle mass and chamber size (Linzbach, 1960): eccentric (volume) hypertrophy characterized by increased chamber size and residual volume, and concentric (pressure) hypertrophy with preserved chamber size and residual volume. Grossman et al. (1975) subsequently articulated this fundamental relationship between myocardial wall stress and ventricular hypertrophy and chamber enlargement: pressure overload associates with sarcomere replication in parallel and increased wall

thickness-to-chamber radius ratio (concentric hypertrophy), allowing for normalization of LV peak systolic meridional wall stress, while volume overload associates with sarcomere replication in series and preserved wall thickness-to-chamber radius ratio (eccentric hypertrophy). The prognostic importance of LV volumes (Hammermeister et al., 1978) and ejection fraction (Hammermeister et al., 1979) for survival in patients with valvular and coronary diseases respectively was them demonstrated by Hammermeister et al. using left ventriculography. These findings were replicated and reinforced by imaging studies of patients with chronic or post-MI LV systolic dysfunction without overt HF in the SOLVD Prevention (SOLVD Investigators et al., 1992; Quinones et al., 2000) and SAVE (Pfeffer et al., 1992; St John Sutton et al., 1994) trials. Subsequent investigations have further demonstrated that both regression of LVH (Devereux et al., 2004) and the prevention or reversal of LV enlargement (Solomon et al., 2010a; Doughty et al., 1997; Merlo et al., 2011) are associated with improved clinical outcomes.

Beyond LV mass and volume, the relationship between LV wall thickness and cavity dimension, which can be assessed by noninvasive imaging modalities and is termed the relative wall thickness (RWT), has been used further refine risk stratification among persons without hypertrophy. Ganau et al. (1992) incorporated RWT with LV mass in a sample of hypertensive persons to identify different patterns of ventricular shape, while Koren et al. (1991) demonstrated the prognostic implications of elevated RWT but normal LV mass for hypertensive patients. These geometric patterns have subsequently been described in patients with cardiovascular risk factors, prevalent coronary disease, and HFpEF, although the prognostic relevance of increased RWT in the absence of LVH (termed concentric remodeling) has been inconsistent (Krumholz et al., 1995; Verdecchia et al., 1996; Ghali et al., 1998; Zile et al., 2011; Apostolakis et al., 2014).

Furthermore, these alterations in LV structure are closely linked to impairments in LV function. LV dilatation and eccentric hypertrophy are associated with a change in the LV from a prolate ellipse to a more spherical shape, reflected in a higher eccentricity index. This change in shape appears to be accompanied by detrimental alterations in myocardial fiber orientation (van Dalen et al., 2010; von Deuster et al., 2016) and associated reduction in the efficiency of myocyte shortening (Sallin, 1969). Concentric remodeling is associated with impaired diastolic function and increased diastolic LV stiffness (Fouad et al., 1984), but may also mask impairments in myocardial systolic function despite preserved or even increased chamber-level measures of systolic function, such as LVEF and fractional shortening (Aurigemma et al., 1995a,b; Palmieri et al., 2001). Quantification of myocardial deformation in persons with preserved LVEF using 2D speckle tracking suggests that progressive concentric remodeling is associated with reduced longitudinal deformation and increased circumferential deformation (Kuznetsova et al., 2008).

Impact of HF Risk Factors on Age-Related Ventricular Remodeling

Longitudinal echocardiographic data from the Framingham Heart Study (FHS) show that HF risk factors modify normal age-related changes in LV structure such that wall thickness increases are more pronounced, cavity size fails to decrease, increases in systolic function (fractional shortening) are attenuated, and increases in LV mass are exaggerated (Cheng et al., 2009, 2010; Lieb et al., 2009). Once present, LV concentric hypertrophy progresses to eccentric hypertrophy in 20%–25% at 5 years (Lieb et al., 2014; Desai et al., 2011), and is associated with a higher risk of subsequent reduced LVEF (Drazner et al., 2004; Kishi et al., 2014). In addition to age-related changes in LV structure and systolic function, LV diastolic function—particularly LV longitudinal relaxation velocities—also appear to decrease with age, in a manner that is accelerated by HF risk factors (Shah et al., 2017b). Indeed, the low rates of LV hypertrophy relative to diastolic dysfunction in population-based studies (Redfield et al., 2003) and clinical trials of hypertension (Solomon et al., 2007, 2010b) and HFpEF (Solomon et al., 2012) suggest that diastolic dysfunction may precede LV remodeling and hypertrophy.

Importantly, the same HF risk factors that modify longitudinal changes in LV structure, including hypertension, diabetes, obesity, and renal dysfunction, correlate with diastolic dysfunction (Abhayaratna et al., 2006; Boyer et al., 2004; Hayashi et al., 2006) and impaired systolic function detected by strain (Narayanan et al., 2009; Fonseca et al., 2004; Andersen et al., 2005; Kosmala et al., 2008; Wong et al., 2004; Tumuklu et al., 2007). Indeed, greater LV mass and cavity size themselves correlate with concomitant abnormalities of LV diastolic function and systolic function detected by strain imaging (Fouad et al., 1984; Hare et al., 2008; Hung et al., 2017), although these measures can be abnormal in the absence of chamber enlargement or hypertrophy.

Ventricular Remodeling in HF With Reduced Ejection Fraction

HFrEF is characterized, by definition, by reduced LVEF and LV dilatation. As previously noted, it is well recognized that both lower LVEF and larger LV volumes—and larger LV end-systolic volumes in particular—predict worse cardiovascular outcomes in HFrEF. Furthermore, imaging substudies of both the SOLVD trial (Konstam et al., 1992, 1993; Greenberg et al., 1995) in HFrEF and the SAVE study (St John Sutton et al., 1994, 1997) in patients with post-MI LV dysfunction demonstrated attenuation of LV enlargement with ACE inhibitor therapy compared to placebo, effects that paralleled the beneficial impact of ACE inhibitor therapy compared to placebo on clinical outcomes. Beyond LVEF and ventricular size, patterns of LV hypertrophy and remodeling, including eccentric and concentric remodeling, influence patient risk. Concentric hypertrophy at baseline predisposes to LV enlargement post-MI (Jilaihawi et al., 2003). Among patients who sustained an MI complicated by LV dysfunction or HF, specific patterns of LV geometry have been associated with death or HF hospitalization, even after adjusting for EF and LV end-diastolic volume (Verma et al., 2008).

Ventricular Remodeling in HF With Preserved Ejection Fraction

Classically, HFpEF has been considered an expression of advanced hypertensive heart disease, with antecedent hypertension present in 60%–90% of HFpEF cases in epidemiologic studies (Aurigemma and Gaasch, 2004; Lam et al., 2011). Biopsy-based pathologic studies in select samples of HFpEF patients demonstrate increased cardiomyocyte stiffness, elevated interstitial myocardial collagen content, and greater cardiomyocyte hypertrophy (van Heerebeek et al., 2006), while invasive hemodynamic studies in select HFpEF patients have demonstrated both impaired early diastolic active relaxation and increased passive stiffness (Zile et al., 2004; Westermann et al., 2008). Further supporting this view, previous studies have described significantly increased LV wall thickness and reduced chamber dimension in HFpEF when compared to healthy controls or hypertensive patients without HF (Kitzman et al., 2002; Melenovsky et al., 2007; Lam et al., 2007). However, in contrast to these findings largely in patients in midlife, data from the Cardiovascular Health Study (CHS) demonstrate that elderly persons with HFpEF have increased LV cavity size and mass compared to hypertensive controls (Maurer et al., 2007)—changes concordant with the observed effects of HF risk factors on longitudinal changes in LV structure from mid- to late-life (Cheng et al., 2009, 2010; Lieb et al., 2009).

Heterogeneity in the cardiac phenotype—including LV structure and function—in HFpEF is increasingly recognized (Shah and Pfeffer, 2012), in parallel with the greater appreciation of the pathophysiologic heterogeneity of this syndrome. Diastolic measures perform poorly in discriminating HFpEF patients from their comorbidity matched symptom-free counterparts (Abhayaratna et al., 2006), and are absent in approximately one-third of HFpEF patients (Zile et al., 2011; Persson et al., 2007; Shah et al., 2014a). Simultaneously, numerous additional pathophysiologic abnormalities have been described in HFpEF, including impaired systolic function despite preserved LVEF (Kraigher-Krainer et al., 2014; Shah et al., 2015), increased ventricular dyssynchrony (Yu et al., 2007; Santos et al., 2014a; Biering-Sorensen et al., 2017), impaired left atrial function (Kurt et al., 2009; Santos et al., 2014b, 2016), pulmonary hypertension (Lam et al., 2009), increased arterial stiffness (Kawaguchi et al., 2003), and impaired peripheral oxygen extraction (Haykowsky et al., 2011). These abnormalities likely underpin the contributions of clinical comorbidities beyond hypertension—including coronary artery disease, atrial fibrillation, and pulmonary dysfunction. Early studies of HFpEF often selected patients based on prior HF hospitalization and/or the presence of concentric structural remodeling which, together with limited sample size, may have limited the cardiac phenotype observed (Kitzman et al., 2002; Melenovsky et al., 2007; Zile et al., 2001).

The least biased phenotypic descriptions of HFpEF originate from community-based epidemiologic cohort studies. However, these studies tend to be limited by relatively small numbers of incident HFpEF cases. Across five epidemiologic studies, mean LV size tended to be normal, with variable degrees of LV wall thickening (Lam et al., 2007; Maurer et al., 2007; Devereux et al., 2000; He et al., 2009; Gupta et al., 2013). Ventricular geometry was only characterized in two (Lam et al., 2007; Gupta et al., 2013). One of the largest and most comprehensive epidemiologic evaluations was in the Olmsted County cohort (Lam et al., 2007), which characterized 244 HFpEF cases. Ventricular hypertrophy was present in only 42% and eccentric in pattern in 16%. LV geometry was normal in 31%. The CHS, an older study of HFpEF cases of similar age and gender, demonstrated similar average LV mass index but somewhat larger ventricles with a lesser degree of concentric remodeling (Maurer et al., 2007).

Hospital-based HFpEF registries facilitate the assessment of larger numbers of HFpEF cases (Klapholz et al., 2004; Tribouilloy et al., 2008; Katz et al., 2013), although referral bias is an important consideration, as frequently only patients admitted with acute decompensation are enrolled. However, these registries obviate many of the inclusion biases inherent in clinical trial populations, particularly with regard to inclusion of patients with advanced comorbidities—such as chronic kidney disease—who are often excluded from therapeutic trials for safety reasons. Unfortunately, uniform implementation, analysis, and reporting of cardiac structure and function have been limited in most large HF registries. Perhaps the most comprehensive assessment of ventricular remodeling in a registry setting to date is The Northwestern HFpEF Registry, which demonstrated greater concentric remodeling and higher prevalence of LV hypertrophy (60%) than many epidemiologic studies (Katz et al., 2013). Interestingly, similar to the Olmsted County cohort (Lam et al., 2007), 12% of patients in this registry demonstrated an eccentric pattern of ventricular hypertrophy. This registry is also one of the few to report on left atrial remodeling and noted a high prevalence of left atrial enlargement with a mean LA volume index of 33.6 mL/m^2 (abnormal >34 mL/m^2).

Much of the data on cardiac structure and function in HFpEF originate from imaging substudies of HFpEF clinical trials, which allow for the accrual of large numbers of cases, robust clinical phenotyping, and prospective assessments. Given the inclusion and exclusion criteria necessarily imposed by such trials, these studies are clearly not reflective of HFpEF epidemiology, and identify specific subsets of patients within the HFpEF syndrome. Across seven major phase 2 and 3 HFpEF clinical trial imaging studies (Cleland et al., 2006; Zile et al., 2011; Solomon et al., 2012; Persson et al., 2007; Shah et al., 2014a; Edelmann et al., 2013; Redfield et al., 2013), mean LV size tended to be normal but with appreciable within trial and between trial variability. Similar variability was noted in LV wall thickness and the prevalence of both increased concentricity (wall thickness relative to chamber diameter) and LV hypertrophy, with values ranging from 14% to 49% and 21% to 59% respectively. For example, in the two largest and most comprehensive studies to date, the echocardiographic substudies of the I-PRESERVE and TOPCAT trials (Zile et al., 2011; Shah et al., 2014a), concentric hypertrophy was present in 29% and 43% of subject respectively, while normal LV geometry was present in 46% and 14% respectively. These observations highlight the marked heterogeneity of ventricular morphology found within this syndrome.

The prognostic relevance of greater LV mass in HFpEF, independent of conventional clinical risk factors, has been well documented in several studies (Zile et al., 2011; Shah et al., 2014b; Burke et al., 2014). Although concentric LVH has classically

characterized HFpEF, no significant differences in event rates have been noted between HFpEF patients with concentric compared to eccentric hypertrophy (Katz et al., 2013; Shah et al., 2014b). In contrast to HFrEF, neither LVEF nor LV size have demonstrated prognostic importance in HFpEF, possibly due to the restricted distribution of values in this syndrome. Importantly, measures of LV diastolic function also provide independent prognostic value in HFpEF (Shah et al., 2014b). These include left atrial enlargement, likely a marker of LV diastolic dysfunction and chronically elevated filling pressure (Zile et al., 2011; Shah et al., 2014b), and E/e′, an index of instantaneous LV filling pressure (Shah et al., 2014b).

Although attention has largely focused on alterations in LV structure and diastolic performance, HFpEF is also characterized by abnormal systolic function, detectable by strain (Kraigher-Krainer et al., 2014; Yip et al., 2011; Tan et al., 2009), but also by M-mode echocardiography (Petrie et al., 2002; Yip et al., 2002) tissue Doppler imaging (Yu et al., 2002; Cioffi et al., 2012; Vinereanu et al., 2005). In the echocardiographic study of the TOPCAT trial in HFpEF, strain was impaired in 52% of participants, was the strongest echocardiographic predictor of cardiovascular death or HF hospitalization, and provided incremental value beyond clinical risk factors, LVEF, and measures of LV structure and diastolic function (Shah et al., 2015).

Conclusions

LV remodeling refers to changes in LV structure in response to physiologic and pathologic hemodynamic stress. Patterns of LV remodeling vary depending on the nature of the insult, but are closely linked to alterations in LV systolic and diastolic performance that underlie the HF syndrome. HFrEF is characterized by ventricular enlargement and spherical remodeling. The cardiac phenotype in HFpEF, while classically associated with LV concentric hypertrophy, is diverse and likely mirrors the clinical and pathophysiologic heterogeneity of this syndrome. Detailed quantification of LV structure and function offers a promising foundation for identifying pathophysiologically relevant subgroups within the HFpEF syndrome.

Introduction

Ventricular tachycardia (VT) is a common tachydysrhythmia. Although the spectrum of its consequences ranges from none to sudden cardiac death, the possibility of the latter demands the practitioner's attention. VT most commonly occurs in patients with significant structural heart disease but can also occur in patients with no detectable structural heart disease, then referred to as idiopathic VT (Kusumoto, 2008). This article will focus on VT that occurs in patients with structural heart disease; specifically, in patients with ischemic cardiomyopathy or nonischemic dilated cardiomyopathy.

Definitions and Classifications

VT is defined as a wide QRS complex (>120 msec) rhythm with a rate exceeding 100 beats per minute. Sustained VT is that which lasts for more than 30 s or that which requires early intervention due to hemodynamic instability (Kusumoto, 2008). Nonsustained VT is sometimes defined as that which lasts for five or more beats at a rate exceeding 100 beats per minute but does not otherwise meet criteria as being sustained. When this definition of nonsustained VT is used, three consecutive QRS complexes of ventricular origin are referred to as a ventricular triplet and four consecutive QRS complexes of ventricular origin are referred to as a ventricular salvo. Others simply define nonsustained VT as that which lasts for three or more beats at a rate exceeding 100 beats per minute but does not otherwise meet criteria as being sustained.

Monomorphic VT presents wide QRS complexes that have a single QRS morphology and usually a stable rate and QRS axis. Polymorphic VT presents wide QRS complexes that have varying QRS morphologies, coupling intervals, and axis (Zipes et al., 2006). Some distinguish monomorphic VT and polymorphic VT from pleomorphic VT that presents wide QRS complexes of two or more morphologies each present for a period of time, including two morphologies that are alternating (bidirectional VT). VTs may also be classification according to the patient's clinical presentation as hemodynamically stable VT (that with minimal symptoms such as palpitations) or as hemodynamically unstable VT (that with symptoms and/or signs of systemic hypotension, pulmonary venous hypertension, myocardial ischemia, cerebral hypoperfusion, or cardiac arrest/death). Three or more episodes of sustained VT within a 24-h period defines a VT storm (Kusumoto, 2008; Israel and Barold, 2007). Approximately 10% of patients who receive an implantable cardioverter defibrillator will experience a VT storm within two years (Raymond et al., 2009). Sustained VT is distinguished from two other sustained ventricular tachydysrhythmias (**Table 1**). Ventricular flutter presents wide QRS complexes without intervening isoelectric periods (like a sine wave) usually at a rate of approximately 300 beats per minute suggesting that the mechanism of the ventricular tachydysrhythmia is macro reentry following a stable reentrant route. Ventricular fibrillation presents wide QRS complexes that are ultrarapid (>300 beats per minute) in the form of baseline undulations varying in morphology and timing.

Table 1 Classification of Ventricular tachycardia

Classification by electrocardiography			
Nonsustained VT		Three or more beats in duration, terminating spontaneously in less than 30 s VT is a cardiac arrhythmia of three or more consecutive complexes in duration emanating from the ventricles at a rate of greater than 100 bpm (cycle length less than 600 ms)	(7)
	Monomorphic	Nonsustained VT with a single QRS morphology	(7)
	Polymorphic	Nonsustained VT with a changing QRS morphology at cycle length between 600 and 180 ms	(7)
Sustained VT		VT greater than 30 s in duration and/or requiring termination due to hemodynamic compromise in less than 30 s	(7)
	Monomorphic	Sustained VT with a stable single QRS morphology	(7)
	Polymorphic	Sustained VT with a changing or multiform QRS morphology at cycle length between 600 and 180 ms	(7)
Bundle-branch re-entrant tachycardia		VT due to reentry involving the His-Purkinje system, usually with LBBB morphology; this usually occurs in the setting of cardiomyopathy	(7)
Bidirectional VT		VT with a beat-to-beat alternans in the QRS frontal plane axis, often associated with digitalis toxicity	(7)
Torsades de pointes		Characterized by VT associated with a long QT or QTc, and electrocardiographically characterized by twisting of the peaks of the QRS complexes around the isoelectric line during the arrhythmia: ● "Typical," initiated following "short-long-short" coupling intervals. ● Short coupled variant initiated by normal-short coupling	(7)
Ventricular flutter		A regular (cycle length variability 30 ms or less) ventricular arrhythmia approximately 300 bpm (cycle length—200 ms) with a monomorphic appearance; no isoelectric interval between successive QRS complexes	(7)
Ventricular fibrillation		Rapid, usually more than 300 bpm/200 ms (cycle length 180 ms or less), grossly irregular ventricular rhythm with marked variability in QRS cycle length, morphology, and amplitude	(7)

From Zipes et al. (2006).

Mechanisms and Substrates

The characteristics of sustained monomorphic VT indicate that the mechanism of monomorphic VT is either reentry with a stable conduction pathway and exit site or automaticity with a stable origin and subsequent conduction route. The former is most common in patients with structural heart disease that includes a ventricular scar while the latter is most common in patients with idiopathic VT in the absence of identifiable structural heart disease (Roberts-Thomson et al., 2011). The ventricular scar forming the substrate for reentrant VT may be the result of ischemic heart disease, nonischemic dilated cardiomyopathy, prior cardiac surgery (often in the setting of corrected congenital heart disease), arrhythmogenic right ventricular cardiomyopathy, cardiac sarcoidosis, or hypertrophic cardiomyopathy (Roberts-Thomson et al., 2011). The substrate regions usually consist of dense fibrosis with some surviving myocardial bundles that help to create conducting channels (Roberts-Thomson et al., 2011). These conducting channels may have reduced cell-to-cell coupling resulting in slow conduction and may be adjacent to anatomical obstacles due to dense fibrosis (Roberts-Thomson et al., 2011). Accordingly, areas of slow conduction, areas of fixed conduction block due to fibrosis, and areas of functional conduction block due to anisotropy represent ideal physiological conditions for reentry initiated by premature beats or cycle length fluctuations (**Fig. 1**). This VT is monomorphic because ventricular activation outside the scar proceeds from a stable location, which is typically the exit of a group of surviving myocyte bundles, which form a channel for conduction through the scar. A single area of scar is often able to support multiple different circuits. Hence, multiple VTs may be induced with programmed stimulation in patients with structural heart disease (Roberts-Thomson et al., 2011).

Mechanisms for VT in Ischemic Cardiomyopathy

The link between ventricular scar and arrhythmia risk suggests that identification and characterization of scar with imaging may allow prediction of arrhythmia risk. In magnetic resonance images (MRI), scar is identified by delayed washout of gadolinium contrast (Nazarian et al., 2005; Kwong et al., 2006). In myocardial infarction survivors, the scar typically extends along a vascular territory supplied by the infarct-related artery (**Fig. 2**). The central zone of the scar is typically transmural with fewer surviving myocytes. The peripheral part of the scar, the "border zone," is typically more heterogeneous and has a mixture of fibrous tissue and surviving myocytes, and may play a more important role in permitting reentry. This has been confirmed by three-dimensional MRI-derived scar reconstruction (Piers et al., 2014), and the size of the border zone has been shown to be a marker for late mortality (Kwong et al., 2006). The burden of scar and its characteristics has also been shown to be related with the presence of both spontaneous and inducible ventricular tachycardia (Gouda et al., 2015; Schmidt et al., 2007). Computer simulations using MRI-derived scar mapping were recently shown to be feasible to predict the existence of VT circuits in animal models (Ng et al., 2012) and in humans (Arevalo et al., 2013). Furthermore, such maps could also predict optimal VT ablation targets within the scar (Ashikaga et al., 2013).

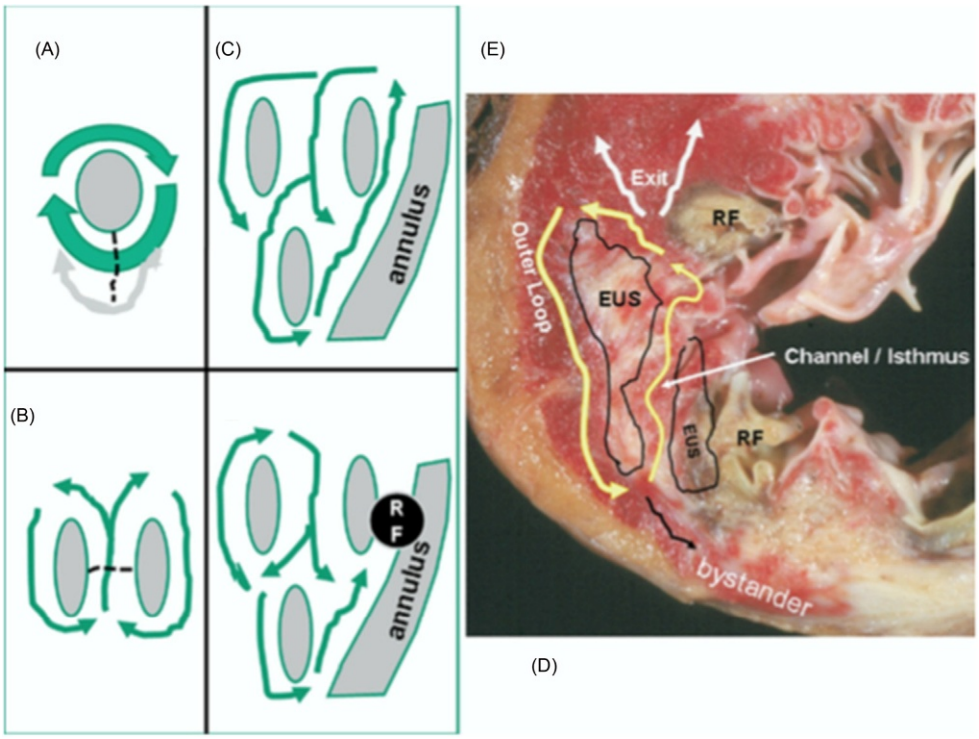

Fig. 1 Theoretical reentry circuits as they relate to areas of block and isthmuses are shown. In the schematics on the left the reentry circuit is indicated by the arrows. Gray regions indicate conduction block that might be from fibrosis, collision of wave fronts, or refractoriness. (A) A simple circuit consisting of a single loop around a region of block. If the loop is broad, ablation in the loop (dotted black line) may increase the reentry path but fail to interrupt reentry. (B) A figure-of-eight type of reentry circuit defined by wave fronts propagating around 2 regions of block and sharing a common isthmus and a common pathway (CP) through which conduction is slowed, creating a "figure-of-eight" configuration. Ablation across the common isthmus (dotted black line) would interrupt reentry. Ablation in either loop alone leaves the other loop to continue reentry. (C) A complex circuit with several regions of conduction block along a valve annulus that creates multiple potential channels. (D) Ablation (RF) that interrupts 1 channel and leaves the other potential channels that may support reentry. (E) Photograph of an explanted heart from a patient who had incessant VT and failed VT ablation with a theoretical reentry circuit (*yellow arrows*) is shown. Areas of dense scar, that may form electrically unexcitable scar (EUS), is indicated. A hypothetical channel/isthmus is present between two EUS areas. The circulating reentry wave front propagates through the channel, emerging at the exit to propagate across the ventricles producing the QRS complex. The circulating wave front propagates along the border of the scar (outer loop) to reenter the channel. A bystander area (*black arrow*) is also shown. RF lesions failed to interrupt VT, likely related to the location of the re-entry circuit deep to the endocardium. From Raymond, J. M., Sacher, F., Winslow, R., Tedrow, U. and Stevenson, W. G. (2009). Catheter ablation for scar-related ventricular tachycardias. *Current Problems in Cardiology* **34**, 225–270.

Mechanisms for VT in Nonischemic Cardiomyopathy

In patients with nonischemic cardiomyopathy (NICM), subendocardial scarring and patchy fibrosis may occur and may contribute to decreased cellular coupling and regional slow conduction, thus providing an anatomic substrate for reentrant VT. However, the extent and degree of fragmented and abnormal endocardial electrograms appear to be significantly less than in patients with ischemic cardiomyopathy (Hsia et al., 2003). In addition, the distribution of scar is more commonly basal, in anatomic relationship with the mitral annulus. In contrast, epicardial patchy fibrosis and abnormal conduction may be detected in 30%–50% of patients with NICM at the time of open heart surgery (de Bakker et al., 1996; Pogwizd et al., 1998) (**Fig. 2**). Several experimental and clinical reports indicate that focal nonreentrant mechanisms may be common in patients with NICM (Pogwizd et al., 1998; Delacretaz et al., 2000). In this population, myocardial macroreentrant circuits may account for only 50%–70% of VT, with focal mechanisms and bundle branch reentry comprising the remainder (Delacretaz et al., 2000). Most patients have multiple distinct QRS morphologies, often with different mechanisms. Given the different mechanisms, it is not surprising that programmed stimulation frequently fails to induce the VT observed clinically.

Bundle Branch Reentry as a Mechanism of VT

Bundle branch reentry VT is a VT that occurs most commonly in patients with nonischemic dilated cardiomyopathy. These patients usually have evidence of conduction system disease that provides the zone of slow conduction. The Purkinje network is integral to this macro reentrant VT (Roberts-Thomson et al., 2011). Most commonly, the right bundle branch is the antegrade limb and the left

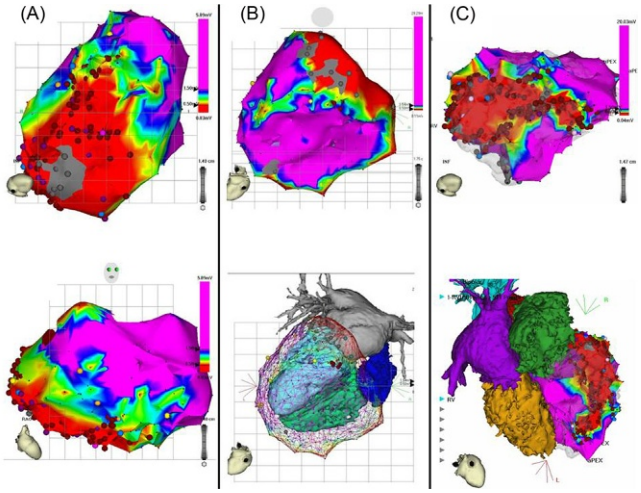

Fig. 2 Representative examples of scar distribution in various types of scar-related ventricular tachycardias. Contact bipolar voltage maps with reduced bipolar voltage (<1.5 mV), representing scar areas are shown in with the provided color scale. Purple areas represent relatively normal bipolar voltage corresponding with normal myocardium. Panel A shows an LV scar extending along the basal and mid inferior wall in a patient with a prior inferior myocardial infarction. Inferior (*top*) and right anterior oblique (*bottom*) views are shown. Panel B shows an epicardial bipolar voltage map of the inferior wall of both LV and RV in a patient with nonischemic dilated cardiomyopathy. The scar location is anatomically related to the basal LV along the inferior mitral annulus (*top*). Integration of the CT-scan image of the cardiac chambers is shown (*bottom*). LV endocardial bipolar voltage map was completely normal in this patient (not shown here). Panel C shows inferior views of the RV in a patient with arrhythmogenic right ventricular cardiomyopathy (ARVC). Notice the scar zone extending along the inferior and lateral RV walls from the tricuspid annulus to the apex (*top*). CT-image integration shows the relatively dilated RV compared to the LV in this patient (*bottom*).

bundle branch is the retrograde limb resulting in a left bundle branch block morphology VT (Roberts-Thomson et al., 2011). Bundle branch reentrant VT can be treated with transcatheter ablation of the right bundle branch; hence recognition of this mechanism is important for treatment.

Mechanisms for Polymorphic VT

The characteristics of polymorphic VT indicate that the mechanism of polymorphic VT is either reentry with varying conduction pathways and/or varying exit sites or abnormal automaticity with varying origins and/or varying subsequent conduction routes. The polymorphic VTs are considered in two groups. Polymorphic VTs without QT-interval prolongation most commonly occur during unstable cardiac disorders such as acute myocardial ischemia or infarction or decompensated congestive heart failure, especially when accompanied by hypoxia, acidosis, or electrolyte disturbances (Zipes et al., 2006). The mechanisms of polymorphic VTs without QT-interval prolongation include spatial and temporal disparities in myocyte excitability, refractory periods, and conduction velocities favoring standard forms of reentry; dispersion of action potential durations allowing phase 2 re-entry; abnormal automaticity; and, altered intracellular calcium handling (Zipes et al., 2006). Polymorphic VTs with QT interval prolongation occur in patients with the congenital QT-interval prolongation syndromes or in patients with acquired QT-interval prolongation (Goldenberg et al., 2008; Zipes et al., 2006; Kuriachan et al., 2015). Although the latter are more common in patients with structural heart disease, they often require hypokalemia, hypomagnesemia, and/or use of QT-interval prolonging drugs. Their mechanisms include prolongation of action potential duration (especially in ventricular M cells), spatial and temporal dispersion of ventricular repolarization, early afterdepolarizations, reactivation or delayed inactivation of L-type calcium channels, and altered intracellular calcium handling (Goldenberg et al., 2008).

Epidemiology

The most common cause of sustained monomorphic VT is that resulting from prior myocardial infarction (Raymond et al., 2009). Other causes of scar-related VT include nonischemic dilated cardiomyopathy, hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, cardiac sarcoidosis, and prior surgical interventions (Raymond et al., 2009). Such VT may be hemodynamically stable, may be hemodynamically unstable, or may degenerate into ventricular fibrillation (VF) or into asystole resulting in sudden cardiac death. Postinfarction ventricular tachydysrhythmias have been better studied than ventricular tachydysrhythmias due to other forms of structural heart disease.

Sudden deaths account for approximately 350,000 deaths per year in the United States (Zipes et al., 2006). When sudden death is defined as that within one hour of onset of symptoms, as many as 13% of all natural deaths may be sudden cardiac death (Zipes et al., 2006). The overall incidence of SCD in the United States is 0.1%–0.2% per year (Zipes et al., 2006). When a patient experiences VT within the first 24–48 h after a transmural myocardial infarction (MI), the subsequent risk of death or VT recurrence

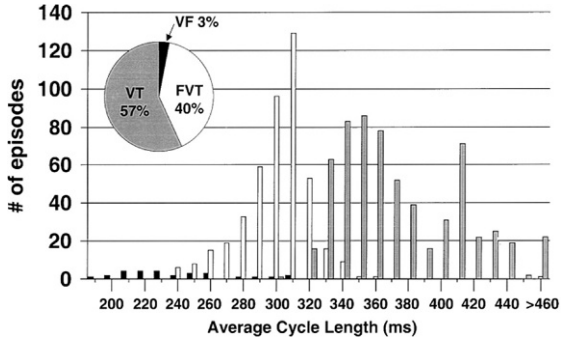

Fig. 3 Distribution of ventricular arrhythmias by detection zone and average cycle length (CL) (derived from last 4 CLs before detection, allowing for irregular or undersensed fast VT rhythms to have CL 320 ms.). Ventricular tachycardia is the predominant dysrhythmia with only 3% ventricular fibrillation. From Wathen, M. S., Sweeney, M. O., Degroot, P. J., Stark, A. J., Koehler, J. L., Chisner, M. B., Machado, C., Adkisson, W. O. and Pain, F. I. (2001). Shock reduction using antitachycardia pacing for spontaneous rapid ventricular tachycardia in patients with coronary artery disease. *Circulation***104**, 796–801.

is not significantly higher than that of a patient with an equivalent MI without early VT (Zipes et al., 2006). The risk of sudden death in the first 30 days after an MI is highest in patients with left ventricular dysfunction and/or heart failure and is in the range of 1.4% (Solomon et al., 2005).

In patients with ischemic cardiomyopathy and in patients with nonischemic dilated cardiomyopathy the probability of experiencing VT is primarily dependent upon the extent of ventricular scar (Zipes et al., 2006) and the degree of the resultant reduction in left ventricular ejection fraction (LVEF). In patients with ischemic cardiomyopathy who received an ICD for standard indications, VT was found to be the initial ventricular tachydysrhythmia much more frequently than was VF (**Fig. 3**) (Wathen et al., 2001). Such observations have led to the hypothesis that, in patients with structural heart disease, VT may lead to sudden death by deteriorating into VF or asystole. However, the details of the relationship between VT and sudden death are not clear and there are many examples of treatments that affect the former without altering the latter.

Clinical Presentation

The presentations of patients with VT range from no symptoms to sudden cardiac death. Patients between these two extremes may present with any cardiac symptom including palpitations, diaphoresis, dyspnea, angina pectoris, presyncope, and syncope. Although patients may initially seem to be hemodynamically stable, careful examination and investigation may reveal otherwise immediately or after a short period of time. For example, significant deterioration in renal function and myocardial necrosis may occur without associated symptoms due to low cardiac output. In general, faster ventricular rates and underlying ventricular systolic or diastolic dysfunction lead to more hemodynamic instability. On the other hand, patients can present in VT with no hemodynamic compromise and with minimal or no symptoms (Morady et al., 1985). When a patient presents with a wide QRS complex tachycardia, regardless of the associated symptoms, a history of known structural heart disease should raise suspicions that the rhythm is VT. Indeed, a history of structural heart disease or symptoms thereof have a positive predictive value of over 95% for a wide QRS complex tachycardia being VT (Roberts-Thomson et al., 2011). Furthermore, in patients approaching the age group of structural heart disease (over age 35 years) who present with a wide QRS complex tachycardia, the positive predictive value of age alone for a diagnosis of VT is 85% (Roberts-Thomson et al., 2011). Accordingly, prior cardiac history and patient age are important features to consider in evaluating the differential diagnosis of a wide QRS complex tachycardia.

Patients who have already received an ICD may also present with symptoms related to antitachycardia pacing or shocks from the device. Of course, if such a patient has VT with a rate below that set for ICD detection, a common scenario in patients after antiarrhythmic drug or ablation therapy, the spectrum of presentations with VT will be similar to that of the patient without an ICD.

On examination, a patient with VT will, by definition, have a heart rate over 100 bpm. The physical examination should focus on assessment of the degree of hemodynamic stability and on the presence of underlying structural heart disease. Relative to the determination that the underlying rhythm is VT, signs of AV dissociation, such as a jugular venous canon A waves and variable intensity of first heart sound, support the diagnosis of VT (Garratt et al., 1994).

ECG Features

The electrocardiogram (ECG) is the key tool in the diagnosis of VT. A wide QRS complex (>120 msec) tachycardia at a rate greater than 100 beats per minute should be considered to be VT unless proven otherwise. This admonition reflects the fact that therapy for supraventricular tachycardia may worsen the state of a patient with VT whereas the converse is unlikely.

Recalling that a narrow QRS complex is the result of simultaneous activation of the two ventricles, wide QRS complex rhythms result from sequential activation of the two ventricles—one ventricle being activated early (a ventricular rhythm or a supraventricular rhythm with ventricular preexcitation) or one ventricle being activated late (a paced ventricular rhythm or a supraventricular rhythm with aberrant AV conduction (right bundle branch block, left bundle branch block, or an intraventricular conduction defect)).

Atrioventricular (AV) dissociation is the only ECG feature that is diagnostic for VT (Wellens, 2001). On an ECG recording VA dissociation is manifest as evident P-waves at a rate that is unrelated to the QRS rate and that is generally slower than the QRS rate. Such P-waves may intermittently conduct to the ventricles resulting in a "capture beat" that has the same QRS morphology as that patient's normal rhythm or a "fusion beat" that has a QRS complex morphology representing the sum of that patient's normal QRS morphology and the QRS morphology of the VT (Wellens, 2001) (**Fig. 4**). Unfortunately, AV dissociation during VT is uncommonly seen on the ECG recording because slower VTs may conduct retrogradely to the atrium, preserving a 1:1 relationship between atrial and ventricular activation, and faster VTs obscure the pattern of background P-waves, precluding recognition of AV dissociation (Roberts-Thomson et al., 2011).

Other ECG findings are not diagnostic but may contribute to the differential diagnosis of a wide QRS complex tachycardia. In general, if the ECG QRS complex pattern is that of typical right or left bundle branch block then a supraventricular tachydysrhythmia with aberrant AV conduction is favored. The less the QRS complex is typical of right or left bundle branch block, the more likely it is a VT. VT is likely if a wide QRS complex tachycardia presents QRS complexes with a right superior axis, precordial concordance (implying early basal or apical activation), and a very wide QRS (left bundle branch block like pattern with a QRS duration >160 ms or a right bundle branch block like pattern with a QRS duration >140 ms) (Roberts-Thomson et al., 2011).

Comparison of the relative time courses of ventricular activation at the beginning of the QRS complex and at the end of the QRS complex may be helpful in the differential diagnosis of a wide QRS complex tachycardia. When ventricular activation involves the Purkinje system, voltage changes are rapid. When ventricular activation depends upon ventricular myocyte conduction, voltage changes are slower. Accordingly, a slurry initial QRS complex associated with a sharp terminal QRS complex suggests VT or ventricular preexcitation while the reverse suggests a supraventricular tachycardia conducted with aberrancy.

These ECG features have been incorporated into formal algorithms designed to assist the differential diagnosis. A four-step algorithm developed by Brugada was reported to have a sensitivity of 98.7% and specificity of 96.5% for the diagnosis of VT (**Fig. 5**) (Brugada et al., 1991). The initial step was to assess the absence of RS complexes in all the precordial leads, a finding that suggests VT. When there was a precordial lead with an RS morphology, an onset of R to a nadir of S interval greater than 100 msec suggests VT provided that the patient was not receiving an antiarrhythmic drug that slows intraventricular conduction. The third step identified AV dissociation. The final step examined morphology criteria in ECG leads V1 and V6 that basically assessed whether the morphology in these leads deviated from a typical left or right bundle branch block pattern as this would also suggest VT. Another algorithm, derived from a patient population that included preexcited supraventricular tachycardias, suggested by Vereckei et al., examined ECG lead aVR for the presence of an initial R wave (Vereckei et al., 2008). This stepwise algorithm suggests that the presence of an initial dominant R wave, the presence of a nondominant r or q wave lasting more than 40 ms, the presence of a notch on the descending limb of a negative onset and predominantly negative QRS, and a ventricular activation velocity ratio, v_i/v_t (v_i is the vertical excursion during the initial part of the QRS and v_t is during the terminal part of the QRS) all suggest VT (Vereckei et al., 2008) (**Fig. 6**).

A VT that emerges from the interventricular septum usually presents QRS complexes that are less wide than those of VT arising from other regions. In patients that already have an underlying wide QRS complex during supraventricular rhythm, a less wide QRS complex during tachycardia should raise suspicion that the tachycardia is VT because a supraventricular tachycardia would have no mechanism to produce a QRS complex less wide than a slower supraventricular rhythm (Wellens, 2001).

The 12-lead ECG may be used to localize the site of origin of VT, useful information for the diagnosis of idiopathic VT (the most common site of origin of which is the right ventricular outflow tract), or when VT ablation is planned. Here the site of origin refers to the site of abnormal automaticity in the case of an automatic VT or the site of exit from the zone of slow conduction in the case of a

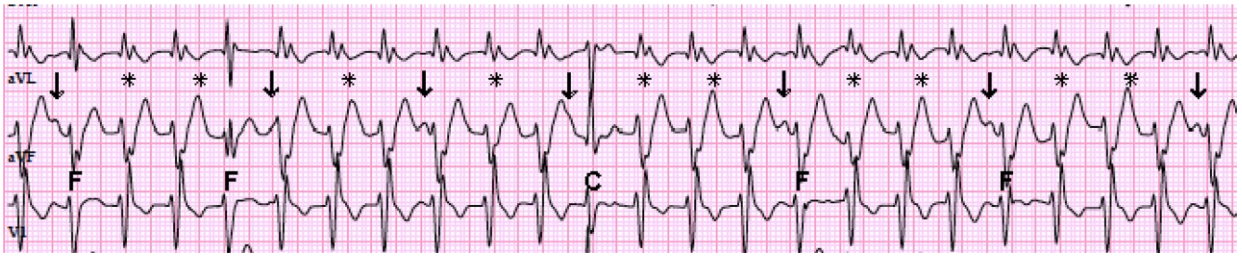

Fig. 4 Simultaneously recorded ECG leads aVL, aVF, and V1 during a regular wide QRS complex tachycardia with left bundle branch block like and superior axis morphology and a ventricular rate of 143 beats per minute with AV dissociation, fusion beats, and a capture beat. P-waves are best seen in lead aVF. The arrows denote evident P-waves including one distorting the onset of the QRS complex (*second arrow*) and one distorting the downslope of the T-wave (*forth arrow*). The asterisks indicate where other P-waves must be although they are obscured by the background rhythm. The atrial rate is 103 beats per minute. C denotes a narrow QRS complex capture beat with normal QRS morphologies in each lead. F denotes three fusion beats with morphologies that are variably intermediate between that of the underlying rhythm and that of the capture beat. The third fusion beat is the least fused with morphology change evident only in V1.

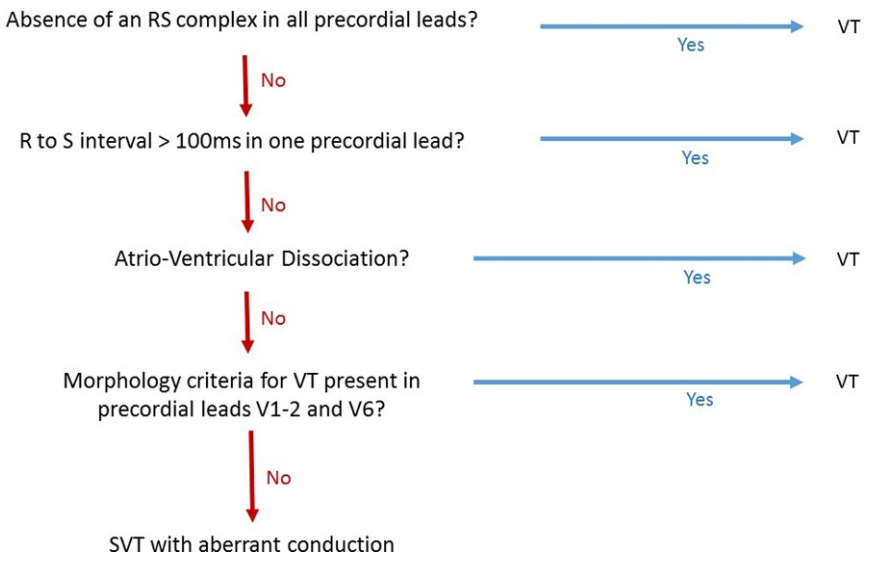

Fig. 5 Algorithm from Brugada et al. for diagnosis of a tachycardia with a widened QRS complex. When an RS complex cannot be identified in any precordial lead, the diagnosis of ventricular tachycardia (VT) is made. If an RS complex is present in one or more precordial leads, the longest RS interval is measured. If the RS interval is longer than 100 msec, the diagnosis of VT is made. If shorter than 100 msec, the next step of the algorithm is considered: whether atrioventricular dissociation is present. If present, the diagnosis of VT is made. If absent, the morphology criteria for VT are analyzed in leads $_{V,}$ and V6. If both leads fulfill the criteria for VT, the diagnosis of VT is made. If not, the diagnosis of supraventricular tachycardia (SVT) with aberrant conduction is made by exclusion of VT. From Brugada, P., Brugada, J., Mont, L., Smeets, J. and Andries, E. W. (1991). A new approach to the differential diagnosis of a regular tachycardia with a wide QRS complex. *Circulation* **83**, 1649–1659.

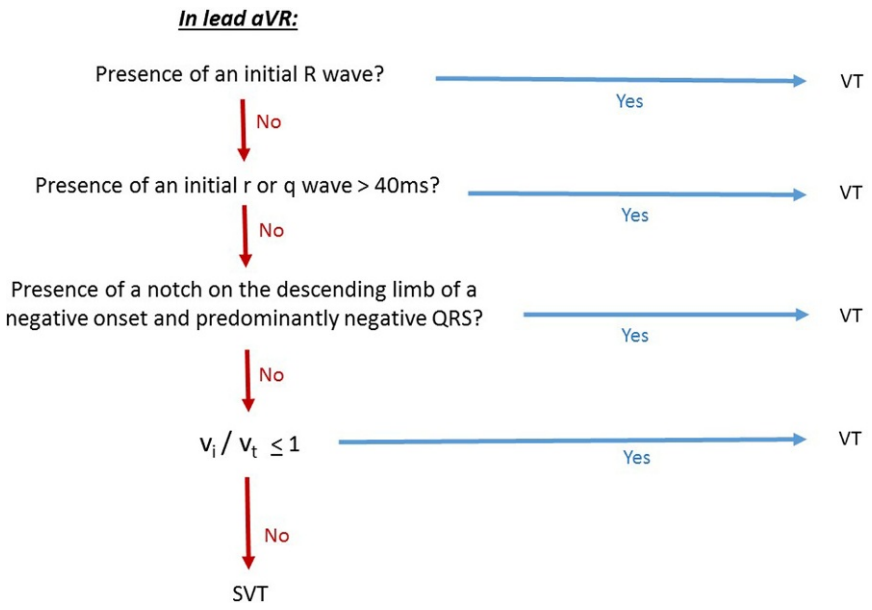

Fig. 6 Algorithm developed by Vereckei et al. for diagnosis of VT from a wide complex tachycardia using aVR. If an initial R wave is seen then VT is diagnosed. If not then presence of r or q wave >40 ms diagnoses VT. If not presence of a notch on the descending limb of a negative onset and predominantly negative QRS suggests VT. Otherwise $v_i/v_t < 1$ suggests VT. From Vereckei, A., Duray, G., Szenasi, G., Altemose, G.T., and Miller, J. M. (2008). New algorithm using only lead aVR for differential diagnosis of wide QRS complex tachycardia. *Heart Rhythm* **5**, 89–98.

reentrant VT. In patients without structural heart disease, using the ECG for localization is reasonably accurate. In patients with structural heart disease, the ECG morphology identifies the zone of epicardial breakthrough, which may be distant from the site of origin when intraventricular conduction is disturbed. VT that originates from the right ventricle or the anterior portion of the interventricular septum usually has a left bundle branch block like morphology in lead V1. VT originating from the left ventricle tends to have a right bundle branch block like morphology in lead V1. VT that presents QRS complexes that are negative in all of the precordial leads (negative concordance) is likely originating from near the apex; VT that presents QRS complexes that are positive in all of the precordial leads (positive concordance) is likely originating from the posterior portion of the left ventricle (Wellens, 2001).

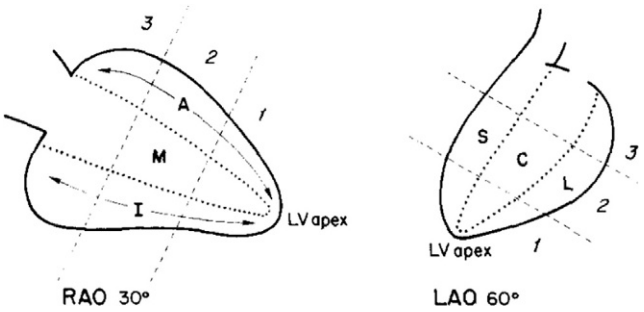

Fig. 7 Left ventricular endocardial mapping grid. The grid is divided into three sections in each of three planes, determined from two fixed fluoroscopic planes. *A*, anterior; *C*, central; *I*, inferior; *L*, lateral; *LAO*, left anterior oblique projection; *M*, middle; *RAO*, right anterior oblique projection; *S*, septal; *1,2,3*, three regions along the long axis of the left ventricle (LV): apical, mid-ventricular and basal. From Kuchar, D. L., Ruskin, J. N. and Garan, H. (1989). Electrocardiographic localization of the site of origin of ventricular tachycardia in patients with prior myocardial infarction. *Journal of the American College of Cardiology* **13**, 893–900.

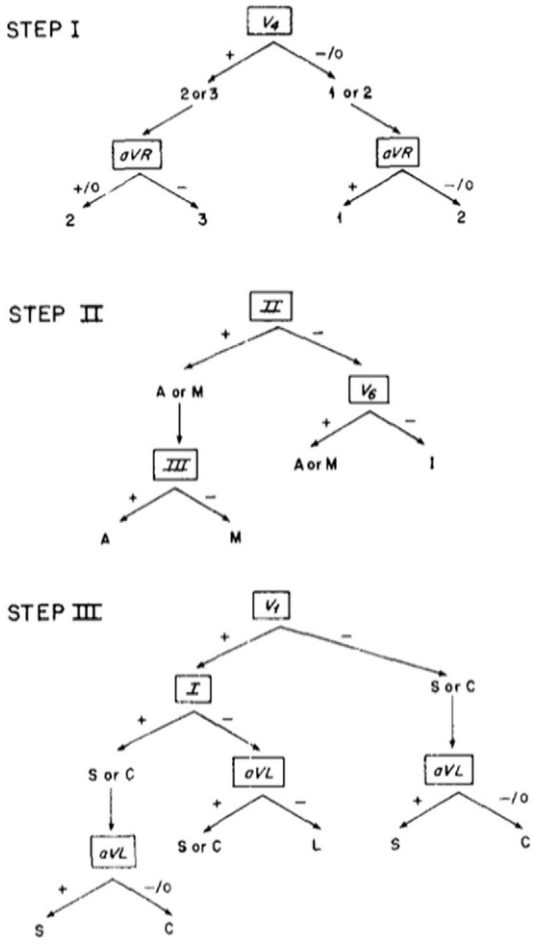

Fig. 8 Flow chart used for predicting site of origin of ventricular tachycardia: a three-step flowchart for predicting each of the three axis coordinates. To determine these sites, begin with the designated electrocardiographic lead and, depending on the QRS morphology in that lead, follow the arrows to the bottom of the diagram. The electrocardiographic leads are enclosed by boxes, whereas endocardial sites are indicated in bold type. Abbreviations as in **Fig. 6**. From From Kuchar, D. L., Ruskin, J. N. and Garan, H. (1989). Electrocardiographic localization of the site of origin of ventricular tachycardia in patients with prior myocardial infarction. *Journal of the American College of Cardiology* **13**, 893–900.

VT with an Inferior axis in the frontal plane suggests an origin in the right or left ventricular outflow tract; VT with a superior axis suggests an origin in the inferior wall.

Kuchar et al. developed an algorithm using the QRS morphology resulting from endocardial pacing (Kuchar et al., 1989) as shown in Figs. 7 and 8. When this algorithm was tested in patients with VT after remote MI the correct location of VT origin was predicted in 39% of patients and an adjacent location of VT origin was predicted in an additional 36% of patients.

An epicardial origin of VT is suggested by a pseudo delta wave (measured from earliest ventricular activation to earliest fast deflection in any precordial lead) with a duration greater than or equal to 34 ms, by an RS complex duration (measured from earliest ventricular activation to nadir of first S wave in any precordial lead) >121 ms, or by an intrinsicoid deflection time (earliest ventricular activation to peak of R wave in V2) greater than or equal to 85 ms (Berruezo et al., 2004). Not infrequently, an epicardial origin of VT is surmised after failed endocardial VT mapping and/or ablation.

Some patients, particularly those with advanced structural heart disease, will already have an ICD when their first VT occurs. In such patients, an ECG documenting the VT will be difficult to obtain and use of device recorded electrograms will be necessary to diagnose VT (Hook et al., 1993).

Investigations

When a patient has been diagnosed as having VT initial investigations are focused on identification of the etiology of and the magnitude of the patient's underlying structural heart disease. These investigations will be guided by the patient's demographics, family history, cardiac risk factors, history, and clinical examination. If no evidence of structural heart disease is found, the VT is likely an idiopathic VT or the result of an inherited channelopathy.

When structural heart disease is documented, it is usually the result of ischemic heart disease or a nonischemic congestive cardiomyopathy. Monomorphic VT in these settings usually originates from a preexisting ventricular myocardial scar. Polymorphic VTs in such patients usually indicate myocardial ischemia and/or decompensated congestive heart failure (Priori et al., 2015). Cardiac enzymes may be elevated in a patient with VT due to a prolonged episode of VT resulting in myocardial supply and demand mismatch, due to resuscitation, and/or due to defibrillator shocks. Accordingly, elevations of cardiac enzymes must be interpreted with caution in a patient presenting with VT.

Patients presenting with VT will usually start their investigations with laboratory investigations and with a transthoracic echocardiogram (Roberts-Thomson et al., 2011). Laboratory investigations include evaluations of electrolytes, renal function, blood counts, liver function, and thyroid function. Abnormalities in these tests are rarely the principle cause for monomorphic VT, but will inform subsequent treatment, particularly with antiarrhythmic drugs. Abnormalities on the transthoracic echocardiogram will prompt further testing which will usually take the form of cardiac catheterization and coronary angiography and cardiac magnetic resonance imaging for infiltrative disorders. If a nonischemic congestive cardiomyopathy is suspected, a workup for cause of such a cardiomyopathy is indicated. The details of this workup will depend on both patient and environmental characteristics and will consider Chagas disease in South America and cardiac sarcoidosis in the presence of coexisting conduction system disease. Arrhythmogenic right ventricular cardiomyopathy is considered when testing reveals no clear left ventricular structural heart disease especially when the VT had a left bundle branch block like morphology (Zipes et al., 2006). Signal-averaged electrocardiography and endomyocardial biopsy may also be necessary in selected patients (Roberts-Thomson et al., 2011).

Patients presenting with VT who already have received an ICD will likely have already had all the required testing performed. Nevertheless, such patients usually have laboratory tests and a transthoracic echocardiogram repeated to assess for contributing electrolyte or metabolic factors and to reassess their structural heart disease, particularly their left ventricular systolic function.

Conclusion

Ventricular tachycardia can portend a poor prognosis in patients with structural heart disease. The mechanism for VT in such patients is usually reentry. Symptoms such as palpitations or syncope should raise suspicion of VT and further investigation and monitoring may need to be performed. Developing technologies include smart phone apps, implantable loop recorders, other ambulatory monitoring devices that will facilitate the diagnosis of VT in patients with structural heart disease, and developments in imaging that may also aid in diagnosis and risk stratification.

Introduction

The clinical spectrum of ventricular tachycardia (VT) in structurally normal hearts, "idiopathic VT," ranges from isolated premature ventricular complexes (PVCs) to sustained VT, and in general portends a benign prognosis. The prognosis is unclear at initial presentation as the arrhythmias are indistinguishable from VT with structural heart disease (SHD) or a reversible cardiomyopathy may be present.

The pathophysiology, epidemiology, prognosis, and treatment of VT with SHD have been extensively characterized with well-developed guidelines for risk stratification and treatment that are generalizable to large populations. On the other hand, idiopathic VT has not been systematically assessed with large population-based studies due to low prevalence.

Elucidating the pathophysiology and developing treatment strategies is confounded by the fact that the definition of a structurally normal or abnormal heart is not rigorously defined. The connotation of this classification differs in among subspecialties of cardiovascular medicine. The absence of obvious ischemic or nonischemic cardiomyopathy implies a structurally normal heart but relies on conventional angiographic and echocardiographic assessment. However, this does not account for microvascular, ultrastructural (i.e., fibrosis or inflammation), molecular, or genetic abnormalities that have become increasingly recognized with advanced imaging techniques, biomarkers, and genetic testing.

 https://doi.org/10.1016/B978-0-12-809657-4.99777-1

The prevailing clinical gestalt suggests that idiopathic VT is benign; however, numerous epidemiologic studies over the previous 50 years have demonstrated that ambient ventricular ectopy is associated with heightened risk of cardiovascular morbidity and mortality and may represent subclinical disease not discernible with conventional assessment.

There are several recognized types of idiopathic VT that have been classified and categorized based on clinical presentation, site of origin, electrocardiographic pattern, response to medication testing, and mechanism. Pharmacologic and ablative treatment strategies targeting ventricular ectopy with or without SHD suggest clinical benefit and also suggests that ventricular ectopy is a modifiable risk factor for cardiovascular morbidity and mortality.

Epidemiology

In 1962 the incidence of PVCs or nonsustained ventricular tachycardia (NSVT) on screening electrocardiograms (ECGs) among apparently healthy United States Air Force flight personnel was estimated at 0.8% (Hiss and LAMB, 1962). Large population studies, such as the Framingham Heart Study (Bikkina et al., 1992) and Atherosclerosis Risk in Communities (Simpson et al., 2002) study, estimate that the prevalence of PVCs or complex ventricular ectopy ranges from 6% to 12% based on ECG. The definition of complex ventricular ectopy includes more than 30 PVCs per hour or multiform PVCs, ventricular couplets, VT, or R-on-T phenomenon (Bikkina et al., 1992). PVC prevalence increases with advancing age, male gender, African-American ethnicity, and hypertension (HTN); HTN is associated with a 23% increase in the prevalence of PVCs (Simpson et al., 2002).

Ambient ventricular ectopy was found in 50% of healthy medical students on 24-hour ambulatory monitoring but only 2% had greater than 50 PVCs (Brodsky et al., 1977). Multiple other studies with 24-h ambulatory monitoring between 1977 and 1982 demonstrated the prevalence of PVCs or complex ventricular ectopy ranging from 40% to 75% (Kennedy et al., 1985). Hingorani et al. recently demonstrated the incidence of PVCs and complex ventricular ectopy as 43% and 16%, respectively, on 24-hour ambulatory monitoring in healthy drug-free participants of phase I clinical trials (Hingorani et al., 2016).

Exercise-induced PVCs has been observed in 2%–27% of healthy patients undergoing exercise stress testing in an assessment of Parisian civil service employees and the Framingham Offspring Study (Jouven et al., 2000; Morshedi-Meibodi et al., 2004). Exercise-induced NSVT occurred in 4% of the Baltimore Longitudinal Study of Aging.

PVCs are commonly encountered in clinical practice; however, the incidence of idiopathic PVCs may be lower since these studies did not fully exclude the presence of SHD.

Prevalence Among Treated VT

Early case series of patients referred for management and treatment of VT estimated the prevalence of idiopathic VT in the range of 7%–38% (Hoffmayer and Gerstenfeld, 2013). More contemporary estimates suggest a prevalence of 10% in the United States (Lerman et al., 1997) and 20% in Japan (Okumura and Tsuchiya, 2002). This may underestimate the true prevalence as the generally benign prognosis of idiopathic VT may limit referral for electrophysiologic evaluation.

Gender Differences

There are well-recognized gender differences in the prevalence and presentation of arrhythmias owing to gender-related variation of ion channels (genetic or molecular), autonomic tone, and modulation of myocardial electrophysiologic properties with sex hormones. The anatomic distribution and presentation differs between men and women.

Idiopathic VT arising from the right ventricular outflow tract (RVOT) has a 1.5–2:1 female predominance, left ventricular outflow tract (LVOT) VT 1.4:1 male predominance, and fascicular VT 3:1 male predominance (Nakagawa et al., 2002; Tanaka et al., 2011).

Marchlinski et al. observed that cyclic and age-related hormonal variation due to menses, pregnancy, and menopause triggers VT from the RVOT (RVOT-VT) in women, whereas exercise or stress more commonly triggers RVOT-VT in men (Marchlinski et al., 2000). Ventricular arrhythmias triggered during pregnancy subside postpartum (M. Nakagawa et al., 2004). Ovulatory peak estradiol and hormone replacement therapy (HRT) both attenuate PVCs (DOGAN et al., 2016; Hu et al., 2011).

Age Distribution

Multiple population studies, as mentioned above, demonstrated that the prevalence of PVCs increase with age (Bikkina et al., 1992; 1993; Hiss and LAMB, 1962; Simpson et al., 2002) (**Fig. 1**).

RVOT-VT frequently occurs between the age of 30 and 50 (M. Nakagawa et al., 2002), whereas VT arising from the LVOT (LVOT-VT) increases with age and frequently occurs between the age of 50 and 70 (Tanaka et al., 2011) (**Fig. 2**). Fascicular VT frequently occurs between the age of 20 and 40 with male predominance; however, women present at an earlier age(M. Nakagawa et al., 2002; Tanaka et al., 2011).

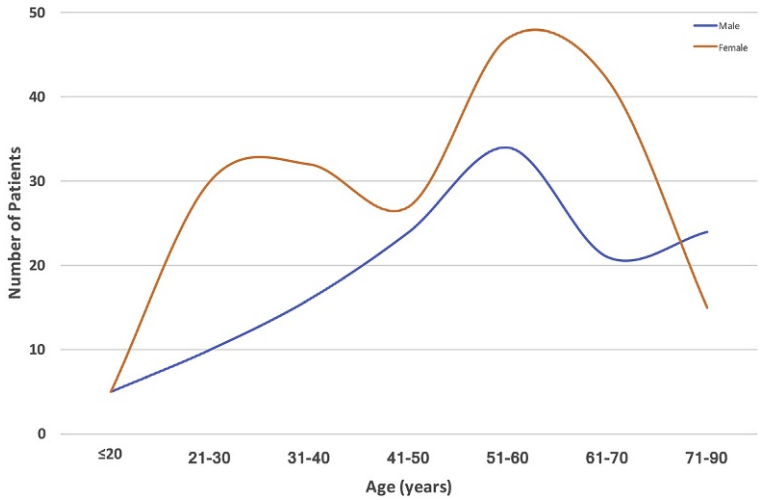

Fig. 1 Age distribution of outflow tract ventricular arrhythmias based on gender. Woman have bimodal age distribution with peaks at 20–30 and 50–60 years of age whereas for men the prevalence linearly increase with age (Tanaka et al., 2011).

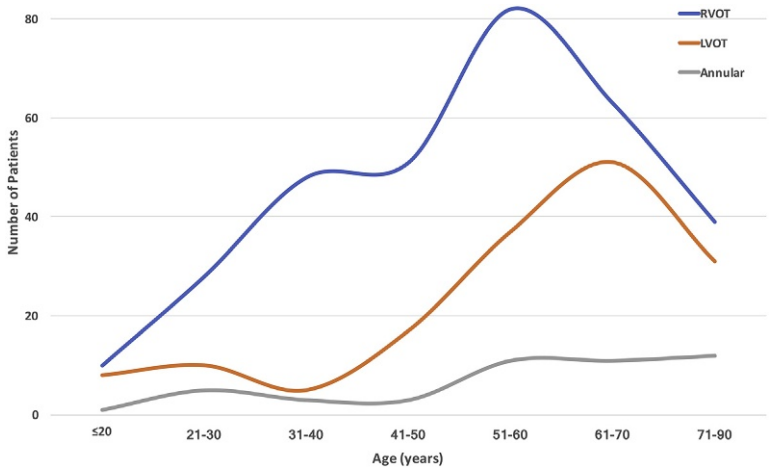

Fig. 2 Age distribution of the most common idiopathic ventricular arrhythmias. Right ventricular outflow tract (RVOT) ventricular arrhythmias are most common and present at an earlier age than either left ventricular outflow tract (LVOT) or annular ventricular arrhythmias (Tanaka et al., 2011).

Prognostic Implications

Initial studies attempted to define the prognostic significance of ventricular ectopy following myocardial infarction (MI) and determined that complex ventricular ectopy after MI increased mortality by a factor of 3 but antiarrhythmic drugs (AADs) worsened outcomes (Kotler et al., 1973; Ruberman et al., 1977).

Multiple population studies demonstrated that PVCs without evidence of cardiac disease similarly increased cardiovascular morbidity and mortality:

- Multiple Risk Factor Intervention Trial found that PVCs conferred a threefold increased risk of sudden cardiac death (SCD) with the effect more pronounced with complex ventricular ectopy (Abdalla et al., 1987).
- Framingham Heart Study found that complex ventricular ectopy without coronary artery disease (CAD) increased MI and mortality in men but not in women (Bikkina et al., 1992). In the same cohort, complex ventricular ectopy with underlying left ventricular hypertrophy (LVH) increased mortality (Bikkina et al., 1993).
- Cardiovascular Health Study found the highest quartile of PVC burden was associated with a 3-fold increase of LV dysfunction over 5 years, 48% increased risk of congestive heart failure (CHF), and 31% increased risk of death (Dukes et al., 2015) (**Fig. 3**).
- Lin et al. demonstrated that PVCs and NSVT conferred a higher risk of mortality and incident CHF while identifying both as independent risk factors for transient ischemic attack and atrial fibrillation (AF) (Lin et al., 2015, 2016).

Exercise-induced PVCs in the absence of SHD is associated with an increased risk of death (Jouven et al., 2000; Morshedi-Meibodi et al., 2004), however, exercise-induced NSVT does not independently increase mortality (Marine et al., 2013) (**Fig. 4**).

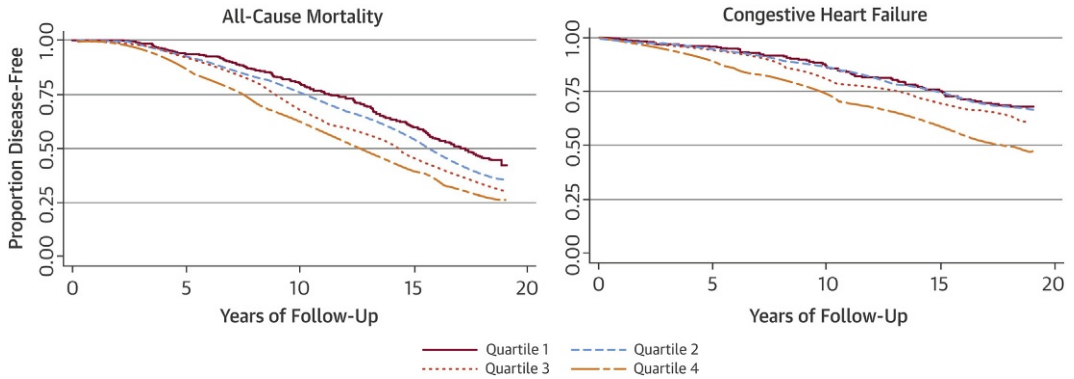

Fig. 3 The population-based risk of disease-free survival from all-cause mortality or incident congestive heart failure (CHF) associated with burden of premature ventricular complexes stratified by quartiles. Quartiles 1–4 represent PVC burden of 0–0.002%, 0.002–0.011%, 0.011–0.123%, and 0.123–17.7%. There is a gradient of risk for all-cause mortality across all four quartiles; however, the risk of CHF similar amongst quartiles 1–3 and lowest with quartile 4.

Clinical Presentation

Symptoms

The most frequent reported clinical symptoms in patients presenting for ablation are palpitations (80%), chest pain (26%), and syncope (24%) (Kim et al., 2007). Exercise- or stress-triggered palpitations are more frequent with sustained monomorphic VT (53%) when compared to NSVT (30%) or PVCs (18%). Other common symptoms include presyncope, dyspnea, fatigue, exercise intolerance, cough, or dysphagia (Laplante and Benzaquen, 2016).

A significant proportion are asymptomatic and diagnosed incidentally when an irregular or slow pulse is noted or an ECG is performed for other reasons.

Triggers

The most common triggers for idiopathic VT are exercise, emotional stress, and stimulants (Table 1). Other triggers include hormonal variation, as discussed above, medications, and metabolic abnormalities.

Circadian variation in autonomic tone results in peak sympathetic tone in the morning, which coincides with the observed early morning risk of VT and SCD. Idiopathic PVCs follow the same circadian pattern (Hayashi et al., 1999). These observations implicate sympathetic tone as a trigger or promoter of ventricular arrhythmias and provide mechanistic insight for the common triggers. A small proportion of patients are paradoxically observed to have PVCs intensify during periods of heightened vagal tone (rest or sleep) and attenuate with increase in sympathetic tone, which may portend a benign prognosis.

Arrhythmia Patterns

Idiopathic VT commonly manifests as frequent monomorphic or pleomorphic PVCs, salvos of NSVT also known as repetitive monomorphic VT (MMVT), and sustained VT (Fig. 5).

Kim et al. observed that sustained MMVT occurred in 28%, NSVT in 36%, and PVCs in 35% among patients with idiopathic VT presenting for ablation (Kim et al., 2007). Sustained VT was elicited during exercise testing in 67%, 10%, and 10% of patients presenting with sustained VT, NSVT, and PVCs, respectively. VT was induced during electrophysiologic testing in 78%, 48%, and 4% across the three groups.

Pheochromocytoma
Hypoxemia
Acidemia
Ischemia
Occult structural heart disease

Fig. 5 Idiopathic ventricular arrhythmias may clinically present as occasional isolated premature ventricular complexes, ventricular bigeminy (A), salvos of repetitive monomorphic ventricular tachycardia (B), and sustained ventricular tachycardia (C).

Anatomic Substrate

Idiopathic VT classically refers to outflow tract or fascicular VT; however, other common endocardial or epicardial sites of origin include the mitral or tricuspid annulus, aortomitral continuity (AMC), and papillary muscles (Table 2).

Understanding the complex anatomy of these sites and the adjacent structures prone to collateral damage is critically important to optimize efficacy and safety of ablation. Real-time integration of multimodality imaging including fluoroscopy, cardiac computed tomography (CCT), cardiac magnetic resonance (CMR) imaging, electroanatomic mapping, and ultrasound further facilitates understanding of the anatomic relationships and procedural outcomes.

RVOT-VT accounts for 50%–80% and LVOT-VT for 15%–25% of all idiopathic VTs (Callans et al., 1997; Kim et al., 2007; Tanaka et al., 2011). The posterior aspect of the RVOT is the most common site for RVOT-VT; LVOT-VT commonly arises from aortic root or coronary cusps (Yamada, 2016).

RVOT or infundibulum is a superiorly located conical structure, extending leftward from the tricuspid annulus to the pulmonic annulus, anteriorly overriding the LVOT (Fig. 6). The distal extent at the pulmonic annulus is superior, leftward, and orthogonal to

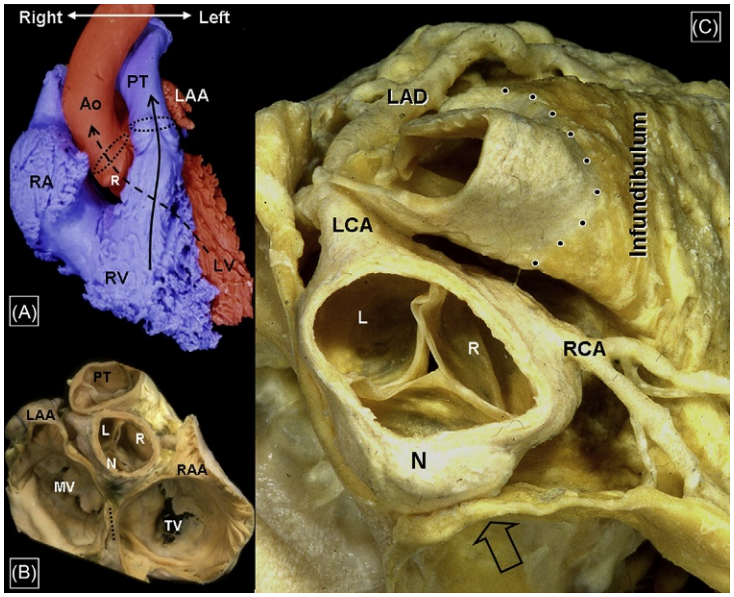

Fig. 6 Anatomic relationship of the right ventricular outflow tract (RVOT) to the left ventricular outflow tract (LVOT): (A) An endocardial cast of the right ventricle (RV) and left ventricle (LV) displayed in an anteroposterior projection. The dotted circles represent the annuli of the aortic and pulmonary valves. RVOT anteriorly overrides the LVOT from right to left. (B) The aortic valve is a central structure that is located anterior and superior to the mitral valve (MV) and tricuspid valve (TV) but posterior to the pulmonary trunk (PT). The dotted line represents the interatrial septum. The non-coronary cusp (N) is posterior and adjacent to the atria and the left (L) and right (R) coronary cusps. (C) The dotted line delineates the junction between the RV and the pulmonary artery; the pulmonic valve is orthogonal and superiorly located to the aortic valve. The septal and posterior RVOT are in proximity to the left main (LCA) coronary artery whereas the right coronary artery (RCA) is separated by more distance and epicardial fat. From Ho, S.Y., 2009. Anatomic insights for catheter ablation of ventricular tachycardia. *Heart Rhythm: The Official Journal of the Heart Rhythm Society* 6(8 Suppl), S77–80, with permission.

the aortic valve (Asirvatham, 2009; Lerman, 2015). The proximal and rightward extent at the level of the tricuspid annulus is adjacent to the His bundle and noncoronary cusp (NCC) of the aortic valve. RVOT is subdivided into septal (posterior and leftward) and free wall (anterior and rightward) segments with the posterior RVOT immediately anterior to the right (RCC) and left (LCC) coronary cusps of the aortic valve and in proximity to the left main coronary artery (LMCA) (**Fig. 7**). The anterior free wall is generally thinner and at increased risk of perforation than posterior or proximal segments. Myocardial sleeves extending up to and beyond the pulmonary artery or sinuses of Valsalva are implicated as the source of automaticity or triggered activity (Gami et al., 2011; Liu et al., 2014) (**Fig. 8**). RVOT and LVOT are intimately involved structures derived from a common embryologic outflow tract with slow conduction properties before incorporating into the embryologic RV and developing rapid conduction properties;

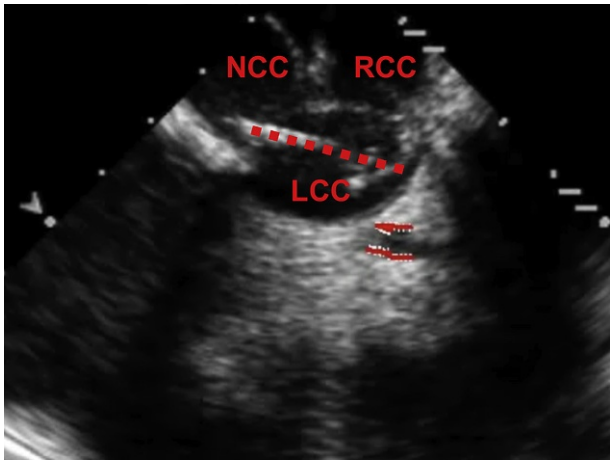

Fig. 7 Intracardiac echocardiography (ICE) of the sinus of Valsalva delineating the non-coronary cusp (NCC), right coronary cusp (RCC), and left coronary cusp (LCC). The two solid lines delineate the course of the left main coronary artery from the LCC and the dotted red line represents a mapping and ablation catheter positioned at the site of earliest ventricular activation in the left coronary cusp.

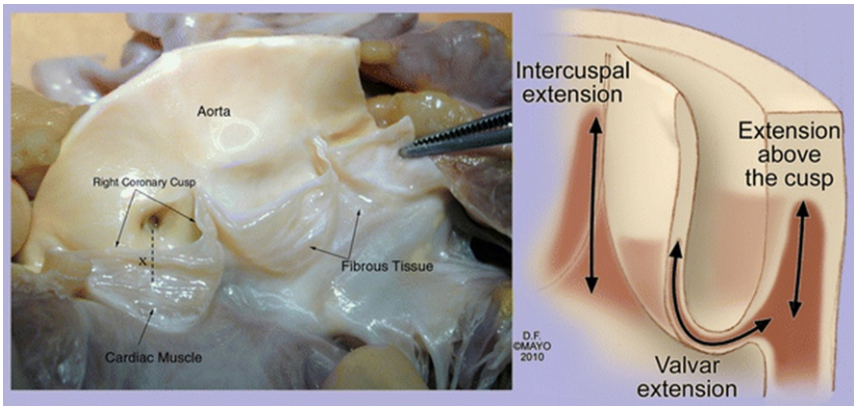

Fig. 8 A longitudinally dissected aortic annulus revealing the cusps of the aortic valve with visible myocardium extending to the right cusp. The adjacent illustration the extension of myocardial tissue above and into the cusps. From Gami, A.S. et al., 2011. persistent remnants of slow conducting tissue may represent the substrate for arrhythmia, the myocardial sleeves (Boukens et al., 2009).

Fascicular VT accounts for approximately 10%–15% and originates from the left-sided Purkinje network including the left posterior (~90%), left anterior, and septal fascicles. The left anterior fascicle traverses the anterior mitral annulus and arborizes to the anterolateral wall and anterolateral papillary muscle. The left posterior fascicle extends from the His bundle through the inferoseptum and arborizes to the inferolateral wall and posteromedial papillary muscle; a septal fascicle is present in approximately 65%.

VT arising from the mitral or tricuspid annulus accounts for approximately 10% of idiopathic VT (Tanaka et al., 2011). Mitral annular VT most commonly originates from the anterolateral followed by the posteromedial aspects (**Figs. 9** and **10**). PVCs may arise from the confluence of the subaortic apparatus and anteromedial aspect of the mitral annulus below the left and NCC, referred as the AMC (**Fig. 11**). Tricuspid annular VT more commonly originates from the anteroseptal region compared to the free wall (Yamada, 2016).

Idiopathic VT of epicardial origin typically arises from the crux or LV summit, basal structures in proximity to the coronary venous and arterial systems. The crux is the confluence of the atrioventricular and posterior interventricular grooves near the posterior descending artery and middle cardiac vein. The LV summit region is the triangular space delineated by the bifurcation of the LMCA and the great cardiac vein. A significant layer of epicardial fat and risk of coronary artery damage limits mapping and ablation in this region.

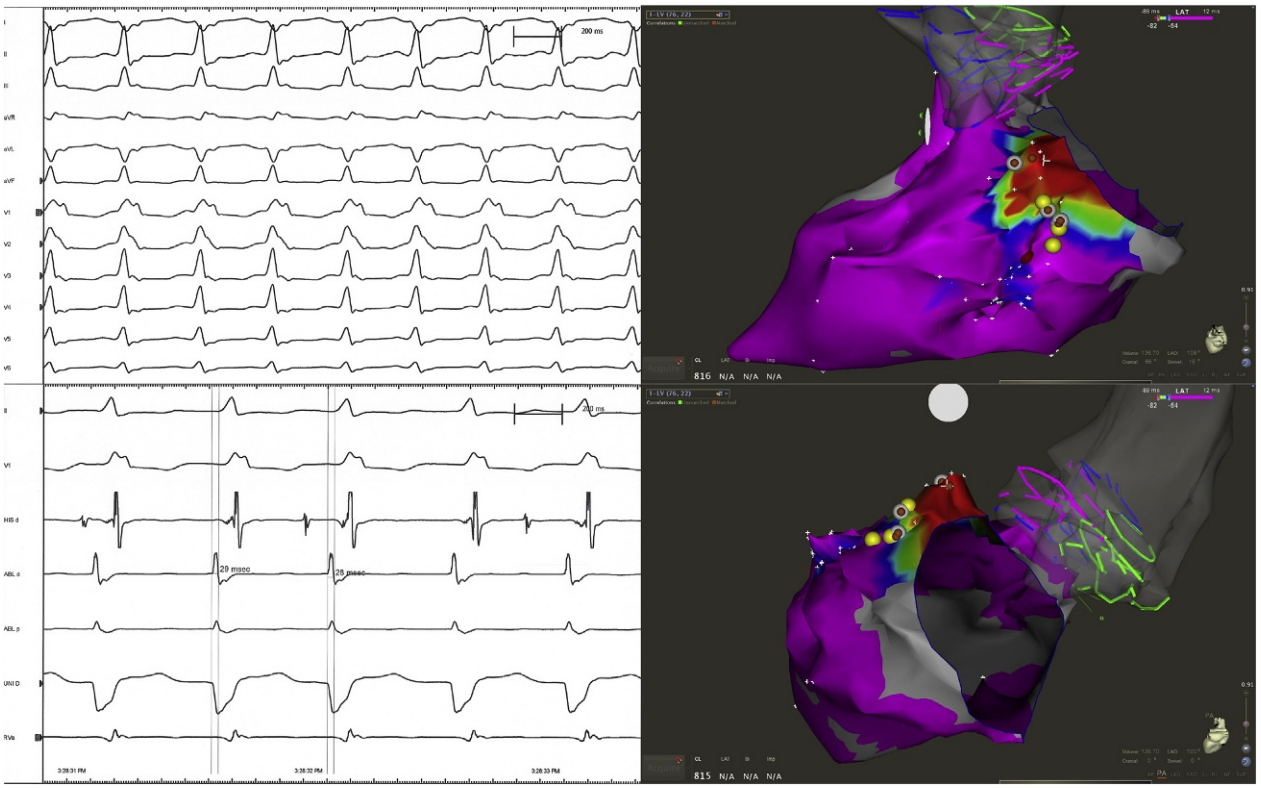

Fig. 9 Sustained monomorphic ventricular tachycardia in a patient with a structurally normal heart with right bundle branch block (RBBB) morphology with inferior and rightward axis. Electroanatomic mapping revealed that the anterolateral mitral annulus was the site of earliest activation with excellent bipolar and unipolar presystolic electrograms where the tachycardia was successfully ablated.

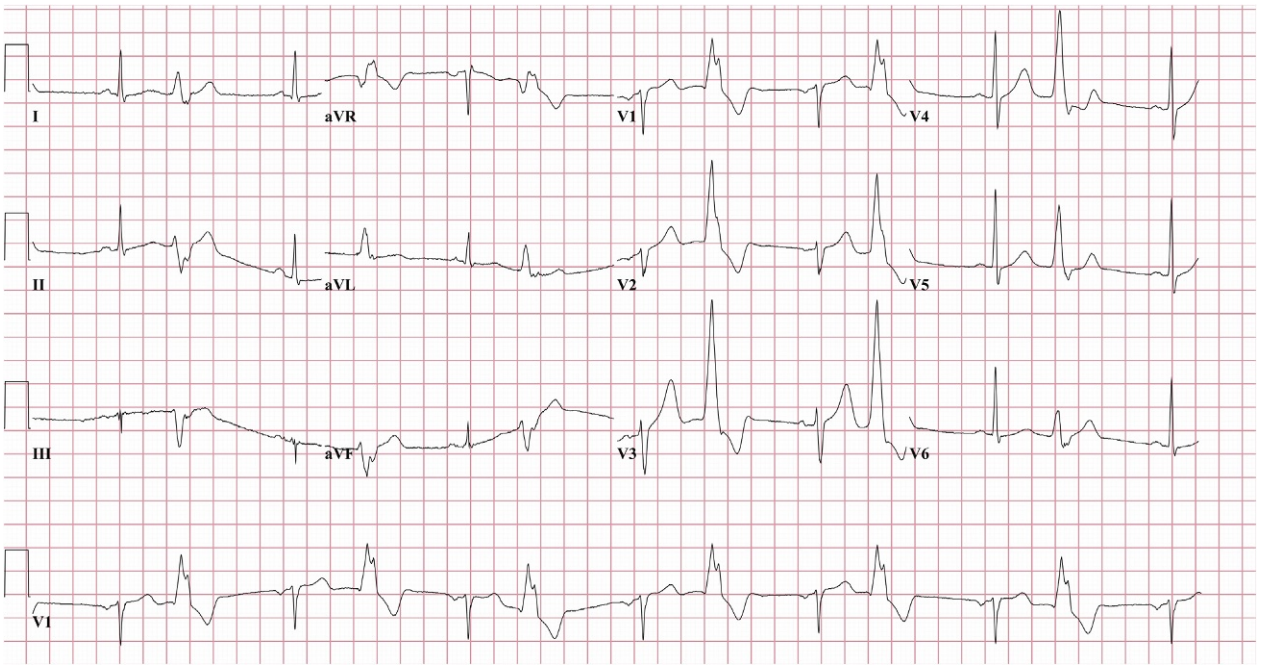

Fig. 10 Bigeminal premature ventricular complexes with right bundle branch block (RBBB) pattern, positive concordance, and superior axis that was mapped and successfully ablated at the inferior mitral annulus.

Malignant Consequences

Cardiomyopathy

Development of reversible PVC-induced cardiomyopathy and heart failure was first described by Duffee et al. (1998). The estimated incidence is 7%–8% among all patients with idiopathic VT (Hasdemir et al., 2011; Kim et al., 2007) with a male predominance (Yokokawa et al., 2012a). Differentiating between primary and secondary cardiomyopathies at presentation is difficult and empiric treatment is performed. The time course for developing LV dysfunction is variable with recovery typically in 4–6 months though up to 4 years was reported. Numerous factors including PVC burden, QRS duration (QRSd) and contour, interpolation, coupling interval, symptoms, and site of origin are associated with heightened risk and suggest a complex interplay of factors including an underlying genetic susceptibility.

Multiple studies demonstrated that PVC burden correlates with incidence and severity of LV dysfunction but without a clear threshold for risk. Kanei et al. observed a graded risk of LV dysfunction based on PVC burden: 4% with <1000, 12% with 1000–10,000, and 34% with >10,000 on 24-h ambulatory monitoring (Kanei et al., 2008) (**Fig. 12**). Dukes et al. similarly observed a graded risk of cardiomyopathy and heart failure with PVC burden stratified quartiles (Dukes et al., 2015). More than 20,000 PVCs in 24 h were associated with LV dysfunction (Niwano et al., 2009) but with less than 15%–20% there was neither difference in LV dysfunction nor improvement with ablation (Hasdemir et al., 2011; Takemoto et al., 2005). PVC burden of 24% is 79% sensitive and 78% specific for PVC-induced cardiomyopathy (Baman et al., 2010). In general, >10,000–20,000 or 20% PVCs in 24 h are considered clinically significant but only a minority is affected in the setting of persistent ventricular bigeminy, whereas reversible cardiomyopathy has been described with less frequent PVCs (Shanmugam et al., 2006). Circadian variability of PVCs impacts the long-term burden and less variability predicts cardiomyopathy independent of PVC burden (Bas et al., 2016). NSVT and pleomorphic PVCs increase the risk of cardiomyopathy (del Carpio Munoz et al., 2011; Kanei et al., 2008).

QRSd and contour predicts underlying heart failure and cardiomyopathy: PVCs with QRSd >160 ms and broad (>40 ms) notching are reliable markers of cardiomyopathy (Moulton et al., 1990). Yokokawa et al. established that PVC QRSd >150 predicts reversible cardiomyopathy and the required burden needed to develop cardiomyopathy was lower at this threshold (Yokokawa et al., 2012b). Further increases in QRSd predict irreversible cardiomyopathy (Deyell et al., 2012). Interestingly, fascicular PVCs are narrower but do not have a lower incidence of cardiomyopathy.

PVCs that do not alter the surrounding sinus rate (R-R interval) are interpolated (**Fig. 13**). Interpolation allows more sinus beats and PVCs due to the coupled relationship to the preceding sinus beat. One study suggested that interpolation independently

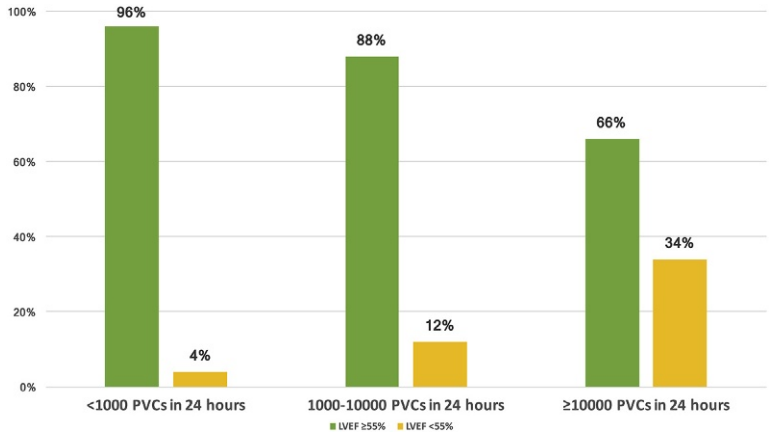

Fig. 12 Association of premature ventricular complex (PVC) frequency during 24-hour ambulatory monitoring with left ventricular systolic function. Adapted from Kanei et al., 2008. Frequent premature ventricular complexes originating from the right ventricular outflow tract are associated with left ventricular dysfunction. *Annals of Noninvasive Electrocardiology* 13: 81–85. https://doi.org/10.1111/j.1542-474X.2007.00204.x.

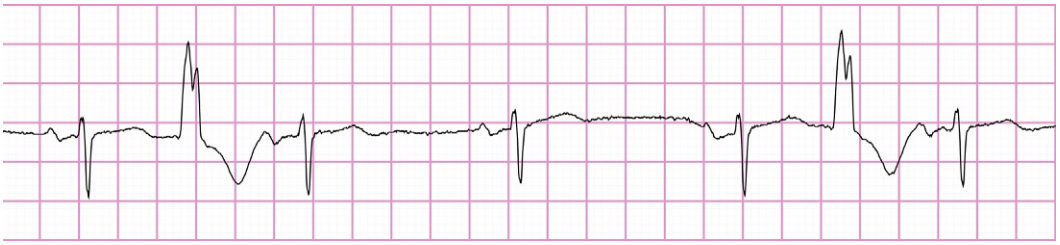

Fig. 13 Interpolated premature ventricular complexes (PVCs) do not alter the underlying sinus rate and are associated with a higher burden of PVCs. Interpolation has been suggested as a marker of risk for developing a PVC-induced cardiomyopathy independent of PVC burden.

predicted PVC induced cardiomyopathy (Olgun et al., 2011); however, other studies did not find relationship (Ban et al., 2013; Bas et al., 2016).

Duration or absence of symptoms correlates with the accumulative PVC burden and both are independently associated with PVC-induced cardiomyopathy (Blaye-Felice et al., 2016; Yokokawa et al., 2012a). Lack of symptoms is associated with a higher 24-hour PVC burden and is 3 times more likely with than without cardiomyopathy (Yokokawa et al., 2012a).

Initially, the mechanism was considered analogous to tachycardia-mediated cardiomyopathy prototypically due to AF but multiple studies demonstrated that heart rate remains unchanged regardless of PVC burden (Olgun et al., 2011; Takemoto et al., 2005). The putative mechanism is considered to be due to dyssynchronous ventricular activation similar to pacing-induced cardiomyopathy or manifest right-sided accessory pathways (Udink ten Cate et al., 2010). Though conceptually appealing, several clinical insights suggest greater complexity. First, LV dysfunction is not triggered by LV only pacing or with left-sided accessory pathways. Second, anatomic origin of PVCs should have differential effects if dyssynchrony was fully explicative; however, both right- and left-sided PVCs trigger cardiomyopathy. The rates of cardiomyopathy are independent of endocardial site of origin (del Carpio Munoz et al., 2011; Yokokawa et al., 2012b) but Del Carpio Munoz et al. observed that fascicular VT was associated with higher LVEF and the critical burden for developing cardiomyopathy was different: >10% for RVOT and >20% for LVOT (del Carpio Munoz et al., 2011). Potfay et al. with multisite pentageminal ventricular pacing demonstrated that markers of dyssynchrony are not associated with anatomic location but rather a longer coupling interval (Potfay et al., 2015). Neither burst ventricular pacing nor pentageminal atrial pacing produced the same degree of dyssynchrony and if causative likely relies on a complex interaction between site of origin and coupling interval. Multiple studies demonstrated that epicardial PVCs are associated with greater QRSd prolongation and PVC-induced cardiomyopathy (Blaye-Felice et al., 2016; Hamon et al., 2016; Yokokawa et al., 2012b).

PVC-induced cardiomyopathy develops after 12 weeks in a canine model of ventricular bigeminy and rapidly reverses in 2–4 weeks upon cessation of PVCs (Huizar et al., 2011). PVCs result in volumetric and electrical remodeling as is evident from developing of systolic dysfunction, dilation, and increased effective refractory period. Interestingly, there was no histopathologic evidence or change in inflammation, fibrosis, apoptosis, or levels of oxidative stress suggesting a functional cardiomyopathic process. The associated electrical remodeling was further characterized by Wang et al. who demonstrated that dispersion of action potential duration (APD) increased with wider beat-to-beat variation establishing a potentially proarrhythmic substrate (Wang et al., 2014). The densities of outward potassium (Ito, IK1) and inward calcium (L-type) currents decreased without change in other potassium currents (IKr or IKs). Furthermore, impairment of sarcoplasmic reticulum (SR) calcium-induced calcium release and

alterations in protein expression (juntophilin-2) responsible for maintaining the optimal interface between the cell membrane and SR may account for contractile dysfunction.

Malignant Arrhythmias

Focal triggers of ventricular fibrillation (VF) arising from the Purkinje network of the RVOT were described by Haïssaguerre et al. (2003) followed by rare case reports of polymorphic ventricular tachycardia (PMVT) or VF triggered by closely coupled RVOT PVCs with ablation mitigating the risk (Noda et al., 2005; Viskin et al., 2005) (**Fig. 14**). The aforementioned electrical remodeling facilitates arrhythmogenesis.

The coupling interval for triggering PVCs is longer than observed in idiopathic VF but shorter than benign PVCs; triggering coupling intervals are longer for MMVT than PMVT (Shimizu, 2009). MMVT with shorter cycle lengths are associated with a more malignant prognosis.

Clinical Evaluation

Idiopathic VT is a diagnosis of exclusion and the principle goal of clinical evaluation is to rule out SHD or heritable arrhythmia syndromes associated with increased risk of SCD or heart failure that persists despite treatment. Initial evaluation should include a comprehensive history and physical examination, 12-lead ECG, and echocardiogram.

History

The history establishes the severity, duration, frequency, and triggers of symptoms and impact on quality of life. High-risk features such as syncope or prior cardiac disease significantly modify the prognosis, diagnostic approach, and treatment. A careful review of symptoms to evaluate for signs or symptoms of angina or CHF as well as excluding secondary causes such as endocrine (thyroid, adrenal, or pituitary) and pulmonary disease is paramount.

Medications including caffeine, prescription drugs, herbal supplements, or illicit drugs need to be reviewed for potential electrophysiologic effects.

Family history should thoroughly evaluate for premature CAD, SCD among first-degree relatives, and heritable cardiomyopathies or electrical disorders.

Physical Examination

The physical examination is focused on evaluating the signs of CHF such as elevated jugular venous pressure, pulmonary rales, and pathologic murmurs or gallops suggestive of elevated filling pressures or valvular disease. Evaluation for other systemic manifestations of thyroid (hyperthyroidism), adrenal (pheochromocytoma), or pituitary (acromegaly) disorders as well as diseases with cardiac manifestations (i.e., muscular dystrophy, hemochromatosis, etc.,) is helpful.

There are numerous other obvious or subtle findings that may suggest occult cardiopulmonary disease such as xanthelasma, abnormal peripheral pulses or bruits, clubbing, psoriasis, or signs for rheumatoid arthritis.

Electrocardiogram

Twelve-lead ECG is generally specific but not sensitive for manifestations of SHD or primary electrical disorders such as q-waves, hypertrophy, conduction delay or block, Brugada pattern, T-wave abnormalities, Epsilon waves, preexcitation, and prolonged QTc. Morphologic assessment of ventricular ectopy allows anatomic localization and assessing complexity of ablation.

Outflow tract VT demonstrates left bundle branch block (LBBB) morphology and inferior axis (positive in lead II, III, and aVF) generally with QRSd $<$140 ms as the Purkinje system is penetrated and allows more rapid ventricular activation. Distinguishing between RVOT and LVOT origin depends on the precordial transition: RVOT-VT inscribe a QS complex in lead V1 and progressively more posterior sites of origin (posterior RVOT to LVOT to mitral annulus) progress from a qR complex then R or Rs complex

Fig. 14 Idiopathic premature ventricular complexes (PVCs) in a bigeminal pattern triggering polymorphic ventricular tachycardia.

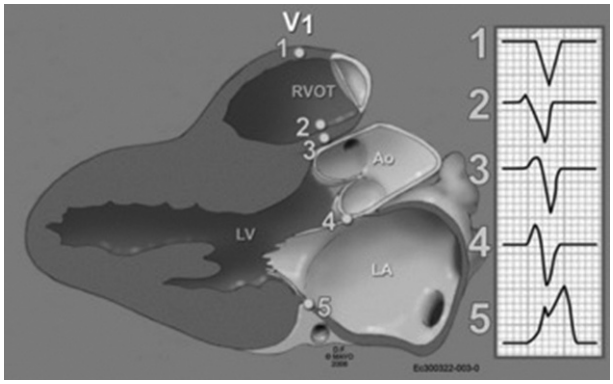

Fig. 15 Transition of V1 morphology from left bundle branch block to right bundle branch block morphology as the site of origin progressed posteriorly from the anterior right ventricular outflow tract to the lateral mitral annulus. From Asirvatham SJ (2009) Correlative anatomy for the invasive electrophysiologist: Outflow tract and supravalvar arrhythmia. *Journal of Cardiovascular Electrophysiology* 20: 955–968. https://doi.org/10.1111/j.1540-8167.2009.01472.x, with permission.

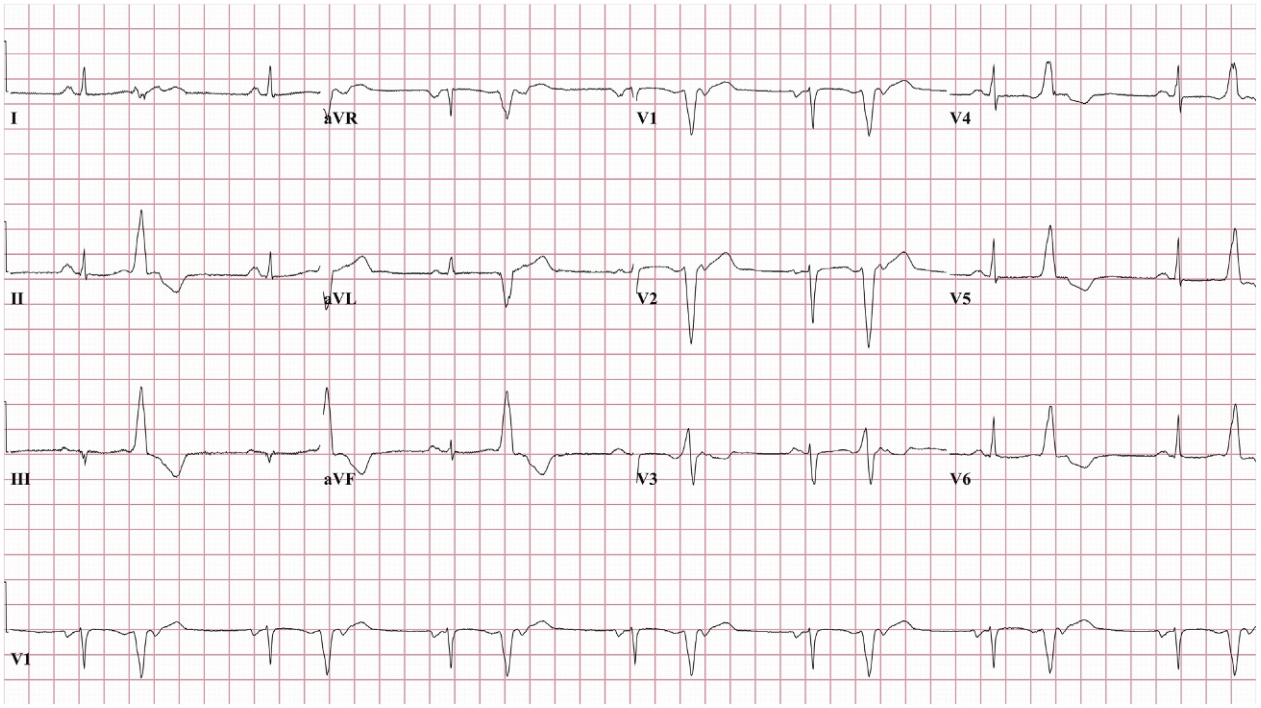

Fig. 16 12-lead electrocardiogram of premature ventricular complexes with left bundle branch block (LBBB) morphology, left and inferior axis, QRSd <140 msec, and precordial transition between leads V3 and V4 suggesting origin from the right ventricular outflow tract (RVOT).

(Jadonath et al., 1995); QRS morphology transitions to a right bundle branch block (RBBB) morphology at the lateral mitral annulus (**Fig. 15**). Accordingly, RVOT-VT typically transitions at or beyond lead V3, mirroring the sinus beat transition; transition earlier than V3 or sinus beats suggests LVOT-VT (Betensky et al., 2011; Callans et al., 1997) (**Figs. 16** and **17**). QS complex in lead aVL and QS or qR in lead I suggest anterior or septal RVOT origin; R or Rs complex in lead I and QS or R in lead aVL suggest posterior RVOT origin (Jadonath et al., 1995). QRSd, presence of fragmentation or notching, and transition differentiate between septal or free wall RVOT-VT: notching, increased QRSd, and delayed transition suggest free wall origin (Dixit et al., 2003).

Multiple electrocardiographic algorithms or signs facilitate localization of VT important for counseling patients regarding the complexity and risk of ablation (Dixit et al., 2003; Jadonath et al., 1995; Kamakura et al., 1998; Ouyang et al., 2002b) (**Table 3**). However, the algorithms are unable to account for variation in anteroposterior chest diameter, cardiac rotation, and lead placement. Betensky et al proposed the V2 transition ratio that reliably distinguishes between RVOT and LVOT origin by comparing the ratio of R to QRS amplitude during VT to sinus, self-controlling for patient-specific variation (Betensky et al., 2011) (**Fig. 18**).

Epicardial VT arises from perivascular structures and depolarization slowly progresses centrifugally from myocyte to myocyte without penetrating the Purkinje network. This manifests as slow or delayed initial forces of the QRS complex (pseudodelta wave). Several different electrocardiographic markers of epicardial origin have been evaluated of which a maximum deflection index (MDI)

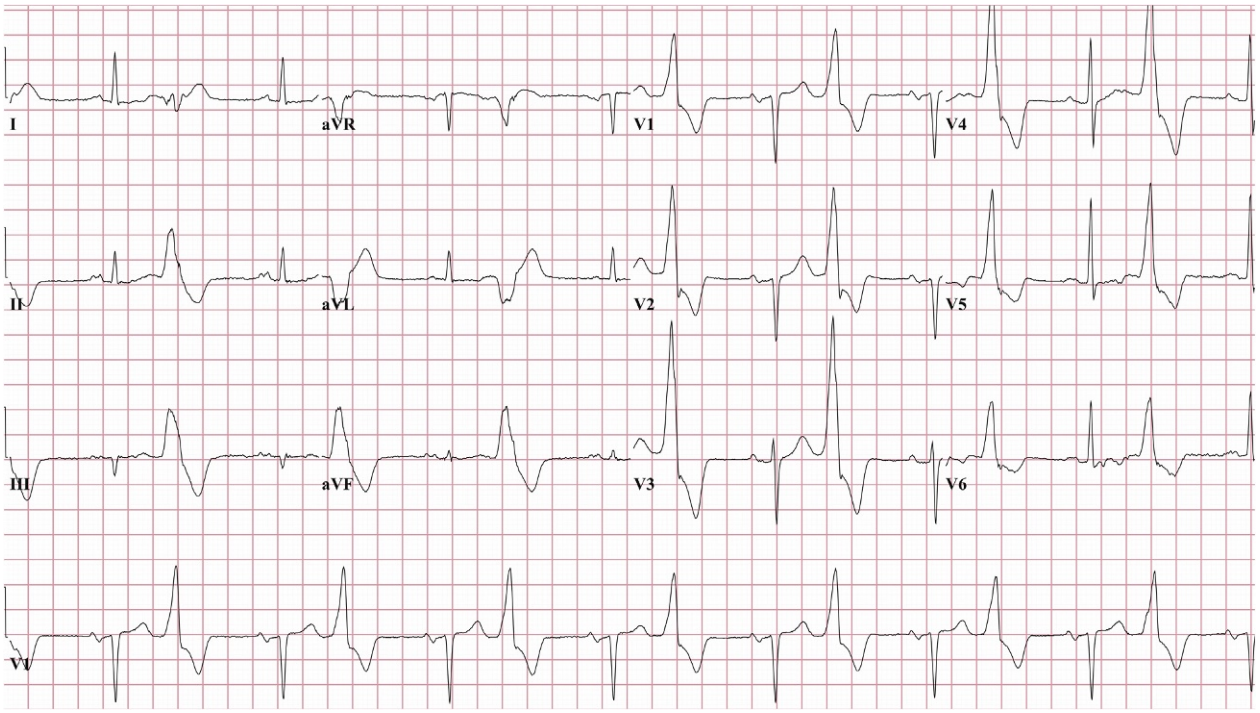

Fig. 17 12-lead electrocardiogram of premature ventricular complexes (PVCs) with inferior axis and R/S ratio ≥ 1 suggestive of an origin from the left ventricular outflow tract (LVOT). PVCs transition much earlier that the sinus beats which also suggests LVOT origin.

greater than 0.55 is considered sensitive and specific (Berruezo et al., 2004; Daniels et al., 2006; Vallès et al., 2010) (**Table 4**). MDI is the time to maximal deflection divided by QRSd (**Fig. 19**). A 3-step ECG algorithm with 100% sensitivity and 98% specificity to discriminate between epicardial and endocardial origin was proposed (Hamon et al., 2016).

Fascicular VT presents with QRSd <140 ms and rapid initial forces due to activation of the Purkinje system. Left posterior fascicular VT presents with right bundle branch block (RBBB) morphology and left superior axis. Left anterior fascicular VT presents with RBBB morphology and right inferior axis (**Fig. 20**).

Echocardiogram

Two-dimensional echocardiography allows a full assessment of cardiac structure, function, and hemodynamics. The presence of left ventricular dysfunction, wall motion abnormalities, hypertrophy, or chamber enlargement such as the right ventricle should prompt further evaluation for nonischemic cardiomyopathy, hypertrophic cardiomyopathy (HCM), or arrhythmogenic right ventricular cardiomyopathy (ARVC).

Evaluation of LV morphology, systolic function, and diastolic function has been rigorously and systematically established. The importance of right ventricular (RV) function has only been recognized recently and lack of normative data and standard assessments for RV function limit full evaluation. Moreover, echocardiography does not reliably diagnose subtle structural abnormalities or allow tissue characterization.

Holter

PVC burden is an important risk factor for cardiomyopathy and quantification with 24-h Holter monitoring remains important to assess prognosis and monitor response to treatment. PVC burden is expressed as percentage or total number of beats with greatest risk for cardiomyopathy when >20% or >20,000 beats. 24-h monitoring at the minimum is needed to assess PVC burden due to diurnal variation. PVC burden varies 5%–40% (Niwano et al., 2009) or clusters, requiring multiple Holters to fully appreciate the problem. Mobile cardiac telemetry systems overcome this limitation but are not a routine part of evaluation.

Exercise Stress Testing

Idiopathic VT is commonly triggered during peak exercise or during recovery but does not provide prognostic value, however, suppression during exercise is reassuring for absence of SHD or a malignant phenotype. Exercise stress testing is helpful when exercise-induced symptoms are present or CAD remains a possibility; myocardial perfusion imaging or echocardiography may be combined to enhance the diagnostic yield.

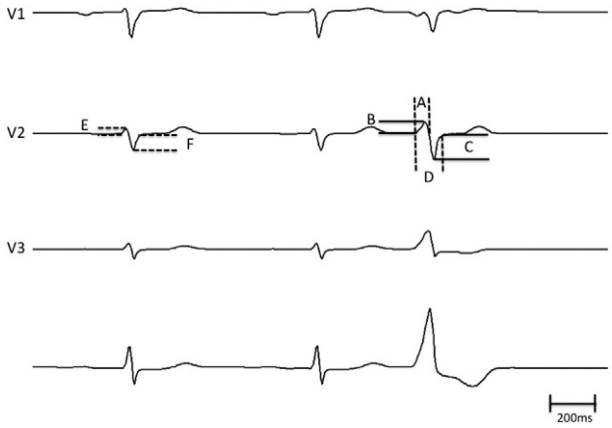

Fig. 18 V2 transition ratio of $\geq$0.60 is a highly sensitive (95%) and specific (100%) marker for origin from the left ventricular outflow tract. The transition ratio is calculated with the following formula: [B/(B + C) ÷ E/(E + F)]. A = PVC R-wave duration (ms); B = PVC R-wave amplitude (mV); C = PVC S-wave amplitude (mV); D = PVC QRS duration (ms); E = sinus rhythm R-wave amplitude (mV); and F = sinus rhythm S-wave amplitude (mV). With permission (Betensky et al. 2011).

Table 4 Electrocardiographic markers indicative of epicardial origin

Criteria	*Sensitivity and Specificity*
Pseudodelta wave $\geq$34 ms	83% and 95%
V2 intrinsicoid deflection $\geq$85	87% and 90%
Shortest RS complex $\geq$121	76% and 85%
Maximum deflection index $\geq$0.55	100% and 98.7%
Q wave in I or inferior leads	88% and 88%

Berruezo et al. (2004). *Circulation*. 109, 1842–1847; Daniels et al. (2006). *Circulation* 113, 1659–1666; Vallès et al. (2010). *Circulation: Arrhythmia and Electrophysiology* 3, 63–71.

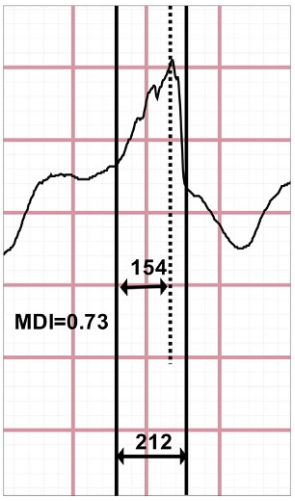

Fig. 19 Maximal deflection index (MDI) is the fraction of the QRS duration represented by the initial forces. The time from onset to maximal deflection (dotted line) is 154 msec and overal QRS duration is 212 msec. MDI is 154/212 or 0.73. MDI $\geq$0.55 is a highly sensitive and specific marker for origin from the epicardium.

Advanced Cardiac Imaging

Advanced cardiovascular imaging techniques such as CCT, CMR, and positron emission tomography (PET) allow for highly detailed anatomic evaluation of cardiac structures and coronary anatomy as well as assessment of microvascular perfusion and tissue characterization for myocardial fibrosis, fibrofatty replacement, and inflammation.

In particular, attention has focused on the relationship between idiopathic outflow tract VT and ARVC. ARVC is a progressive disease with sites for VT from the outflow tract, apex, and sub-tricuspid area (triangle of dysplasia) associated with RV dilation and

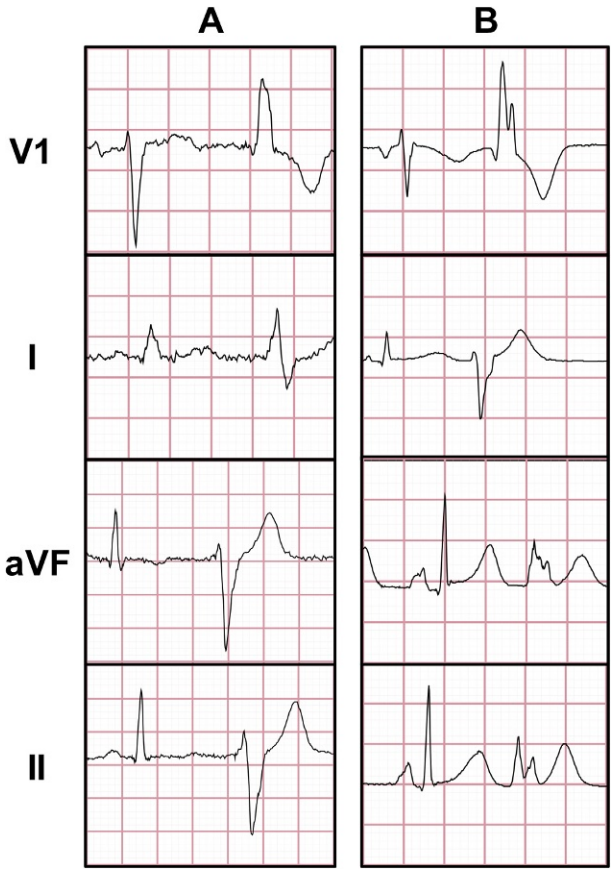

Fig. 20 Fascicular premature ventricular complex (PVC) morphology from both the posterior (A) and anterior (B) fascicles. Left posterior fascicular PVCs have right bundle branch block (RBBB) morphology and left superior axis. Left anterior fascicular PVCs have RBBB morphology and right inferior axis.

aneurysms (**Fig. 21**). The overlap of VT from the outflow tract raises the question of whether idiopathic outflow tract VT is an early manifestation or forme fruste of ARVC.

Mehta et al. demonstrated approximately 40% of patients with idiopathic RVOT-VT had abnormal endomyocardial biopsies of which 73% had abnormal echocardiograms; echocardiogram was abnormal in 6% with a normal biopsy. Sustained VT with LBBB morphology and superior axis suggests occult RV cardiomyopathy (Mehta et al., 1989, 1994) (**Fig. 22**).

Interestingly, Carlson et al. demonstrated that RVOT-VT is associated with focal RV structural abnormalities only detected on CMR including focal wall thinning, decreased systolic thickening, and abnormal wall motion (Carlson et al., 1994). This finding was confirmed by multiple other studies that additionally observed mild fibrofatty infiltration in RVOT-VT (Globits et al., 1997; O'Donnell et al., 2003; Proclemer et al., 1997). Gaita et al. reevaluated 61 patients with idiopathic RVOT-VT after a mean follow-up of 15 years and found that none experienced SCD or developed ARVC but 8 of 11 (73%) patients who underwent CMR displayed focal fibrofatty replacement (Gaita et al., 2001).

18-fluorodeoxyglucose (FDG) PET combines different imaging modalities including myocardial FDG avidity as a marker of metabolic activity, rubidium-82 perfusion imaging, and morphologic assessment with CCT where a mismatch between metabolic and perfusion imaging suggests regions of scar due to active myocardial inflammation. PET is helpful when cardiac sarcoidosis is suspected as there is no specific cardiac presentation pattern and may mimic other diseases such as ARVC. Nery et al. found that 42% of all patients presented with sustained MMVT had abnormal FDG-PET scans suggesting myocardial inflammation and 28% were confirmed to have cardiac sarcoidosis (Nery et al., 2014). FDG-avidity without evidence of sarcoidosis may represent myocarditis or is nonspecific. Variability in QRS morphology and cycle length may distinguish VT associated with cardiac sarcoidosis from idiopathic VT (Panda et al., 2015).

CCT, CMR, or FDG-PET is not routinely indicated in the presence of a normal 12-lead ECG, monomorphic ventricular ectopy, normal echocardiogram, and in the absence of high risk features such as syncope or family history of sudden death. These imaging modalities are generally reserved for case when the history, ECG, and echocardiogram raise the specter of congenital heart disease, infiltrative disease, hypertrophic cardiomyopathy, or ARVC. Other imaging modalities with limited utility are routine coronary angiography, RV angiography, myocardial perfusion scintigraphy, and endomyocardial biopsy.

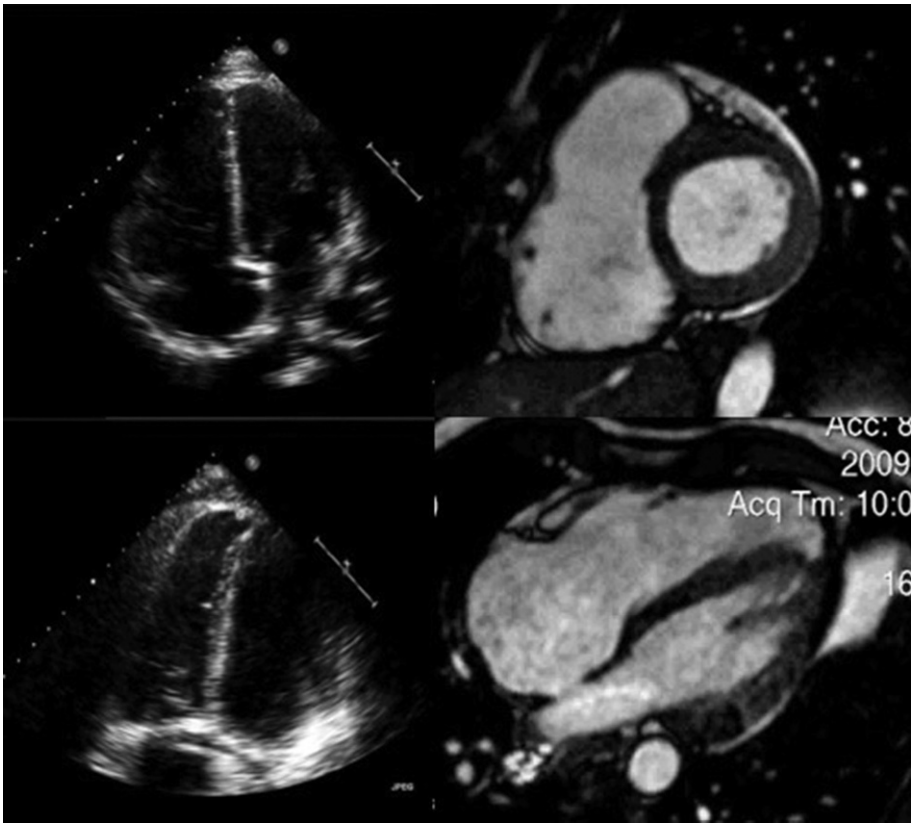

Fig. 21 Morphological changes of the right ventricle consistent with arrhythmogenic right ventricular (RV)cardiomyopathy. The two echocardiographic panels on the left show a dilated RV with a thin walled apical aneurysm wrapping around the left ventricular apex (LV) on parasternal long axis views. The two cardiac magnetic resonance imaging panels on the right confirm severe RV dilation and a RV apical aneurysm.

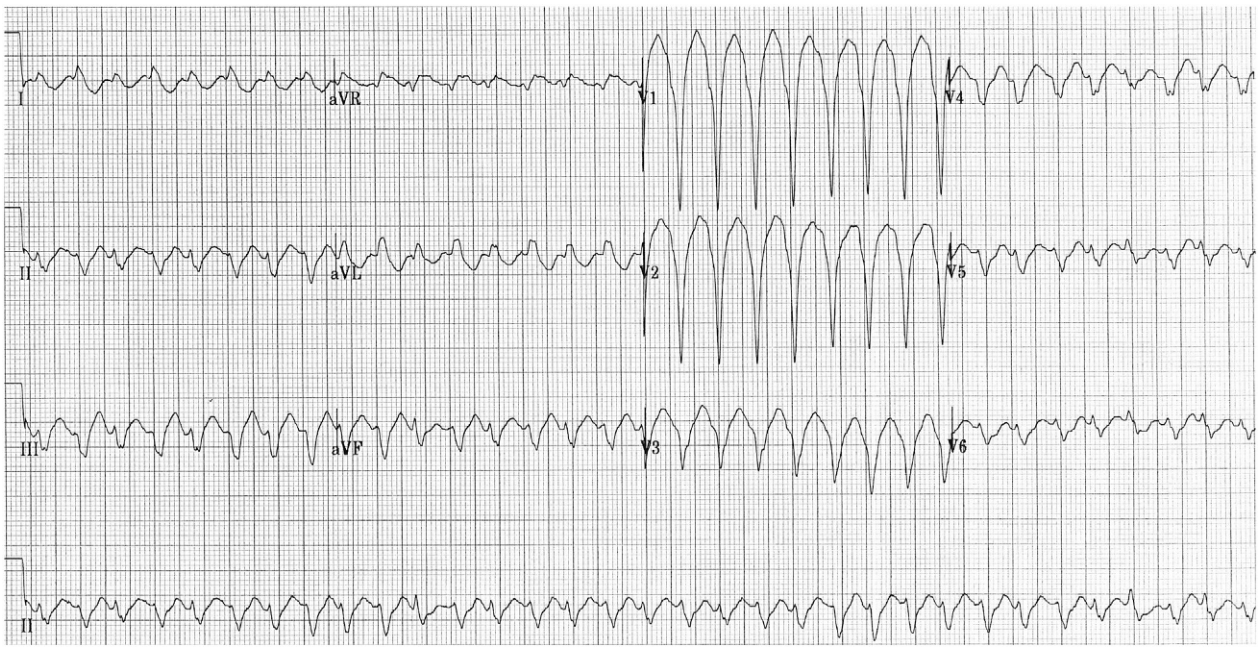

Fig. 22 Sustained monomorphic ventricular tachycardia with left bundle branch block morphology, negative concordance, and superior axis suggestive of origin from the inferoapical right ventricle suggestive of arrhythmogenic right ventricular cardiomyopathy.

Table 5 Electropharmacologic classification of idiopathic ventricular arrhythmias

	Adenosine-sensitive	*Verapamil-sensitive*	*Propranolol-sensitive*
Mechanism	*Triggered activity cAMP-mediated calcium overload leading to DADs*	*Intrafascicular reentry*	*Enhanced automaticity*
Pattern	Monomorphic PVCs, salvos, sustained VT	Monomorphic PVCs, salvos, sustained VT	Monomorphic or polymorphic Incessant
ECG Morphology	LBBB with inferior axis	RBBB with left-superior axis RBBB with right-inferior axis	RBBB, LBBB, polymorphic
Anatomic Origin	RVOT or LVOT	LAF or LPF	RV and LV
Induction			
PES (rapid pacing)	(+)	(+)	(−)
Catecholamines	(+)	(+)	(+)
Exercise	(+)	(+)	(+)

Mechanisms of Arrhythmogenesis

The clinical presentation and electropharmacologic profiles of idiopathic VT are variable but classification is possible by differences in electrocardiographic pattern, anatomic origin, response to exercise or catecholamines, response to programmed electrical stimulation (PES), or medications including adenosine, verapamil, or propranolol. The most common classification framework is based on response to adenosine, verapamil, or propranolol as drug response provides mechanistic insight: triggered activity, reentry, and automaticity, respectively (**Table 5**).

Adenosine-Sensitive

Lerman et al. first characterized the response of idiopathic VT with LBBB morphology and inferior axis, now recognized as outflow tract VT, to pharmacologic agents and PES (Lerman, 1993; Lerman et al., 1986; Wilber et al., 1993). Burst pacing reliably induces and terminates VT; isoproterenol facilitates induction; beta-blockade suppresses induction; and VT terminates with adenosine, verapamil, beta-blockers, Valsalva maneuver, or carotid sinus massage. Kim et al. demonstrated that the clinical presentation, electrophysiologic provocation, and drug response are similar across the spectrum of outflow tract VTs suggesting a common mechanism of arrhythmogenesis (Kim et al., 2007).

The sensitivity to adenosine provided the central insight to understand the clinical observations and mechanism. Adenosine (A1) receptors are found in atrial and ventricular myocardium with greater density in atrial versus ventricular myocardium (Lerman and Belardinelli, 1991). A1 receptors couple to an inhibitory G protein with two principal signal transduction pathways: cAMP and phosphatidylinositol. The response of supraventricular tachycardia to adenosine is due to cAMP-independent activation of the outward potassium current with resultant decrease in APD; however, this is not observed in ventricular myocardium. Adenosine inhibits adenylate cyclase- and cAMP-mediated activation of the inward calcium current (L-type) resulting in negative chronotropic and inotropic effects. Acetylcholine, via cardiac muscarinic receptors, yields identical effects explaining the unusual response to vagal maneuvers. Calcium channel blockers (CCBs) directly inhibit the L-type calcium current (**Fig. 23**).

The findings are consistent with a mechanism dependent on cAMP-mediated calcium overload. cAMP activates protein kinase A leading to phosphorylation of the L-type calcium channel and ryanodine receptor resulting in increased inward calcium current and calcium release from the SR that feeds back to further stimulate calcium-induced calcium release. Intracellular calcium overload results in an increase in the transient inward sodium current due to the activation of the sodium-calcium exchanger during phase 4 of the action potential (AP), triggering delayed afterdepolarizations (DADs). DADs reaching the critical threshold will trigger another AP that may result in development of successive APs leading to triggered VT. Accordingly, adenosine sensitivity is the sine qua non of cAMP-mediated triggered activity.

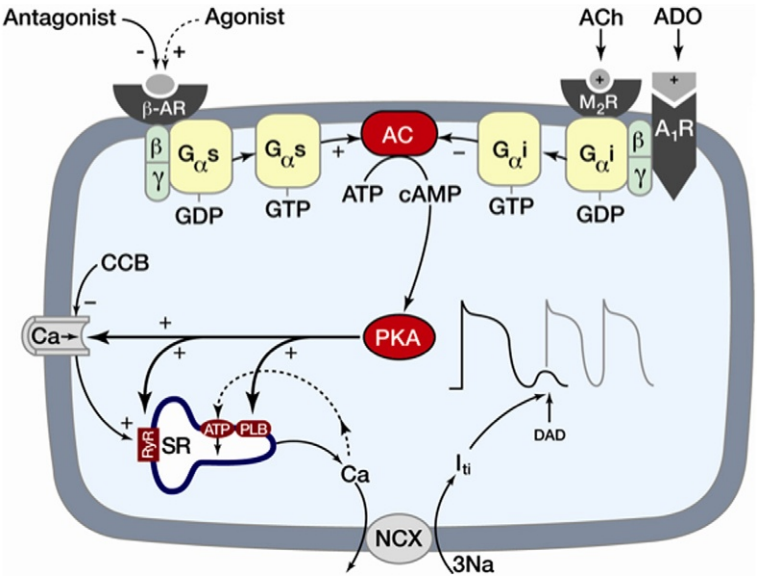

Fig. 23 Signal transduction pathway for cAMP-mediated triggered ventricular tachycardia. AC = adenylate cyclase; Ach = acetylcholine; ADO = adenosine; A1R = A1-adenosine receptor; β-AR = β-adrenergic receptor; CCB = calcium channel blocker; DAD = delayed after depolarization; Iti = transient inward current; M2R = muscarinic receptor; NCX = Naþ/Ca2þ exchanger; PLB = phospholamban; PKA = protein kinase A; RyR = ryanodine receptor; SR = sarcoplasmic reticulum. From Lerman, B.B., 2007. Mechanism of outflow tract tachycardia. *Heart Rhythm : The Official Journal of the Heart Rhythm Society* 4(7) 973–976, with permission.

Verapamil Sensitive

Zipes et al. in 1979 first described idiopathic VT with RBBB morphology and left axis deviation that was induced with atrial pacing (Zipes et al., 1979) and later described by Belhassen et al. to be sensitive to verapamil (Belhassen et al., 1981). Multiple studies suggested intrafascicular reentry as the mechanism due electrocardiographic morphology, response to PES with entrainment, early retrograde His potential suggesting fascicular origin and identification of an area of slow in the region of the fascicles (Belhassen et al., 1981; German et al., 1983; Lin et al., 1983; Ohe et al., 1988; Okumura et al., 1987, 1996; Zipes et al., 1979). Common triggers include exercise or catecholamines.

The antegrade limb extends from the basal to mid apical septum and slowly conducting verapamil-sensitive fascicular fibers with decremental conduction properties are implicated as the retrograde limb of the reentrant circuit (Lin et al., 1983). It was postulated that presystolic Purkinje potentials would be appropriate targets for ablation and was confirmed by Nakagawa et al. (1993) (Fig. 24). Diastolic Purkinje potentials have been observed (Nogami et al., 2000). Targeting Purkinje potentials for ablation during sinus rhythm has proved successful (Ouyang et al., 2002a). Interestingly, successful ablation of the left posterior fascicle for fascicular VT does not result in QRS widening or fascicular block, suggesting that the fascicles are not critical substrate (Kuo et al., 2003). Two studies suggest that the fascicle is in fact a bystander and that the retrograde limb is LV myocardium (Maeda et al., 2014; Morishima et al., 2012). The optimal site of ablation therefore cannot be identified if VT is not induced and an anatomic linear ablation to transect the region of the posterior fascicle is necessary to sufficiently modify the substrate.

Propranolol Sensitive

The clinical characteristics and mechanisms of propranolol-sensitive VT are poorly defined but may present as MMVT or PMVT that is modulated by catecholamines (Lerman et al., 1997; Sung et al., 1988). VT may be induced with exercise or isoproterenol and conversely suppressed with beta-blockers. PES characteristically is unable to initiate or terminate VT. Adenosine suppresses, not terminates, VT. These characteristics suggest an automatic mechanism arising from fully repolarized myocardium (normal, −90 mV) not abnormal automaticity (−60 mV).

Management Strategies

Observation

In the absence of symptoms and underlying cardiomyopathy there is no immediate need for intervention if the burden of PVCs is <20% and NSVT is not present. A monitoring strategy may be employed with a higher burden assuming LV function is normal; however, close clinical and echocardiographic follow-up is required to monitor for incipient LV dysfunction. Niwano et al. validated

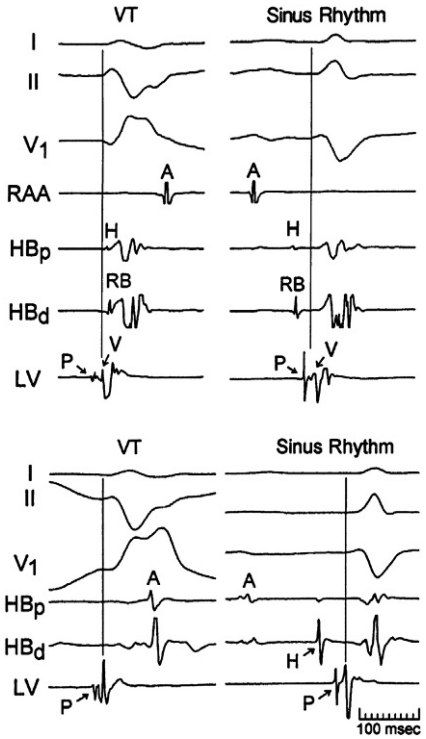

Fig. 24 Electroanatomic mapping of fascicular ventricular tachycardia (VT) revealing a presystolic Purkinje potential (left) during tachycardia and in sinus rhythm (right) at the site of successful ablation in two different patients (upper and lower panels). From Nakagawa, H. et al., 1993. Radiofrequency catheter ablation of idiopathic left ventricular tachycardia guided by a Purkinje potential. *Circulation* 88(6) 2607–2617, with permission.

this approach by following patients over 4 years with greater than 1000 PVCs daily in whom SHD was excluded with echocardiography and cardiac MR (Niwano et al., 2009). SCD, VT, syncope, or heart failure was not observed during follow-up. However, a small but significant decline in LVEF and increase in LV dimension were observed with >20,000 PVCs.

Avoidance of Triggers

A common recommendation is to avoid potential triggering substances, medications, food, or illicit drugs including caffeine, alcohol, tobacco, chocolate, beta-agonists, marijuana, cocaine, amphetamines, and other stimulants. While recommendations to avoid illicit stimulants, alcohol, or tobacco are beneficial for a myriad of reasons, there is little data supporting avoidance or behavioral modification for caffeine, alcohol, and tobacco in regard to ventricular arrhythmias (Glatter et al., 2012). In fact, Debacker et al. did not find any benefit from cessation or reduction of caffeine, tobacco, or alcohol (DeBacker et al., 1979).

Pharmacotherapy: Beta-Blockers and Calcium Channel Blockers

Beta-blockers and CCBs are generally first-line therapy for asymptomatic or symptomatic idiopathic VT but overall efficacy is not well established. Generally, the effectiveness of beta-blockers and CCBs are considered to be modest and limited by potential side effects encountered in doses sufficient for arrhythmia suppression. Beta-blockers inhibit activation of adenylate cyclase thus reduce cAMP-dependent phosphorylation of L-type calcium channels and ryanodine receptors leading to reduced intracellular calcium thus suppressing automaticity and afterdepolarizations.

Atenolol significantly reduced PVC burden by 33% and reduced symptoms but placebo resulted in a similar degree of symptom reduction without change in PVC burden (Krittayaphong et al., 2002). Verapamil reduces PVC burden by 35% (Gill et al., 1992). A retrospective analysis found that beta-blockers and calcium channel blockers resulted in 36% and 43% reduction in PVC burden, respectively (Zhong et al., 2014).

Intravenous adenosine and verapamil both have been used for the acute treatment of idiopathic VT as well as sympatholytic maneuvers (Valsalva or carotid sinus massage). The vasodilatory and electrophysiologic effects of adenosine or verapamil may lead to hemodynamic compromise or rhythm degeneration, especially in the presence of SHD, which is rarely known at the time of presentation.

Pharmacotherapy: Antiarrhythmic Drugs (AADs)

The clinical response to AADs has been evaluated in several small studies and included mexiletine, tocainide, flecainide, disopyramide, and sotalol (Capucci et al., 1989, 1991; Gill et al., 1992; Masotti et al., 1984; Tanabe et al., 1991). Amiodarone, mexiletine, flecainide, sotalol, and propafenone result in 70%–89% reduction in PVC burden (Zhong et al., 2014).

Of these medications, sotalol and flecainide are most commonly used. Sotalol has been used safely in the presence of SHD and appears to be greater than 89% effective for the treatment of RVOT-VT (Gill et al., 1992). These medications are generally well tolerated but care must be taken when administering to patients at risk for or with cardiomyopathy due to negative inotropic effects, QT prolongation, and proarrhythmia. AADs are generally reserved for risk averse or frail patients or for specific anatomic sites of origin (i.e., epicardial) that suggest lower ablation success with higher complication rates.

Catheter Ablation

Chugh et al. first described a patient with cardiomyopathy and high burden of PVCs in whom successful catheter ablation resulted in reversal of cardiomyopathy (Chugh et al., 2000).

Takemoto et al. in 2005 systematically evaluated the role of ablation for RVOT PVCs and found that the success rate was 93% with 3% complication and 3% recurrence rates (Takemoto et al., 2005). Ablation of patients with a high burden (>20%) of PVCs was associated with improvement in LVEF and LV dimensions. Yarlagadda et al. confirmed this finding with an 85% success rate of ablation (Yarlagadda et al., 2005).

Multiple subsequent single-center experiences have demonstrated that ablation is successful in 66%–92% all associated with significant reduction in PVC burden and improvement in LVEF and dimensions (Ban et al., 2013; Bogun et al., 2007; Penela et al., 2013; Sarrazin et al., 2009; Yokokawa et al., 2012a; 2013). Ablation was further associated with improvement in functional class and decrease in brain natriuretic peptide levels (Penela et al., 2013). Ineffective ablation was associated with a further decline in LVEF (Bogun et al., 2007). The time to recovery was generally within 4–6 months (Bogun et al., 2007; Yokokawa et al., 2013) but a significant minority (32%) of patients experienced more delayed improvement (Yokokawa et al., 2013). Epicardial PVCs or wider QRSd are independently associated with delayed recovery (Yokokawa et al., 2013). The recurrence rate of PVCs following an initially successful ablation appears to range from 9% to 17%. Tanaka et al. (2011) found that the success of ablation was 88% for RVOT origin but only 58% for LVOT origin.

Latchamsetty et al. published an extensive retrospective multicenter outcomes study for catheter ablation of idiopathic PVCs from eight high volume ablation centers with mean PVC burden of 20% and LVEF 55% in which the acute success of ablation was 84% (Latchamsetty et al., 2015). The success rate was as high as 93% for RVOT origin and as low as 67% for epicardial origin (**Fig. 25**). 71% experienced a durable decline in PVC burden (80% reduction) over 20 months of follow-up; 19% were on antiarrhythmic medications at follow-up. Among patients with cardiomyopathy, LVEF improved ≥10% in 67%, <10% in 18%,

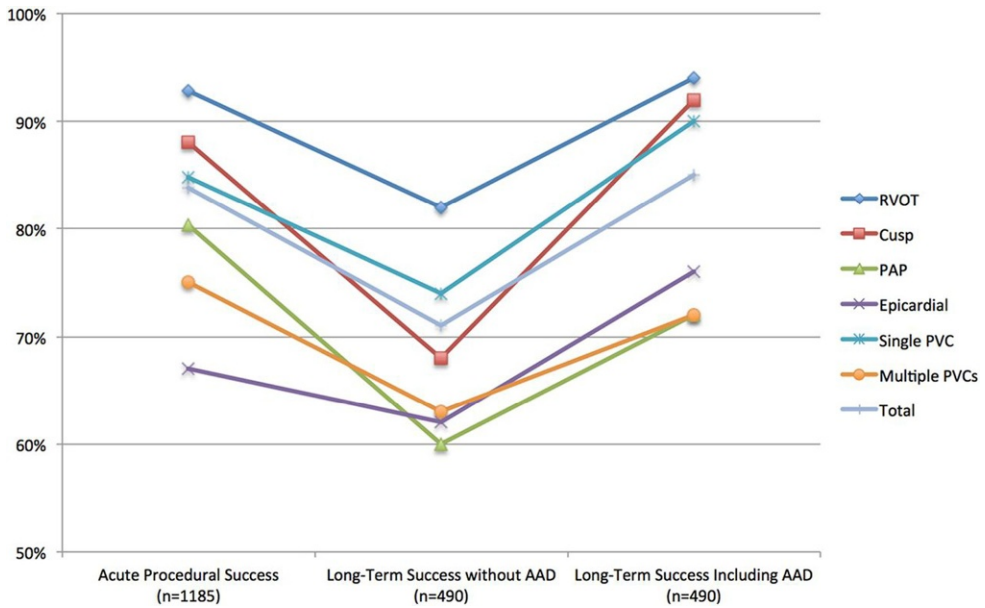

Fig. 25 Acute and long-term success (without and with AAD) of catheter ablation for idiopathic premature ventricular complexes by site of anatomic origin without and with AAD therapy. PAP = papillary muscle; RVOT = right ventricular outflow tract; AAD = antiarrhythmic drugs. From Latchamsetty R, Yokokawa M, and Morady F (2015) Multicenter outcomes for catheter ablation of idiopathic premature ventricular complexes. *JACC: Clinical Electrophysiology* 1(3): 116–123. https://doi.org/10.1016/j.jacep.2015.04.005, with permission.

and was unchanged or worsened in 15%. The overall complication rate was 5% with a near even distribution between major and minor complications; tamponade occurred in 0.8%.

The differential success of ablation based on anatomic location and significant complication rate raises the question of the relative benefits of AADs vs. ablation. Two recent studies sought to compare AADs with catheter ablation:

- Zhong et al. retrospectively analyzed 510 patients of whom 40% underwent ablation and 60% were treated with AADs (Zhong et al., 2014). Ablation was associated with a 93% decrease in the PVC burden that was significantly greater than AADs. LVEF improved significantly after ablation but there was no change with AADs; normalization of LVEF was two times more likely with ablation than AADs (47% vs. 21%).
- Ling et al. prospectively randomized 330 patients with idiopathic RVOT PVCs to catheter ablation or AADs (Ling et al., 2014). Ablation was associated with a greater decrease in PVC burden and lower recurrence at 1 year (19% vs. 89%). LVEF improved in both treatment arms. QS morphology in lead I predicted a more successful ablation.

These results of these studies suggest that while medical therapy is effective, ablation has incremental value over AADs and is more likely to result in durable clinical response and recovery of LVEF.

Conclusion

VT with structurally normal hearts has a diverse clinical presentation with a predominantly benign prognosis. However, epidemiological studies suggest a heightened risk of cardiovascular morbidity and mortality due to malignant presentations with cardiomyopathy and sudden death. Risk stratification is dependent on the careful evaluation for cardiomyopathy or subclinical heart disease, arrhythmia burden, and electrocardiographic characteristics. The anatomic substrate, arrhythmia mechanisms, and treatment strategies can be ascertained from the electrocardiographic and electropharmacologic profiles. Ablation is potentially curative with improved outcomes compared to pharmacotherapy and is increasingly first-line therapy; but careful consideration of the anatomic location and the implications for success and complications need to be factored.

Challenges

Several challenges need further investigation:

- Improving risk stratification for those at risk of developing idiopathic VT or malignant phenotypes.
- Improving evaluation for SHD
- Improving efficacy and safety of antiarrhythmic drugs or catheter ablation.
- Improving understanding of the mechanisms for cardiomyopathy or SCD.

Introduction and Definitions

Wide complex tachycardia (WCT, sometimes referred to as "broad complex tachycardia," BCT) is a term used to describe the ECG appearances of an arrhythmia, whose underlying mechanism can be broad and undifferentiated. Correct diagnosis of the mechanism of the WCT has significant implications for the clinical outcomes, acute and chronic management, and prognosis.

The common definition of a WCT is a rhythm with a ventricular rate over 100 beats per minute (bpm) and a QRS duration of $\geq$120 ms (Miller and Das, 2009). However, it is also understood that the term "tachycardia" may be used loosely when patients have structural heart disease or are undergoing treatment with antiarrhythmic drug therapy. In these situations, ventricular tachycardia (VT) may present with rates under 100 bpm.

Several descriptive terms are used to describe the ECG appearances of a WCT and may aid in diagnosing the underlying mechanism. These include:

- *Regularity*: predictability of the rhythm from beat to beat with a fixed cycle length.
- *Capture beats*: QRS complexes during a WCT which match the morphology of the patient's conducted beats (Fig. 1).
- *Fusion beats*: QRS complexes during a WCT which are intermediate in morphology between the WCT and the patient's conducted beats (Fig. 1).
- *Atrioventricular (AV) dissociation*: independent activation of the atria and ventricles (Fig. 1)
- *Positive concordance*: the predominant direction of the QRS in each of the precordial leads (V1–V6) is positive, for example, qR, Rs, or monophasic R waves (Fig. 2).
- *Negative concordance*: the predominant direction of the QRS in each of the precordial leads (V1–V6) is negative, for example, Qr, rS, or monophasic QS waves (Fig. 3).
- QRS Morphology
  - *Polymorphic*: QRS complexes vary in amplitude, duration, and axis (Fig. 4).
  - *Monomorphic*: QRS complexes are uniform in appearance within one episode of WCT (e.g., Figs. 2 and 3).
  - *Pleomorphic (or pleiomorphic)*: more than one morphology of WCT at different times. For example, this may occur when scar-related VT activates the ventricle via a different exit point during different instances of the dysrhythmia.
  - *Alternating, or bidirectional*: two different QRS morphologies present on alternate beats (Fig. 5).

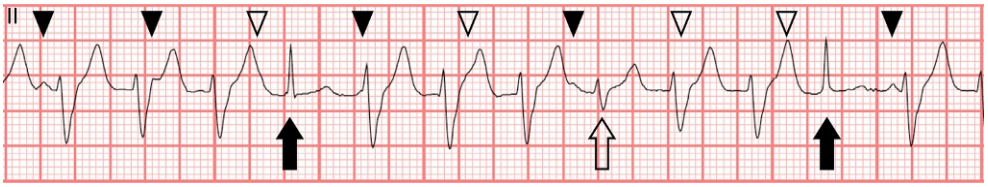

Fig. 1 Lead II rhythm strip, recorded at 25 mm s^{-1}, of a wide complex tachycardia, demonstrating AV dissociation. Independent P waves are seen (black arrowheads) or inferred (open arrowheads). Two capture beats can be identified (black arrows), occurring a suitable interval after the location of a preceding P wave. There is also a fusion beat (open arrow) which is intermediate in morphology between the conducted beats and the wide complex tachycardia.

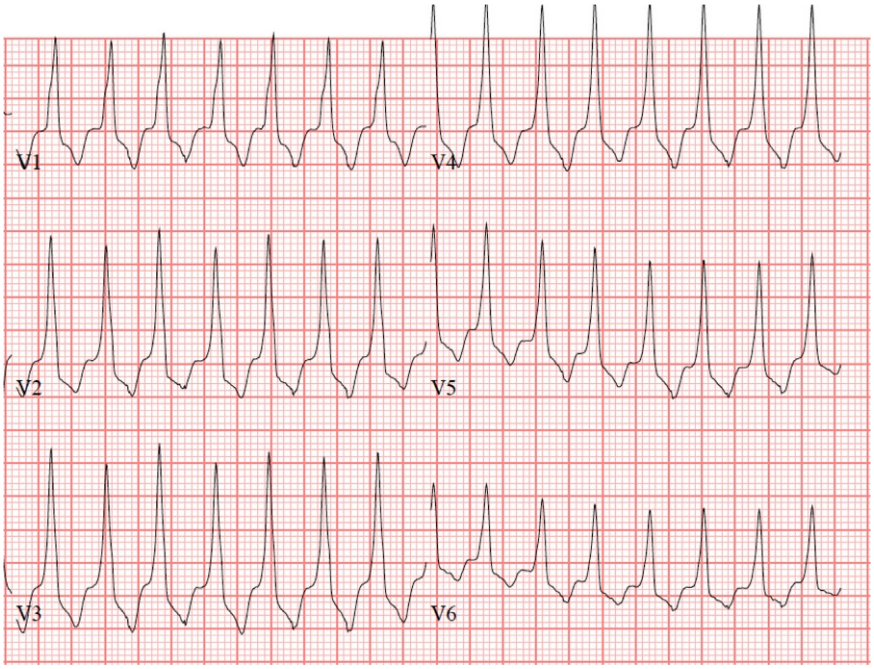

Fig. 2 Chest leads of a WCT showing positive concordance, with upright QRS complexes across all the leads. Since the complexes in V1 are predominantly positive (in this case, monophasic R waves), this tachycardia would be described as having a "right bundle branch block (RBBB) morphology," even though the appearances are in no way typical for actual block in the right bundle. The ECG suggests VT with an exit at the base of the LV. ECG recorded at 25 $mm.s^{-1}$.

- "Right bundle branch block (RBBB) morphology" refers to a predominant positive deflection in V1, for example, qR, Rsr′, rsR′, or monophasic R wave (e.g., **Fig. 2**).
- "Left bundle branch block (LBBB) morphology" refers to a predominant negative deflection in V1, for example, Qr, rS, or monophasic QS wave (e.g., **Fig. 3**). Importantly, the latter two terms are purely descriptive in this context, referring to the ECG morphology alone and do not necessarily imply that either bundle branch is mechanistically linked to the WCT.
- "RBBB morphology" and "LBBB morphology" may further be described as "typical" when they match the expected morphology for block in each respective bundle, and "atypical" when they do not (see later discussion).
- Slurred onset: slow rather than abrupt initial depolarization. This has been defined in several ways, including:
  - Width of the R wave in V1-2 exceeding 60 ms for WCT with a LBBB morphology (Kindwall et al., 1988)).
  - RS interval of >100 ms in one or more precordial leads (Brugada et al., 1991)).
  - V_i/V_t ratio <1 (Vereckei et al., 2008; see later discussion).
  - R-wave peak time >50 ms (Pava et al., 2010).
- Ventricular flutter: continuous, oscillatory monomorphic waveform, with no isoelectric line and T waves may not be clearly visible (**Fig. 6**).

The diagnostic utility of these features will be covered in more detail in the discussion of how they help to differentiate VT from other etiologies.

Differential Diagnosis

When attempting to make a diagnosis of the mechanism of any tachycardia on ECG, it is useful to start by asking two simple questions:

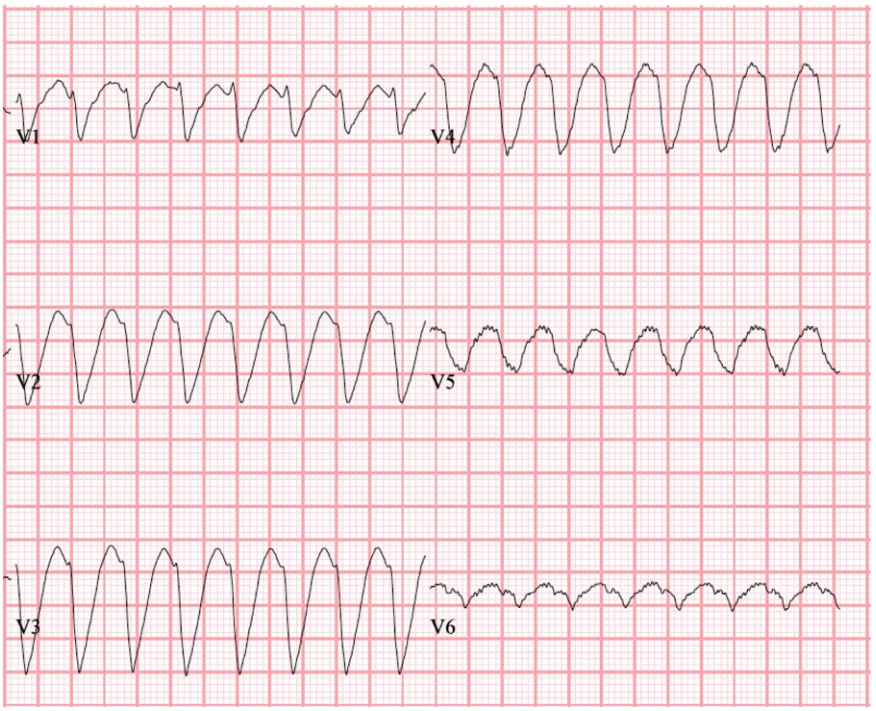

Fig. 3 Chest leads of a WCT showing negative concordance, with predominantly negative QRS complexes across all the leads. Since the complexes in V1 are predominantly negative (in this case, rS waves), this tachycardia would be described as having a "left bundle branch block (LBBB) morphology," even though the appearances are not typical for actual block in the left bundle. The ECG suggests VT with an apical exit. ECG recorded at 25 mm s^{-1}.

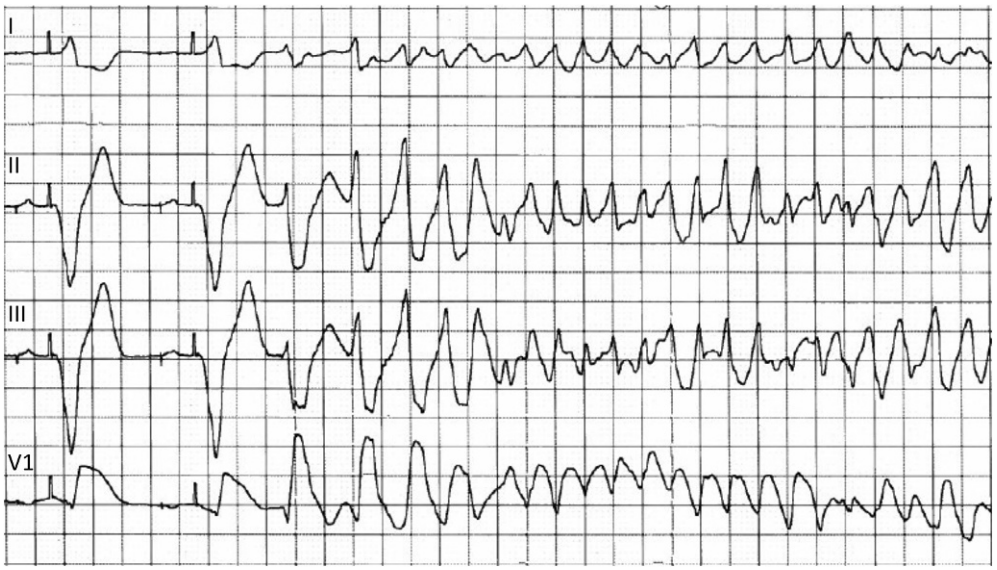

Fig. 4 ECG leads I, II, III, V1, recorded at 25 mm s^{-1}, showing dual-chamber pacing followed by irregular, polymorphic VT. On the first two beats the ST segments appear abnormal in lead I and V1, even given the fact that the rhythm is paced. In this case the polymorphic VT was occurring in the setting of acute ischemia.

- Is the rhythm visibly regular or irregular?
- Are the QRS complexes narrow (<120 ms) or wide (≥120 ms)?

Any tachycardia will then fall into one of four mutually exclusive groups, each with their own differential diagnosis. This article will address irregular and regular WCTs, with the main focus being on the latter since this is the area where most diagnostic doubt may occur.

Before considering the differential diagnosis, it is useful to review first the mechanisms by which the QRS can become wide. In general, to produce a narrow QRS complex (<120 ms) activation of the ventricles must occur via antegrade activation of the His–Purkinje system, including both the left and right bundle branches. This achieves rapid depolarization of the entire ventricular

Fig. 5 Lead II rhythm strip, recorded at 25 mm s^{-1}, showing an alternating (bidirectional) rhythm.

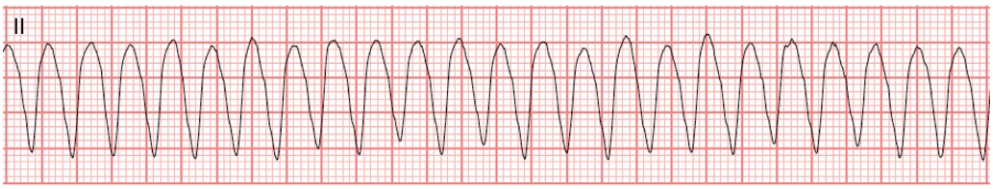

Fig. 6 Lead II rhythm strip, recorded at 25 mm s^{-1}, showing ventricular flutter at 255 bpm.

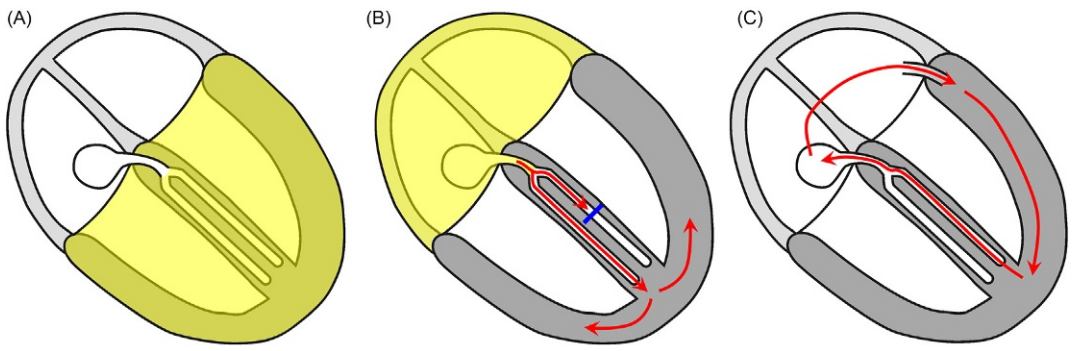

Fig. 7 Schematic diagrams outlining potential mechanisms for producing wide (>120 ms) QRS complexes. Panel A indicates a rhythm originating below the bifurcation of the His bundle (*yellow shading*), with common causes including VT and ventricular pacing. Panel B indicates abnormal conduction of a supraventricular rhythm (yellow shading, including rhythms such as orthodromic AVRT), with QRS widening caused by bundle branch block (e.g., diagram indicates LBBB) or abnormal myocardial conduction. Panel C indicates a preexcited tachycardia, with the diagram showing antidromic AV reciprocation. Other supraventricular rhythms conducted predominantly over an accessory pathway would similarly produce wide QRS complexes. *AFL*: atrial flutter; *AT*: atrial tachycardia; *AVNRT*: atrioventricular nodal reentry tachycardia; *AVRT*: atrioventricular reciprocating tachycardia; *BBB*: bundle branch block; *LVH*: left ventricular hypertrophy; *VT*: ventricular tachycardia.

myocardium in a short space of time (often <100 ms). If the ventricles are not activated via this route, then the QRS complex will generally exceed 120 ms. As outlined in Fig. 7, this includes:

- Rhythms where the ventricles are activated by conduction from myocyte to myocyte, not involving the specialized conduction tissue, for example, VT or ventricular pacing.
- Rhythms where there is antegrade conduction over the His bundle, but there is block or marked conduction delay in one of the bundle branches.

- Rhythms where the ventricle is activated via antegrade conduction over an accessory pathway, that is, preexcited rhythms. This is because subsequent spread of activation to complete depolarization of the ventricles occurs by myocyte-to-myocyte conduction, as in mechanism 1.
- Circumstances where there is generalized abnormal slowing of depolarization in the conducting tissue and/or ventricular myocardium, for example, with marked electrolyte disturbance (such as severe hyperkalemia), ischemia, inherited channelopathies, or presence of drugs or toxins, particularly those which affect sodium channel function.

Differential Diagnosis of an Irregular WCT

This includes:

- Atrial fibrillation (AF) with bundle branch block
- Atrial flutter (AFL) with a variable AV conduction ratio and bundle branch block
- Atrial tachycardia (AT) with a variable AV conduction ratio and bundle branch block
- Multifocal atrial tachycardia (MAT) with bundle branch block
- AF with preexcitation
- AFL with a variable AV conduction ratio and preexcitation
- AT with a variable AV conduction ratio and preexcitation
- MAT with preexcitation
- Polymorphic VT, including torsades de pointes VT
- Ventricular fibrillation (VF)
- Artifact

Differential Diagnosis of a Regular WCT

This includes:

- VT
- "Supraventricular" tachycardia (SVT) with bundle branch block, where in this context "SVT" refers to:
  - sinus tachycardia
  - AT with a fixed AV conduction ratio
  - AFL with a fixed AV conduction ratio
  - AV nodal reentrant tachycardia (AVNRT)
  - orthodromic (i.e., with antegrade conduction over the normal conduction system) AV reentant tachycardia (AVRT).
- SVT with preexcitation, where in this context "SVT" refers to:
  - sinus tachycardia
  - AT with a fixed AV conduction ratio
  - AFL with a fixed AV conduction ratio
  - AVNRT with conduction over a bystander accessory pathway
  - antidromic (i.e., with retrograde conduction over the normal conduction system) AVRT
- Ventricular pacing, including tracking of atrial rates >100 bpm and pacemaker-mediated tachycardia
- Artifact

Ventricular pacing (Fig. 8) should be suspected in a patient who has had a pacemaker or defibrillator and ventricular rates at, or below, the upper tracking rate of the device (130 bpm is a common default upper tracking rate of many devices). If previous ECGs are available, the WCT can be compared with any previously documented paced beats. Pacing spikes themselves may not be readily apparent on the ECG, especially with bipolar pacing. The QRS morphology will often indicate activation originating from the right ventricular apex, with negative QRS complexes in the inferior leads and negative concordance in the chest leads.

Artifact can appear regular or irregular and should be suspected if a narrow QRS can be seen superimposed at regular intervals upon what appears to be a WCT (Fig. 9). This can be correlated with a lack of clinical symptoms (e.g., palpitation, hypotension, and syncope) along with other signs such as shivering, tremor, or regular muscular activity. Occasionally it can be very difficult to

Fig. 8 Pacemaker-mediated tachycardia, with a ventricular rate of 146 bpm. Pacing spikes are seen in front of the QRS complexes. In this case the pacemaker was tracking retrograde P waves in the atrium (not clearly shown on this strip), triggering ventricular pacing. The paced rate was below the programmed maximum tracking rate (150 bpm in this case). ECG recorded at 25 mm s^{-1}.

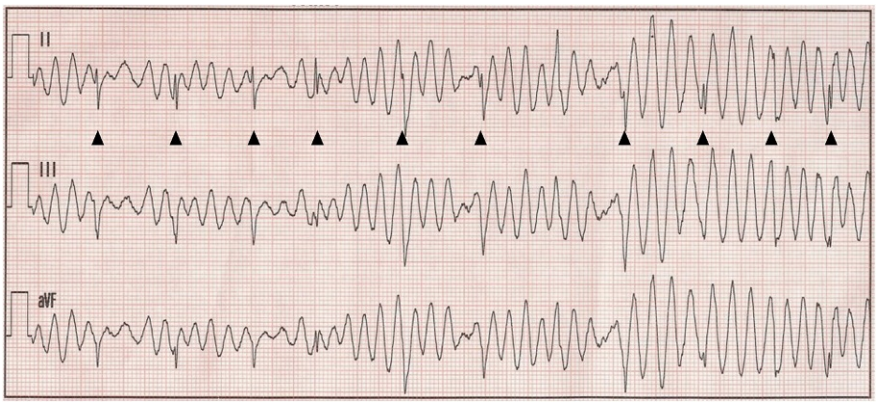

Fig. 9 ECG leads II, III, and aVF from a 77-year-old female with dizziness, nausea, and shaking, treated as torsades de pointes VT with intravenous magnesium sulfate. Closer inspection reveals sharply inscribed complexes occurring across the strip, best seen in Lead II (black arrowheads). The other apparent complexes are due to artifact caused by her muscle tremor. The intrinsic rhythm is slightly irregular, making it even harder to distinguish. The rhythm was later seen to be sinus with premature atrial beats. ECG recorded at 25 mm s^{-1}.

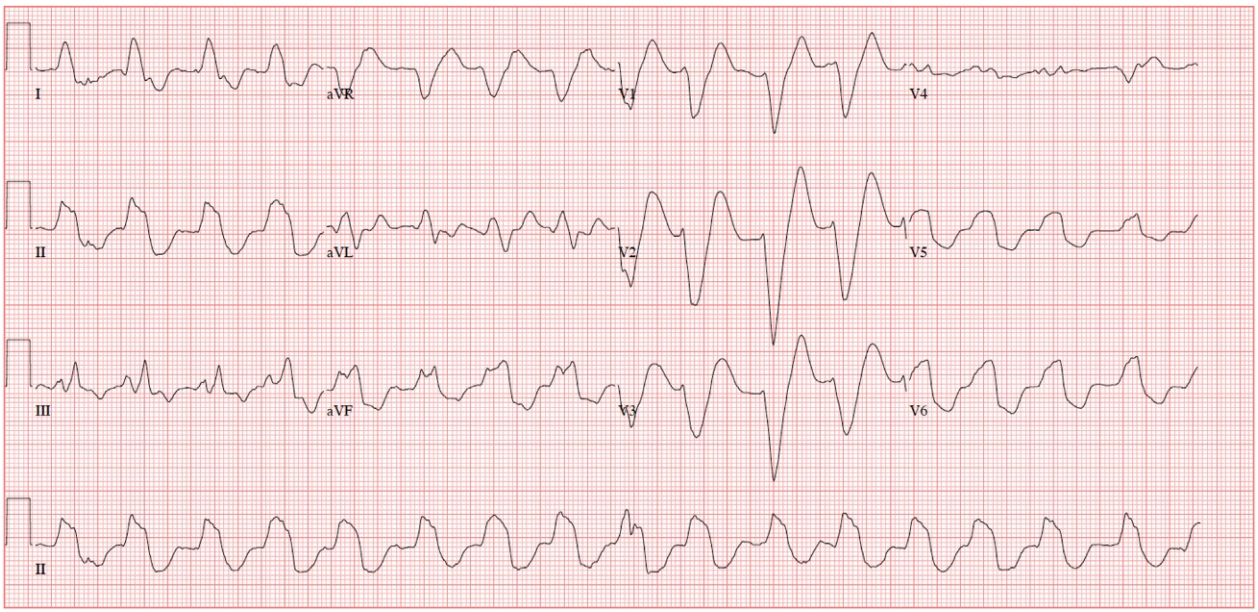

Fig. 10 ECG showing wide complex rhythm at around 100 bpm, with markedly widened, bizarre QRS complexes, in the context of hyperkalemia ($K^+ = 6.4$ mmol L^{-1}) and systemic illness. ECG recorded at 25 mm s^{-1}.

distinguish artifact from a genuine WCT, particularly if only one or two ECG leads are available, for example, on telemetry or Holter monitoring (Knight et al., 2001), and there is a danger of instituting inappropriate therapy.

For both irregular and regular WCT, electrolyte disturbance (Fig. 10), generalized ischemia, drugs, and toxins should also be considered as a cause for widening of the QRS. This mechanism may be obvious from the circumstances (e.g., cardiac arrest, antiarrhythmic drug overdose, renal failure) and/or initial blood test results. One particular circumstance worth noting is bidirectional VT in the context of digoxin overdose, since this is a "classic" finding.

Approach to Regular WCT

Prevalence and Likelihood

Before applying any diagnostic reasoning, it is important to review the most likely causes for a regular WCT presenting to medical attention, since this will help determine the pretest probability of each potential cause. Akhtar et al. performed a prospective assessment of 150 patients presenting with a regular WCT. One hundred and twenty-two patients (81%) had VT, 21 (14%) had SVT

with aberrant conduction, and 7 (5%) had preexcited tachycardias (Akhtar et al., 1988). Of those with SVT, 6 had preexisting BBB, while 15 had rate-related (functional) BBB. Similarly, Steinman et al. found that 17 of 20 patients (85%) presenting with WCT had VT, while 3 (15%) had SVT (Steinman et al., 1989). Miller et al. evaluated 650 WCTs, with the final diagnosis confirmed by electrophysiology (EP) study (Miller et al., 2006). They found VT in 73% of cases, SVT with aberrancy in 20%, and preexcited tachycardia in 6%. Two patients had SVT with abnormal baseline QRS complexes and a further two had paced ventricular rhythms. Thus, even before obtaining any clinical information, or analyzing the ECG, around 75–85% of WCT presenting for emergency care will turn out to have VT.

This section will focus on distinguishing between the two most common causes for regular WCT: VT and SVT with aberrant conduction. Clues to the presence of a preexcited tachycardia will be addressed briefly in a later section.

Diagnosis

A diagnostician has several tools at his disposal to make the proper diagnosis. These include:

- Clinical history
- Physical examination and bedside maneuvers
- ECG
- Cardiac imaging
- Cardiac implantable device Interrogation
- Invasive EP studies

Clinical history

Many of the studies looking at clinical history as an aid to the diagnosis of WCT were conducted in the late 1980s and early 1990s (Baerman et al., 1987; Tchou et al., 1988; Griffith et al., 1991). Common variables examined include age, sex, history of myocardial infarction (MI), congestive heart failure (CHF), cardiac surgery, smoking, syncope, and chest pain. Univariate analysis suggested that history of MI, age, CHF, and prior cardiac surgery were significant predictors for VT. However, history of MI remained the only independent variable on multivariate analysis, with a positive predictive value (PPV) for VT of over 95%. The PPV of age >35 years as a predictor of VT was lower at 85%. There were no strong predictors of SVT, with the best predictor being age <35 years with a PPV of 70% (Griffith et al., 1991).

Therefore, a careful history should be taken, with a focus on any known cardiac disease, such as prior MI, known heart failure and/or reduced LV function, cardiac surgery, valvular or congenital heart disease, and presence of a pacemaker or implantable cardioverter defibrillator (ICD). Any family history of cardiac disease or sudden cardiac arrest should also be determined. Any recent increase in angina-type symptoms or change in New York Heart Association functional class should also be noted. A full list of current medication should be obtained, noting any of which could cause widening of the QRS, either at therapeutic dosage or with overdose. Such agents are generally those with sodium channel-blocking effects, for example, Class 1A or 1C antiarrhythmic agents, psychiatric drugs (including tricyclic antidepressants, carbamazepine, citalopram), some antihistamines (e.g., diphenhydramine), chloroquine and hydroxychloroquine, and illicit drugs such as cocaine (Hollowell et al., 2005).

Physical examination and bedside maneuvers

Findings on physical examination of the patient may be helpful but generally nondiagnostic. Some have made the incorrect supposition that a patient with a hemodynamically stable WCT must be in SVT, but this has been shown to be incorrect. Hypotension was seen in only 36% of VT in one study, with hemodynamically stable VT being more common than SVT due to higher numbers of VT in general (Griffith et al., 1991). This was consistent with a prior study showing 30% of patients with VT present with significant clinical symptoms of poor tissue perfusion as evidenced by presyncope and syncope (Morady et al., 1985). The 2006 ACC/AHA/ESC guidelines on ventricular arrhythmias remind us that hemodynamic stability is a function of "the rate of the tachycardia, presence of retrograde conduction, ventricular function, and compensatory mechanisms" and should not be presumed to indicate absence of heart disease (Zipes et al., 2006). Neither does stable WCT reflect a benign prognosis as it can be a cause of hemodynamic deterioration. Other physical signs thought to be helpful in differentiating between SVT and VT include (Marriott, 1970; Harvey and Ronan, 1966):

- Examination of the JVP for cannon A waves, which are intermittent pulsations in the JVP, typically of varying amplitude and timing
- Variable intensity of the first heart sound (S1) on breath hold
- Variation in systolic blood pressure (unrelated to respiration)

The underlying mechanism common to these physical findings is AV dissociation. Cannon A waves are caused by right atrial contraction against a closed tricuspid valve which occurs with AV dissociation or intermittent retrograde activation of the atria. Similarly, variable intensity of S1 suggests variable degrees of opening of the mitral and tricuspid valve at the time of ventricular systole and variation in systolic blood pressure with different degrees of ventricular filling. However, though AV dissociation is quite specific for VT, it is not sensitive as VT may be associated with 1:1 retrograde activation of the atria through the conduction system. Thus, absence of these findings does not exclude VT.

Termination of a WCT with maneuvers that increase vagal tone (such as a Valsalva maneuver or carotid sinus massage) or administration of adenosine suggests that the AV node is part of the circuit and thus favors SVT over VT as the mechanism of the tachycardia. However, some uncommon forms of VT may be adenosine-sensitive or influenced by vagal tone (e.g., outflow tract VT and idiopathic left ventricular VT). The Advanced Cardiac Life Support (ACLS) Guidelines from 2015 include a class IIb indication for using adenosine if the etiology of a WCT cannot be determined, the rate is regular, and the QRS is monomorphic (Link et al., 2015). Evidence includes a small retrospective observational study of patients who had adenosine administered for WCT (Marill et al., 2009). There were 116 patients with SVT and 81 with VT. 104/116 (90%) of SVTs responded to adenosine versus 2/81 (2%) of VTs. Adenosine was felt to be safe, with only two patients experiencing angina after adenosine, and one becoming hypotensive but not requiring therapy. Please note that there is also a contraindication (Class III) in those with unstable, irregular, or polymorphic WCT as adenosine may cause degeneration of the rhythm into VF. The concern is that adenosine can cause a coronary artery "steal" syndrome through vasodilation which can lead to hypotension and myocardial ischemia in patients with coronary disease. Therefore, while termination of a WCT with adenosine favors SVT, it is not specific enough to be used for diagnostic purposes. Vagal maneuvers and adenosine may be considered for termination of a WCT in patients where the physician is certain of the presence of SVT or adenosine-sensitive VT (e.g., when the diagnosis has previously been determined with an EP study).

ECG

Examination of the ECG during the tachycardia and in baseline rhythm often yields clues regarding the mechanism of the WCT.

Baseline ECG

A prior ECG, or an ECG after termination of the WCT, will often be available and should be examined for:

- Pathological Q waves, indicating prior MI.
- ST and T wave changes, indicating acute infarction or ischemia.
- Baseline QRS duration, including whether there is preexisting BBB. If aberrant conduction is present, then it should be determined whether this closely matches the QRS morphology of the WCT. This may indicate a supraventricular origin for the WCT although there are important exceptions, such as bundle branch reentry VT. If the baseline ECG and the WCT show "contralateral" block, this suggests VT. For example, a patient with underlying RBBB would not be expected to conduct with a LBBB pattern during SVT. If the QRS duration of the WCT is narrower than the baseline QRS duration (e.g., in the presence of BBB) then this strongly suggests VT. Although extremely rare, this would be considered to be quite specific for VT.
- Preexcitation, noting that for some accessory connections (e.g., left lateral pathways) the delta wave may be quite subtle (**Fig. 11**).
- Ectopic beats. Even if the baseline ECG has narrow (<120 ms) QRS complexes, premature atrial contractions (PACs) may be seen to conduct with BBB (Ashman's phenomenon). The morphology of these beats should be compared with the WCT, since they may suggest that functional BBB could be present at higher heart rates. If frequent premature ventricular contractions (PVCs) are seen, these too can be compared to the morphology of the WCT.
- Paced beats.

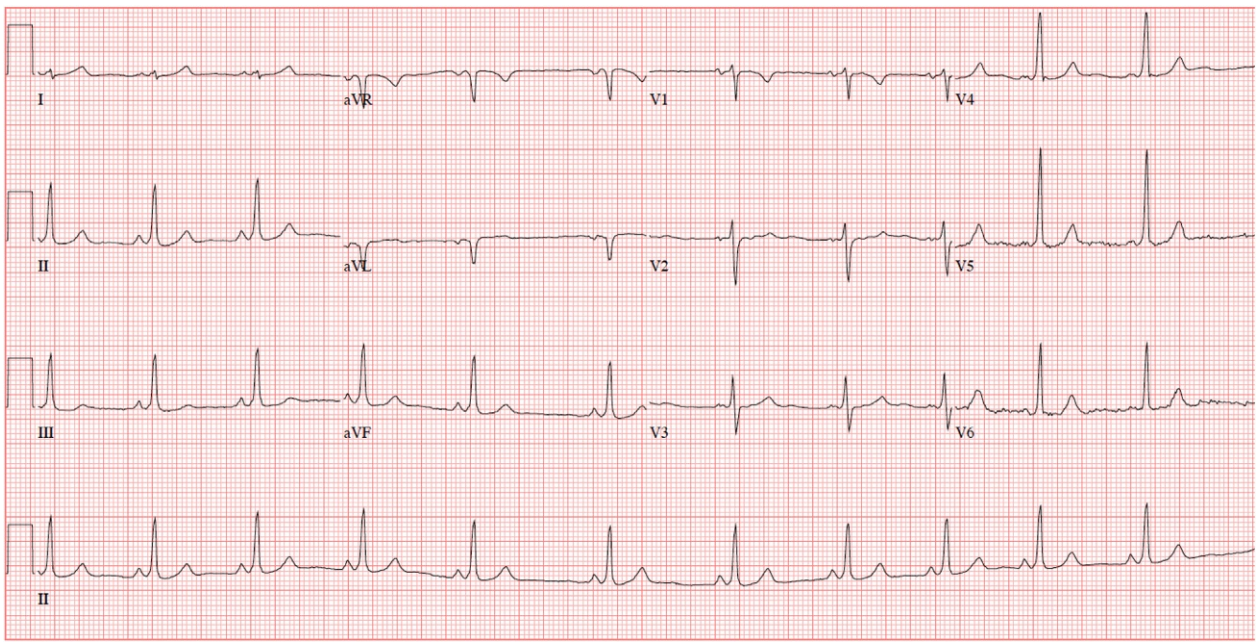

Fig. 11 ECG in sinus rhythm showing subtle preexcitation, with small delta waves seen most clearly in the inferolateral leads. ECG recorded at 25 mm s^{-1}.

- Evidence of channelopathies such as Brugada syndrome or long-QT syndrome; and other cardiomyopathies such as hypertrophic cardiomyopathy or arrhythmogenic right ventricular cardiomyopathy (ARVC). The presence of these conditions would increase the likelihood of VT, although, of course, other supraventricular dysrhythmias could coexist.
- The baseline atrial rhythm. If sinus rhythm is present then it should be noted which ECG leads have the largest P wave amplitude, since this may help to identify dissociated atrial activity during the WCT. If AF is the baseline rhythm, then AV dissociation is unlikely to be seen during the WCT. If AFL or AT is the baseline rhythm, then it should be determined whether the cycle length of the atrial rhythm is related to the cycle length of the WCT (e.g., in a 1:1 or 2:1 relationship).
- The overall QRS morphology should be noted and can help when examining the WCT for capture or fusion beats.

ECG during tachycardia

A systematic approach to the WCT ECG may help to discern diagnostic clues. The following aspects should be examined.

AV relationship

The ECG should be carefully examined for any evidence of atrial activity, including P waves or flutter waves. If AV dissociation is seen, where independent rhythms are identified in the ventricle and atria (usually sinus rhythm) then this is highly specific for VT. Capture and fusion beats (see **Fig. 1**) are further evidence of AV dissociation and will generally also indicate VT (although note that during SVT with BBB, an appropriately timed PVC ipsilateral to the side of the BBB could "fuse" with the conducted rhythm, causing that QRS complex to be narrower). It should be noted too that AV relationships other than complete dissociation can also be diagnostically useful. Any time more ventricular beats than atrial beats are seen, it is highly likely that the WCT is VT. In addition to a (slower) dissociated atrial rhythm, this also includes 2:1 retrograde atrial activation (**Fig. 12**) or retrograde Wenckebach conduction. Conversely, if more atrial beats than ventricular beats are seen then the WCT most likely has a supraventricular origin (usually AFL [**Fig. 13**] or AT).

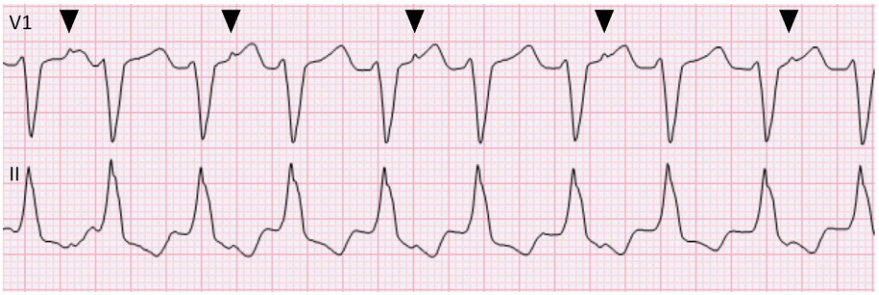

Fig. 12 ECG rhythm strip, recorded at 25 mm s^{-1}, showing a wide complex tachycardia with 2:1 retrograde conduction. P waves are visible after every other QRS (black arrowheads). This finding is highly specific for ventricular tachycardia.

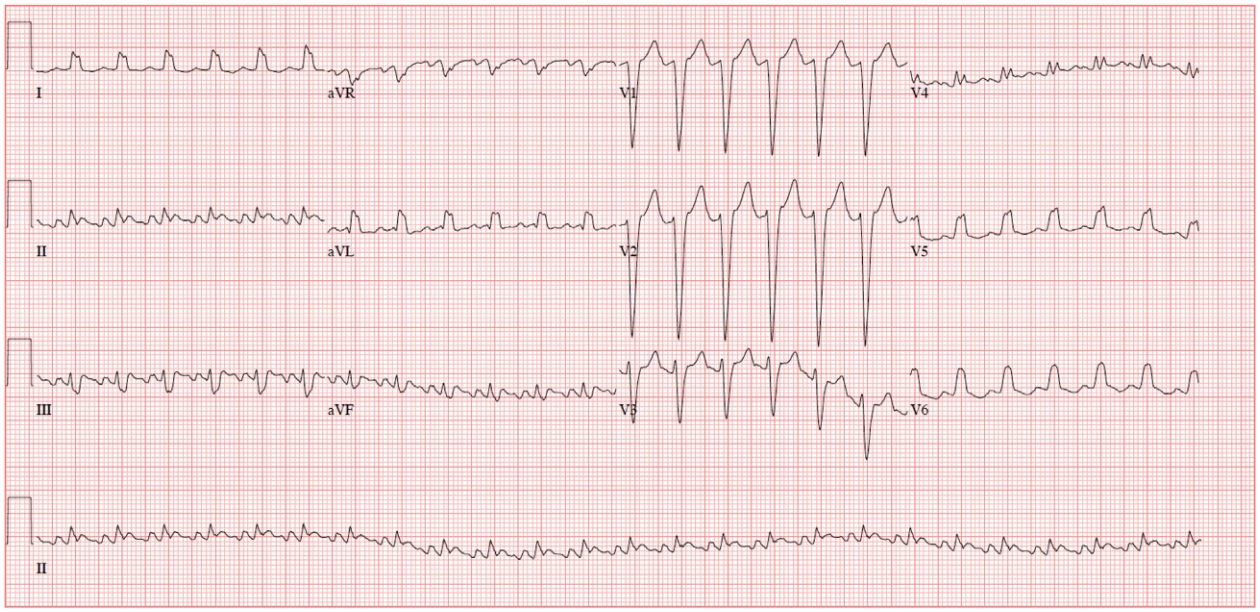

Fig. 13 ECG from a 48-year-old female with a wide complex tachycardia at 150 bpm. In the inferior leads there is the suggestion of atrial activity at twice the ventricular rate. When the rhythm was later slowed pharmacologically, the atrial rhythm was found to be typical atrial flutter. The QRS morphology is typical for left bundle branch block. ECG recorded at 25 mm s^{-1}.

The presence of AV dissociation in VT ranges from 21% to 31%. Brugada et al. noted in their prospective study that only 21% of 172 VTs had readily apparent AV dissociation (Brugada et al., 1991). Miller et al. examined the AV relationship in 473 cases of VT and 132 cases of SVT with aberrant conduction (Miller et al., 2006). The first thing to note is that the AV relationship could not be determined in around half of all cases. A 1:1 AV relationship was more likely to be seen in SVT cases (52%) than VT cases (8%). In the cases proven to be VT, AV dissociation was seen in 31%, 2:1 VA conduction in 4% (see **Fig. 12**), and VA Wenckebach in 1%, making the VA relationship diagnostically useful in 36% of VT cases. These three findings were never seen in SVT, making them 100% specific for VT. However, given the discussion earlier, the absence of these findings does not rule out VT.

QRS width

The width of the QRS during tachycardia also yields clues regarding the nature of the tachycardia. The typical QRS duration during RBBB is 120–130 ms with LBBB being longer at around 140 ms. It is unusual for SVT to have a QRS with RBBB morphology and a QRS duration >140 ms or LBBB morphology and a QRS duration >160 ms (Wellens et al., 1978). Therefore, in these cases, VT should be suspected. Some caveats are that: (1) in the presence of drugs which prolong the QRS duration (particularly Class 1C agents like flecainide) the aberrantly conducted beats can be wider than usual; (2) preexcited tachycardias can have markedly widened QRS complexes, especially when conduction is over a right or left free wall accessory pathway; (3) some patients with congenital heart disease may have RBBB with a markedly widened QRS (**Fig. 14**).

QRS axis

Analysis of the QRS in the frontal plane (I, II, III, aVL, aVR, aVF) can also be helpful in differentiating SVT from VT. The QRS axis can easily be measured and can be quite useful if the axis is between −90 and −180 degrees otherwise known as the "northwest quadrant" or "right superior" axis (**Fig. 15**). Typical fascicular blocks range between −30 and −90 degrees for left anterior fascicular block, and 110 and 150 degrees for left posterior fascicular block. Therefore, a marked deviation from these suggests VT (Wellens et al., 1978). This observation is true for VT with a RBBB configuration but has been questioned in VT with a LBBB configuration (Kindwall et al., 1988).

QRS concordance

Analysis of the precordial leads (V1–V6) is useful as it may show abnormal progression of the QRS complexes. If the QRS is predominantly positive or negative in leads V1–V6, it is said to have positive or negative concordance, respectively, which favors VT with a specificity of 90%–95% (Miller et al., 2006), see **Figs. 2** and **3**). A rhythm with negative concordance suggests an origin at the apex of the heart (e.g., consider the morphology of RV apical pacing), while positive concordance suggests an origin from the base or posterior wall of the left ventricle. The latter would include VT from this site or conduction over a left posterior accessory pathway, so it is not 100% specific for VT.

QRS morphology

Morphological criteria suggesting VT or BBB can be subtle and depend largely on a clinician's familiarity with typical bundle branch block patterns. In general, these criteria rely on identifying how closely the QRS morphology of the tachycardia matches the

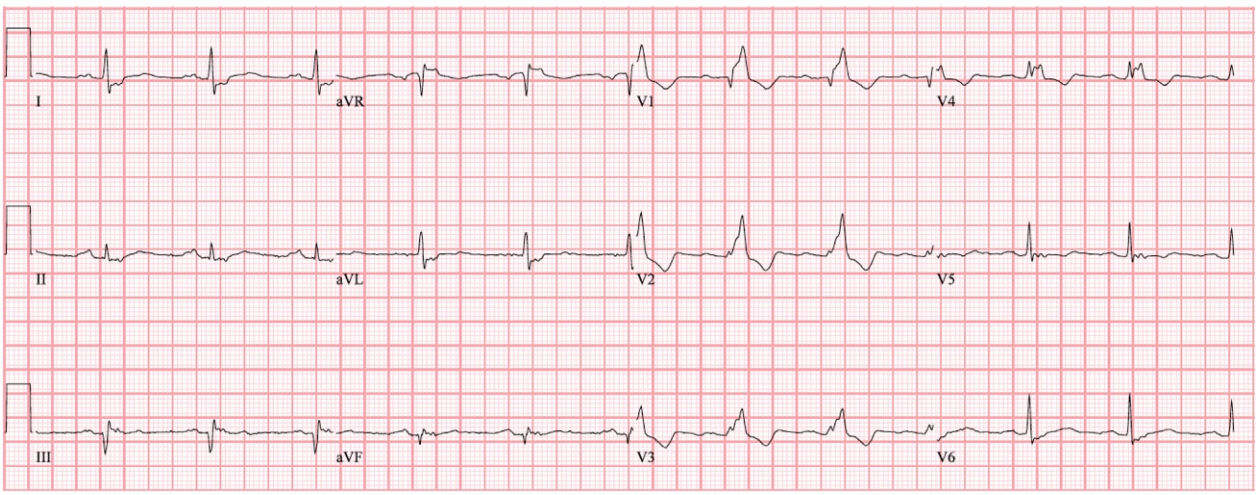

Fig. 14 Baseline ECG in a patient with congenital heart disease (Uhl's anomaly) demonstrating right bundle branch block with markedly widened QRS complexes (QRS duration 200 ms). ECG recorded at 25 mm s^{-1}.

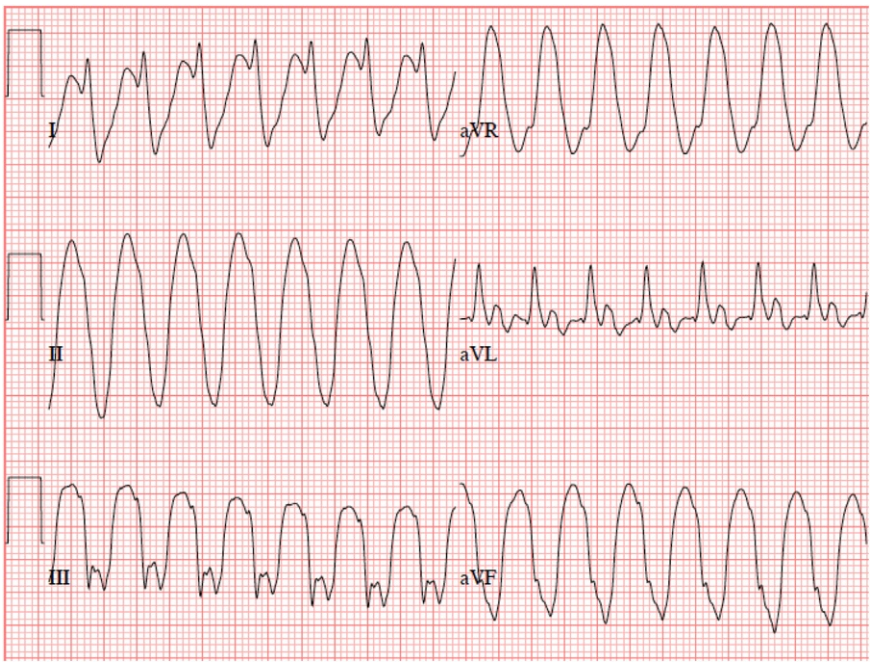

Fig. 15 ECG limb leads, recorded at 25 mm s^{-1}, showing right superior or "Northwest" axis deviation, and wide, bizarre QRS complexes, in a patient with ventricular tachycardia.

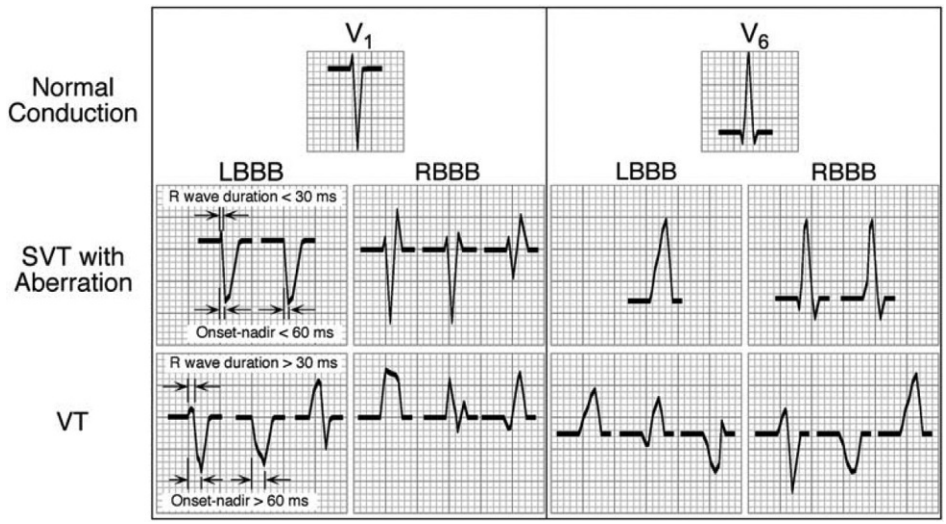

Fig. 16 QRS morphology patterns in leads V1 and V6 which may help differentiate SVT with aberrant conduction from VT. In the case of SVT with aberration, the QRS morphology shows the typical appearances for left or right bundle branch block, generally with rapid initial forces and delay later in the QRS. In the case of VT, the QRS morphology is more atypical, often with delay at the start of the QRS complex. *LBBB*: left bundle branch block; *RBBB*: right bundle branch block; *SVT*: supraventricular tachycardia; *VT*: ventricular tachycardia. Reproduced, with permission, from Miller, J. M., Das, M. K., Yadav, A. V., Bhakta, D., Nair, G., Alberte, C. (2006). Value of the 12-lead ECG in wide QRS tachycardia. *Cardioliology Clinics* **24**, 439–451 (their Fig. 5).

expected typical findings for BBB, where the closer the match, the more likely it is to be SVT with BBB, and the more disparate the appearances, the more likely it is to be VT. Within these criteria, attention is also focused on the initial portion of the QRS since in BBB the activation here is generally rapid (since it uses the normal conduction system of the working bundle) while in VT it is slowed (since it occurs by cell-to-cell conduction). Fig. 16 summarizes some of these criteria.

WCT with "RBBB-morphology" QRS In an SVT with typical RBBB, one should note:

- The QRS duration exceeds 120 ms.
- The QRS in V1 is described as triphasic with an rsr′, rsR′, or rSR′ pattern. The initial r reflects normal septal activation; the S reflects LV activation and the R′ reflects late activation of the RV. Whereas in leads I, aVL and the left precordial leads, the S wave is wider than the preceding R wave due to the late depolarization of the right ventricle via slow conduction from myocyte-to-myocyte (Wellens and Conover, 2006; Mirvis and Goldberger, 2015).
- In the absence of coexisting left fascicular block, the axis is typically normal in the limb leads.

"RBBB" QRS patterns that are highly suggestive of VT include a monophasic (R), or biphasic (qR, QR) in V1 (Marriott, 1970). It is important to note that there are limitations to these generalizations as large Q waves on baseline ECGs can make an SVT look biphasic. When these characteristics were assessed by Brugada et al., they noted 84% specificity for VT for the monophasic R, 98% specificity for a QR or RS, and 91% specificity for the triphasic configuration (Brugada et al., 1991). Therefore, looking at additional leads can help provide consistency in findings. The QRS morphology in lead V6 suggests VT if the R:S ratio is <1 (Wellens et al., 1978). However, the specificity of this finding was found to be only moderately useful with a value of 76%–79% in other studies (Miller et al., 2006; Brugada et al., 1991).

WCT with "LBBB-morphology" QRS WCTs with a LBBB morphology are more complicated and careful examination of leads V1, V2, and V6 are critical. In an SVT with typical LBBB, one would expect (Wellens and Conover, 2006; Mirvis and Goldberger, 2015):

- The QRS duration exceeds 120 ms
- Broad, notched, or slurred R waves in leads I, aVL, V5, and V6. The initial R from septal activation is reversed from that seen in a RBBB or narrow QRS, as septal depolarization occurs from right to left. Depolarization then occurs from the RV followed by LV activation.
- There is a small or absent initial r in V1 and V2 (less than 30 ms) followed by a deep S wave.
- The downstroke of the S wave is rapid without slurring or notching.

ECG criteria for distinguishing VT from SVT with BBB Kindwall et al. suggested four ECG criteria to differentiate VT from SVT in LBBB-morphology WCT (Kindwall et al., 1988). These are:

1. The width of the r in V1–V2. Durations of longer than 30 ms are suggestive of VT.
2. Presence of a Q wave in V6. As described earlier, septal depolarization in a typical LBBB occurs from right to left due to the LBBB. Thus, an initial R would be expected.
3. Onset of QRS to the nadir of the S wave in V1 or V2 being >60 ms.
4. Notching on the downstroke of the S wave in V1 or V2.

All four criteria were found to be specific for VT in the original paper (ranging from 94% to 100%), but less so in subsequent papers, including Miller et al. who reported that the specificity of QRS onset to nadir of the S wave >60 ms was 85% (Miller et al., 2006).

Where Kindwall et al. had suggested that onset of the R to the deepest part of the S in V1 and V2 in LBBB WCT could be used to differentiate VT from SVT, Brugada et al. suggested that the longest RS interval in any precordial lead exceeding 100 ms would be suggestive of VT (Brugada et al., 1991). This removes the complexity of having the observers be comfortable with recognizing the bundle branch block morphology and their individual nuances. Brugada et al. observed that RS intervals of >100 ms were only seen in VT, and that absence of any RS complex in any of the precordial leads was seen only in VT. They concluded these findings were 100% specific. Absence of RS was only seen in 21% of VTs, and an RS interval >100 ms was seen in 66% of VTs in the original report. Subsequent reports found these to be 93% specific (Vereckei et al., 2007; Vereckei et al., 2008).

As a measure of slow conduction through myocardium, Verekei et al. proposed that a ratio of the amplitude of the initial 40 ms of the QRS to the terminal 40 ms of the QRS (V_i/V_t) of <1 would be specific to VT (Vereckei et al., 2007). These could be measured in any lead where the QRS was best visualized. They noted the $V_i/V_t < 1$ criteria had a specificity of 82% for VT.

In the subsequent year, Verekei et al. published another paper focusing on lead aVR, using the width of the initial q or r wave >40 ms as a marker for VT (Vereckei et al., 2008). While this was insensitive, with only 28% of VTs having a q or r wave in aVR, it was fairly specific with a reported specificity of approximately 92%.

Another group proposed using lead II to assess slow ventricular depolarization in VT, using the R-wave peak time (RWPT) >50 ms to detect VT (Pava et al., 2010). RWPT was defined as onset of the QRS to the first change of polarity, independent of whether the QRS deflection was positive or negative. They looked at 218 patients who had undergone EP studies for different reasons and reported an initial sensitivity of 93% and specificity of 99%. Its main benefit over the previous algorithms is simplicity. RWPT was assessed by another group, comparing it to the Verekei aVR algorithm and found it did surprisingly well despite its apparent simplicity, with 74%–85% specificity (Szelényi et al., 2013). However, its sensitivity was quite low at 62%–79% versus the Verekei aVR algorithm which had sensitivities in the 91%–93% range.

The presence of multiple WCT morphologies also suggests VT. Scar tissue can result in circuits with different exit points and thus different morphologies in VT. Miller and Das analyzed 861 patients assessed for WCT with an EP study and found that 266/524 (50%) of patients with VT had multiple WCT morphologies whereas only 31/392 (8%) of patients in SVT did (Miller and Das, 2009).

Application of a new algorithm in the differential diagnosis of wide QRS complex tachycardia. *European Heart Journal* **28**, 589–600 (their Fig. 3); Vereckei, A., Duray, G., Szénási, G., Altemose, G. T., Miller, J.M. (2008). New algorithm using only lead aVR for differential diagnosis of wide QRS complex tachycardia. *Heart Rhythm* **5**, 89–98 (their Figs. 1 and 3).

Stepwise algorithms for distinguishing VT from SVT with BBB Several algorithms have been published to improve the sensitivity and specificity by combining multiple ECG findings. The most popular of these were published by Brugada et al. (1991), see Fig. 17) and the two algorithms by Verekei et al. (2007); Vereckei et al. (2008), see Figs. 18 and 19). Initial sensitivities and specificities were >90%, but real-world application by cardiologists and emergency doctors tends to yield poorer results (Isenhour et al., 2000; Jastrzebski et al., 2012; Szelényi et al., 2013).

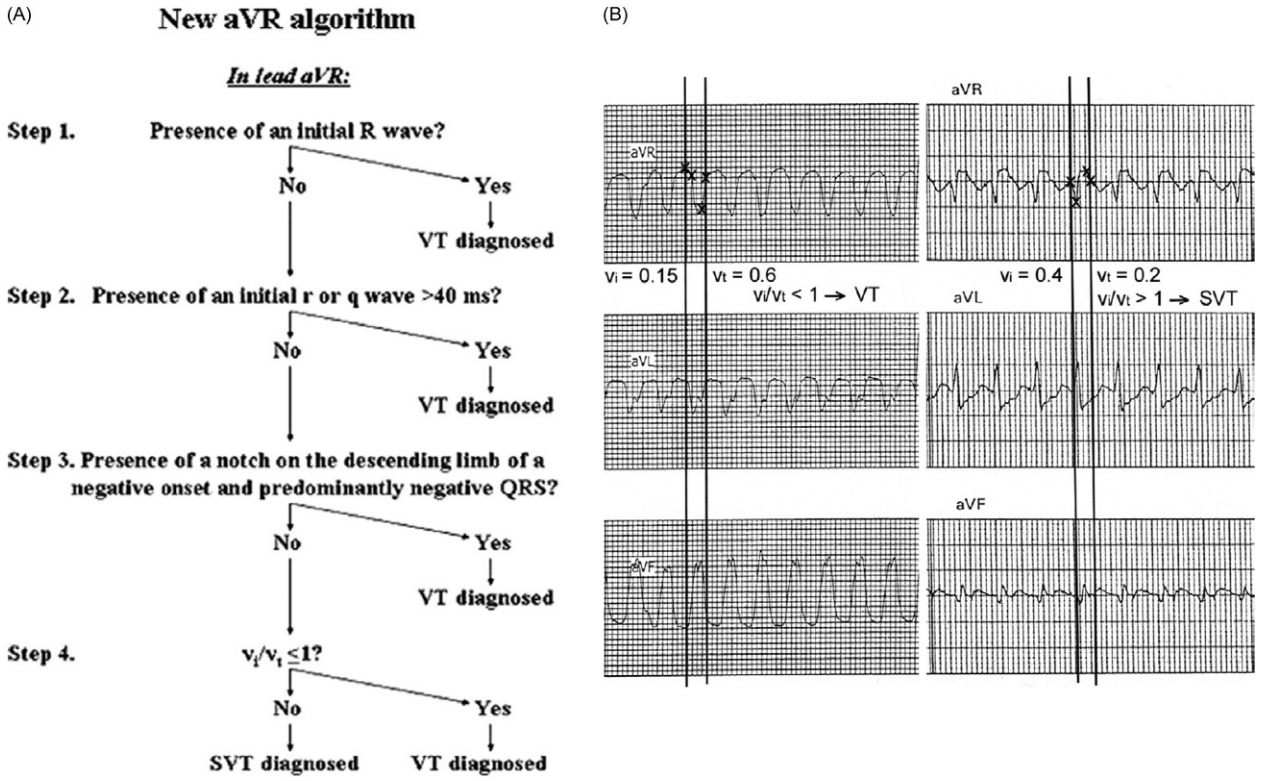

Fig. 19 (A) Simplified stepwise algorithm from Vereckei et al for differentiating VT from SVT with aberrant conduction, using Lead aVR alone. (B) Method for calculating V_i/V_t for step 4 of the algorithm. V_i is the voltage change, in mV, of the initial 40 ms of the QRS complex, while V_t is the same measurement made for the terminal 40 ms of the QRS complex. SVT: supraventricular tachycardia; VT: ventricular tachycardia. Reproduced, with permission, from Vereckei, A., Duray, G., Szénási, G., Altemose, G. T., Miller, J. M. (2008). New algorithm using only lead aVR for differential diagnosis of wide QRS complex tachycardia. *Heart Rhythm* **5**, 89–98 (their Figs. 1 and 3).

One of these studies assessed the performance of several algorithms/methods: Brugada, Bayesian, Griffith, Verekei aVR and RWPT (Jastrzebski et al., 2012). All five methods had only moderate accuracy (69%–77%). Overall, the Brugada algorithm had the best balance of sensitivity (89%) and specificity (59%) compared to the other criteria. A Bayesian approach involving 19 features (Lau et al., 2000) did not perform better than the much simpler Brugada algorithm. The Griffith approach yields slightly better sensitivity (94%) as it presumes all WCT to be VT until proven otherwise. However, this is at the expense of specificity (39%). The lead II RWPT had the highest specificity (83%) but at the expense of sensitivity (60%).

Despite the advances and further refinements in ECG interpretation, there is no single algorithm that can reliably differentiate SVT from VT. The most specific finding for VT, AV dissociation, is found only in a small proportion of VTs (approximately 30%). Attempts to increase the sensitivity unfortunately decrease the specificity. The more tools a clinician has in his toolbox, the greater the chance of an accurate diagnosis, although sometimes assuming that the WCT is VT can be the safest approach, particularly if the diagnostic criteria give disparate results.

Cardiac imaging Most of the literature on the differentiation of SVT from VT aims at interpretation of the ECG. However, imaging may also prove useful in assessing the likelihood the arrhythmia is VT, by providing an assessment for structural heart disease. While a normal echo or magnetic resonance imaging (MRI) cannot rule out VT, an abnormal study would increase the likelihood of VT (Tandri et al., 2004). Reduced LV ejection fraction is a crude measure which correlates with the risk of VT and sudden cardiac arrest (Vest and Gold, 2010). Some imaging studies have tried to provide a more refined estimate of the risk of ventricular arrhythmias. Cardiac MRI studies suggest that the extent of the ventricular scar, as well as tissue heterogeneity may be correlated to an increased likelihood of ventricular arrhythmia in ischemic heart disease (Schmidt et al., 2007). Cardiac MRI has also been shown to predict VT in other patient groups including hypertrophic cardiomyopathies (Nojiri et al., 2011; O'Hanlon et al., 2010), dilated cardiomyopathies (Gao et al., 2012), ARVC (Mavrogeni et al., 2012; Jain et al., 2008; Sen-Chowdhry et al., 2007), Tetralogy of Fallot (Tsai et al., 2010)), and chronic Chagas' disease (Rochitte et al., 2005).

Cardiac implantable device interrogation It is becoming more and more common for patients to present with an undifferentiated arrhythmia in the presence of a cardiac device. Proper interpretation of stored device episodes and electrograms may aid in the differentiation of VT from SVT and lead to the appropriate clinical management. The amount of information available will depend on the type of device (implantable loop recorder, pacemaker, or ICD), manufacturer of the device, and number of leads (single versus dual chamber).

The first consideration is that any patient with an ICD in place will either have had prior ventricular arrhythmias (secondary prevention ICDs) or have been judged to be at higher risk of ventricular arrhythmias (primary prevention ICDs). Thus, their pretest probability of VT will already be significantly elevated. However, such patients may also have BBB and coexisting arrhythmias, including SVT and other atrial arrhythmias, so it is not unusual for them to have other mechanisms for a WCT. Some device findings may be diagnostically useful.

The ventricular rate of an episode alone is a fairly poor discriminator and can lead to inappropriate therapy for SVT in up to 45% of cases at 1 year (Dorian et al., 1999). The MADIT-RIT trial noticed a very high rate of inappropriate therapies with frequent atrial tachyarrhythmias occurring in the range of 170–199 bpm and failure of the device to discriminate between atrial and ventricular tachyarrhythmias (Moss et al., 2012). ATs were significantly less frequent at higher rates (over 200 bpm). Changes in local or far-field electrogram morphology compared to the baseline rhythm are also poor discriminators for VT versus SVT with BBB, since differences may occur in both cases. In a dual-chamber device, the most useful diagnostic information can come from examining the AV relationship during an episode of WCT. In contrast to ECG interpretation, where P waves can be difficult to discern, up to 90% of VTs have been reported to show AV dissociation on dual-chamber ICDs (Swerdlow, 2001). In approximately 3% of patients with ICDs, VT occurs in the setting of AF (Stein et al., 1999). The combination of regularity of the ventricular rhythm and AF (not AFL) in the atrium is highly successful in distinguishing VT.

Invasive EP study For many of the published studies on differentiation of SVT from VT, the EP study was used as the gold standard for diagnosis, and this can also be the case in clinical practice. Pacing protocols can allow the induction of tachycardia, which can be compared to the clinical WCT. Intracardiac recordings and pacing maneuvers can identify substrates for SVT or confirm that the rhythm is ventricular. There is also the opportunity for curative ablation of SVT circuits. Ablation would not typically be employed as first-line therapy for VT in the setting of ischemic or nonischemic cardiomyopathy but could be considered for outflow tract VT, fascicular (Belhassen) VT, and bundle branch reentry VT.

Particular Types of WCT With Classic Electrocardiographic Features

Table 1 outlines several forms of WCT which may be recognized from their classic ECG appearances. Identification of these mechanisms is important since they may be treated with ablation (also reviewed in Issa et al., 2012).

Identification of Preexcited Tachycardias

Access to an ECG in sinus rhythm greatly aids in the identification of preexcited tachycardias, especially when the preexcitation is readily apparent and can be compared to the WCT being considered. It is important to remember that ventricular activation in sinus rhythm will usually involve fusion between activation over the normal conduction system and activation over the accessory pathway. Often in a regular preexcited tachycardia, ventricular activation occurs exclusively over the accessory pathway (the ECG shows maximal preexcitation), so there can be significant differences in the overall QRS morphology between these two situations. ECG clues may be used to help differentiate between VT and SVT with antegrade conduction over an accessory pathway. Brugada and coworkers developed some criteria for distinguishing preexcited tachycardias (Antunes et al., 1994). These focused on the following features:

- Preexcited tachycardias activate from base to apex, therefore leads V4–V6 are predominantly positive. Negative complexes in V4–V6 therefore favor the diagnosis of VT.
- In the absence of structural heart disease, QR complexes should not be observed during preexcited tachycardia; therefore this favors the diagnosis of VT.
- AV dissociation, as this is nearly 100% specific for VT.

Based on these criteria, they found that preexcited tachycardias were all appropriately identified. However, 25% of VTs were misdiagnosed as preexcited tachycardias, signifying caution when applying these criteria. This is not surprising, since VT with an exit near the mitral or tricuspid annulus could look identical to a preexcited tachycardia with the ventricular insertion of the accessory pathway at this site.

Approach to Irregular WCT

As listed earlier, the main differential diagnosis of an irregular WCT includes atrial dysrhythmias (AF, AFL with variable AV conduction, AT with variable AV conduction, MAT) conducted with BBB or over an accessory pathway, polymorphic VT, VF, and artifact. In keeping with the approach to regular WCT, the patient's prior medical history (including medications) and current clinical context can aid in making the rhythm diagnosis. Baseline ECGs should be examined in particular for the atrial rhythm, any evidence of ischemia, infarction, or preexcitation, and any QT prolongation or other abnormalities suggesting a cardiomyopathy. The serum potassium level should be checked since hypokalemia can induce or exacerbate QT prolongation and increase the risk of torsades de pointes VT.

Table 1 Selected wide complex tachycardia diagnoses with classic electrocardiographic features

Tachycardia	*WCT type*	*Classic ECG findings*	*Notes and references*
Right ventricular outflow tract (RVOT) VT	VT	• LBBB-morphology QRS • Inferior frontal axis • V3 R/S <1	Lerman (2015)
Left ventricular outflow tract (LVOT) VT	VT	• LBBB-morphology QRS • Inferior frontal axis • V3 R/S >1 • V3 R $=$ S	Origin can be below or above the aortic valve. Nogami (2002) and Lerman (2015)
Idiopathic LV VT (also referred to as "Belhassen VT" and LV fascicular VT)	VT	• RBBB-morphology QRS • QRS duration 100–140 ms • Left axis deviation • R/S <1 in V1–V2	"Common type" of idiopathic LV VT has left-axis deviation; other types can have rightward or normal axis Nogami (2002)
Bundle branch reentry VT	VT	• BBB pattern matching conducted rhythm • AV dissociation may be apparent	Generally seen in the context of significant baseline conduction system disease $\pm$ structural heart disease LBBB morphology is the most common (normal or left-axis deviation) Bundle branch reentry with a RBBB morphology usually has a normal or right axis deviation
Bidirectional VT	VT	• Alternating QRS axis	Associated with CPVT, digitalis toxicity, and Anderson–Tawil syndrome Wellens and Canover (2006) and Smith et al. (2006)
Atriofascicular reentry tachycardia	SVT	• LBBB-morphology QRS • Frontal axis can be normal, horizontal, or leftward • QRS duration often minimally prolonged or normal	Gandhavadi et al. (2013)

AV: atrioventricular; *BBB*: bundle branch block; *CPVT*: catecholaminergic polymorphic ventricular tachycardia; *LBBB*: left bundle branch block; *LV*: left ventricular; *RBBB*: right bundle branch block; *SVT*: supraventricular tachycardia; *VT*: ventricular tachycardia; *WCT*: wide complex tachycardia.

Some types of irregular WCT have very characteristic ECG appearances and are often easily recognized. Irregular VT with continuously varying QRS morphology is termed polymorphic VT. When this is associated with baseline QT prolongation and displays a typical "twisting" appearance of the QRS axis around the baseline, it is termed torsades de pointes VT (**Fig. 20**). The other circumstance where polymorphic VT is typically seen is in the context of acute ischemia (**Fig. 21**). In this case the baseline QT interval is generally normal and the QRS morphology of the tachycardia tends to vary in a more unpredictable manner than it does with torsades de pointes VT. Ventricular fibrillation (VF) also displays irregularity of ventricular activity in terms of cycle length, amplitude and axis, with a chaotic continuous waveform on the ECG (**Fig. 22**). "Coarse" VF, with larger average amplitudes, may be indistinguishable from polymorphic VT, and both can have the same hemodynamic consequences.

In cases where the QRS complexes are uniform in appearance but occur at an irregularly irregular rate, it should be suspected that the underlying rhythm is AF and that the widening of the QRS complex is due to BBB (**Fig. 23**). The ECG should then be analyzed for the typical appearances of left or right bundle branch block, as described earlier. In the presence of tachycardia and wide QRS complexes it can be hard to determine on the ECG whether the atrial rhythm is AF, AFL, or MAT; however the relative prevalence of each condition means that AF is by far the most likely rhythm. Often the atrial activity can only be determined with certainty when the ventricular rate has been slowed, for example, by medication. Also, if the bundle branch block is functional (rate-related), it may resolve at slower ventricular rates or not be present with every beat, facilitating diagnosis of the atrial rhythm.

AF with preexcitation (**Fig. 24**) is an important diagnosis to make since it has immediate consequences for the acute care of the patient and also strongly suggests that subsequent management should include an ablation procedure. The hallmarks of this dysrhythmia are:

- An irregularly irregular rhythm (which should always raise the suspicion of AF, irrespective of the QRS morphology)
- Variable QRS morphology, typically with differing QRS duration and often the presence of some narrow QRS complexes
- The wide QRS beats show a slurred onset and do not resemble typical left or right bundle branch block

Fig. 20 (A) Lead II rhythm strip, recorded at 25 mm s^{-1}, from a 51-year-old female with chronic nausea and diarrhea, after bowel preparation for colonoscopy. After an initial conducted sinus beat there is an irregular wide complex tachycardia with a characteristic "twisting" of the axis, indicating torsades de pointes VT. (B) Baseline rhythm strip, showing marked QT prolongation (around 600 ms). Her serum potassium was 2.6 mmol L^{-1}, and her medications included fluoxetine and hydrochlorothiazide.

Fig. 21 ECG recorded from a 60-year-old male with chest pain. There are repeated bursts of irregular, polymorphic VT, and the inferior leads show around 1 mm of ST elevation. This ECG was taken shortly after reperfusion of an inferior ST elevation myocardial infarction. ECG recorded at 25 mm s^{-1}.

- Very short coupling intervals may be seen (<250 ms), and when present this increases the risk of sudden cardiac arrest (Attoyan et al., 1994; Orczykowski et al., 2013)
- There is often significant left or right axis deviation.

Bayesian Approach to Diagnostic Testing

Diagnostic tests are rarely, if ever, performed on a homogeneous population of subjects, all with the same probability of having the condition and identical to the population in which the test was originally developed. When applying any diagnostic test in

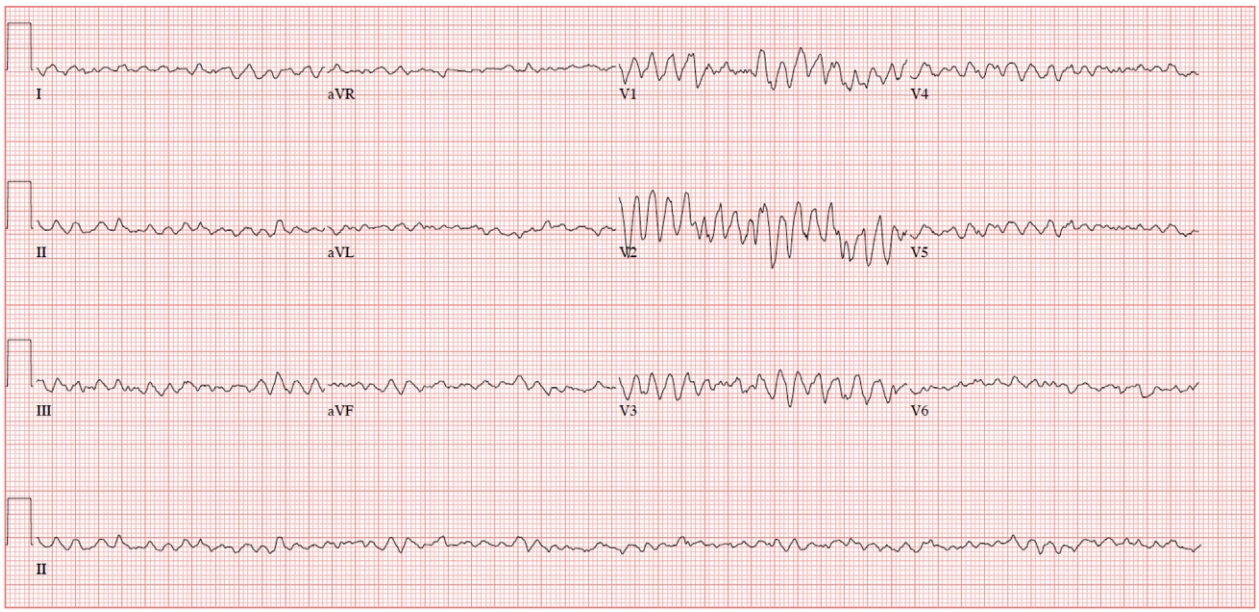

Fig. 22 12-lead ECG showing ventricular fibrillation, recorded from a 60-year-old male with a left ventricular assist device. ECG recorded at 25 mm s^{-1}.

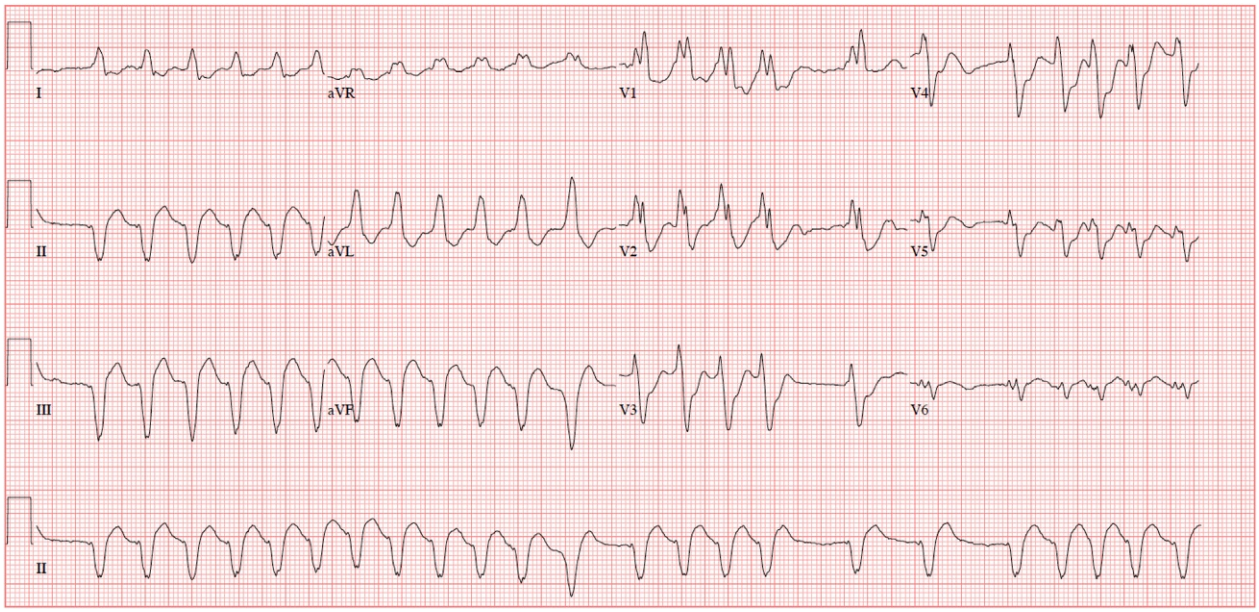

Fig. 23 ECG showing an irregular wide complex tachycardia, recorded from a 66-year-old male with ischemic cardiomyopathy. The ventricular rhythm is irregularly irregular, with no P waves visible during the longer R–R intervals, in keeping with atrial fibrillation. This is conducted with right bundle branch block and left anterior fascicular block, with significant QRS widening (QRS duration around 200 ms). ECG recorded at 25 mm s^{-1}.

medicine, it is important to consider a number of factors when interpreting the test result (or even when deciding to perform the test at all):

- How closely does the patient undergoing the test resemble the population in which the test was derived? For example, if a test was developed in a predominantly male population of subjects over the age of 60, how likely is it to perform well in an 18-year-old female? If there is a large discrepancy in patient demographics and/or comorbidities between a proposed test subject and the test derivation cohort, then there is an increased risk that the test result will be misleading. In these circumstances, it may be better not to perform the test.

Fig. 24 ECG from a 39-year-old female with presyncope. The rhythm is irregularly irregular, with variable QRS morphology, including some narrow QRS complexes. The wide beats show a slurred onset, and there are some very short R–R intervals present (160 ms). These characteristics are typical for preexcited atrial fibrillation. ECG recorded at 25 mm s^{-1}.

- What is the pretest probability that the patient undergoing the test has the condition being tested for? This should take into account the overall prevalence of the condition (is it rare or common?) and any individual patient factors which influence their baseline chance of having the condition. For example, considering a screening test for lung cancer, a smoker will have a higher pretest probability of having the condition than a nonsmoker. As we will shortly see, the pretest probability of the condition can have a critical influence on how the test result should be interpreted. Counterintuitive results can be encountered when the pretest probability is very low or very high, such that for a very rare condition a positive test result can be more likely to be a false positive than a true positive, and, conversely, for a very common condition a negative test result can be more likely to be a false negative than a true negative.
- How well does the test perform? A perfect test would correctly identify all the subjects with and without the condition 100% of the time. In clinical medicine, it is rare for a diagnostic test to perform at this level. Thus, we should always consider how diagnostically accurate the test is when interpreting the results. The performance characteristics of a test can be reported in a number of ways, including the sensitivity (the proportion of subjects with the condition correctly identified by the test, or true positive rate), specificity (the proportion of subjects without the condition correctly identified by the test, or true negative rate), positive predictive value (the proportion of subjects with a positive test result that truly have the condition), and negative predictive value (the proportion of subjects with a negative test result that truly do not have the condition). Another useful measure with regard to diagnostic testing is the likelihood ratio (LR), where the positive-likelihood ratio (LR+) is the true positive rate divided by the false positive rate, and the negative LR (LR−) is the false negative rate divided by the true negative rate. LR+ can also be calculated as sensitivity/(1-specificity) and LR− as (1-sensitivity)/specificity. A likelihood ratio of 1 means that the test has no discriminating ability, a LR >1 means that a positive test increases the chance that the condition is present, while a LR <1 means that a negative test decreases the chance that the condition is present.

The practical application of these factors to diagnostic testing was facilitated by the publication of a nomogram by Fagan in 1975 to aid in calculating the posttest probability of a condition based on the pretest probability and likelihood ratios of the test (Fagan, 1975; Caraguel and Vanderstichel, 2013). This can be applied to the diagnosis of WCT using published ECG algorithms, as shown in **Fig. 25**. For example, if we use the Vereckei aVR algorithm (Vereckei et al., 2008), then the LR+ and LR− for the diagnosis of VT can be calculated from their paper as 3.86 and 0.05, respectively (accepting that in "real-world" circumstances the LRs may not be as good) (Szelényi et al., 2013). Considering a hypothetical patient with a pretest probability of VT of 50% (i.e., VT and SVT+BBB are both felt to be equally likely) then if the algorithm is "positive" for VT, the posttest probability of VT increases to around 80%, and if the algorithm is "negative" then the probability of VT drops to around 5% (**Fig. 25A**). In this case the test (algorithm) provides a good dichotomy between the likelihood of VT or SVT+BBB depending on whether it is positive or negative. Note, however, that a negative test still means there is a 5% chance that the WCT is actually VT. A practitioner should consider whether this is an acceptable "miss rate" for a potentially life-threatening condition. We can now consider a hypothetical patient aged 70 years with prior MI and LV dysfunction, where we judge the pretest probability of VT to be 98% (**Fig. 25B**). If the algorithm is positive then the posttest probability of VT is 99.5%, however if the test is negative then the posttest probability of VT is 70%. This last point is worth stressing:

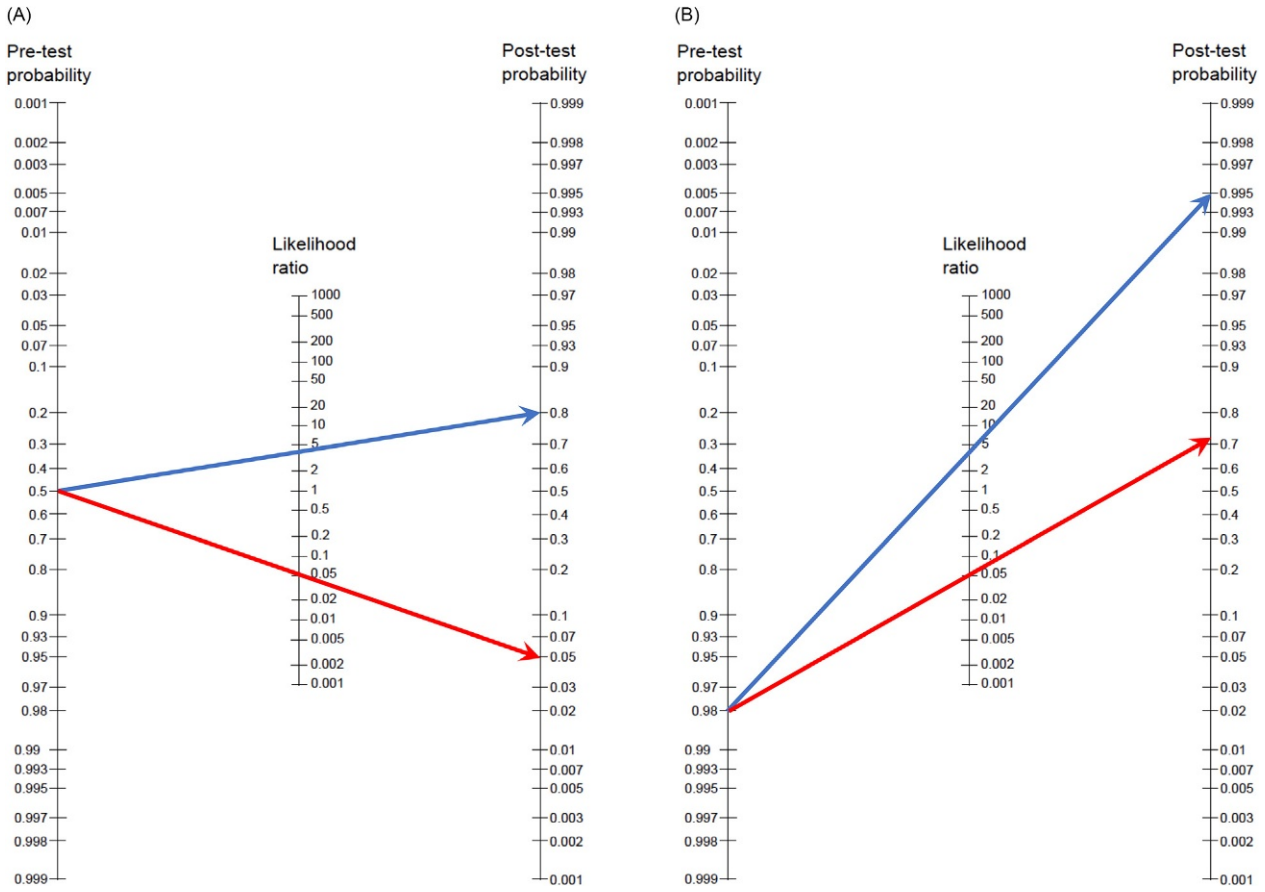

Fig. 25 Illustrative examples of the use of a nomogram for calculating the posttest probability of a condition, based on the pretest probability and performance characteristics (positive- and negative-likelihood ratio) of the diagnostic test. In Panel A, the pretest probability of the condition (in this case VT) is estimated at 0.5 (50%). The diagnostic algorithm of Vereckei et al. is applied, with positive- and negative-likelihood ratios of 3.86 and 0.05, respectively (Vereckei et al., 2008). Each arrow will then indicate the posttest probability for VT if the algorithm is "positive" (*blue arrow*) or "negative" (*red arrow*). In this case the posttest probabilities of VT are 0.8 (80%) for a positive test and 0.05 (5%) for a negative test. Panel B applies the same approach, but for a hypothetical patient with a pretest probability of VT of 98%. In this case the posttest probabilities of VT are around 0.995 (99.5%) for a positive test and 0.7 (70%) for a negative test, the latter indicating a probable false negative result. See text for full discussion. Nomograms from Wikimedia Commons.

in these circumstances a negative test (i.e., the algorithm suggests SVT+BBB) still means there is a 70% chance that the true diagnosis is VT (i.e., a false negative result). Practitioners should bear this counterintuitive fact in mind before deciding to manage the patient according to the test result alone. This reinforces the maxim: if in doubt, treat as VT.

AF Atrial fibrillation
AP Accessory pathway
AV Atrioventricular
WPW Wolff–Parkinson–White syndrome

Preexcitation syndrome is detected in 0.15%–0.5% of the general population. It can be asymptomatic or revealed by a paroxysmal tachycardia and in this case is called Wolff–Parkinson–White syndrome (WPW) with a variable frequency of 4%–90% according to the mode of recruitment. Atrial fibrillation (AF) is rarer. Preexcitation syndrome generally is benign, but ventricular fibrillation may be the first event of this syndrome in 0.1%–0.6% of cases per year. At the time of the curative treatment of preexcitation syndrome by radiofrequency ablation (Warin et al., 1988; Jackman et al., 1991), it is particularly important to detect the forms at risk of sudden death (Klein et al., 1979). Sudden death in preexcitation syndrome is related to the degeneration of AF with high ventricular rates into ventricular fibrillation.

If the prognosis evaluation actually is known, the management of preexcitation syndrome remains dependent on several factors as symptoms, age, sport activity, electrophysiological data, and location of the accessory pathway (AP).

Mechanism of Preexcitation Syndrome

Ventricular preexcitation syndrome is defined by the premature activation of all or part of the ventricles by atrial activity and is related to the presence of an atrioventricular (AV) AP. APs are present during fetal development and should disappear during the first 3 months of fetal development. The bypass of AV node, a physiologic barrier of AV conduction, explains the possible severity of the disease. Bypass tracts that involve the AV node are relatively rare and do not have the same adverse consequences that can occur with bypass of the AV node. Examples include atrionodal APs (called James or Brechenmacher pathways) and nodoventricular APs (also called Mahaim fibers).

Preexcitation can be associated with a congenital heart disease. The frequency (7.5%–17%) is higher in children and mainly concerns Ebstein's anomaly. All heart diseases have been associated with the preexcitation syndrome with a debatable significance but a higher risk of AF.

ECG Diagnosis of Preexcitation Syndrome

The surface ECG in sinus rhythm diagnoses preexcitation with a typical pattern associating a short PR interval (<0.12 s in adults) and a widening of QRS complex with a delta wave (Fig. 1). It is often associated with disorders of repolarization. The pattern is

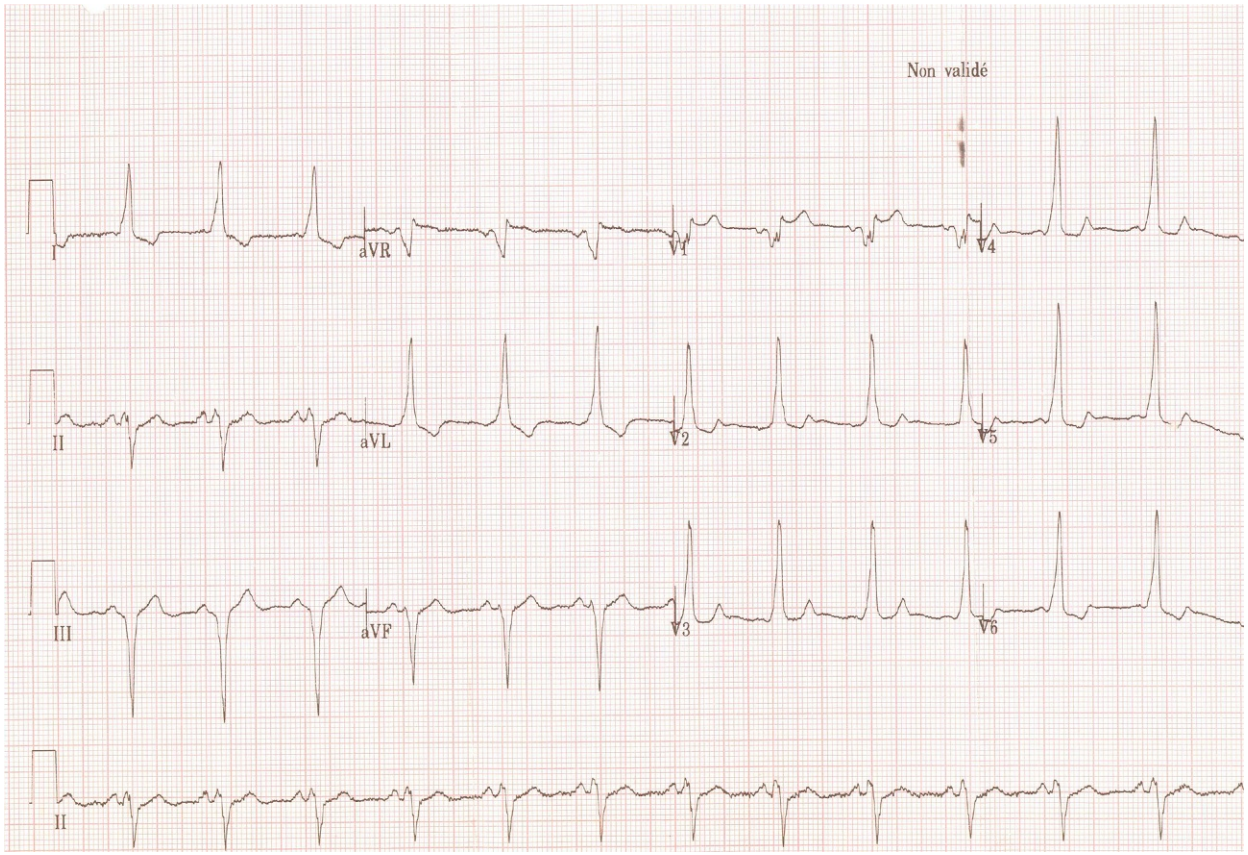

Fig. 1 Typical pattern of a preexcitation syndrome: short PR interval, large QRS complex, delta wave.

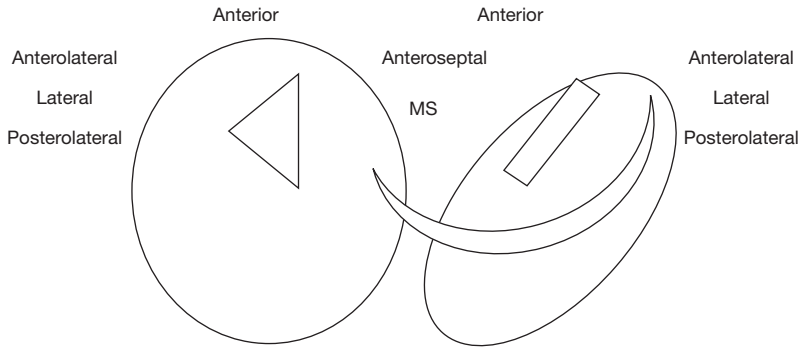

Fig. 2 Schematic cartoon figure with the different pathway locations.

dependent on the location of AP (different AP locations are shown in **Fig. 2**) but also of the properties of AV node and His Purkinje system and there is a wide spectrum of types encountered ECG.

The importance of ventricular preexcitation on ECG in sinus rhythm depends on the quality of the nodohisian conduction and the distance between the AP and the normal conduction system (Brembilla-Perrot et al., 2013a). Ventricular preexcitation is less visible the further away that the AP is from the sinus node and the normal AV system. Therefore, classical electrocardiographic criteria of preexcitation are sometimes not visible on ECG recorded in sinus rhythm (**Fig. 3**).

Spontaneous normalization of ECG with intermittent preexcitation is reported in 20%–30% of cases (Teo et al., 1991; Fujiki et al., 1990). An explanation for the intermittent loss of the delta wave in the preexcitation syndrome may result from precarious conduction over the AP and, as such, would predict a benign prognosis when AF occurs.

Several pharmacological tests were proposed to enhance the pattern of preexcitation when it is doubtful. Under the influence of exercise or emotion, or after isoproterenol infusion, the facilitation of anterograde conduction occurs only in those capable of spontaneous conduction (Easley et al., 1988; Yamamoto et al., 1990; Przybylski et al., 1980). The method was used to differentiate the concealed AP, which has lost its anterograde conduction, from the masked or intermittent preexcitation. Adenosine by blocking

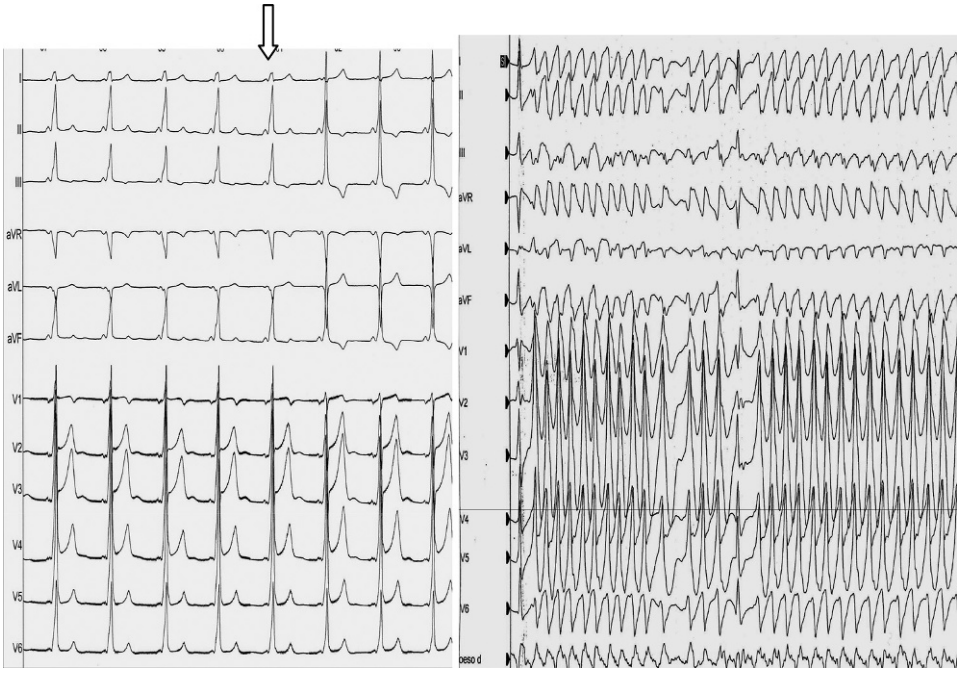

Fig. 3 Masked preexcitation; the minor signs in sinus rhythm only are visible after ablation of AP (the *arrow* indicates the beginning of ablation). However this patient presented with a spontaneous malignant form (AF with minimal cycle conducted by AP $\leq$250 ms).

the conduction in the AV node was used to unmask preexcitation (Garratt et al., 1990; Morgan-Hughes et al., 1993), but the test rarely is used and it is not specific.

Atrial pacing remains the most reliable technique to identify anterograde conduction over AP.

Natural History of Preexcitation Syndrome

A pattern of preexcitation is noted among 0.1%–0.5% of the population (Pelliccia et al., 2007). The frequency is higher in young children; AP tends to degenerate earlier than the normal AV conduction system, but the disappearance occurs early generally before the age of 1 year (50%) and more rarely before the age of 12 years (Vignati et al., 2000) and in this last case only when the refractory period of AP is long (Perry and Garson, 1990). Despite a normalization of ECG, the AP still can conduct by the retrograde way explaining the reentrant tachycardia in patients with a normal ECG. When the refractory period of AP noted before the age of 12 years is short, no disappearance can be expected (Chen et al., 1996).

Detected after the age of 5 years, spontaneous regression is rare since the appearance ECG remains unchanged in 75% after a mean follow-up of 7 years (Perry and Garson, 1990). However, electrophysiological data change with an increase in the refractory period of AP but an increased risk of AF (Chen et al., 1996).

Clinical Signs and Prognosis

The presence of AP exposes to the occurrence of two tachycardias: the most common is the reciprocal tachycardia rhythm called orthodromic AV reentrant tachycardia that usually characterizes the symptomatic forms of the disease (WPW syndrome). This tachycardia uses AV node for the anterograde conduction and AP for the retrograde conduction (**Fig. 4**). Tachycardia presents as a narrow-regular QRS tachycardia. Antidromic tachycardia, related to the anterograde conduction over AP and the retrograde conduction over AV node, is rare and generally a finding of electrophysiological study (**Fig. 5**). The tachycardia presents as a wide QRS tachycardia mimicking a ventricular tachycardia.

The less common is AF (10%) but represents the possible severity of the condition when the AP has a short refractory period: arrhythmia is conducted in 1/1 to the ventricles and can degenerate into ventricular fibrillation, leading to sudden death (**Fig. 6**). The sudden death presentation has mainly been reported in athletes. This is likely because they are subject to a high level of catecholaminergic influence that facilitates the occurrence of arrhythmias and improves conduction in the AP.

However, the prognosis of preexcitation syndrome is discussed according to the type of study population and recruitment. If this is a population detected in preventive medicine, the risk of sudden death is low. However, this event may occur in a subject completely asymptomatic until then, with a similar impact to that of symptomatic subjects: 26%–56% of patients with a

Fig. 4 Induction of an orthodromic AV reentrant tachycardia, when the refractory period of AP is obtained.

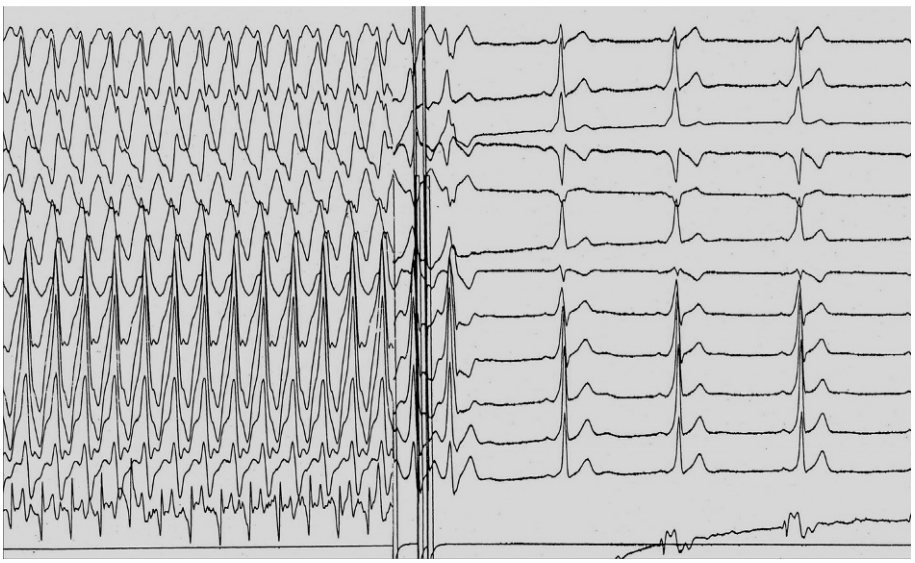

Fig. 5 Antidromic tachycardia (stopped by atrial stimulation): wide QRS tachycardia presenting as a ventricular tachycardia).

preexcitation syndrome were asymptomatic before sudden death (Klein et al., 1979; Timmermans et al., 1995; Torner Montoya et al., 1991). Sudden death incidence however is low and rare in children (0.02%–0.6% per year) (Timmermans et al., 1995; Munger et al., 1993; Beckman and Lamb, 1968; Fitzsimmons et al., 2001; Pappone et al., 2003; Brembilla-Perrot et al., 2010). The most recent study (Fitzsimmons et al., 2001) reports a sudden cardiac death risk of 0.02%/patient/year, while the supraventricular tachycardia incidence was 1% per patient-year. In addition, adverse events sometimes have been reported in very old patients or very early but exceptionally in young children between 6 days and 12 years, especially in cases of associated congenital heart disease. In symptomatic subjects, adverse event may be due to a prolonged supraventricular tachycardia responsible for ischemic events or heart failure. Sudden death also can be related to the use of drugs that promote conduction in the AP as calcium channel blockers (Brembilla-Perrot et al., 2010) or more rarely digoxin. The risk of sudden death is low, but these sudden deaths are very regrettable, concerning patients with normal heart but the presence of AP and easy to cure. Therefore, the detection of patients with preexcitation syndrome at risk of sudden death is fundamental.

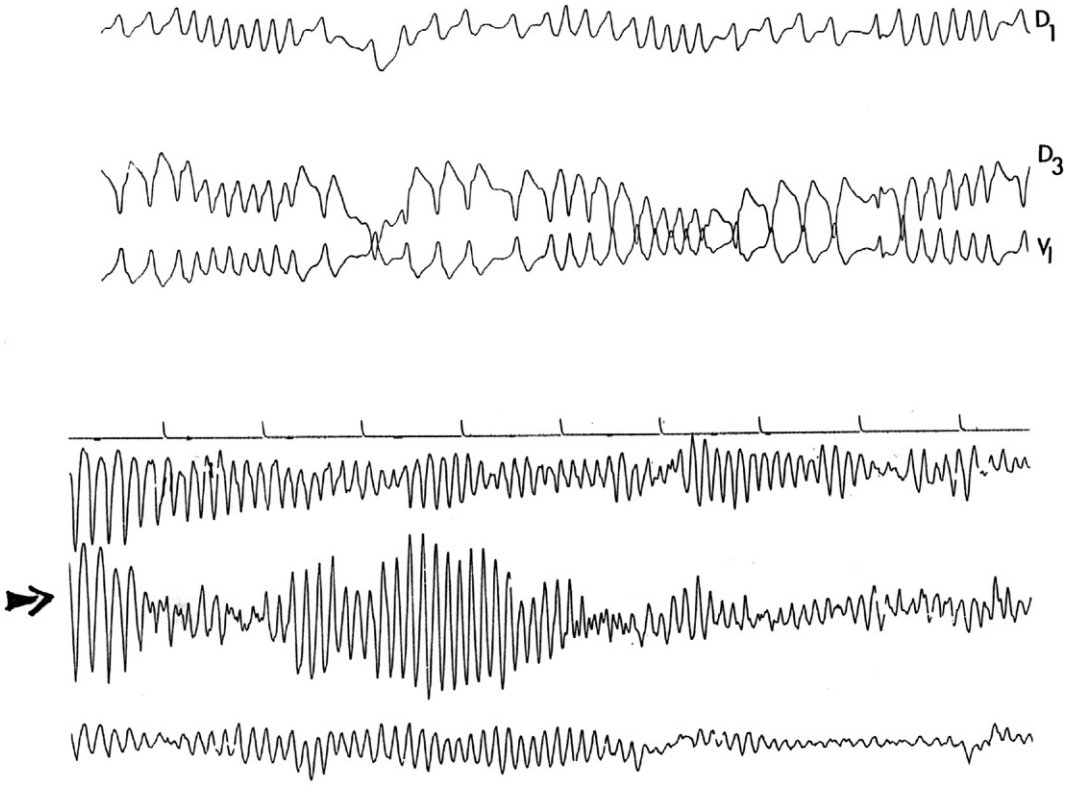

Fig. 6 AF conducted by AP and degenerating into ventricular fibrillation, classical (but rare cause of sudden death in preexcitation syndrome).

Methods of Evaluation

Several noninvasive methods have a low sensitivity and specificity:

ECG: The pattern of preexcitation on 12 lead surface ECG, the permanent or intermittent feature are not specific enough, although posteroseptal location is more frequently noted in patients at risk of rapid arrhythmias (Wellens, 2005) and the intermittent preexcitation is often associated with a benign form. False tests were reported and other tests are required in subjects at risk of arrhythmias as athletes.

Exercise testing was reported at first by Levy et al. (1979) as an important test of prognosis: the abrupt disappearance of preexcitation during an exercise stress testing was proposed as a sign of long refractory period of AP (Levy et al., 1979; Bricker et al., 1985; Strasberg et al., 1980; Sharma et al., 1987; Czosek et al., 2011) (**Fig. 7**) and argues that the AP is benign. In subjects who are not of athletic competition, this disappearance is sufficient to stop the investigations (class I level B grade of recommendation) (Page et al., 2016). While specific, this finding is seldom observed because exercise improves the conduction in the normal AV node conduction system, which can just mask the AP. The gradual loss of preexcitation can be noted in malignant form (Daubert et al., 1986). Therefore, the sensitivity is low (20%) and preexcitation can persist in benign form. Exercise testing is not useful as a provocative test for arrhythmia. However, occasionally the preexcitation will become manifest preexcitation during exercise.

Holter monitoring is rarely useful but can detect spontaneous asymptomatic tachycardias in children who rarely complain of tachycardia as in study of Paponne et al. (2004).

Pharmacological tests (class I antiarrhythmic drug injection) was used several years ago: the disappearance of the pattern of preexcitation was reported as a sign of long refractory period of the AP (Wellens et al., 1980); however, many false positive tests were reported (Critelli et al., 1984) and the test is no longer used.

Electrophysiological study appears as the most reliable method to establish the prognosis of the preexcitation syndrome.

Methods: Patients might be studied by transesophageal (Brembilla-Perrot et al., 2007) or intracardiac route. The first route is indicated in asymptomatic patients and the second in symptomatic patients to perform catheter ablation of AP in a second time. Several advantages concern esophageal route: (1) the patient is not hospitalized and is leaving hospital after study. Only those with induced atrial arrhythmias are awaiting and followed until sinus rhythm is restored. (2) No radiation is used (Bacher et al., 2005) and catheter-related risks are avoided (Paponne et al., 2004; Vitello et al., 1998). (3) The method is feasible from the age of 5 years without sedation (and in newborns) while general anesthesia is required in young children for an intracardiac catheter study. (4)

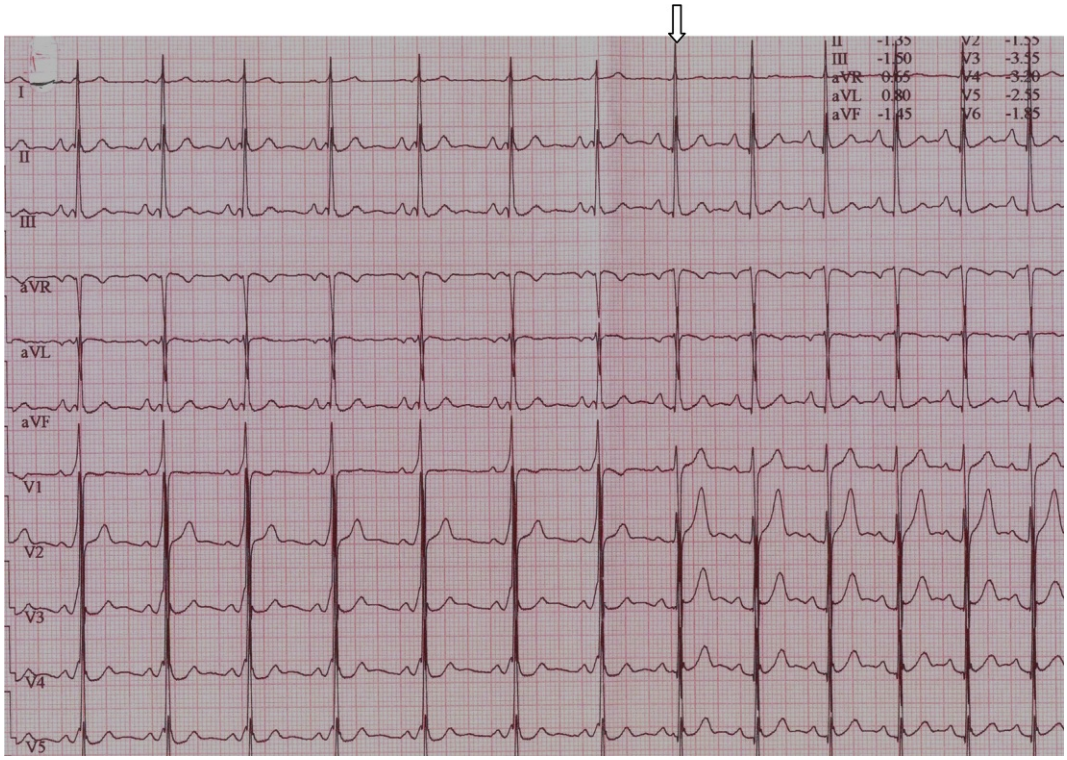

Fig. 7 Abrupt disappearance of preexcitation, sign of a benign form.

There is an overestimation of AF induction in the young patients when intracardiac study is used (Brembilla-Perrot et al., 2001). However, there also some disadvantages. (1) The main problem is related to the appropriate placement of the esophageal electrode complicated by an important gag reflex in children younger than 10 years. (2) The method is associated with chest pain and anxiety related to pacing; the presence of the parents recommended in young children and rapid rates of pacing should be avoided in children. (3) Finally, it is not possible to pace atria in 5%–10% of patients.

It should be noted that all electrophysiological studies in preexcitation syndromes may be dangerous and should be performed with an external defibrillator ready to be used, because a poorly tolerated arrhythmia can be induced in asymptomatic or symptomatic patients.

Cardiac stimulation is performed with a biphasic stimulator. Pulses of 1 ms duration and 0.5–3 mA are used for intracardiac study and pulses of 10 ms duration, output from 8 to 18 mA are used for esophageal study. For a simple intracardiac electrophysiological study, only one catheter is needed: a bipolar silicone esophageal lead or one bipolar intracardiac catheter.

The classical protocol is as following:

Incremental atrial pacing is performed until second degree AV block occurred. The maximal rate of 1:1 conduction over AP is noted.

Programmed atrial stimulation at a basic cycle length of 600 and 400 ms with the introduction of one and two extrastimuli is performed: the disappearance of preexcitation syndrome indicates that the refractory period of AP is longer than that of the AV node. The coupling interval (S1S2 or S2S3) at which the AP becomes refractory will depend on the drive train cycle length (S1S1 interval), with shorter drive trains associated with shorter refractory periods.

The method also is used to induce a supraventricular tachycardia, generally an orthodromic tachycardia, rarely an antidromic tachycardia, or an atrial tachycardia or fibrillation.

These data should be studied under adrenergic situations, except in patients who have a form at risk of sudden death in control state. Two methods are used: atrial pacing might be repeated during an exercise testing which is the most physiological situation, but which is difficult to perform. Many authors prefer the infusion of isoproterenol, a beta-adrenergic drug and which is simpler to use during an electrophysiological study (Crick et al., 1985; Mabo et al., 1992). Isoproterenol (0.02–1 μg min^{-1}) is infused to increase the sinus rate to >130 min^{-1} and the pacing protocol is repeated (Wellens et al., 1981). Beta-adrenergic stimulation results in shortening of the anterograde AP refractory period and in increasing in ventricular rates during atrial pacing and during AF. Isoproterenol test was also previously used to verify the efficacy of antiarrhythmic drug before the time of catheter ablation of AP. The loss of efficacy of some antiarrhythmic drugs was demonstrated after isoproterenol administration (Brembilla-Perrot et al., 1985), although the use of isoproterenol infusions in this setting can be controversial.

At the end of the protocol, using the following definitions, the prognosis of the preexcitation syndrome can be established:

- Sustained AF or reciprocating tachycardia is defined as a tachycardia that is longer than 1 min. The exact duration of induced tachycardia to be considered as pathological is controversial and varies from 30 s up to 5 min.
- Conduction over the AP evaluated by the measurement of the shortest atrial cycle length at which there is 1 to 1 conduction over the AP and the shortest atrial tachycardia cycle length at which there is 1 to 1 conduction over the AP.

The preexcitation syndrome is considered as presenting a risk of sudden death when the following association is observed (Brembilla-Perrot et al., 2010; Milstein et al., 1986; Klein et al., 1989): sustained AF is induced and the shortest RR interval between preexcited beats is ≤250 ms in the control state in adults, ≤220 ms in children (Bricker et al., 1985) or ≤200 ms during isoproterenol infusion (Strasberg et al., 1980; Brembilla-Perrot et al., 2007, 2014). These criteria were those classically retained before the recommendations of 2012 (Cohen et al., 2012). It should be noted that for Klein et al. (1979) have broken up the risk of sudden death on the basis of the shortest RR interval during AF as follows: (1) definite risk, shortest preexcited RR interval <220 ms; (2) probable risk, shortest preexcited RR interval <250 but >220 ms; (3) possible risk, shortest preexcited RR interval <300 but >250 ms; and (4) negligible risk, shortest preexcited RR interval >300 ms. Electrophysiological study now was considered as negative if no tachycardia was induced and a long refractory period of AP (>250 ms in control state and >200 ms after isoproterenol) was noted. Recent papers have looked at labeling a patient as being considered high-risk (malignant) only using minimal cycle length of preexcitation in the absence of inducible AF: in the PACES/HRS 2012 Management of Asymptomatic Preexcitation Recommendations it was recommended that in the absence of inducible AF the minimal cycle length of preexcitation should be used as an alternative (Cohen et al., 2012).

General Results of Electrophysiological Studies

The exact nature of the preexcitation syndrome is assessed. Most preexcitations are related to an AV AP (Kent bundle): the degree of preexcitation increases during premature atrial stimulation until the refractory period of AP is reached, because the conduction does not change in AP with the shortening of atrial cycle length and increases in the AV node. Rarely preexcitation is related to a nodoventricular AP or Mahaim bundle; the degree of preexcitation remains unchanged during premature atrial stimulation. Furthermore, atrial pacing also is an important method to detect or confirm or infirm the presence of a preexcitation syndrome when delta wave is not evident.

In symptomatic patients it is easy to reproduce the spontaneous tachycardia. Reentrant tachycardias are easily induced by stimulation (**Fig. 3**): orthodromic tachycardia which is a reciprocating tachycardia using the normal AV conduction system for the anterograde conduction and the AP for the retrograde conduction is rarely induced in asymptomatic patients (<10%) (Critelli et al., 1984; Brembilla-Perrot et al., 2007) but represents the most frequent tachycardia of symptomatic patients complaining of tachycardia and palpitations (90%) (Rinne et al., 1987).

In patients with spontaneous adverse events the sensitivity of electrophysiologic study to induce sustained AF with the shortest RR interval between preexcited beats ≤250 ms in the control state or ≤200 ms after isoproterenol infusion also is excellent (Brembilla-Perrot et al., 2010). Therefore, electrophysiological study is considered as the most sensitive and specific method to assess the prognosis of preexcitation (Wellens, 2005; Milstein et al., 1986; Klein et al., 1989).

AF easily is induced during intracardiac studies by salvos of rapid atrial stimulation and is not specific (Brembilla-Perrot et al., 2001). AF induction by intracardiac programmed stimulation is obtained in 27%–75% according to the studies, in asymptomatic patients and in patients with only documented reentrant tachycardia (Rinne et al., 1987); AF is induced in 95% of those with documented AF (Rinne et al., 1987). The important variations of the incidence of induced AF depends on the technique of programmed stimulation, on the interpretation of the duration of induced arrhythmia and on the use of isoproterenol infusion or other means to reproduce the effects of adrenergic stimulation. In our experience, the induction of AF during transesophageal pacing is more clinically significant than with intracardiac pacing (Brembilla-Perrot et al., 2001): AF induction is rarer with TEE pacing from 10% to 30% according to the age in patients without documented AF (less false positives) and remained sensitive to induce AF in those with documented AF (95%). The incidence of induced AF also depends on the presence of associated heart disease and on the age of the patient: AF is rarely induced in children younger than 10 years (Brembilla-Perrot et al., 2007), is induced in 20% of teenagers and adults without heart disease and becomes relatively frequent in elderly (31%) (Brembilla-Perrot et al., 2016).

Ventricular tachyarrhythmias also are easily used in asymptomatic or symptomatic patients by programmed ventricular stimulation and are not specific in preexcitation syndrome: ventricular fibrillation is induced in 4% syndrome and nonsustained multiform ventricular tachycardia in 37% of them (Brembilla-Perrot et al., 1987).

Antidromic tachycardia which is a reciprocating tachycardia using the AP for the anterograde conduction and the normal AV conduction system is a rare finding (5%), more frequently noted in young patients with a good retrograde normal VA conduction or in patients with several APs and seems more frequent in patients at risk of rapid arrhythmias.

- The presence of syncope does not increase the risk to find a potential dangerous form in adults (Auricchio et al., 1991); in young patients (<25 years) the significance of syncope seems different and associated with occurrence of AF with a rapid ventricular response (Paul et al., 1990; Brembilla-Perrot et al., 2013b). Reentrant tachycardia remains the main cause of syncope (Brembilla-Perrot et al., 2013b).

- The incidence of forms considered at risk of rapid arrhythmias is similar in symptomatic and asymptomatic patients and concerns 10% of the total population with preexcitation (Milstein et al., 1986; Auricchio et al., 1991; Brembilla-Perrot and Ghawi, 1993; Michelucci et al., 1988; Fan et al., 1991), independently on the age of the patient (Auricchio et al., 1991).
- In asymptomatic patients important variations of results also are reported. The percentage of induction of reentrant tachycardias varies from 11% to 50%. The percentage of AF induction varies from 0% in children <11 years (Brembilla-Perrot et al., 2007) to 20%–50% in adults. The percentage of induction of AF induction with a short RR interval between preexcited beats varies from 15% to 25%. These variations depend on the age of patient (Michelucci et al., 1988; Fan et al., 1991). Children considered as asymptomatic sometimes have spontaneous tachycardia without a clear feeling. In our experience, AVRT induction is not rare (most children recognize the tachycardia usually well tolerated). In the study of Paponne et al. (2004) five apparently asymptomatic patients in the control group had documented silent episodes of sustained AF at Holter monitoring. They remained asymptomatic despite extremely rapid ventricular responses over AP. High incidences of events (one sudden death and two ventricular fibrillations) were reported in these "asymptomatic" children, who had documented rapid AF and were not treated.

The exact clinical significance of the electrophysiological form at risk of sudden death in asymptomatic patients remained controversial. A low incidence of adverse events during a mean follow-up of 4 years was reported in previous studies using the intracardiac evaluation of preexcitation (Klein et al., 1989; Brembilla-Perrot and Ghawi, 1993; Leitch et al., 1990). However several studies of Pappone and Santinelli recently have shown that electrophysiological study could predict sudden death of asymptomatic patients (Pappone et al., 2003; Paponne et al., 2004; Santinelli et al., 2009). In 2009 (Santinelli et al., 2009) they consider that a short AP ERP <240 ms, the tachycardia inducibility and the presence of multiple APs are the main factors of risk in children.

Besides the serious forms, 75%–80% of asymptomatic patients have a benign form of preexcitation.

Indications of Electrophysiological Studies in Preexcitation Syndrome

The indications are now large in symptomatic patients to perform in a second time the catheter ablation of patients complaining frequent sustained tachycardias. The study should be performed using intracardiac catheterization (Page et al., 2016).

In patients with syncope, but no documented tachycardia, electrophysiological study is necessary and might be performed by transesophageal route because the role of the AP in the occurrence of syncope remains rare in adults (Auricchio et al., 1991).

In patients who have a documented rapid or syncopal AF, electrophysiological study is not indicated, because direct AP catheter ablation is recommended (Page et al., 2016). The induction of AF should be avoided.

In asymptomatic patients, the indications are more debatable (Page et al., 2016).

- In asymptomatic patients who are not competitive athletes, the abrupt disappearance of preexcitation is sufficient to stop the investigations (class I, level B grade of recommendation) (Czosek et al., 2011; Page et al., 2016).
- In other patients it is recommended to use techniques with a low risk of adverse events but a good diagnostic value is mandatory. Esophageal route when possible should be the preferred means of evaluation, because the probability to find a form at potential risk of sudden death remains rare (10%).

Some indications of a systematic electrophysiological are actually recommended:

1. Most of sudden deaths have the peculiarity to occur during exercise (Wiedermann et al., 1987). Because of the important development of sports from the infancy to the elderly, it is important to detect those patients with a preexcitation at risk of sudden death who practice a sportive activity; the indication generally begins after 10 years, because the risk of induction of a rapid AF is very small and the level of sport still low. The competitive athlete should be studied in all ranges of age (Cohen et al., 2012; Heidbüchel et al., 2006). The indications are also recommended in professions with a high level of sportive activity (policemen, soldier, fireman, . . .).
2. Electrophysiological study is recommended in patients with high responsibility profession such as professional pilot (plane, truck, bus, train).
3. These indications are largely accepted in teenagers and adults up to middle age. The indications in children or elderly are more controversial.

In children, it is rare to indicate an electrophysiological study <10 years of age because AF is unusual in the absence of associated heart disease (Vignati et al., 2000; Brembilla-Perrot et al., 2007). The recommendations of 2005 (Wiedermann et al., 1987) reported that "in children <12 years of age, the risk of AF and/or SCD is considered virtual, and assessment of the risk may be postponed." However the age of 5 years is the recommended age for Pappone (Pappone et al., 2003; Santinelli et al., 2009). Furthermore, conduction over AP and normal AV conduction system are more rapid without probably a clinical significance: in the study of Bromberg (Bromberg et al., 1996; Sarubbi et al., 2005) a cycle length <220 ms in basal state is considered at risk of severe arrhythmias in children <18 years; in adults, the value of ≤250 ms is admitted as a sign of a dangerous form. However, because rare sudden deaths were reported in children (Santinelli et al., 2009; Sarubbi et al., 2005), the indications should be large in young children practicing sports competition and in all children >10 years.

In elderly, the shortest atrial pacing cycle length with 1:1 anterograde conduction via the AP increased progressively with age (Brembilla-Perrot et al., 2016; Michelucci et al., 1988; Fan et al., 1991; Rosenfeld et al., 1991). However, the propensity for AF was shown to be higher in older patients compared to younger patients (Brembilla-Perrot et al., 2016; Michelucci et al., 1984). While the exact mechanism is uncertain, degenerative changes associated is the most commonly proposed mechanism and the dispersion of

atrial refractoriness increases progressively with age (Michelucci et al., 1984). The risk to have a severe arrhythmia as the first manifestation of preexcitation syndrome in an old patient was previously reported (Brembilla-Perrot et al., 2003, 2010). High-level sporting activity is rare in elderly, but other causes for adrenergic tone increase might be encountered, as important surgery.

Therefore, because of the increase of the sport in all ranges of age and in particularly in young children or after 60 years, the risk of occurrence of a potentially severe arrhythmia in an asymptomatic patient should be not underestimated.

Management of Preexcitation Syndrome

Acute Treatment of Arrhythmias (Page et al., 2016)

In the case of hemodynamically stable narrow-complex QRS tachycardia, after failure of sinocarotid massage, adenosine triphosphate injection is the recommended treatment (class I, level B). Rarely other treatments are required (class IIA): Intravenous diltiazem, verapamil (level of evidence: B-R), or beta blockers (level of evidence C-LD) can be effective for acute treatment in patients with orthodromic AV reentrant tachycardia who do not have preexcitation on their resting ECG during sinus rhythm. Intravenous amiodarone preferentially is used in Europa after failure of other drugs.

In the case of antidromic tachycardia or AF conducted by the AP, the treatment depends on tolerance. In poorly tolerated tachycardias, urgent cardioversion after sedation is the recommended treatment (class I, level B).

In other cases calcium inhibitors and digoxin are prohibited because they facilitate the conduction over AP and are the causes of ventricular fibrillation (Brembilla-Perrot et al., 2010).

Amiodarone or preferentially intravenous flecainide (1 mg kg^{-1}) when associated heart disease is excluded are the recommended treatments.

Preventive Treatment (Page et al., 2016)

Ablation of AP, which is a curative treatment, now is recommended in preexcitation syndrome requiring a treatment. However, the results and risks of the method still need to be compared with the symptoms and preexcitation-related risks. Age of the patient, competitive sport activity, particular jobs (fireman, military, train, or airplane pilot), and location of AP are some of several factors that should be considered before the indications of treatment.

Risks and benefits related to the ablation of the AP

Introduced in 1990, the ablation of AP is able to permanently cure the subject with a ventricular preexcitation syndrome (Warin et al., 1988; Jackman et al., 1991). The immediate success of ablation has increased since 1990 and is currently around 93/95%. Nevertheless, it is lower in case of right lateral location (78%), in very young children, and in the presence of heart disease, particularly in cases of Ebstein's anomaly.

Also it is necessary to consider the risk of recurrence of preexcitation, which averages 10% and is dependent on the location of AP (right sided 24%, midseptal 17%, left AP 5%). The phenomenon usually occurs early (first 2 months). In addition, the risks of complications also have decreased from 4.3% to 2.9% (average 3%). It remains most common in young children: Mortality fortunately is exceptional (0%–0.2%). The complications are mainly related to radiation exposure (Bacher et al., 2005) (less important if using a mapping system is used), vascular access (e.g., hematoma, pneumothorax, arteriovenous fistula), catheter manipulation (coronary dissection, perforation of the coronary sinus, microemboli), and the application of radio frequency (risk of complete AV block, coronary stenosis) (Vitello et al., 1998; Fujiki et al., 1990; Schuffer et al., 1996). Complete AV block is a known complication of the ablation of a parahisian AP and has been reported for posteroseptal AP. The risk is exceptional when using cryoablation in place of radiofrequency ablation, but this technique is not used in all the teams because of a risk of higher recurrence of preexcitation.

Indications of ablation in 2016 (Page et al., 2016) (Table 1)

The recommendations are based on the 2012 publications in children (Cohen et al., 2012), on the 2015/2016 data in the symptomatic or asymptomatic adults (Page et al., 2016). Several elements are to be considered:

A. The patient is symptomatic or not;
B. What is the patient's age?
C. Does the patient participate in a competitive sport or is does their profession prohibit the presence of an AP (e.g., pilot)?
D. What is the location of AP?

A—The subject is symptomatic (reentrant tachycardia or AF with rapid conduction over the AP): Ablation is recommended (class I level B), especially in adults. Drug treatment is a class I level C recommendation only when AP is concealed (Page et al., 2016).

It must be remembered that successful ablation prevents the risk of AF than in subjects <50 years (Dagres et al., 2001) and especially when it was proved that AF was due to reciprocal tachycardia rhythm. Otherwise ablation is used to prevent too rapid conduction through the AP during AF. This fact has been confirmed by Bunch et al. (2015) who also showed a lower mortality in patients who underwent ablation.

Table 1 Indications of ablation of AP

Class	*Level of proof*	*Indications*
I	B	• Symptoms (tachycardia) • No symptoms: malignant form at electrophysiology • No symptoms: sport competition, job at risk
II a	B	Asymptomatic: malignant form at electrophysiology Symptomatic; child
III		Asymptomatic, benign form at electrophysiology

Malignant form at electrophysiology (AF induced with minimal cycle conducted by AP $\leq$250 ms).
Benign form: no inducible tachycardia, refractory period of the AP >250 ms.

B—The subject is asymptomatic: Ablation is recommended (class IIa level B) in the case of detection of a form to high risk at electrophysiology study (AF with a minimum cycle length conducted by AP $\leq$250 ms) but also systematically in the subject exercising a profession at risk (e.g., pilots or drivers) (Page et al., 2016).

It should be noted that the simple monitoring of asymptomatic individuals also has the same class of recommendation (class IIa level B) and a recent study of Papponne and Santinelli (Pappone et al., 2014) the prognosis of preexcitation syndrome essentially depends on intrinsic electrophysiological properties of AP rather than on symptoms. For these authors ablation performed during the same procedure after electrophysiological testing is of benefit in improving the long-term outcomes.

C—In young children, the indications are discussed because of radiation risks and catheterization complications (Bacher et al., 2005; Vitello et al., 1998). They should be discussed with parents (Cohen et al., 2012).

AF risk is low unless associated with congenital heart disease. In addition, the involution of AP is possible before the age of 12 years if the AP refractory period is long and finally the sports in competition do not apply to young children. Drug treatment is usually effective in young symptomatic children.

In practice, the ablation can be exceptionally indicated before the age of 12 if antiarrhythmic drugs or beta-blockers are ineffective or not tolerated but requires general anesthesia.

In 2012, ablation is recommended (class II level A) in asymptomatic children ($\geq$8 years) if AF with rapid conduction is induced and if reciprocal tachycardia is inducible (class II, level B) (Cohen et al., 2012). However the recommendation is the same (class II level B) in the absence of inducible tachycardia in special cases (sports) and in the absence of parahisian location. The absence of induction of tachycardia and the induction of AF with a driving cycle >250 ms leads to a simple monitoring (recommendation of class II (level A).

D—Athletic competition: Evaluation and ablation indications are wider. Sport is authorized without ablation if the subject is asymptomatic and if systematic electrophysiological study shows that this is a benign form (refractory period >250 ms and no inducible tachycardia) (Heidbüchel et al., 2006).

E—Location of AP: In the case of parahisian location, the risk of complete AV block is important except when cryoablation is used, but there is a high risk of recurrence (Swissa et al., 2015). This location is particularly important to consider in asymptomatic subjects where ablation indications remain questionable.

In conclusion, several data should be considered in patients with a preexcitation syndrome

- Confirmation of the diagnosis.
- Evaluation of the prognosis. Electrophysiological study is the best means to define this prognosis. The method is easily performed in the out-patient clinic by transesophageal route. The indications should be large to avoid the misdiagnosis of a form at risk of rapid arrhythmias. This dangerous form is relatively rare in asymptomatic patients, symptomatic patients, or those with unexplained syncope. Most of these patients (>85%) would be allowed to continue their activities, without specific treatment, because they have a benign form of preexcitation syndrome.
- Discussion of the treatment. Ablation of AP is required in symptomatic subject. It remains controversial in asymptomatic subject except in the case of sport competition or in the case of a profession at risk and in the in case of detection of a potentially serious form at electrophysiology (induction of AF conducted by the AP with a $\leq$250 ms cycle length). The recommendations are contradictory because the risks are low and ablation does not have a success rate of 100%. The indications rarely are needed in children before 12 years.

Introduction

Research History

The zebrafish (*Danio rerio*) is an important and widely used vertebrate model organism in scientific research. It is a freshwater fish, native to the streams of the tropical Asia region (Mayden et al., 2007), and is found in parts of India, Pakistan, Bangladesh, Nepal, Myanmar, and Burma (retrieved information from U.S. Geological Survey on April 4, 2017). The male is torpedo-shaped, with gold stripes between blue stripes (**Fig. 1B**); the female has a larger, whitish belly and silver stripes instead of gold (**Fig. 1A**). The zebrafish can grow to 6.4 cm (2.5 in.) in length, and its lifespan is around 2–3 years (Gerhard et al., 2002).

Use of zebrafish as a laboratory animal was pioneered by the American biologist Dr. George Streisinger, he and his colleagues initiated genetic studies of zebrafish at the University of Oregonin in the 1970s and 1980s (Stahl, 1985). The approximate generation time for *Danio rerio* is 3 months; this particular feature made it an appealing genetic system to Dr. Streisinger. A male must be present for ovulation and spawning to occur. Females can spawn at intervals of 2–3 days, laying hundreds of eggs in each clutch, making it an ideal system for genetic studies. Upon release, eggs are fertilized, and embryonic development begins. Fertilized eggs almost immediately become transparent, a characteristic that makes *Danio* rerio an ideal research model species for imaging and observation of developing internal organs.

Fig. 1 A typical adult female (A) and male (B) zebrafish at 3-month old. The characteristic stripes running along the body and the fins gave this species its name.

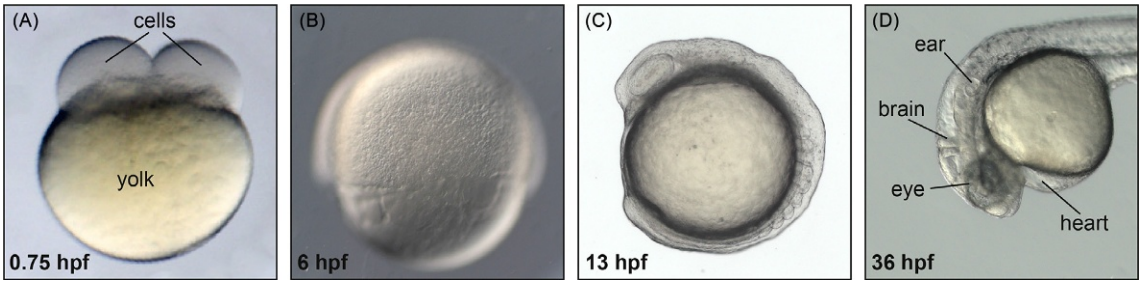

Fig. 2 The embryonic development of zebrafish. The zebrafish embryo begins as a yolk with a single enormous cell on top (0 hpf, not shown), which divides into two (0.75 hpf) (A) and continues dividing until there are thousands of small cells. The cells then migrate down the sides of the yolk during gastrulation movements (B) and begin forming a head and tail (C). The 36 hpf old zebrafish has major organs being formed in the body (D).

Research Advantage

The zebrafish embryo develops rapidly, and precursors to all major organs appear within 36 h postfertilization (hpf) (**Fig. 2D**). Upon egg activation, the cell cytoplasm separates from the yolk. The first cell cleavage occurs at 0.75 hpf (**Fig. 2A**) and divisions continue synchronously and without cell growth until there are thousands of small cells that form the blastoderm at 3.25 hpf. After genome activation, the cells migrate down the sides of the yolk around 6 hpf (**Fig. 2B**). The germ layers are specified at the shield stage, and formation of the head and tail begins at 13 hpf (**Fig. 2C**). The tail then extends away from the yolk at 24 hpf. The yolk shrinks over time as the embryo uses the yolk as food during the first few days. After a few months, the adult fish reaches reproductive maturity (Kimmel et al., 1995).

Today, as an established model biological system, the zebrafish possesses numerous advantages for scientists. Its genome has been fully sequenced, and it has well-understood, readily observable, and testable developmental behaviors. As mentioned, embryonic development is very rapid, and the embryos are relatively large and transparent, and importantly develop outside of the mother. Furthermore, well-characterized mutant strains are readily available or are easy to characterize. Significantly, the Zebrafish Information Network (ZFIN: http://zfin.org) provides a dedicated online database of genetic, genomic, and developmental information that is a vital resource for zebrafish scientists globally.

Research with *Danio rerio* has yielded advances in the fields of developmental biology, genetics, cardiovascular biology, stem cell research and regenerative medicine, oncology, toxicology, reproductive studies, teratology, neurobiology, environmental sciences, and evolutionary theory. In the field of cardiovascular research, due to a unique combination of visual access to the early embryonic cardiovascular system and established tools and methods for genetic analysis, the zebrafish is recognized as an ideal model organism for investigating the molecular mechanisms underlying heart and blood vessel formation (Stainier and Fishman, 1994; Liu and Stainier, 2012; Evans et al., 2010; Gore et al., 2012; Covassin et al., 2009; Lawson and Weinstein, 2002; Vogel and Weinstein, 2000; Isogai et al., 2001; Yelon and Stainier, 1999). Besides, the zebrafish embryo does not require a functional cardiovascular system for its survival through 5 dpf (Alexander et al., 1998; Stainier et al., 1996; Pelster and Burggren, 1996), thus cardiovascular defects can be analyzed in detail throughout embryogenesis.

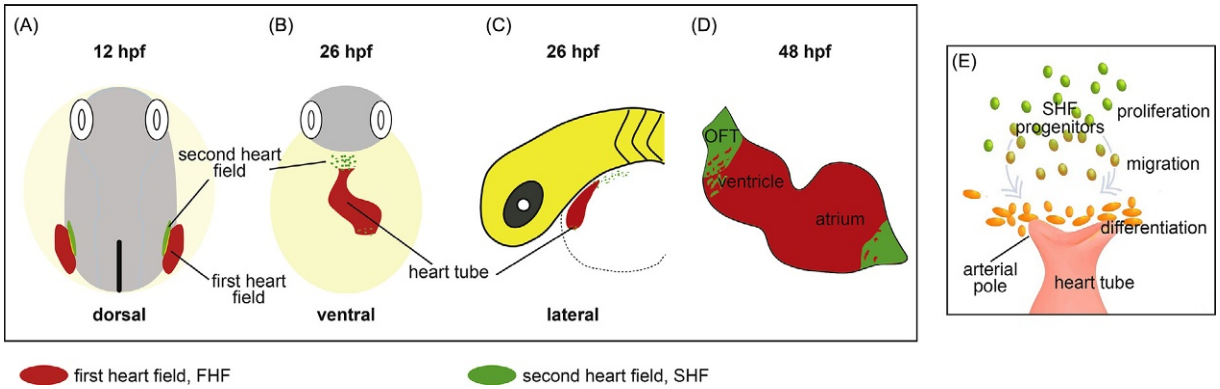

Fig. 3 The formation of the embryonic vertebrate heart involves two temporally distinct phases of cardiomyocyte differentiation. Schematics depict locations of cells derived from the first heart field (FHF in red) and the second heart field (SHF in green) in the zebrafish embryo. (A) Initially, the SHF is located medially adjacent to the FHF at 12 hpf. (B, C) A pool of progenitor cells is located adjacent to the arterial pole at the ventral (B) and lateral view (C) at 26 hpf. (D) The SHF-derived cardiomyocytes contribute to both poles of the heart at 48 hpf. (E) A schematic dorsal view of the arterial pole of the heart tube around 26 hpf. A pool of proliferative progenitor cells (green) is detected in a distal region to the arterial pole. They initially exhibit a dispersed pattern, before actively moving toward the arterial pole and accumulating proximal to the primitive heart tube, and they seem to express different combinations of molecular markers as they initiate the cardiac differentiation process. Eventually, these cells are matured into cardiomyocytes and are incorporated into the forming the cardiac outflow tract (OFT).

In this article, we will highlight the advantages of zebrafish in cardiovascular and biomedical research, including the sophisticated methods in genetic screening, gene manipulation, genome editing, and implementation of these technologies toward the study of regeneration biology and small-molecule drug discoveries.

Zebrafish Cardiovascular System

Heart Development

As early as the late blastula stage (~5 hpf), myocardial progenitor cells are already spatially organized in bilateral zones near the embryonic margin (Keegan et al., 2004). When gastrulation is complete (~12 hpf), both ventricular and atrial myocardial progenitors reside in bilateral heart fields within the anterior lateral plate mesoderm (ALPM) (**Fig. 3A**), and retain their spatial organization as the gastrula forms (Schoenebeck et al., 2007), and myocardial differentiation initiates. Subsequently, cardiomyocytes move to the embryonic midline and form a cardiac cone; characteristic molecular markers *ventricular myosin heavy chain* (*vmhc*) and *atrial myosin heavy chain* (*amhc*) are expressed around this stage (~19 hpf) (Berdougo et al., 2003). At 26 hpf, cardiomyocytes migrate and elongate the cardiac cone to form the heart tube (**Fig. 3B, C**). By 48 hpf, further growth and morphogenesis of the heart tube results in a morphologically distinct ventricle and atrium, with a constriction at the atrioventricular canal separating both chambers (**Fig. 3D**). In the adult zebrafish heart, blood enters the sinus venosus and passes through a single atrium and ventricle. The ventricle then pumps venous blood through the bulbus arteriosus to the ventral aorta for distribution to the gills for oxygenation.

Despite apparent anatomic differences between the two-chambered zebrafish heart and four-chambered mammalian heart, many studies have highlighted similarities in the genes and regulatory networks that specify cardiac fates, extensively reviewed (Evans et al., 2010). Work in birds and mammals has demonstrated that the multichambered vertebrate heart is built by two waves of cardiac progenitors: first heart field progenitors and second heart field progenitors, which differ in their timing of differentiation and in their contributions to specific regions of the heart (Buckingham et al., 2005; Dyer and Kirby, 2009; Abu-Issa and Kirby, 2007). Initially, an early wave of cardiomyocytes contributes to the formation of the primitive heart tube; these cells arise from a set of cardiac progenitor cells located in the ALPM, termed the first heart field (**Fig. 3A**). Subsequently, the gradually controlled addition of cardiomyocytes to the arterial poles of the maturing heart occurs via a second and late-differentiating cell lineage originating from the second heart field (**Fig. 3A,E**) (Buckingham et al., 2005). In zebrafish, assays using fluorescent reporters to capture the timing of differentiation have confirmed the existence of two waves of cardiac differentiation (de Pater et al., 2009). Further, lineage-tracing and cell-labeling analyses have validated the existence of distinct pools of progenitor populations similar to those seen in mammals, and deepened the concept of the first and second heart fields in lower vertebrates (Zhou et al., 2011; Zeng and Yelon, 2014; Hami et al., 2011).

Since many of the genes and signaling pathways essential to embryogenesis are conserved between zebrafish and mammals, the characterization of two distinct phases of cardiomyocyte differentiation in the zebrafish heart have significant implications.

Vascular Development

Vascular development includes a series of cellular and molecular events, from endothelial cell differentiation to blood vessel assembly and morphogenesis. During the last several decades, extensive research utilizing model animals has demonstrated that the

embryonic vasculature develops in a conserved manner in all vertebrates: endothelial progenitor cells differentiate from mesodermal cells, then migrate and assemble into the dorsal aorta and the cardinal vein. This primitive circulatory loop undergoes sprouting and branching to form the trunk vascular network (Risau and Flamme, 1995).

In the vertebrate embryo, the dorsal aorta and the posterior cardinal vein form in the trunk to establish the circulatory loop prior to the first heartbeat. The endothelial tubes of the great vessels in the embryo proper assemble through migration and de novo coalescence of endothelial progenitors (angioblasts), a process termed vasculogenesis (Risau and Flamme, 1995; Risau, 1996). Subsequent angiogenesis occurs, where intersomitic vessels sprout from the dorsal aorta and the cardinal vein to form anastomotic arterial and venous systems, allowing blood to circulate in the developing embryo. In higher vertebrates, the embryonic yolk sac also forms a vascular network. First, angioblasts assemble and form a complex capillary plexus via vasculogenesis. This primitive plexus undergoes pruning and remodeling to develop into the vitelline artery and vitelline vein. In zebrafish embryos, vascular development occurs in a conserved manner compared with other vertebrates (Isogai et al., 2001; Zhong, 2005). The zebrafish yolk sac does not develop a separate vascular system. Instead, part of the cardinal venous system, the duct of Cuvier, comes together to form the common cardinal vein.

Genetic Manipulation in Zebrafish

Forward Genetic Screening Identifies Novel Genes and Pathways in Cardiovascular System

Genetic factors contribute to the pathogenesis of cardiovascular diseases. Due to disease heterogeneity, variable penetrance, and high mortality, human genetic studies have been combined with animal models to elucidate the genetic basis of cardiovascular diseases. Notably, animal models have emerged as powerful tools for identifying novel genes that are involved in cardiovascular pathology, and further to verify the effect of disease gene candidates on cardiovascular function.

Enabling the unbiased identification of novel cardiovascular genes, zebrafish are exceptionally suitable for forward genetics approaches as an animal model system. Large-scale ENU-based mutagenesis screens have been conducted in zebrafish since 1996, and several hundred mutants with cardiovascular defects have been identified (Stainier et al., 1996; Alexander et al., 1998). Many of these mutations have now been characterized in detail and positionally cloned. According to the disease-related genes listed in the Online Mendelian Inheritance in Man (OMIM) database, 82% have at least one zebrafish ortholog (Howe et al., 2013).

The spectrum of cardiac phenotypes that were isolated in zebrafish mutants has demonstrated close correlation with human disease, such as congenital heart disease, cardiomyopathies, and arrhythmias. For example, several important genes encoding key transcription factors that have been shown to cause the pathogenesis associated with human congenital heart defects are also critical for heart development in zebrafish, such as *gata4/5/6* (Peterkin et al., 2007; Garg et al., 2003; Wei et al., 2013; Holtzinger and Evans, 2005; Reiter et al., 1999; Holtzinger and Evans, 2007), *tbx5* (Li et al., 1997; Garrity et al., 2002), *hand2* (Lu et al., 2016; Schoenebeck et al., 2007; Yelon et al., 2000), and *nkx2.5* (Schott et al., 1998; Tu et al., 2009) genes. Prostaglandin signaling has been recently discovered to regulate heart laterality and ciliogenesis through zebrafish genetics studies (Jin et al., 2014).

Similarly, components of the molecular signaling pathways (such as TGF-β, BMP, VEGF, etc.) involved in embryonic vascular development have been implicated in adult human disease, including pulmonary arterial hypertension, hereditary hemorrhagic telangiectasia, and preeclampsia (Venkatesha et al., 2006; The International PPH Consortium et al., 2000; Johnson et al., 1996). Although studies in many vertebrate systems, including chick, frog, and mouse, have contributed significantly to our understanding of embryonic vascular development, genetic approaches in zebrafish have led to the identification of novel mutations and molecules that are responsible for specification of endothelial progenitor cells, differentiation of arterial and venous cells, and patterning of the dorsal aorta and intersegmental vessels. These studies highlight the benefits of the zebrafish system for studying the development of embryonic blood vessels. For example, the discovery of the *gridlock* (*grl*) mutation and identification of *grl*/*hey2* gene as a novel hairy-related basic helix–loop–helix (bHLH) transcription factor in arterial endothelial development proves the strength of zebrafish as an excellent genetic system studying vascular development (Weinstein et al., 1995; Zhong et al., 2001; Zhong et al., 2000). Another good example was the discovery that Semaphorin–Plexin signaling guides patterning of the developing vasculature (Torres-Vazquez et al., 2004). Studies in zebrafish revealed that proper blood vessel path finding requires the endothelial receptor PlexinD1 and semaphorin signals, and indicates a fundamental conservation of repulsive patterning mechanisms between axonal migration in the central nervous system and vascular endothelium during angiogenesis.

Morpholino Antisense Technology Continues to Serve as a Powerful Tool for Functional Analysis

Zebrafish mutants identified in small- and large-scale forward genetic screens were primarily the foundation for genetic analysis of zebrafish development and physiology (Chakrabarti et al., 1983; Driever et al., 1996; Haffter and Nusslein-Volhard, 1996). While forward genetics was instrumental in establishing zebrafish as vertebrate model system, a reliable technology to conduct reverse genetics in this model was sought by the community. The use of antisense oligonucleotides also known as morpholinos (MOs) was first introduced in frogs (Heasman et al., 2000) and then in zebrafish (Nasevicius and Ekker, 2000). This technology has spread rapidly and widely through both research communities for transiently knocking down gene function.

The MO antisense technology is based on nucleic acid bases that are linked to morpholine rings and a noncharged phosphorodiamidate backbone (Summerton and Weller, 1997). The rationale for this design was that MOs would not bind electrostatically to protein, hence would cause less toxicity, while at the same time would be resistant to nucleases (Summerton, 2007). MOs are

injected into one-cell stage zebrafish embryos using standard microinjection techniques, and it makes them convenient, easy, and accessible to even small-sized research groups.

Commonly, MOs are ~25-mers designed to be an exact antisense match against the region surrounding the first translated ATG start codon to block translation; or against a splice donor or acceptor site to interfere with precursor mRNA splicing (Summerton and Weller, 1997). To date, countless studies using this technology have been published, including some using MOs to knock down proteins produced from maternally deposited transcripts to generate maternal-zygotic mutants (Ciruna et al., 2002), and others using caged MOs (Griepenburg et al., 2015; Wang et al., 2012; Shestopalov and Chen, 2011; Ouyang et al., 2009), which allow for an inducible release of these antisense reagents and result in a spatially and temporally controlled gene function regulation (Shestopalov et al., 2012).

Recently, serious concerns have been raised as to the specificity of MO effects. There are several examples in which the developmental delays, defects in organ asymmetry, and pericardial edema are associated with nonspecific MO artifacts (Shmukler et al., 2016; Shmukler et al., 2015; Kok et al., 2015). After rounds of discussion in scientific journals and at conferences, the zebrafish community concludes that adequately controlled MOs should still continue to be accepted as useful loss-of-function approach with careful evaluation guidelines being implemented (Lawson, 2016; Schulte-Merker and Stainier, 2014; Stainier et al., 2015; Rossi et al., 2015).

New Era in Genome Editing: TALENs and CRISPR/Cas Systems

The introduction of new genome editing tools such as ZFNs (zinc finger nucleases), TALENs (transcription activator-like effector nucleases), and more recently, the CRISPR (clustered regularly interspaced short palindromic repeats)/CRISPR-associated (Cas) system has greatly expanded the ability to knockout genes in different animal models with surprisingly high efficiency (Beumer et al., 2008; Tesson et al., 2011; Yang et al., 2013), including zebrafish (Chang et al., 2013; Sander et al., 2011a; Sander et al., 2011b; Hwang et al., 2013a; Hwang et al., 2013b; Zu et al., 2013; Gagnon et al., 2014). Particularly, CRISPR/Cas systems have been providing exciting new opportunities for high-efficiency mutagenesis (Hwang et al., 2013a; Shah et al., 2016; Shah et al., 2015), and have been reviewed extensively (Auer and Del Bene, 2014).

In bacteria, exogenous foreign nucleic acids are silenced by CRISPR–Cas systems (Barrangou, 2015; Morange, 2015; Mojica et al., 2005). Originally, bacterial type II CRISPR systems were adapted to create guide RNAs that direct site-specific DNA cleavage by the Cas9 endonuclease in cultured cells (Cong et al., 2013; Mali et al., 2013). Owing to their effectiveness as a genome editing tool, several efficient protocols have been generated in the zebrafish field, and numerous studies have shown that the CRISPR–Cas system functions in vivo to induce targeted genetic modifications in zebrafish embryos with efficiencies similar to those obtained using ZFNs and TALENs (Talbot and Amacher, 2014; Gagnon et al., 2014; Yin et al., 2016).

By using the CRISPR–Cas genome editing system, both research time and costs required for the screening of a huge number of zebrafish animals, aimed to identify first founder fishes (F0), and then carriers (F1) are relatively affordable. Currently, high-resolution melting (HRM) analysis, real-time PCR system, and even traditional restriction enzyme-based assays resolved using agarose gel electrophoresis are common and efficient technologies for large-scale InDels detection that are easily adapted in research laboratories to distinguish between the mutant and the wild-type genotypes.

Taking advantage of the simplicity, rapidity, and cheapness of these methods, one can set up a pilot approach for massive screening of F0-injected founders. The scope can then be restricted to a limited number of F1 embryos for the next step, which is sequencing the affected gene to identify the induced mutation.

Zebrafish Model in Cardiac Regeneration Biology

Cardiac Regeneration in Zebrafish

Myocardial infarction and ischemic heart disease are caused by an acute reduction of blood to the myocardium, which has the direct effect of diminishing oxygen supply. This results in a loss of a vast number of cardiomyocytes, leading to hypertrophy and heart failure. Care of such patients places enormous burdens on the health care system, requiring 1 million hospitalizations every year at an annual cost of $35 billion in the United States (Bernstein and Srivastava, 2012). Development of therapeutics that can facilitate new cardiomyocyte generation would be of enormous medical and economic impact. Given the limited treatment options for advanced human heart failure, there is considerable interest in identifying ways to regenerate cardiomyocytes to restore myocardial function. For instance, treatments that can stimulate endogenous cardiomyocyte regeneration in areas of infarction could be the new frontier of regenerative therapy. Eventually, an ideal therapeutic option would be to employ small-molecules that have the capacity to stimulate and accelerate endogenous cardiomyocyte regeneration after injury.

In contrast to adult mammals, adult zebrafish can regenerate heart tissue following partial surgical resection (**Fig. 4A**) (Poss et al., 2002). In experimental settings, approximately 3% of cardiomyocytes in the compact myocardium of adult zebrafish hearts incorporated the thymidine analog bromodeoxyuridine (BrdU) during a 7-day pulse-labeling experiment. Two weeks after amputation of the cardiac apex, the fraction of BrdU-positive cardiomyocytes had increased 10-fold, and this parameter remained as high as 20% 1 month after injury. Strikingly, the authors found that by 60 days postamputation the lost cardiomyocytes had completely regenerated. Of functional and therapeutic significance, the study showed that the cardiac muscle supplanted the fibrin clot without generating scar tissue, leading to restoration of vascularized cardiac muscle and normal electrical coupling with adjacent cells.

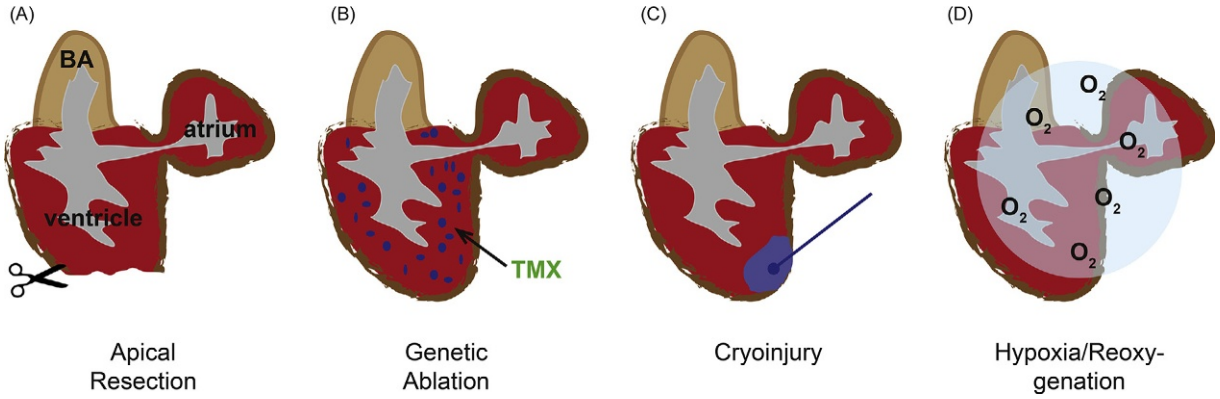

Fig. 4 Methods to induce cardiac injury in zebrafish adult hearts. The adult zebrafish heart consists of one ventricle, one atrium, and the balbus artieriosis (BA). Since the adult zebrafish heart regenerates spontaneously after injury, current models to study mechanisms of cardiac regeneration include resection of the ventricular apex (A), ventricular cryoinjury (B), genetic ablation of cardiomyocytes (C), and cardiac injury induced by hypoxia/reoxygenation (D).

The cellular and molecular basis underlying cardiac regeneration is of significant interest. In the case of zebrafish, the regeneration process predominantly occurred through dedifferentiation of proliferating cardiomyocytes at the injury site based on the observed reactivation of cardiac developmental genes as well as disassembly of sarcomeric structure of existing cardiomyocytes. A stem/progenitor cell-mediated mechanism was probably not involved in this zebrafish cardiac regeneration model (Jopling et al., 2010).

Three additional unrelated injury models—genetic ablation (Wang et al., 2011), cryocauterization (Gonzalez-Rosa et al., 2011), and hypoxia/reoxygenation (Parente et al., 2013) (**Fig. 4B, C, D**)—also stimulated robust myocardial regeneration in zebrafish. In these studies, the wounded heart had entirely regenerated after 30, 130, and 30 days, respectively. Heart tissue throughout the organ is responsive to injury during zebrafish heart regeneration, not just tissue near the site of trauma. All major cardiac tissues, including epicardium, endocardium, and myocardium, appear to employ this strategy, in which epicardium and endocardial cells show the early responses (Kikuchi et al., 2011a). Over different time courses and depending on the cell type, these initial widespread injury-activated expression signatures disappear globally and eventually seem to localize to the injury site. Factors released during cardiac inflammation may help trigger an organ-wide injury response, which might be a key to regenerative success. Signaling pathways that participate in zebrafish heart regeneration have been identified, including fibroblast growth factor (Lepilina et al., 2006), platelet-derived growth factor (Kim et al., 2010), and retinoic acid pathways (Kikuchi et al., 2011b).

Cardiac Regeneration is Conserved between Zebrafish and Mammals

In mammals, the heart of 1-day-old neonatal mice can regenerate after partial surgical resection or left anterior descending artery (LAD) ligation (Porrello et al., 2011; Haubner et al., 2012). Similar to the injured zebrafish adult heart, local injury induces global changes in cardiomyocyte morphology and proliferation in the neonatal mouse heart. This regenerative capacity is lost 7 days after birth when resection or ligation surgery leads to the formation of a fibrotic scar. The timeline coincides with the withdrawal of cardiomyocytes from the cell cycle through the completion of mitosis without cytokinesis, resulting in the formation of binucleated cells. This postnatal switch in cardiomyocyte proliferation leads to the transient presence of regenerative capacity in the neonatal mouse heart. Scar formation may also cause loss of regeneration capacity by 7 days.

Several hypotheses speculate why the mammalian heart only has a short period in regenerative capacity after birth (Foglia and Poss, 2016). One of the interesting models posits that a transition to the oxygen-rich postnatal environment results in the cell-cycle arrest of cardiomyocytes. Studies in mice have shown that postnatal hypoxemia, reactive oxygen species (ROS) scavenging, or inhibition of DNA damage response (DDR) all extend the postnatal proliferative status of cardiomyocytes, in contrast hyperoxemia and ROS conditions can reduce its length (Puente et al., 2014).

Following this rationale, Hesham Sadek and colleagues show that chronic severe hypoxia enhances the regeneration capacity of injured hearts in adult mice (Nakada et al., 2017). After myocardial infarction treatment, experimental mice that were placed in a hypoxic environment for a prolonged period could make new cardiomyocytes and restore partial cardiac function, through a mechanism involving a reduction of ROS concentration and cardiomyocyte cell-cycle reentry. Thus, targeting components in this hypoxia relevant pathway have potential to induce myocardial regeneration and eventually might provide a viable therapeutic strategy for use in humans.

In humans, over the course of an average lifetime, almost 45% of cardiomyocytes slowly turnover in adulthood, while 55% remain after birth (Bergmann et al., 2009). This turnover is very low and decreases significantly with age. Both the integration of radioactive ^{14}C (generated by nuclear bomb tests during the Cold War) into DNA and the infusion of iododeoxy uridine (IdU, a thymidine analog used as a radio sensitizer for therapy (Kajstura et al., 2010)) provide evidence for this measurable ability in the adult human heart.

Compared with the zebrafish heart, the mammalian heart has more fibroblasts. Mammalian cardiomyocytes have a higher DNA content (binucleated cells with a diploid nucleus in rodents, mononucleated cells with a polyploid nucleus in humans). These cardiac cell properties are thought to result in poor regenerative capacity when the mammalian heart is injured.

Cardiac Regeneration Involves Dedifferentiation and Proliferation of Existing Cardiomyocytes

Lineage mapping of the heart during regeneration using inducible genetic markers has demonstrated that zebrafish heart regeneration occurs through cardiomyocyte dedifferentiation and proliferation (Jopling et al., 2010; Kikuchi et al., 2010). The 4-hydroxytamoxifen (4-HT)-inducible Cre/lox system in zebrafish has been established to prelabel cardiomyocytes with enhanced green fluorescent protein (EGFP) prior to regeneration tests. After amputation of the apex, the new apical myocardium is 100% EGFP+, indicating that new cardiomyocytes arise from an existing cardiomyocyte lineage rather than through recruitment of cardiomyogenic precursors. A subpopulation of cardiomyocytes within the ventricular wall expresses Gata4 to reactivate an embryonic program that facilitates dedifferentiation and proliferation and contributes substantially to local muscle regeneration. This is consistent with the results of a cardiac sarcomere study, indicating that proliferating cardiomyocytes detach from one another and acquire a less organized sarcomeric structure during regeneration.

In accordance with this notion, recent studies suggest that mammalian cardiomyocytes regenerate through the division of preexisting cardiomyocytes (Senyo et al., 2013). By combining genetic line age mapping with stable isotope labeling, the nonradioactive tracer [^{15}N] thymidine and DNA synthesis can be measured using multiisotope imaging mass spectrometry (MIMS) in the adult heart of double-transgenic MerCreMer/ZEG mice. During normal mammalian myocardial homeostasis, mature resident cardiomyocytes are the dominant source of cardiomyocyte replacement, at a rate of about 0.76% per year. This process is increased fivefold during recovery from myocardial infarction. Adult cardiomyocytes retain some capacity to re-enter the cell cycle, but after injury, most DNA synthesis occurs in preexisting cardiomyocytes, without completion of cell division. In contrast, cardiac progenitor cells do not make a significant contribution to myocardial homeostasis in mammals, and their roles after injury are also limited. The epicardium and endocardium also appear to play vital signaling roles in heart regeneration. Some of the activated epicardial cells can transdifferentiate into cardiomyocytes at a low rate when preconditioned with thymosin β4 injections (Smart et al., 2011). Together, these findings provide strong evidence that the adult human heart is capable of regenerating cardiomyocytes to preserve cardiac function, although the cell turnover is extremely low throughout the life.

Studying the cellular and molecular regenerative mechanisms in lower vertebrate animals, such as zebrafish, could greatly contribute to developing strategies for promoting endogenous cardiac regeneration. In the future, an ideal therapeutic option would be to employ small-molecules that have the capacity to stimulate and accelerate endogenous cardiomyocyte regeneration after injury.

Chemical Biology and Drug Discovery in Zebrafish

Embryo-Based Small-Molecule Screens Identify Novel Chemical Probes and Drug Candidates

The zebrafish has emerged as a model organism used in multiple steps of the drug discovery process through their use in in vivo phenotypic screens (Wiley et al., 2017; Tan and Zon, 2011). Whole-embryo screens offer considerable advantages in drug discovery by evaluating complex target cell populations in organs, within a relevant physiological context. The identified compounds normally have efficacy with little toxicity, which can be further developed as medicines. Given the ease and rapidity with which the zebrafish embryos can be manipulated, small-molecule screens in zebrafish have contributed to identifying novel suppressors of disease phenotypes and characterization of the associated molecular pathways. For instances, several compounds have been shown to disrupt cardiac valve morphogenesis, vessel formation and others have been shown to influence cardiac action potential.

Grl/Hey2 inhibitor

Direct visualization of vascular phenotypes in zebrafish has enabled high-throughput small-molecule screening to elucidate the mechanisms behind congenital vascular defects. For example, zebrafish expressing the *gridlock* mutation *grl* in the *hey2* gene exhibit malformation of the aorta (Weinstein et al., 1995). As a result, there is disruption of circulation to the tail and trunk and compromised development of collateral vessels, analogous to human aortic coarctation. Using this model, a chemical screen of 5000 candidate small-molecules identified two structurally similar compounds that rescued the *gridlock* phenotype in a dose-dependent manner, resulting in normal flow through the aorta (Peterson et al., 2004). Subsequent experiments demonstrated that these drug candidates acted by upregulating expression of vascular endothelial growth factor (VEGF), which plays a crucial role in the formation of the aorta. These types of chemical suppressor screens offer insight into the molecular pathways responsible for developmental vascular defects such as aortic coarctation.

BMP inhibitor

Dorsomorphin was initially discovered as a BMP inhibitor that regulates dorsal–ventral axis formation in zebrafish embryos (Yu et al., 2008). Dorsomorphin selectively inhibits the BMP type I receptors ALK2, ALK3, and ALK6 and thus blocks BMP-mediated SMAD1/5/8 phosphorylation. Further studies demonstrated that the administration of dorsomorphin promotes

myocardial differentiation in mouse pluripotent embryonic stem (ES) cells (Hao et al., 2008). In addition, dorsomorphin derivatives were developed through initial medicinal chemistry optimization and prepared for clinical testing in patients with fibrodysplasia ossificans progressiva (FOP), which is a rare, fatal disease marked by inappropriate BMP signaling that causes growth of bone fragments within the muscles, ligaments, and other connective tissues, causing pain and progressive immobility (Martelli and Santos, 2014; Shore et al., 2007; Shore et al., 2006).

PGE2 agonist

Another drug with therapeutic potential identified through studies using zebrafish is Prohema. Currently being developed by fate therapeutics, the drug was discovered in a zebrafish screen (in the laboratory of Dr. Leonard Zon at Boston Children's Hospital) for compounds that increased or decreased the numbers of hematopoietic stem cells (HSCs). Prohema's therapeutic potential was first demonstrated in adult zebrafish, where it was shown to enhance the rate of marrow recovery after sublethal irradiation (North et al., 2007). As a stabilized derivative of prostaglandin E2 (PGE2), Prohema is currently in clinical trials in patients undergoing umbilical cord blood (UCB) transplantation for leukemia or lymphoma.

Embryo-Based Small-Molecule Screens Focusing on Cardiomyocyte Generation

Although small-molecule screens focused on heart regeneration are challenging in adult zebrafish, they can be readily carried out in zebrafish embryos. Based on the prior work showing that developmental programs are activated and similar signaling molecules and pathways are employed during regeneration of the injured adult heart (Kikuchi, 2014; Laflamme and Murry, 2011), it is highly likely that the compounds identified from developmental heart screens may have the capacity to induce heart regeneration in adults.

IGF, TGFβ, and Hh agonists

A newly developed fluorescent ubiquitylation-based cell-cycle indicator (FUCCI) screening system employs two fusion proteins (mCherry-zCdt1 and Venus-hGeminin) that are expressed during the G1 and S/G2/M phases. The FUCCI system enables the visualization of cell proliferation events in live animals. Transgenic *mylc7:FUCCI* embryos were exposed to a panel of compounds targeting various developmental signaling pathways, revealing that small-molecules that activate Hedgehog (Hh), insulin-like growth factor (IGF), and TGFβ signaling pathways can be seen to regulate cardiomyocyte proliferation (Choi et al., 2013). Direct examination of zebrafish heart regeneration after mechanical or genetic ablation injuries confirmed that Hh, IGF, and TGFβ signaling pathways are activated in regenerating cardiomyocytes.

Wnt inhibitor

Since the embryonic heart size primarily reflects cardiomyocyte generation, the size of a fluorescence-expressing heart can also be used as a visual indicator to screen for cardiomyocyte phenotypes. Three structurally related compounds with the same pharmacophore, namedcardionogen-1 (CDNG1) to -3 (CDNG3), have been found to enlarge heart size by causing myocardial hyperplasia (Ni et al., 2011). The increased cardiomyocyte number in CDNG1-treated embryos is due to an expansion of the cardiac progenitor cell population, and it may also promote cardiac cell proliferation. Mechanistically, CDNG functions as an inhibitor of the Wnt/β-catenin signaling pathway and can rescue cardiomyocyte deficiency and heart-specific phenotypes induced by Wnt8 overexpression during development. Expanding the panel of pharmacological manipulations that regulate this process will help reveal mechanisms that induce myocardial development and regeneration. Compounds identified from the unbiased screens in zebrafish are likely to represent promising tools for probing and potentially enhancing cardiomyocyte proliferation and regeneration in the injured mammalian heart.

Mammalian cells have also been used to screen for small-molecules that enhance cardiomyogenesis. The small-molecules IWR1 (inhibitor of Wnt response) and IWP3 (inhibitor of Wnt production) were identified as inducers of cardiogenesis, and demonstrated that Wnt inhibition is sufficient to drive human ESCs to form cardiomyocytes (Willems et al., 2011). However, treating zebrafish embryos with IWR1 results in truncation of the posterior axis and disruption of cardiac chamber formation. Notably, CDNG treatment induces cardiac cell formation without causing tail truncation and atrium disruption in zebrafish, indicating that CDNG has less toxicity compared to IWR1. Consistent with the in vivo activities, CDNG blocks Wnt/β-catenin-dependent transcription in embryos and ESCs but not in HEK293 cells, while IWR1 blocks Wnt signaling in embryos, ESCs, and HEK293 cells. These findings suggest that CDNG selectively reduces Wnt signaling associated with certain embryonic or cardiac factors, revealing the benefits of whole-embryo screens by targeting cardiac cell types. This may ultimately aid in design of therapeutic approaches for cardiac regeneration and repair.

Conclusions

We highlight the advantages of the zebrafish as a model animal for cardiovascular research. Zebrafish have a closed cardiovascular system and a cardiac cycle that is highly reminiscent of human physiology. Zebrafish can be easily genetically manipulated, and their genome has been fully sequenced. Transparent zebrafish embryos are particularly suitable for high-resolution phenotypic analyses of cardiovascular morphology as well as high content small-molecule screens for identification of chemical probes or

potential drug candidates. Zebrafish have two distinct phases of cardiomyocyte differentiation that are analogous to the differentiation of the two cardiac progenitor cell populations in mammals, termed as the first and second heart fields. The unique ability of zebrafish cardiomyocytes to regenerate offers a particularly exciting opportunity to develop much-needed therapies for cardiac injuries and heart failure following myocardial infarction. Future studies will undoubtedly take advantage of the zebrafish model to pair human genetic mutations with their molecular functions.

Acknowledgment

We are grateful to members of our laboratories for comments on the manuscript and helpful discussions. We also thank D.S. Sepich, F. Marlow, J.A. Schumacher, and A.Q. Phan for their helpful advice and critical reading of the manuscript, and offer our apologies to many authors whose work we have not cited in this review. This research was supported in part by grants from the National Basic Research Program of China (MOST2013CB945301, MOST2012CB944501; TPZ); National Natural Science Foundation of China (NSFC31530044, NSFC31471357, NSFC31172173; TPZ).

Introduction

Congenital heart diseases (CHDs) are heart defects present at birth caused by abnormal embryonic development. In the US alone, CHD affects approximately 0.8% of live births, and approximately 40% of those affected babies die in infancy (Reller et al., 2008) making CHD the most prevalent type of birth defect. Therefore, understanding the molecular mechanisms that underpin CHD is vitally important to improve diagnostics and therapeutic opportunities.

After decades of research it has become evident that CHD is defined by a complex genetic architecture. Two types of CHD exist, syndromic and nonsyndromic. Patients that fall in the latter category present only isolated defects of the heart and constitute approximately 90% of all CHD patients. The further 10% of patients, in addition to defects in the heart, have other developmental problems such as defects in other organs or an intellectual disability. Until recently, it was accepted that both the syndromic and nonsyndromic variations of the disease resulted from spontaneous de novo mutations. Recently, though, Sifrim et al. (2016) showed that patients suffering from syndromic CHD often had noninherited mutations which are likely to result in defects in the heart. Interestingly, they also showed that nonsyndromic CHD was likely caused by mutant gene variants inherited from healthy parents.

Accumulation of de novo mutations and copy number variation (CNV) of genes involved in cardiac developmental are found to contribute to the majority of CHD cases, with most mutations responsible for CHD identified in a small set of developmental genes. For example in Homeobox containing transcription factor 2.5, NKX2-5 (Schott et al., 1998), GATA4 transcription factor (Garg et al., 2003), and Notch homolog1, NOTCH1 (Garg et al., 2005).

Two back-to-back landmark studies by Iafrate et al. (2004) and Sebat et al. (2004) revealed that CNVs commonly occur in the population. CNVs are manifested throughout the genome as both deletions and duplications which may disrupt none, one or several genomic elements. CNVs that are common (i.e., present at >1%–5% in the population) may be phenotypically neutral or function as regulators of disease susceptibility. On the other hand, rare CNVs (i.e., at a frequency of <1%) are more likely than common CNVs to cause disease, especially developmental disorders like CHD (Costain et al., 2016; Edwards and Gelb, 2016; Lee and Scherer, 2010). However, as CNVs are expected to show some variable expression and/or incomplete penetrance, differentially identified CNVs between unaffected and CHD affected human genomes may not always result in a phenotype. Moreover, CNVs encompass large genomic regions that can contain over 100 genes, making the task of identifying the causative gene more difficult without proper validation in animal models. Currently, CNVs are thought to be involved in ~10% of CHD cases.

The bulk of CHD is expected to be caused by de novo point mutations. NGS has been pivotal in identifying CHD mutations at high read depths ($\geq$20 reads per base) in the exome or the genome. Indeed recent whole exome sequencing (WES) studies have identified hundreds of possible mutations associated with CHD, suggesting that the major part of genes and genetic lesions associated with CHD pathogenesis remain unidentified. Furthermore, the targeted mutation of over 500 genes in mice resulted in heart defects (Andersen et al., 2014). This highlights the scope for the discovery of novel CHD-causing mutations in humans.

Identifying deleterious de novo mutations is a daunting task, as they do not follow Mendelian inheritance and large cohorts of patients and controls are required to have enough statistical power to call disease variants. Therefore, in order to uncover the genetic mechanisms that underlie CHD, the National Heart, Lung, and Blood Institute (NHLBI) created the Pediatric Cardiac Genomics Consortium (PCGC) (https://benchtobassinet.com/About/AboutPCGC/PCGCResearch.aspx) in 2013. As a multicenter initiative, the PCGC has the capacity to enlist the large number of patients and relatives that these studies require. To understand the link between genetic factors and pathological phenotypes, the PCGC established the Congenital Heart Disease Genetic Network Study (CHD GENES) (Pediatric Cardiac Genomics et al., 2013). CHD GENES analyzed a combined total of 1575 CHD trios (pediatric patients who had unaffected parents) and 1164 control trios by employing WES (Homsy et al., 2015; Zaidi et al., 2013). Nonconserved missense, conserved missense, protein changing, and damaging protein altering mutations were identified in both patient and control sets. Notably, a total of 1202 and 894 mutations were discovered in the patient and control sets, respectively

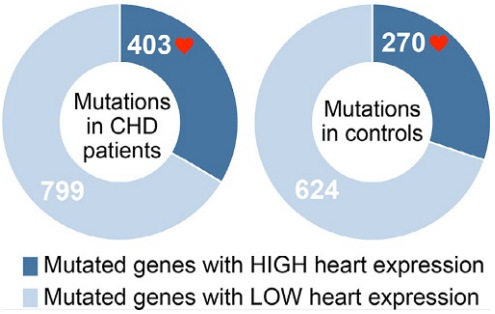

Fig. 1 Pie charts indicating the combined numbers of de novo mutations identified by WES from Homsy et al. (2015) and Zaidi et al. (2013). These studies yielded a total of 1202 and 894 mutations in patient and control sets, respectively, from 1575 CHD trios and 1164 control trios. 403 and 270 mutations were identified in high heart expression genes in the patient and control sets, respectively.

(Homsy et al., 2015; Zaidi et al., 2013). These WES studies uncovered mutations in high heart expressed (HHE) genes in both patient and control sets. 403 (33%) of mutations were identified in HHE genes from the patient cohort. Surprisingly, 270 (30%) mutations were also identified in HHE genes from the control set (**Fig. 1**). Assuming that mutations identified in the control cohort do not contain false positives, these results suggest that mutations in heart genes, even those that occur in highly expressed genes, are not necessarily disease causing. The contribution of de novo CNVs to CHD cases was also investigated by Glessner et al. (2014). They identified 57 and 242 novel CNVs within high heart and low heart expression, respectively, from 538 CHD trios using both genome-wide dense single nucleotide polymorphism (SNP) arrays and WES.

Despite these spearheaded efforts to uncover the genetic basis of CHD, future research should be aimed at addressing the causal relationship between the genes uncovered by the consortium and congenital heart malformations. This need for a casual validation can be also extended to other cardiac diseases, like atrial fibrillation (Tucker et al., 2016). However, the high number of candidate gene variants unearthed to date makes it difficult to validate them all using traditional methods and demands a more nimble approach. Overall, these studies iterate the need for a robust, high-throughput, and fast validation tool. Targeted genome editing in zebrafish using CRISPR/Cas9 knockout technology has the potential to fulfill this requirement to quickly screen through gene variants and become the gold standard for validating candidate disease-causing genes.

Several features of zebrafish development make for an exceptional model organism to study heart development. First, high fertility rates and external fertilization means that hundreds of embryos are available daily for microinjection experiments. Second, complete optical clarity of the embryo coupled to transgenic fluorescent reporters in different tissues provides an excellent platform to visualize in vivo heart development and function with cellular resolution. Third, as oxygen readily diffuses passively into the embryo, the zebrafish can survive without a cardiovascular system for several days, giving researchers ample time to analyze even the most deleterious mutations (Pelster and Burggren, 1996). Fourth, the two-chamber organization of the zebrafish heart (ventricle and atrium) lined with endocardium, myocardium, and pericardium simplifies the morphological and functional analysis. And finally, thanks to the rapid development of zebrafish embryos, heart beating and blood circulation are evident 30 h after fertilization, significantly accelerating the discovery process.

Most recent work is targeted at coupling the accessibility of zebrafish with the new mutagenic technologies, as a systematic and translational strategy, to uncover causative genes of CHD.

Using Zebrafish to Study Cardiovascular Development and Disease

Identifying disease-causing sequence variants from the many nondeleterious gene variants using NGS alone is challenging (Richards et al., 2015). For example, Narasimhan et al. (2016) show that even rare homozygous loss-of-function variants can be detected in unaffected individuals using NGS, suggesting such variants may not be clinically significant. Clearly, falsely assigning variant pathogenicity would hamper our understanding of disease. Thus, it is of the utmost importance that candidate disease-causing gene variants are validated for pathogenic causality. Typically, this is achieved by generating a loss-of-function mutant. The presence of an abnormal phenotype is strong evidence to assign pathogenicity to the particular gene variant (MacArthur et al., 2014). Traditionally, mouse is the model of choice to study disease mechanisms and the efficacy of new therapies (Dow and Lowe, 2012). However, the mouse model is not conducive for high-throughput analyses because of their small number of progeny and higher costs to maintain. Zebrafish may represent a more advantageous alternative for translational research (Gama Sosa et al., 2012).

From the genomic point of view, the zebrafish model is particularly amenable to studying human cardiac development and disease. For example, there is striking similarity between zebrafish and human genomes: 70% of protein-coding human genes and 84% of genes associated with human disease have an analog in zebrafish (Howe et al., 2013). Also, the transcription programs that direct cardiogenesis and maintenance of cardiac physiology are conserved between zebrafish and humans. Furthermore, mutations in genes encoding transcription factors and cell signaling molecules in zebrafish have been linked to CHD in humans. For example,

the human transcription factors: GATA4/5/6, NKX2.5, TBX5, HAND2; the human cell signaling molecules and growth factors: NOTCH1, SMAD6, FLK1, SEMA3 are also important for heart development in zebrafish (Brown et al., 2016). Indeed, because of the high degree of conservation between zebrafish and humans, the structural and functional defects that cause human heart disease also lead to the same defects in heart size, shape, or function in the zebrafish model. Lastly, despite the zebrafish heart contains only two chambers (atrium and ventricle) compared to the human heart, both human and fish hearts are assembled using comparable cell types and both function in similar manner. Thus zebrafish has rapidly become the organism of choice to study the effect of gene variants in human heart disease.

Thanks to the rapid embryonic development of zebrafish, the embryonic heart starts contracting just 24 h postfertilization, and is developmentally equivalent to a 3-week-old human heart. Furthermore, zebrafish and human share a similar cardiac physiology. Though, the optical transparency of zebrafish embryos provides arguably the greatest advantage to study cardiac development. For example, structures such as blood vessels are easily seen using a light microscope. Also the optical clarity of zebrafish embryos allows the use of tissue-specific transgenic reporters in which cells are labeled with fluorescent protein markers, such as GFP (Lawson and Weinstein, 2002; Shafizadeh et al., 2002). Zebrafish reporter lines that label specifically the endocardium, myocardium, or epicardium are readily available in the community (Poon et al., 2010). This allows for defects to be directly observed in live zebrafish embryos. Importantly, even the most severe cardiovascular defects, incompatible with life in other model organisms, can be studied in zebrafish, as embryos receive oxygen by diffusion and do not require an active blood flow during the first week of life (Bakkers, 2011; Pelster and Burggren, 1996).

The ability to produce transgenic zebrafish lines is a further attraction to use this organism to model human CHD. For example, transgenic zebrafish have been generated to overexpress defective candidate proteins linked to human cardiac diseases. Huttner et al. (2013) established a transgenic zebrafish line that stably expresses a human arrhythmogenic SCNA5A channel variant. Phenotypically, these modified zebrafish show bradycardia and conduction abnormalities. This approach of expressing a human protein in zebrafish further highlights the power of using zebrafish as a means to study human CHD in vivo.

There is also an outstanding record of unbiased forward genetic screens that have taken advantage of these zebrafish features to make significant contributions to our understanding of heart tube formation (Alexander et al., 1998; Chen et al., 1996; Stainier et al., 1996) and cardiac function (Chen et al., 1996; Stainier et al., 1996; Warren et al., 2000). More recently, targeted knockdown with morpholinos (MOs) (Thienpont et al., 2010) or mRNA overexpression (Smith et al., 2009) has been used to validate mutations found in human patients and uncover the molecular mechanisms that underlie cardiac development and disease.

Cofunctional Networks to Identify Candidate Disease-Causing Genes

As alluded to above, recently, several large-scale population studies coupled to NGS have provided evidence indicating that a significant subset of these identified gene variants were in fact either polymorphisms or are also present in unaffected individuals. This notion was further supported by the fact that disease-relevant phenotypes were not observed following knockdown of the predicted causal gene variants. Despite this, such variant-driven approaches have been pivotal in the identification of a number of genes potentially implicated in CHD. However to increase the stringency with which candidate genes are identified, cofunctional networks can be used. A cofunctional network is a way to represent sequencing data as gene functional information (van Dam et al., 2017). This is a proven platform to study gene functions as most genes exert their function through their molecular interactions. These networks are assembled by the transfer of functional gene annotations based on the "closeness" of genes. Recently, applying network-based gene prioritization approaches has identified many disease-causing genes. The idea involves the identification of candidate genes based on "relatedness" to a gene variant with a disease annotation. Ultimately this allows for novel predicted functions to be assigned to genes. Generally these cofunctional networks are achieved by either guilt-by-association (GBA) or guilt-by-profiling (GBP) approaches. GBA works on the principle that genes with related functions are connected by genetic or physical interactions, while GBP exploits the relationship between function and other gene characteristics.

Musso et al. (2014) combined GBA and GBP approaches for the de novo discovery of gene functions implicated in CHD. This method, accurately predicted known mutant phenotypes, suggesting robustness in the approach taken. Using targeted MO knockdown, Musso et al. (2014) validated 16 high-confidence cardiac predictions in zebrafish embryos using transient knockdown mediated by MOs, observing a significant enrichment for cardiac phenotypes as compared to controls. Notably, they identify *tmem88a* as an effector of the intercellular coupling pattern in zebrafish cardiac epithelium.

Zebrafish combines the amenability and wide extensive genetic toolkit typically available in invertebrate model organisms like *C. elegans* and *D. melanogaster* with a developmental ontology closer to humans as both are vertebrates. This genomic similarity between zebrafish and human was recently exploited by Shim et al. (2016) to compile a cofunctional network of zebrafish genes as an integrated genomics resource. They selected a total of 18,971 coding genes, with reliable Ensembl annotation, for network modeling. The networks were established from 18 genomics datasets using a Bayesian statistical framework in a database named DanioNet (http://www.inetbio.org/danionet/) (Shim et al., 2016). DanioNet can be used as a means to predict pathway/phenotype information for a given gene, or to predict particular pathway/phenotypes affected by new genes. For example, pathway/phenotype information can be predicted for a gene of interest by analyzing pathway/phenotype annotations of network neighbors. Notably, information gained from DanioNet can easily be extended to humans as human orthologs of zebrafish genes are also included. Future updates of DanioNet will include the compilation of RNA-seq datasets, which will provide gene expression information. This will provide a useful resource for the identification candidate genes implicated in CHD.

Genetic Toolkit to Validate the Causal Link Between Candidate Genes and Disease in Zebrafish

Overexpression

To uncover CHD causative genes embedded in de novo CNVs or to test the role of a putative dominant negative mutant, transient overexpression and monitoring of cardiac development is required (**Fig. 2**). Transient overexpression is easily achieved in zebrafish by injecting an in vitro transcribed mRNA (in the range of 100 pg per embryo) encoding the protein of interest into one-cell stage embryos. Due to the reductive nature of embryonic cell divisions, any product injected at one-cell stage will be present in all cells of the embryo. While this feature will ensure a robust overexpression of the candidate gene, in some cases it may impede expression of test genes that require precise tissue specificity or have other gain-of-function when expressed ectopically.

Using the approach of overexpressing a mutant gene variant in zebrafish embryos, Smith et al. (2009) identified a dominant negative mutation of the bone morphogenetic protein receptor (ALK2) being responsible for a particular CHD. More specifically, Smith et al. (2009) identified 11 SNPs in genes involved in atrioventricular septum development. These SNPs were expected to detrimentally affect protein function and therefore present high-confidence candidates as drivers of atrioventricular septum defects. Overexpression of the mutant form of ALK2, by microinjection in zebrafish, induced improper atrioventricular canal formation. In this way, Smith et al. (2009) were able to demonstrate the casual link between a mutant variant of ALK2 and CHD.

Morpholinos

Traditionally, loss-of-function mutants in zebrafish were achieved by microinjection of short antisense modified oligonucleotides, or MOs, in early zebrafish embryos resulting in transient knockdown of the gene of interest (**Fig. 2**) (Shestopalov and Chen, 2010; Yuan and Sun, 2009). Partial to full loss-of-function is observed leading to a hypomorphic phenotype in a reverse genetics approach. Mechanistically, MOs function by either binding to the complementary sequence surrounding the first translated ATG to block mRNA translation, or by binding to splice or donor sites to block precursor mRNA splicing.

MOs have been used successfully to faithfully identify genes implicated in CHD. For example, MO knockdown of *nphp4* gene in zebrafish was linked to a fault in the looping of the heart. This was further supported by partial rescue of the mutant phenotype following injection of wild type but not mutant gene variants of NPHP4 in zebrafish (French et al., 2012).

Wang et al. (2013) identified that loss of fatty acid-binding protein 3 (FABP3) causes CHD through MO knockout in zebrafish. Loss of FABP3 resulted in multiple phenotypes including a linear heart tube, incomplete cardiac loop formation, and abnormal positioning of the ventricles and atria. FABP3-MO injected zebrafish (morphants) also exhibited delayed development, down-regulated expression of cardiac-specific markers, and decreased heart rate. The authors noted the increased expression of the retinoic acid (RA) catabolizing enzyme Cyp26a1 in FABP3-MO zebrafish. However, there was no significant change in levels of

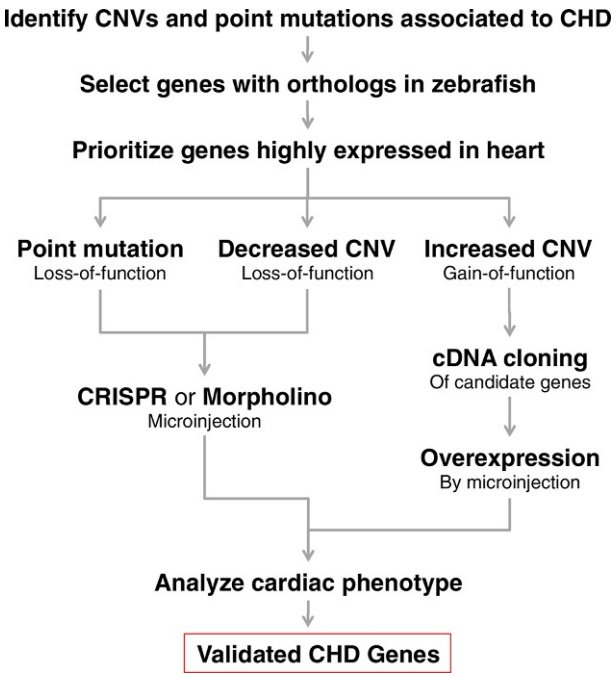

Fig. 2 A schematic outlining the methods to validate candidate CNVs and point mutations associated with CHD. Point mutations or loss-of-function CNVs can be validated by injecting CRISPRs into zebrafish embryos to knockout the gene of interest and observing the resulting phenotype. Gain-of-function CNVs can be validated with overexpression studies by injecting the mRNA of interest into zebrafish embryos and observing the resulting phenotype.

the RA synthesizing enzyme Raldh2 between mutant and wild-type zebrafish. That is, FABP3 is a critical regulator of RA signaling and is required for proper cardiac development. Ultimately, this study identifies that the loss of FABP3 underpins the etiology of CHD.

More recently, Schuster et al. (2015) showed that by injecting MOs against the cohesin protein Rad21 into zebrafish, similar types of heart defects were observed to Cornelia de Lange Syndrome (CdLS) affected patients. CdLS is a rare developmental syndrome that is manifested as both physical and cognitive defects, with up to 70% of patients having CHD (Chatfield et al., 2012). Broadly, mutations in the subunits or regulators of the cohesin proteins are responsible for CdLS. As the morphant zebrafish embryos only showed evidence of heart structural abnormalities, this suggested that the observed phenotype was caused by knockdown of Rad21 rather than an off-target effect. Furthermore, they showed that cells involved in developing heart structures failed to migrate to the heart upon depletion of Rad21. Significantly, this study suggests that the amount of Rad21 and cohesin is a critical regulator of heart development, and that mild mutations in cohesin may cause some fraction of CHD.

The transcription factor NKX2.5 is required for cardiac differentiation (Targoff et al., 2008). NKX2.5 is the earliest marker of heart development, driving development of the ventricle over the atrium. Zebrafish embryos were injected with MOs against NKX2.5 and p53; mutants exhibited less ventricular cardiomyocytes and more atrial cardiomyocytes in comparison to wild type (Targoff et al., 2013). In humans nkx2.5 mutations are associated with congenital heart defects (Abou Hassan et al., 2015).

Despite these successful MOs examples, there is a rising concern in the zebrafish field regarding the false positive rates of MOs. This has been recently emphasized in a study by Kok et al. (2015) where they applied site-specific nucleases (zinc finger, TALENs, CRISPRs) in zebrafish targeting more than 20 genes. They find that 10 different mutant zebrafish lines do not recapitulate published MO-induced phenotypes. The authors also confirm that the absence of phenotype was not influenced by the maternal contribution or the failure to eliminate gene function. In addition, the authors compare published morphant defects with the Sanger Zebrafish Mutation Project (Kettleborough et al., 2013) and conclude that approximately 80% of morphant phenotypes were not observed in mutant embryos. Therefore, it is of the utmost importance that MOs experiments shall be complemented with careful titration and rescue. The rescue is achieved by injecting mRNA of the wild-type candidate gene with the MO-binding sites mutated to prevent repression. Only when the rescue restores the wild-type phenotype can the absence of MO-mediated toxicity or off-target effects be confirmed. This strategy is even more relevant in the case of cardiac analysis. It was shown that MOs result in the upregulation of the apoptosis factor p53 (Robu et al., 2007) and can induce a phenotype with a cardiovascular component. Thus, this off-target effect may conceal the actual phenotype, complicating the phenotype analysis. To overcome this problem, co-injection of a p53-specific MO is important (Bedell et al., 2011).

CRISPR

Genome editing using CRISPR/Cas9 system has taken the zebrafish field by landslide. Their high mutagenic efficiency (Hwang et al., 2013) coupled with the fast development of zebrafish embryos allows for phenotype screening to be performed 24–48 h postinjection of CRISPRs (Moreno-Mateos et al., 2015; Ota et al., 2014; Shah et al., 2015).

CRISPRs were first noted in 2005 as a bacterial host defense system against viruses (Mojica et al., 2005). However it was not until 2010 when Cas9 was shown to cleave DNA. Garneau et al. (2010) demonstrated that CRISPR–Cas9 creates double-stranded breaks in target DNA. More specifically, they confirm that Cas9 protein is required for cleavage and has a domain that binds to a short DNA sequence termed the protospacer adjacent motif (PAM). Cas9 cleaves at precisely three nucleotides upstream of the PAM sequence. It was then in 2013 that CRISPR–Cas9 was successfully adapted for genome editing in eukaryotic cells (Cong et al., 2013). They engineered two different Cas9 orthologs (from *S. thermophilus* and *S. pyogenes*) and showed site-specific genome editing in both human and mouse cells. Mechanistically, genome editing is accomplished by complementarity of the guide RNA to a specific DNA sequence, directing Cas9 endonuclease activity at that specific site. Currently, the CRISPR/Cas9 system is widely regarded as a specific, efficient tool to manipulate the genome.

sgRNAs can vary in their activity; thus it is critical to uncover the rules that instruct efficient targeting in vivo. To this end, several groups tested the cleavage efficiency of 122 (Gagnon et al., 2014), 168 (Varshney et al., 2015), and 1280 (Moreno-Mateos et al., 2015) sgRNAs in zebrafish embryos and established the rules that orchestrate efficient CRISPR/Cas9-mediated mutagenesis.

Gagnon et al. (2014) showed that injection of recombinant Cas9 protein precomplexed with sgRNAs increased the mutagenic efficiency. In addition, they tested the strategy of knocking in an oligonucleotide with multiple stop codons in all three reading frames to avoid nonframe shifting recurrent repairs and ensure protein truncations. Varshney et al. (2015) targeted 168 loci with a stunning efficiency of 99%. However, only 28% show germ line transmission to the next generation. Moreno-Mateos et al. (2015) determined the characteristics of stability, activity, and loading into Cas9 in vivo for 1280 sgRNA. They observed that sgRNA stability and activity were increased with guanine enrichment and adenine depletion. Furthermore, they found that differential sgRNA loading, nucleosome positioning, and Cas9 off-target binding did not influence sgRNA stability and activity. Based on these observations they developed a predictive sgRNA-scoring algorithm, CRISPRscan, that allows the user to design sgRNAs in a host of organisms including zebrafish. More recently, Varshney et al. (2016) complied CRISPR targets derived from a large-scale mutagenesis project and published validated targets into a database, CRISPRz (https://research.nhgri.nih.gov/CRISPRz/?mode=search).

Regarding the specific use of CRISPR/Cas9 to study zebrafish development, Shah et al. (2015) used engineered CRISPRs to efficiently knockout genes of interest to identify genes that affect synaptogenesis during zebrafish development. They achieved high mutagenic activity by injecting a codon-optimized Cas9 mRNA with two nuclear localization sequences (Jao et al., 2013). Significantly, their high levels of biallelic disruption enabled the phenotyping of the CRISPR-injected embryos (F0 screening)

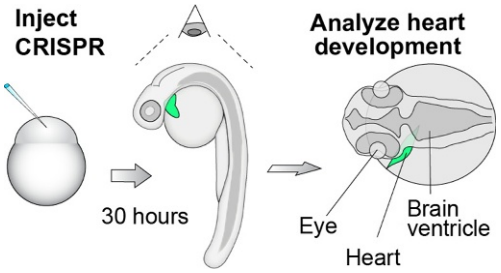

Fig. 3 Cartoon that illustrates the experimental strategy to manipulate gene expression in zebrafish. CRISPRs are injected in one-cell stage zebrafish embryos. 30 h postinjection, cardiac phenotypes are already visible.

within 48 h postinjection (**Fig. 3**). These results demonstrate that phenotype analyses can be performed in as little as 24–48 h postinjection.

The definitive proof of principle that F0 screenings can tackle CHD in zebrafish was delivered by Ota et al. (2014). The authors injected sgRNAs directed against s1pr2 (sphingosine 1′phosphate receptor 2) whose zebrafish mutant *miles apart* manifests its characteristic *spina bifida* phenotype caused by the failure of the cardiac precursor cells to fuse in the midline after migrating from the anterior lateral plate mesoderm (Kupperman et al., 2000). One day after injection of the CRISPRs, the authors were able to observe the *cardia bifida* in the CRISPR-injected embryos even though they were chimeric for the mutation (**Figs. 2** and **3**). These results provide evidence that accurate sgRNA selection and injection allows the analysis of complex cardiac phenotypes in as little as 24 h after injection. Thus, the power of CRISPRs coupled with the range of observable phenotypes in zebrafish translates into a broadly valuable approach as a means to validate candidate genes associated with many biological processes in a timely manner.

Although this approach is a rapid and powerful tool for the initial validation of CHD candidate genes, there are important caveats to note. CRISPR animals are mosaic, in part, as a result of the delay in Cas9 mRNA translation and protein folding. Thus, each CRISPR-injected animal (F0 generation) can display many different allele variants; mosaicism will inevitably complicate genotyping and phenotyping analyses. Furthermore, it is expected that one-third of indels would be in frame and therefore potentially hypomorphic or silent. To confirm the phenotype of CRISPR-injected F0 embryos, they should be rescued by co-injection of the wild-type mRNA. In addition, the mutant fish obtained from these screenings can be raised to adulthood to establish a mutant line to study, in detail, the molecular mechanisms driving cardiac disease.

Finally, these mutant zebrafish lines provide an invaluable resource to the community, as they have the potential to be used in small molecule screenings to uncover novel drugs. Peterson et al. (2004) screened over 5000 small molecules for their ability to rescue the hey2 zebrafish mutant, which exhibit malformation of the aorta and is a model for human aortic coarctation. They were successful in isolating two compounds that were able to restore blood flow through the aorta. This highlights the potential of zebrafish to not only discover mutations that are causative of the CHD but also to uncover novel therapies that would ameliorate the burden of CHD in the affected children.

Conclusions

Zebrafish is emerging as a model organism of choice to understand the etiology of human CHD. The genetic underpinnings of heart development in zebrafish are highly similar to that in humans, while zebrafish presents many advantages that allow for rapid screening of candidate CHD-associated gene variants. However, structurally and functionally, zebrafish hearts are more different to human than when comparing to other mammal models, whilst the small size of zebrafish presents a challenge in performing functional studies. Despite these limitations, the advancement of genome editing technologies and their application in zebrafish have provided an avenue to effectively study the causal link between mutant gene variants and various cardiovascular diseases, especially CHD.

Fundamental processes associated with heart functions appear to be conserved in zebrafish. This strongly supports the use of zebrafish as a model to study cardiovascular disease. Indeed, zebrafish has been successfully used to study CHD, but other emerging zebrafish models are beginning to answer fundamental questions in atherosclerosis (e.g., Fang et al., 2014), cardiomyopathy (e.g., Hassel et al., 2009) and arrhythmias (e.g., Milan et al., 2003).

INDEX

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization, and it is arranged in set-out style, with a maximum of four levels of heading. Location references refer to the volume number, in bold, followed by the page number. Page numbers suffixed by *b*, *f* and *t* refers to boxes, figures and tables terms respectively. *vs*. indicates a comparison. **Bold locators** refers to main articles.

with classic electrocardiographic features, 4:739, 4:740*t*
definition, 4:725
irregular, 4:729, 4:739–741, 4:741–744*f*
preexcited tachycardias, 4:739
regular, 4:729–730, 4:729–730*f*
clinical history, 4:731
diagnosis, 4:731–739
ECG, 4:732–739, 4:732*f*
physical examination, 4:731–732
prevalence, 4:730–731
Wild-type ATTR amyloidosis, 1:35
Wild-type transthyretin cardiomyopathy, 1:68–70, 1:77
Williams–Beuren syndrome (WBS) (Williams syndrome), 4:95, 4:96*f*
Williams syndrome, 1:683
Wilson's disease, 1:520
Wireless cardiac stimulation system (WiCS), 1:27, 1:27*f*
WiSE CRT trial, 1:466
Wistar Kyoto rat model, 4:416
Wnt inhibitor, zebrafish, 4:766
Wnt signaling, 3:426, 3:427*f*
Wolff–Parkinson–White syndrome (WPW), 1:747, 1:749, 4:14
Women's Ischemia Syndrome Evaluation (WISE) study, 3:358
World Congress on Neurology in Rome, 3:222
World Health Organization (WHO), 1:535, 2:231, 2:256
World Symposium on Pulmonary Hypertension (WSPH), 4:181
WOSCOPS trial, 1:308
Wrapping, 4:648

X

X-inactive specific transcript (XIST), 2:261
X-linked myxomatous valvular dystrophy (XMVD), 2:320

Y

Yacoub procedure, 1:137
Yap gain of function, 3:426
Years of life lost (YLL), 2:249–251, 2:252*f*
Yohimbine, 3:587

Z

ZAHARA maternal cardiovascular risk scores, 4:163, 4:163*t*
ZAHARA score, 3:284–285, 3:285*t*
Zebrafish *(Danio rerio)*, 4:759, 4:760*f*
blood vessel, 4:760–762
BMP inhibitor, 4:765–766
candidate disease-causing genes, 4:773
cardiac regeneration process, 4:763–764, 4:764*f*, 4:766
cardiomyocyte differentiation, 4:761, 4:761*f*

chemical biology, 4:765–766
CRISPR, 4:775–776
drug discovery, 4:765–766
embryonic development, 4:760–761, 4:760*f*
features, 4:772
genetic manipulation, 4:762–763
grl/*hey2* inhibitor, 4:765
heart development, 4:761
Hedgehog agonists, 4:766
insulin-like growth factor, 4:766
molecular signaling pathway, 4:762
morpholino, 4:762–763, 4:774–775
multiisotope imaging mass spectrometry, 4:765
overexpression, 4:774
PGE2 agonist, 4:766
Semaphorin–Plexin signaling, 4:762
to study cardiovascular development and disease, 4:772–773
TGFβ, 4:766
vascular development, 4:761–762
Wnt inhibitor, 4:766
Zebrafish Information Network (ZFIN), 4:760
Zebrafish, vasculogenesis, 4:640
arteriovenous specification, 4:647–648
embryonic vessels, assembly, 4:644–647, 4:645*f*
endothelial progenitor cells
developmental route and factors, 4:644*f*
Etv2 role, 4:641
signaling pathways, 4:643–644
vertebrates, 4:642*f*
intraembryonic, 4:640–641
sites of, 4:640–641
VEGF signaling during, 4:642–643
vessel lumenization, 4:648, 4:649*f*
ZINBA, 1:280
Zinc, 4:274*t*, 4:276
Zinc finger homeobox 3 (ZFHX3), 2:305, 2:309
Zio Patch, 2:205–206

VOLUME 4

Encyclopedia of Cardiovascular Research and Medicine

Editors in Chief

Ramachandran S. Vasan and Douglas B. Sawyer

Section Editors

Ragavendra R. Baliga
Thomas Di Salvo
Chris P. Gale
Thorsten Kessler
Yoshihiro Kokubo
Daniel Lenihan
Lucy Liaw
Amy Major
Satish R. Raj
Heribert Schunkert

Set ISBN

ISBN 978-0-12-809657-4

9 780128 096574

Volume ISBN

ISBN 978-0-12-814441-1
