Hypothalamic neurones projecting to autonomic neurones are found in the paraventricular nucleus (oxytocin and vasopressin neurones), perifornical and dorsomedial nuclei (atrial natriuretic peptide neurones), lateral hypothalamic area (α-melanocyte-stimulating hormone; α-MSH neurones) and zona incerta (dopamine neurones). These fibres run through the medial forebrain bundle into the tegmentum, ventrolateral medulla and dorsal lateral funiculus of the spinal cord. In the brainstem, fibres innervate the parabrachial nucleus, nucleus ambiguus, nucleus tractus solitarius and dorsal motor nucleus of the vagus. In the spinal cord, they terminate on sympathetic and parasympathetic preganglionic neurones in the intermediolateral column. Both oxytocin- and vasopressin-containing fibres can be traced to the most caudal spinal autonomic neurones.

The medial mammillary nucleus gives rise to a large ascending fibre bundle that diverges into the mammillothalamic and mammillotegmental tracts (see Fig. 30.9). The mammillothalamic tract ascends through the lateral hypothalamus to reach the anterior thalamic nuclei, from which massive projections radiate to the cingulate gyrus. The mammillotegmental tract curves inferiorly into the midbrain ventral to the medial longitudinal fasciculus and is distributed to tegmental reticular nuclei.

PITUITARY GLAND (HYPOPHYSIS)

The pituitary gland (hypophysis) is a reddish-grey, ovoid body, about 12 mm in transverse and 8 mm in anteroposterior diameter, and with an average adult weight of 500 mg (**Fig. 30.10**; see Fig. 25.20). It is continuous with the infundibulum, a hollow, conical, inferior process from the tuber cinereum of the hypothalamus, and lies within the pituitary (hypophysial) fossa of the sphenoid bone, where it is covered superiorly by a circular diaphragma sellae of dura mater. The latter is pierced centrally by an aperture for the infundibulum and separates the anterosuperior aspect of the pituitary gland from the optic chiasma. Inferiorly, the gland is separated from the floor of the fossa by a venous sinus that communicates with the circular sinus. The meninges blend with the capsule of the pituitary gland and are not separate layers.

The pituitary gland has two major parts, the neurohypophysis, which is posterior, and the adenohypophysis, which is anterior (Sam and Frohman 2008). They differ in their origin, structure and function. The neurohypophysis is a diencephalic downgrowth connected with the hypothalamus and the adenohypophysis is an ectodermal derivative of the stomatodeum (Ch. 14).

Both the neurohypophysis and the adenohypophysis include parts of the infundibulum (whereas the older descriptive terms, 'anterior lobe' and 'posterior lobe', do not). The infundibulum has a central infundibular stem that contains neural hypophysial connections and is continuous with the median eminence of the tuber cinereum. The neurohypophysis includes the pars posterior (pars nervosa, posterior or neural lobe), infundibular stem and median eminence. The adenohypophysis includes the pars anterior (pars distalis or glandularis), pars intermedia and pars tuberalis. The latter surrounds the infundibular stem.

Neurohypophysis

Axons arising from groups of hypothalamic neurones (e.g. the magnocellular neurones of the supraoptic and paraventricular nuclei) terminate in the neurohypophysis. The long magnocellular axons pass to the main mass of the neurohypophysis: they form the neurosecretory hypothalamohypophysial tract and terminate near the sinusoids of the posterior lobe. The neurohormones stored in the main part of the neurohypophysis are vasopressin (antidiuretic hormone; ADH), which controls reabsorption of water by renal tubules, and oxytocin, which promotes the contraction of uterine smooth muscle in childbirth and the ejection of milk from the breast during lactation (pituitary hormones are summarized in **Table 30.4**). Storage granules containing active hormone polypeptides bound to a transport glycoprotein, neurophysin, pass down axons from their site of synthesis in the neuronal somata (**Fig. 30.11**).

Adenohypophysis

The adenohypophysis is highly vascular. It consists of epithelial cells of varying size and shape arranged in cords or irregular follicles, between

The unmyelinated axons of the neurohypophysis are ensheathed by typical astrocytes in the infundibulum. Near the posterior lobe, astrocytes are replaced by pituicytes, dendritic neuroglial cells of variable appearance, often with long processes running parallel to adjacent axons and that constitute most of the non-excitable tissue in the neurohypophysis. Typically, their cytoplasmic processes end on the walls of capillaries and sinusoids between nerve terminals. Axons also end in perivascular spaces, lying close to the walls of the sinusoids but separated from them by two basal laminae, one around the nerve endings and the other underlying the fenestrated endothelial cells. The spaces between the basal laminae are occupied by fine collagen fibrils.

The trabecula is a compact band of connective tissue and blood vessels lying within the pars distalis on either side of the midline; it forms a prominent fibrovascular tuft close to the junction of the central and lateral parts of the pars distalis (Xuereb et al 1954).

which lie thin-walled vascular sinusoids supported by a delicate reticular connective tissue (Fig. 30.12). Most of the hormones synthesized by the adenohypophysis are trophic (see Table 30.4). They include GH, involved in the control of body growth, and prolactin, which stimulates growth of breast tissue and milk secretion; TSH, which stimulates thyroid follicular cells to release thyroxine (T4) and triiodothyronine (T3); FSH, which stimulates growth and secretion of oestrogens in ovarian follicles and spermatogenesis in the testis; and LH, which induces progesterone secretion by the corpus luteum and testosterone synthesis by Leydig cells in the testis. The pro-hormone pro-opiomelanocortin (POMC), synthesized in the adenohypophysis and in the arcuate nucleus of the hypothalamus, is post-translationally cleaved into a number of peptide hormones including adrenocorticotropin (ACTH), α-, β- and γ-melanocyte stimulating hormone (MSH) and β-lipotropin in the corticotrophs of the adenohypophysis, and β-endorphin in the melanotrophs of the pars intermedia (Cawley et al 2016, Navarro et al 2016, Toda et al 2017).

Neurones that secrete the peptides and amines that control the adenohypophysis are widely distributed within the hypothalamus, mainly in the periventricular zone, arcuate nucleus and medial parvocellular part of the paraventricular nucleus.

TABLE 30.4 Pituitary hormones

Hormone	Cell type	Function/effector site	Releasing factor	Inhibitor
ACTH	Corticotrophs (basophils)	Suprarenal cortex	CRH	
TSH	Thyrotrophs (basophils)	Thyroid gland	TRH	Somatostatin
LH, FSH	Gonadotrophs (basophils)	Gonads	GnRH (pulsatile)	GnIH
GH	Somatotrophs (acidophils)	Body growth and metabolism	GHRH	Somatostatin
Prolactin	Lactotrophs (acidophils)	Mammary gland		Dopamine
Vasopressin (ADH)	Magnocellular hypothalamic neurones	Water absorption in distal renal tubule		
Oxytocin	Magnocellular hypothalamic neurones	Contraction of uterine smooth muscle and ejection of breast milk		

Abbreviations: ACTH, adrenocorticotrophic hormone; ADH, antidiuretic hormone; CRH, corticotrophin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnIH, gonadotrophin-inhibitory hormone; GnRH, gonadotrophin-releasing hormone; LH, luteinizing hormone; TRH, thyrotrophin-releasing hormone; TSH, thyroid-stimulating hormone.

Arteries and veins of the pituitary gland

The arteries of the pituitary arise from the internal carotid arteries via a single inferior and several superior hypophysial arteries on each side (Page 1982). The former come from the cavernous part of the internal carotid artery, the latter from its supraclinoid part and from the anterior and posterior cerebral arteries. The inferior hypophysial arteries divide into medial and lateral branches, which anastomose across the midline and form an arterial ring around the infundibulum. Fine branches from this circular anastomosis enter the neurohypophysis to supply its capillary bed. The superior hypophysial arteries supply the median eminence, upper infundibulum and the lower infundibulum. A confluent capillary net, extending through the neurohypophysis, is supplied by both sets of hypophysial vessels. Reversal of flow can occur in cerebral capillary beds lying between the two supplies.

The arteries of the median eminence and infundibulum end in characteristic sprays of capillaries, which are most complex in the

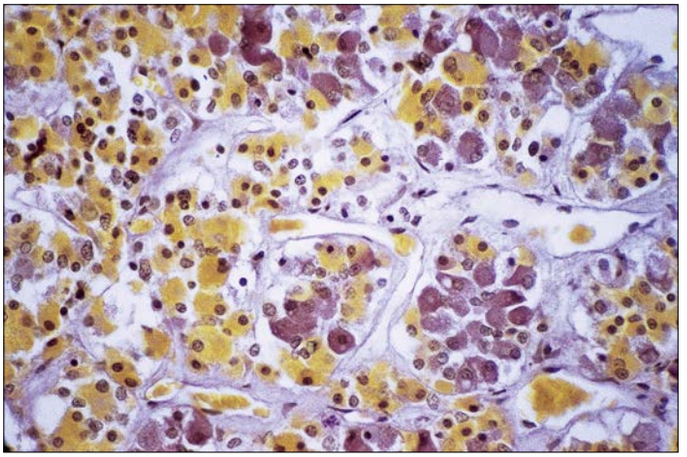

Fig. 30.12 The endocrine cells of the adenohypophysis (trichrome-stained). Chromophils can be distinguished as acidophils (yellow) and basophils (pink), whereas chromophobes are pale-staining cells. A network of sinusoids is seen between clusters of secretory cells.

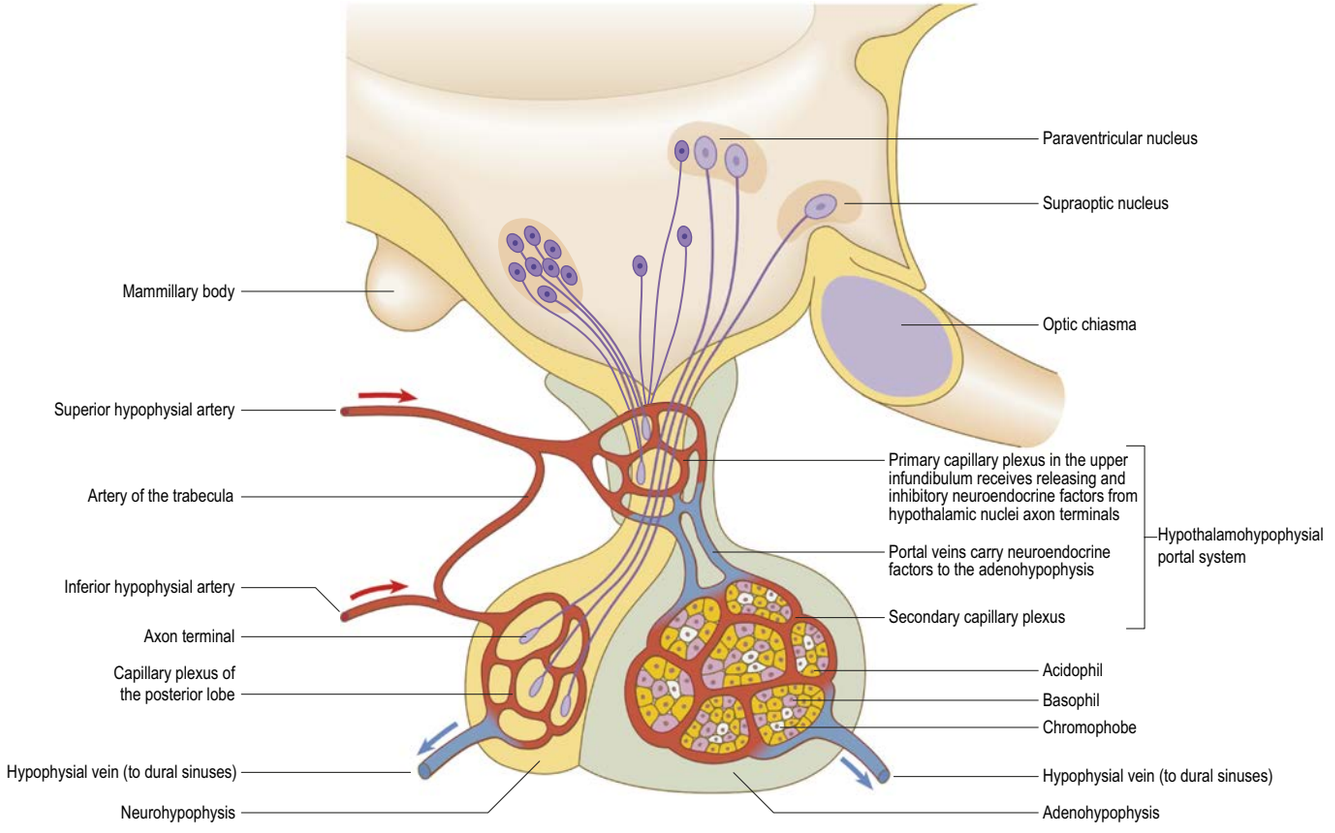

Fig. 30.11 The main systems controlling the endocrine secretory activities of the pituitary gland.

upper infundibulum. In the median eminence, these form an external or 'mantle' plexus and an internal or 'deep' plexus. The external plexus, fed by the superior hypophysial arteries, is continuous with the infundibular plexus and is drained by long portal vessels that descend to the pars anterior. The internal plexus lies within and is supplied by the external plexus. It is continuous posteriorly with the infundibular capillary bed and, like the external plexus, is drained by long portal vessels. Short portal vessels run from the lower infundibulum to the pars anterior. Both types of portal vessel open into vascular sinusoids, which lie between the secretory cords in the adenohypophysis and provide most of its blood. There is no direct arterial supply to the adenohypophysis. The portal system carries hormone-releasing and hormone-inhibiting hormones synthesized in parvocellular hypothalamic neurones, and these control the secretory cycles of cells in the adenohypophysis.

There are three possible routes for venous drainage of the neurohypophysis: via long and short portal vessels to the adenohypophysis; via the large inferior hypophysial veins into the dural venous sinuses; via capillaries passing to the median eminence to the hypothalamus. The venous drainage carries hypophysial hormones from the gland to their targets and also facilitates feedback control of secretion. The venous drainage of the adenohypophysis appears more restricted because few vessels connect it directly to the systemic veins.

SUBTHALAMUS

The subthalamus is a complex region of nuclear groups and fibre tracts. The main nuclear groups are the subthalamic nucleus, the reticular nucleus, the zona incerta, the fields of Forel and the pregeniculate nucleus tracts (see Fig. 31.11). The rostral poles of the red nucleus and substantia nigra also extend into this area. The main subthalamic tracts are the upper parts of the medial, spinal and trigeminal lemnisci and the solitariothalamic tract, which all approach their terminations in the thalamic nuclei; the dentatothalamic tract from the contralateral superior cerebellar peduncle; the fasciculi lenticularis, retroflexus and subthalamicus; the ansa lenticularis; fascicles from the prerubral field (H field of Forel); the continuation of the fasciculus lenticularis (in the H_2 field of Forel); and the fasciculus thalamicus (the H_1 field of Forel).

Subthalamic nucleus

The subthalamic nucleus is structurally and functionally related to the basal ganglia and is therefore considered with them in Chapter 31.

Zona incerta and fields of Forel

The zona incerta is an aggregation of small cells that lies between the ventral part of the external medullary lamina of the thalamus and the cerebral peduncle. It extends from the rostral pole of the thalamus, level with the caudal pole of the hypothalamic paraventricular nucleus, to the rostral pole of the medial geniculate nucleus. The central portion of the zona incerta (dorsal zona incerta) lies between the subthalamic nucleus (ventrolaterally), the ventrolateral and ventromedial thalamic nuclei (dorsally) and the superior cerebellar peduncle medially. Caudally, the zona incerta lies between the base of the cerebral peduncle and the substantia nigra ventrolaterally, the thalamic fasciculus (H_1 field of Forel) and ventroposterior thalamic nucleus dorsally, the subthalamic nucleus anteriorly, and the lateral and medial lemnisci posteriorly (Watson et al 2014).

The zona incerta receives fibres from the sensorimotor cortex, the pregeniculate nucleus, the deep cerebellar nuclei, the trigeminal nuclear complex and the spinal cord. It contains neurones that project to the cerebral cortex, superior colliculus, pretectal region and basilar pons.

The H fields of Forel lie within the posterior subthalamus: they consist of a scattered group of cells in a dense matrix of fibres that include corticofugal, pallidothalamic and cerebellothalamic projections (Neudorfer and Maarouf 2018) (Ch. 31). Field H_1 of Forel consists of the thalamic fasciculus, which lies dorsal to the zona incerta. Field H_2 of Forel contains the fasciculus lenticularis and lies ventrally, between the zona incerta and the subthalamic nucleus (see Fig. 31.11).The scattered neurones of the H field of Forel (prerubral area) receive afferents from the spinal cord (fibres of the medial and trigeminal lemniscus and spinothalamic tract), the reticular formation of the brainstem and, possibly, the internal pallidum.

In addition to terminal parts of the lemniscal and dentatothalamic tracts, the subthalamus contains massive fibre tracts derived from the globus pallidus. The fasciculus lenticularis is the dorsal component of pallidofugal fibres that traverse the internal capsule. It turns medially near the medial aspect of the capsule, partly intermingled with the dorsal zone of the subthalamic nucleus and the ventral part of the zona incerta, where the fasciculus traverses the H_2 field of Forel. Reaching the medial border of the zona incerta, the fasciculus intermingles with fibres of the ansa lenticularis, scattered elements of the prerubral nucleus, and dentatothalamic fibres.

The ansa lenticularis has a complex origin from both parts of the globus pallidus and possibly other adjacent structures. It curves medially round the ventral border of the internal capsule and continues dorsomedially to mingle with other fibres in the prerubral field. Some of the fibres in the fasciculus lenticularis and ansa lenticularis synapse in the subthalamic nucleus, prerubral field and zona incerta. The remainder continue medially, with other fascicles, into the thalamic nuclei, particularly the ventral anterior, ventral lateral and centromedian nuclei.

The thalamic fasciculus extends from the prerubral field; its territory is termed the H_1 field of Forel. It lies dorsal to, and also partly traverses, the zona incerta, and is related dorsally to the ventral thalamic nuclei. It contains continuations of the fasciculus lenticularis and ansa lenticularis, dentatothalamic and thalamostriate fibres.

The subthalamic fasciculus connects the subthalamic nucleus with the globus pallidus. It contains an abundant two-way array of fibres that traverse the internal capsule, interweaving with it at right-angles.

EPITHALAMUS

The epithalamus consists of the anterior and posterior paraventricular nuclei, the medial and lateral habenular nuclei, the stria medullaris thalami, the posterior commissure and the pineal body.

Habenular nuclei and stria medullaris thalami

The habenular nuclei lie posteriorly at the dorsomedial aspect of the thalamus, immediately deep to the ependyma of the third ventricle; the stria medullaris thalami are superior and lateral (see Fig. 30.3). Each nucleus is divided into medial and lateral parts, connected by the habenular commissure. Experimental evidence from electrophysiological studies in monkeys, optogenetic studies in rodents and genetic studies in fish have revealed that habenular neurones are predominantly glutamatergic, but neurones in the ventral medial habenula co-release acetylcholine and those in the dorsal medial habenula co-release the neuropeptide substance P (Namboodiri et al 2016).

The fasciculus retroflexus (habenulo-interpeduncular tract) emerges from the ventral margin of the nuclei and courses ventrally, skirts the inferior zone of the thalamic mediodorsal nucleus, and traverses the parafascicular thalamic nucleus and the superomedial region of the red nucleus to reach the interpeduncular nucleus. The habenular nuclear complex is limited laterally by a fibrous lamina that enters the fasciculus retroflexus. Posteriorly, the nuclei of the two sides and the internal medullary laminae are linked across the midline by the habenular commissure. The tela choroidea of the third ventricle usually arises from the ependyma at the superolateral corner of the medial habenular nucleus.

Afferent fibres to the habenular nuclei travel in the stria medullaris from the prepiriform cortex bilaterally, the nucleus basalis (of Meynert) and the hypothalamus. Afferents from the internal pallidum ascend through the thalamus and may be collaterals of pallidothalamic axons. Additional inputs come from the pars compacta of the substantia nigra, the midbrain raphe nuclei and the lateral dorsal tegmental nucleus. The afferent pathways mostly end in the lateral habenular nucleus; the only identified afferent fibres to the medial habenular nucleus come from the septofimbrial nucleus.

The medial habenular nucleus sends efferent fibres to the interpeduncular nucleus of the midbrain. The lateral habenular nucleus sends fibres to the raphe nuclei and the adjacent reticular formation of the midbrain, the pars compacta of the substantia nigra and the ventral tegmental area, and the hypothalamus and basal forebrain. Collectively, the main habenular outflow reaches the interpeduncular nucleus, mediodorsal thalamic nucleus, mesencephalic tectum and reticular formation: the largest component constitutes the fasciculus retroflexus to the interpeduncular nucleus. The latter provides relays to the midbrain reticular formation, from which tecto-tegmento-spinal tracts and dorsal longitudinal fasciculi connect with autonomic preganglionic neurones

controlling salivation, gastric and intestinal secretory activity and motility, and motor nuclei for mastication and deglutition.

The stria medullaris crosses the superomedial thalamic aspect, skirts medial to the habenular trigone and sends many fibres into the ipsilateral habenula. Other fibres decussate, as the habenular commissure, to reach the contralateral habenula. Some fibres are really commissural and interconnect the amygdaloid complexes and hippocampal cortices. They are accompanied by crossed tectohabenular fibres. Serotonin-containing fibres from the ventral ascending tegmental serotoninergic bundle, which join the fasciculus retroflexus to reach the nuclei, may control neurones of the habenulopineal tract, and thus influence innervation of pinealocytes. Similarly, habenular nuclear afferents from the dorsal ascending tegmental noradrenergic bundle may influence pinealocytes.

What little is known about the physiological functions of the habenular nuclei in humans is based very largely on research in non-human primates and rats (Boulos et al 2017). Together with the stria medullaris and fasciculus retroflexus, the habenula is considered to be part of the dorsal diencephalic conduction system that is thought to play crucial roles in the modulation of reward and goal-directed behaviours (Fakhoury 2018) and has also been implicated in regulation of sleep homeostasis, anxiety, pain and analgesia.

Posterior commissure

The posterior commissure is a small fasciculus that decussates in the inferior pineal lamina. Various small nuclei are associated with it, including the interstitial nuclei of the posterior commissure; the nucleus of Darkschewitsch in the periaqueductal grey matter; and the interstitial nucleus of Cajal near the upper end of the oculomotor complex, closely linked with the medial longitudinal fasciculus. Fibres from all these nuclei and the medial longitudinal fasciculus cross in the posterior commissure. It also contains fibres from thalamic and pretectal nuclei and the superior colliculi, and fibres that connect the tectal and habenular nuclei. The destinations and functions of many of these fibres are obscure.

Pineal gland

The pineal gland or epiphysis cerebri (see Fig. 25.20) is a small, reddish-grey organ, occupying a depression between the superior colliculi. It is inferior to the splenium of the corpus callosum, from which it is separated by the tela choroidea of the third ventricle and the contained cerebral veins: it is enveloped by the lower layer of the tela, which is reflected from the gland to the tectum. The pineal is about 8 mm long. Its base, directed anteriorly, is attached by a peduncle, which divides into inferior and superior laminae that are separated by the pineal recess of the third ventricle and contain the posterior and habenular commissures, respectively. Aberrant commissural fibres may invade the gland but do not terminate near parenchymal cells.

Septa extend into the pineal gland from the surrounding pia mater. They divide the gland into lobules and carry blood vessels and sympathetic axons. The pineal gland has a rich blood supply: pineal arteries are branches of the medial posterior choroidal arteries, which are themselves branches of the posterior cerebral artery. Within the gland, branches of the arteries supply fenestrated capillaries where the endothelial cells rest on a tenuous and sometimes incomplete basal lamina. The capillaries drain into numerous pineal veins that open into the internal cerebral veins and/or into the great cerebral vein. Unmyelinated postganglionic adrenergic sympathetic axons (derived from neurones in the superior cervical ganglion) enter the dorsolateral aspect of the pineal gland from the region of the tentorium cerebelli as the nervus conarii, which may be single or paired. The nerve lies deep to the endothelium of the wall of the straight sinus and is associated with intraglandular blood vessels and parenchymal cells.

The pineal gland contains cords and clusters of pinealocytes, associated with astrocyte-like neuroglia, which are the main cellular component of the pineal stalk. Pinealocytes are highly modified neurones. They contain multiple synaptic ribbons, randomly distributed between adjacent cells, and are coupled by gap junctions. Two or more processes extend from each cell body and end in bulbous expansions near capillaries or, less frequently, on the ependymal cells of the pineal recess. These terminal expansions contain rough endoplasmic reticulum, mitochondria and dense-cored vesicles that store melatonin. Melatonin, and its precursor 5-HT (serotonin), are synthesized from tryptophan by the pinealocytes, and secreted into the surrounding network of fenestrated capillaries.

The pineal gland is an endocrine gland of major regulatory importance (Macchi and Bruce 2004). It modifies the activity of the adenohypophysis, neurohypophysis, endocrine pancreas, parathyroids, suprarenal cortex, suprarenal medulla and gonads. Its effects are largely inhibitory. Indoleamine and polypeptide hormones secreted by pinealocytes are believed to reduce the synthesis and release of hormones by the pars anterior, either by direct action on its secretory cells or indirectly by inhibiting production of hypothalamic releasing factors. Pineal secretions may reach their target cells via the cerebrospinal fluid or the blood stream. Some pineal indoleamines, including melatonin and enzymes for their biosynthesis (e.g. 5-HT, *N*-acetyltransferase), show circadian rhythms in concentration. The levels rise during darkness and fall during the day, when secretion may be inhibited by sympathetic activity. The intrinsic rhythmicity of an endogenous circadian oscillator in the suprachiasmatic nucleus of the hypothalamus apparently governs cyclical pineal behaviour (see above).

From the second decade, calcareous deposits accumulate in pineal extracellular matrix, where they are deposited concentrically as corpora arenacea or 'brain sand' (**Fig. 30.13**). Pineal gland and choroid plexus calcifications are the most frequent sites of intracranial calcifications that are incidentally discovered among head CT scans; calcification can provide a useful indicator of a space-occupying lesion if the gland is significantly displaced from the midline.

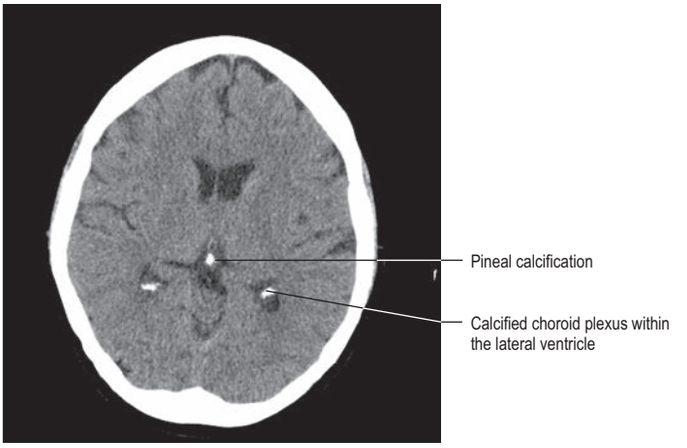

Fig. 30.13 An axial CT image showing calcification of the pineal gland and choroid plexus.

Basal ganglia

CHAPTER 31

The term basal ganglia is used to denote a number of subcortical nuclear masses that lie in the inferior part of the cerebral hemisphere, in close relationship with the internal capsule (**Fig. 31.1**). The traditional definition of the basal ganglia included the corpus striatum, claustrum and amygdaloid complex. The term has now been restricted to the corpus striatum and, according to some authorities, other nuclei in the diencephalon and midbrain (principally the subthalamic nucleus and substantia nigra) that collectively form a functional complex involved in the control of movement and motivational aspects of behaviour (Jankovic 2012). The function of the claustrum is unknown; the amygdala is more closely related to the limbic system and is, therefore, described in that context.

Disorders of the basal ganglia are principally characterized by abnormalities of movement, muscle tone and posture. There is a wide spectrum of clinical presentations ranging from poverty of movement and hypertonia at one extreme (typified by Parkinson's disease) to abnormal involuntary movements (dyskinesias) at the other. The underlying pathophysiological mechanisms that mediate these disorders have been much studied in recent years and are better understood than for any other type of complex neurological dysfunction (Penney and Young 1986, Jankovic 2012). This improved understanding has led to the introduction of new rational therapeutic strategies for both medical and neurosurgical treatments of movement disorders.

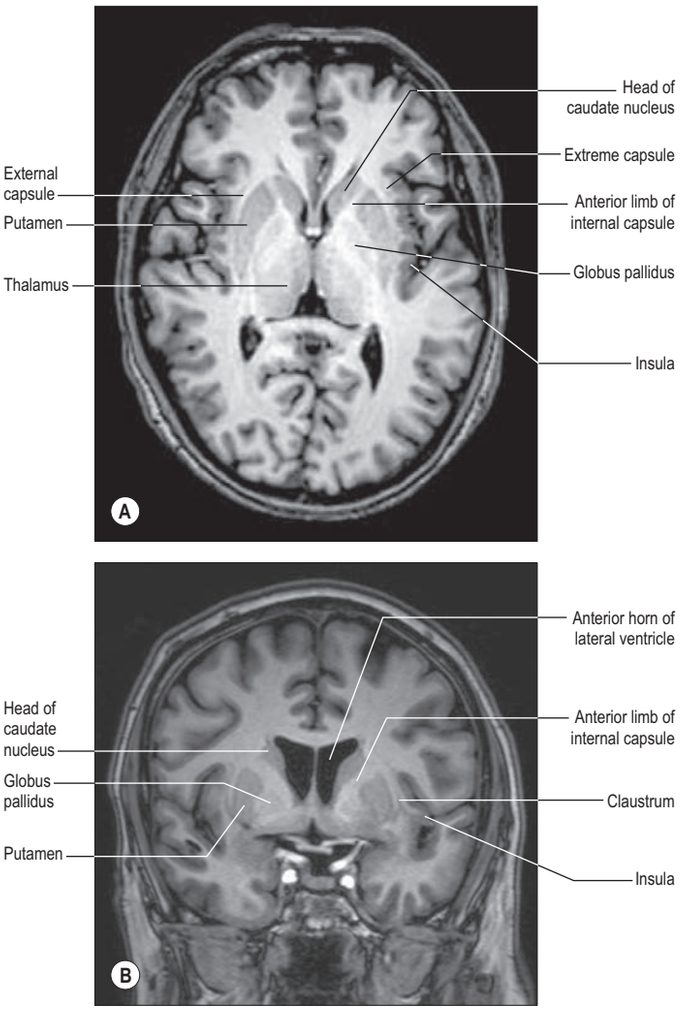

Fig. 31.1 Axial (**A**) and coronal (**B**) magnetic resonance images of the brain showing the basal ganglia, thalamus and internal capsule. (Courtesy of Alan Jackson.)

CORPUS STRIATUM

The corpus striatum consists of the caudate nucleus, putamen and globus pallidus (**Fig. 31.2**). Because of their close proximity, the putamen and globus pallidus were once considered as a single entity, the lentiform (lenticular) complex or nucleus. However, although the name has been retained in gross anatomical terminology and in some compound names (e.g. sublenticular, retrolenticular thalamic projections), the putamen and globus pallidus have quite different connections and functions. Rather, it is now known that the putamen and caudate nucleus share a common chemocytoarchitecture and connections, and they are referred to jointly as the neostriatum, or simply the striatum.

The striatum is considered to be the principal 'input' structure of the basal ganglia since it receives the majority of afferents from other parts of the neuraxis. Its principal efferent connections are to the globus pallidus and the substantia nigra, pars reticulata. The globus pallidus and, more particularly, its medial (internal) segment, together with the pars reticulata of the substantia nigra, is regarded as the main 'output' structure because it is the source of basal ganglia efferent fibre projections, mostly directed to the thalamus.

Lentiform complex

The lentiform complex (see Fig. 31.1; **Fig. 31.3**) lies deep to the insular cortex, with which it is roughly coextensive, although they are separated by a thin layer of white matter and by the claustrum. The latter splits the insular subcortical white matter to create the extreme and external capsules. The external capsule separates the claustrum from the putamen and the internal capsule separates the lentiform complex from the caudate nucleus.

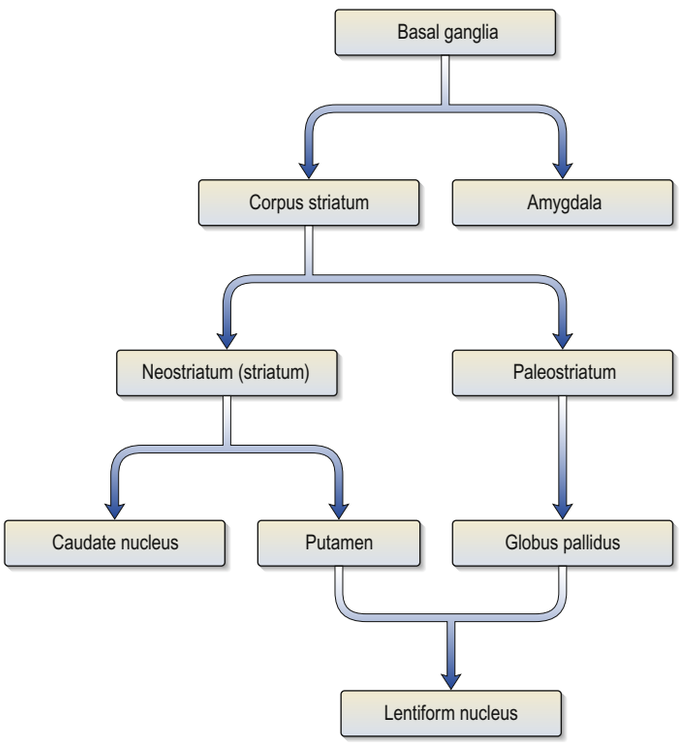

Fig. 31.2 Terminology and relationships of structures forming the basal ganglia.

The lentiform complex consists of the laterally placed putamen and the more medially placed globus pallidus (pallidum), separated by a thin layer of fibres, the external medullary lamina. The globus pallidus is itself divided into two segments, a lateral (external) segment and a medial (internal) segment, separated by an internal medullary lamina. The two segments have distinct afferent and efferent connections. Inferiorly, a little behind the fundus striati, the lentiform complex is grooved by the anterior commissure that connects inferior parts of the temporal lobes and the anterior olfactory cortex of the two sides (see Fig. 31.6). The area above the commissure is referred to as the dorsal pallidum, and that below it as the ventral pallidum.

STRIATUM

The striatum consists of the caudate nucleus, putamen and ventral striatum, which are all highly cellular and well-vascularized. The vast bulk of the caudate nucleus and putamen are often referred to as the dorsal striatum. A smaller inferomedial part of the rostral striatum, referred to as the ventral striatum, includes the nucleus accumbens. The caudate and putamen are traversed by the anterior thalamic projections and by numerous small bundles of thinly myelinated, or unmyelinated, small-diameter axons, which are mostly striatal afferents and efferents. They radiate through the striatal tissue as though converging on, or radiating from, the globus pallidus. These bundles are occasionally referred to by the archaic term 'Wilson's pencils' and they account for the striated appearance of the corpus striatum.

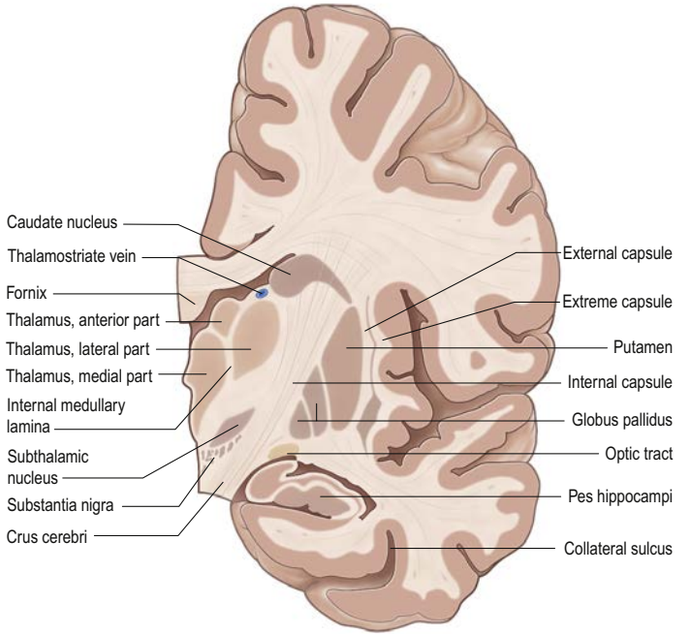

Fig. 31.3 Anterior aspect of a coronal section through the left cerebral hemisphere.

Caudate nucleus

The caudate nucleus is a curved, tadpole-shaped mass. It has a large anterior head that tapers to a body, and a down-curving tail (Fig. 31.4). The head is covered with ependyma and lies in the floor and lateral wall of the frontal (anterior) horn of the lateral ventricle, anterior to the interventricular foramen. The tapering body is in the floor of the body of the ventricle, and the narrow tail follows the curve of the temporal (inferior) horn, and so lies in the ventricular roof, in the temporal lobe. Medially, the greater part of the caudate nucleus abuts the thalamus, along a junction that is marked by a groove, the sulcus terminalis. The sulcus contains the stria terminalis, lying deep to the ependyma (Fig. 31.5). The sulcus terminalis is especially prominent anterosuperiorly (because of the large size of the head and body of the caudate nucleus relative to the tail), and here the stria terminalis is accompanied by the thalamostriate vein.

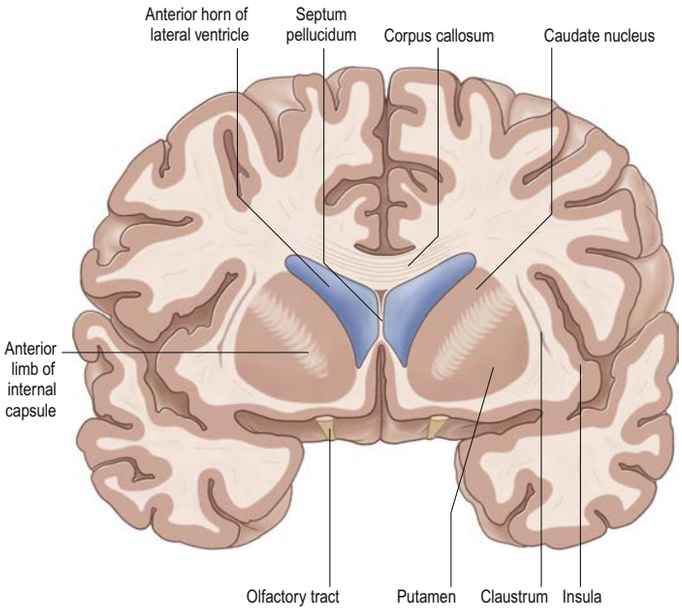

Fig. 31.7 Posterior aspect of a coronal section through the frontal (anterior) horn of the lateral ventricles.

The corpus callosum is superior to the head and body of the caudate nucleus. The two are separated by the fronto-occipital fasciculus laterally and by the subcallosal fasciculus, which caps the nucleus, medially (see Fig. 31.5). The caudate nucleus is largely separated from the lentiform complex by the anterior limb of the internal capsule (**Figs 31.6–31.7**). The inferior part of the head of the caudate becomes continuous with the most inferior part of the putamen immediately above the anterior perforated substance; this junctional region is sometimes known as the fundus striati (see Fig. 31.6A). Variable bridges of cells connect the putamen to the caudate nucleus for most of its length. They are most prominent anteriorly, in the region of the fundus striati and the head and body of the caudate nucleus, where they penetrate the anterior limb of the internal capsule (see Fig. 31.7). In the temporal lobe, the anterior part of the tail of the caudate nucleus becomes continuous with the posteroinferior part of the putamen.

Ventral striatum

The ventral striatum consists of the nucleus accumbens and the olfactory tubercle. Anterior to the anterior commissure, much of the grey matter of the anterior perforated substance, and especially the olfactory tubercle, is indistinguishable from, and continuous with, the fundus striati, in terms of cellular composition, histochemistry and interconnections. The caudate nucleus is continuous medially with the nucleus accumbens (see Fig. 31.6A), which abuts the nuclei of the septum, close by the para-olfactory area, diagonal band of Broca and the fornix.

The nucleus accumbens receives a dopaminergic innervation from the midbrain ventral tegmental area (cell group A10). It is believed to represent the neural substrate for the rewarding effects of several classes of drugs and is, therefore, a major determinant of their addictive potential. The experimental observation that the locomotor activating effects of psychomotor stimulant drugs such as amphetamine and cocaine (which act presynaptically on dopaminergic neurones to either enhance dopamine release or block its reuptake) are dependent on dopamine transmission in the nucleus accumbens, led to the hypothesis that the reinforcing or rewarding properties of these drugs are mediated by the mesolimbic dopamine system.

Striatal connectivity

Neurones of both dorsal and ventral striatum are mainly medium-sized multipolar cells. They have round, triangular or fusiform cell bodies, mixed with a smaller number of large multipolar cells. The ratio of medium to large cells is at least 20:1. The large neurones have extensive spherical or ovoid dendritic trees up to 60 μm across. The medium-sized neurones also have spherical dendritic trees, approximately 20 μm across, which receive the synaptic terminals of many striatal afferents. The dendrites of both medium and large striatal cells may be either spiny or non-spiny. The most common neurone (approximately 75% of the total) is a medium-sized cell with spiny dendrites (so-called medium spiny neurones). These cells utilize γ-aminobutyric acid (GABA) as their transmitter and also express the genes coding for either enkephalin or substance P/dynorphin, depending on their efferent connections. Enkephalinergic neurones express D2 dopamine receptors. Substance P/dynorphin neurones express D1 receptors. These neurones are the major, and perhaps exclusive, source of striatal efferents to the pallidum and substantia nigra pars reticulata. The other medium-sized striatal neurones are aspiny, and are intrinsic cells that contain acetylcholinesterase (AChE), choline acetyltransferase (CAT) and somatostatin. Large neurones with spiny dendrites contain AChE and CAT; most, perhaps all, are intrinsic neurones. Aspiny large neurones are all intrinsic neurones.

Intrinsic synapses are probably largely asymmetric (type II), while those derived from external sources are symmetric (type I). The aminergic afferents from the substantia nigra, raphe and locus coeruleus all end as profusely branching axons with varicosities that contain dense-core vesicles (the presumed store of amine transmitters). Many of these varicosities have no conventional synaptic membrane specializations, and may release transmitter in a way analogous to that found in peripheral postsynaptic sympathetic axons.

Neuroactive chemicals, whether intrinsic or derived from afferents, are not distributed uniformly in the striatum. For example, 5-HT (5-hydroxytryptamine, serotonin) and glutamic acid decarboxylase (GAD) concentrations are highest caudally, while substance P, acetylcholine (ACh) and dopamine are highest rostrally. However, there is a finer-grain neurochemical organization showing that the striatum consists of a mosaic of islands or striosomes (sometimes referred to as patches), each 0.5–1.5 mm across, packed into a background matrix. Striosomes contain substance P and enkephalin. During development, the first dopamine terminals from the substantia nigra are found in striosomes: although this exclusivity does not persist after birth, striosomes in the adult caudate nucleus still contain a higher concentration of dopamine than the matrix. The latter contains ACh and somatostatin, and is the target of thalamostriatal axons. Receptors for at least some neurotransmitters are also differentially distributed. For example, opiate receptors

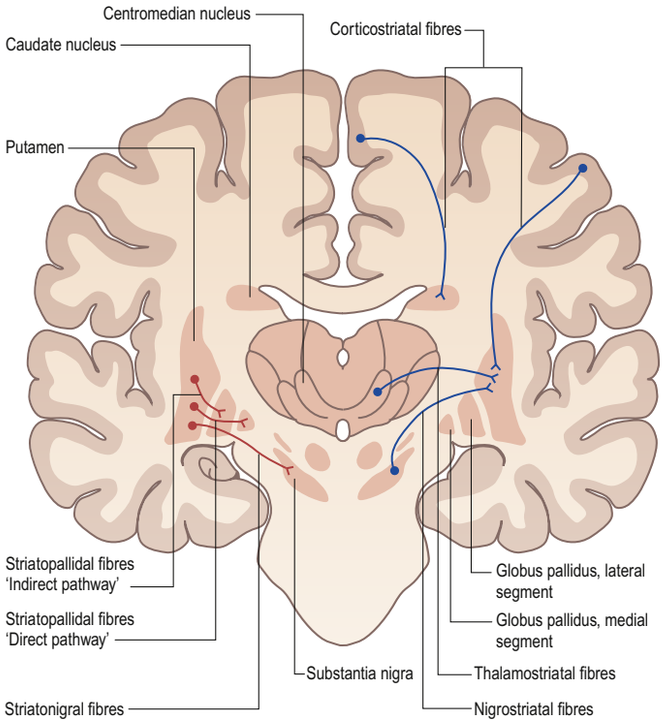

Fig. 31.8 Connections of the striatum. The major afferent projections to the striatum are shown on the right and major efferent projections from the striatum on the left.

are found almost exclusively within striosomes, and muscarinic receptors predominantly so. Moreover, the distribution of neuroactive substances within the striosomes is not uniform. In humans, the striosome/matrix patchwork is more evident in the caudate than the putamen, the latter consisting predominantly of matrix.

All afferents to the striatum terminate in a mosaic manner. The size of a cluster of terminals is usually 100–200 μm across. Some afferent terminal clusters are not arranged in register with the clear striosome/matrix distributions seen in nigrostriatal and thalamostriatal axons. In general, afferents from the neocortex end in striatal matrix and those from the allocortex end in striosomes. However, the distinction is not absolute: although afferents from the neocortex arise in layers V and VI, those from the superficial part of layer V end predominantly in striatal matrix, whereas those from deeper neocortex project to striosomes. Striatal cell bodies that are the sources of efferents also form clusters but, again, are not uniformly related to striosomes. For example, the cell bodies of some striatopallidal and striatonigral axons lie clustered within striosomes, but others lie outside them, still in clusters. The neurones and neuropil of the ventral striatum are essentially similar to those of the dorsal striatum, but the striosomal/matrix organization is less well-defined and seems to consist predominantly of striosomes.

The major connections of the striatum are summarized in **Fig. 31.8**. The connections of the dorsal and ventral divisions overlap, however, the generalization can be made that the dorsal striatum is predominantly connected with motor and associative areas of the cerebral cortex, whilst the ventral striatum is connected with the limbic system and orbitofrontal and temporal cortices. For both dorsal and ventral striatum, the pallidum and substantia nigra pars reticulata are key efferent structures. The fundamental arrangement is the same for both divisions. The cerebral cortex projects to the striatum, which in turn projects to the pallidum and substantia nigra pars reticulata. Efferents from the pallidum and substantia nigra pars reticulata influence the cerebral cortex (either the supplementary motor area or prefrontal and cingulate cortices via the thalamus) and the superior colliculus (see below).

The entire neocortex sends glutamatergic axons to the ipsilateral striatum. Previously, these axons were thought to be collaterals of cortical efferents to other regions, but it is now known that they arise exclusively from small pyramidal cells in layers V and VI. It has also been suggested that some of the cells of origin lie in the supragranular 'cortical association' layers II and III. The projection is organized topographically. The greater part of the input from the cerebral cortex to the dorsal striatum is derived from the frontal and parietal lobes; the input from the occipitotemporal cortex is relatively small. The orbitofrontal association cortex projects to the inferior part of the head of the caudate nucleus, which lies next to the ventral striatum. The dorsolateral frontal association cortex and frontal eye fields project to the rest of the head of the caudate nucleus, and much of the parietal lobe projects to the body of the nucleus. The somatosensory and motor cortices project predominantly to the putamen: their terminals establish a somatotopic pattern, in which the lower body is represented laterally and the upper body is represented medially. The motor cortex is unique in also sending axons through the corpus callosum to the opposite putamen, where they end with the same spatial ordering. The occipital and temporal cortices project to the tail of the caudate nucleus and to the inferior putamen.

The striatum receives afferents from the polysensory intralaminar thalamus and these are more crudely organized spatially. The nucleus centralis lateralis, which receives a cerebellar input, projects to the anterior striatum (especially the caudate nucleus), while the centromedian nucleus, which receives input from both the cerebellum and medial globus pallidus, projects to the putamen.

The aminergic inputs to the caudate and putamen are derived from the substantia nigra pars compacta (dopaminergic group A9; see Fig. 28.17), the retrorubral nucleus (dopaminergic group A8), the dorsal raphe nucleus (serotoninergic group B7) and the locus coeruleus (noradrenergic group A6). The nigrostriatal input is sometimes referred to as the 'mesostriatal' dopamine pathway; it reaches the striatum by traversing the H fields (of Forel) in the subthalamus and running in the medial forebrain bundle. These aminergic inputs appear to modulate the responses of the striatum to cortical and thalamic afferent influences.

Efferents from the striatum pass to both segments of the globus pallidus and to the substantia nigra pars reticulata, where they end in a topically ordered fashion. Fibres ending in either the lateral or medial pallidum originate from different striatal cells (see Fig. 31.8). Those projecting to the lateral pallidum are axons of neurones that co-localize GABA and enkephalin, and give rise to the so-called 'indirect pathway'. This name refers to the fact that these striatal neurones influence the activity of basal ganglia output neurones in the medial pallidum via the intermediary of the subthalamic nucleus. Other striatal neurones, which co-localize GABA and substance P/dynorphin, project directly to the medial pallidum and are, therefore, described as the 'direct pathway'.

The striatal projection to the pars reticulata of the substantia nigra also has both direct and indirect components, via the lateral pallidum and subthalamic nucleus (**Figs 31.9–31.10**). The axons of the direct striatonigral projection constitute the laterally placed 'comb' system, which is spatially quite distinct from the ascending dopaminergic nigrostriatal pathway. Striatonigral fibres end in a spatially ordered way in the pars reticulata.

The ventral striatum is the primary target of fibres from limbic cortices, including allocortex, and from limbic associated regions (see Fig. 31.9). Thus, the hippocampus (through the fornix) and orbitofrontal cortex (through the internal capsule) project to the nucleus accumbens, and the olfactory, entorhinal, anterior cingulate and temporal visual cortices project to both the nucleus accumbens and olfactory tubercle. The olfactory tubercle also receives afferents from the amygdala. The contiguity of the cortical areas that project to the ventral striatum and neighbouring dorsal striatum emphasizes the imprecise nature of the boundaries between these two divisions. All the cortical regions abut and overlap with neighbouring areas and they project to neighbouring parts of the dorsal striatum as well as to the ventral striatum. The fundus striati and ventromedial caudate nucleus abut the olfactory tubercle and nucleus accumbens (see Fig. 31.6A) and receive connections from the orbitofrontal cortex and, to a lesser extent, from the lateral prefrontal and anterior cingulate cortices (which also project to the head of the caudate nucleus).

This continuity of the ventral and dorsal striata, as revealed by the arrangements of corticostriatal projections, is reinforced by consideration of the aminergic inputs to the ventral striatum. These are derived from the dorsal raphe (serotoninergic group B7), the locus coeruleus (noradrenergic group A6) and the ventral tegmental area (dopamine group A10), as well as the most medial part of the substantia nigra, pars compacta (A9) (see Fig. 28.17). The dopamine projections constitute the so-called mesolimbic dopamine pathway, which also projects to the septal nuclei, hippocampus and amygdala, and the prefrontal and cingulate cortices through the medial forebrain bundle. The lateromedial continuity of cell groups A9 and A10 is reflected in the relative positions of their ascending fibres in the subthalamus and hypothalamus (the H fields and medial forebrain bundle, respectively), as well as in the lateromedial topography of the dorsal and ventral striata, which in turn have contiguous and overlapping sources of cortical afferents.

As with the dorsal striatum, efferents from the ventral striatum project to the pallidum (in this case, the ventral pallidum) and the

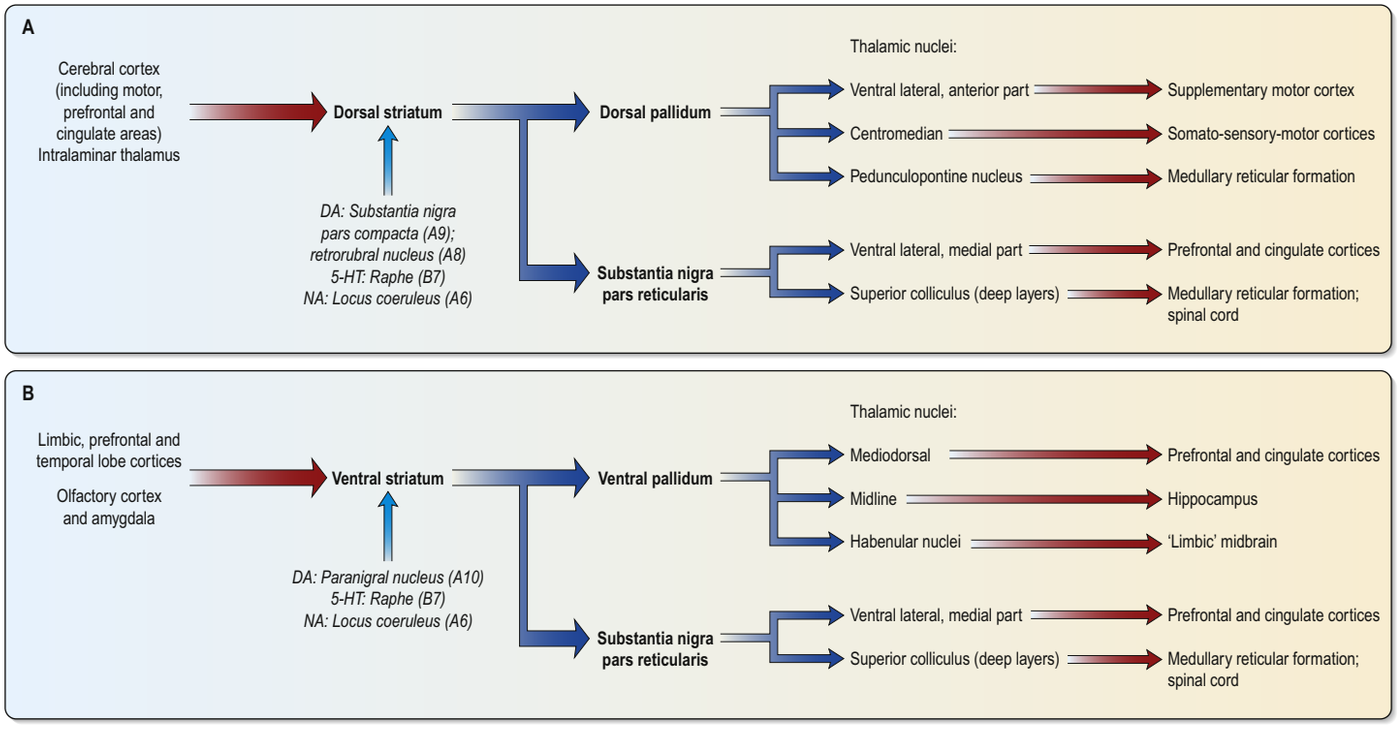

Fig. 31.9 Principal output connections of the basal ganglia derived from dorsal (**A**) and ventral (**B**) divisions of the striatum. In each case, pathways established through the pallidum are distinguished from those passing through the substantia nigra pars reticularis. Abbreviations: DA, dopamine; NA, noradrenaline (norepinephrine); 5-HT, 5-hydroxytryptamine (serotonin).

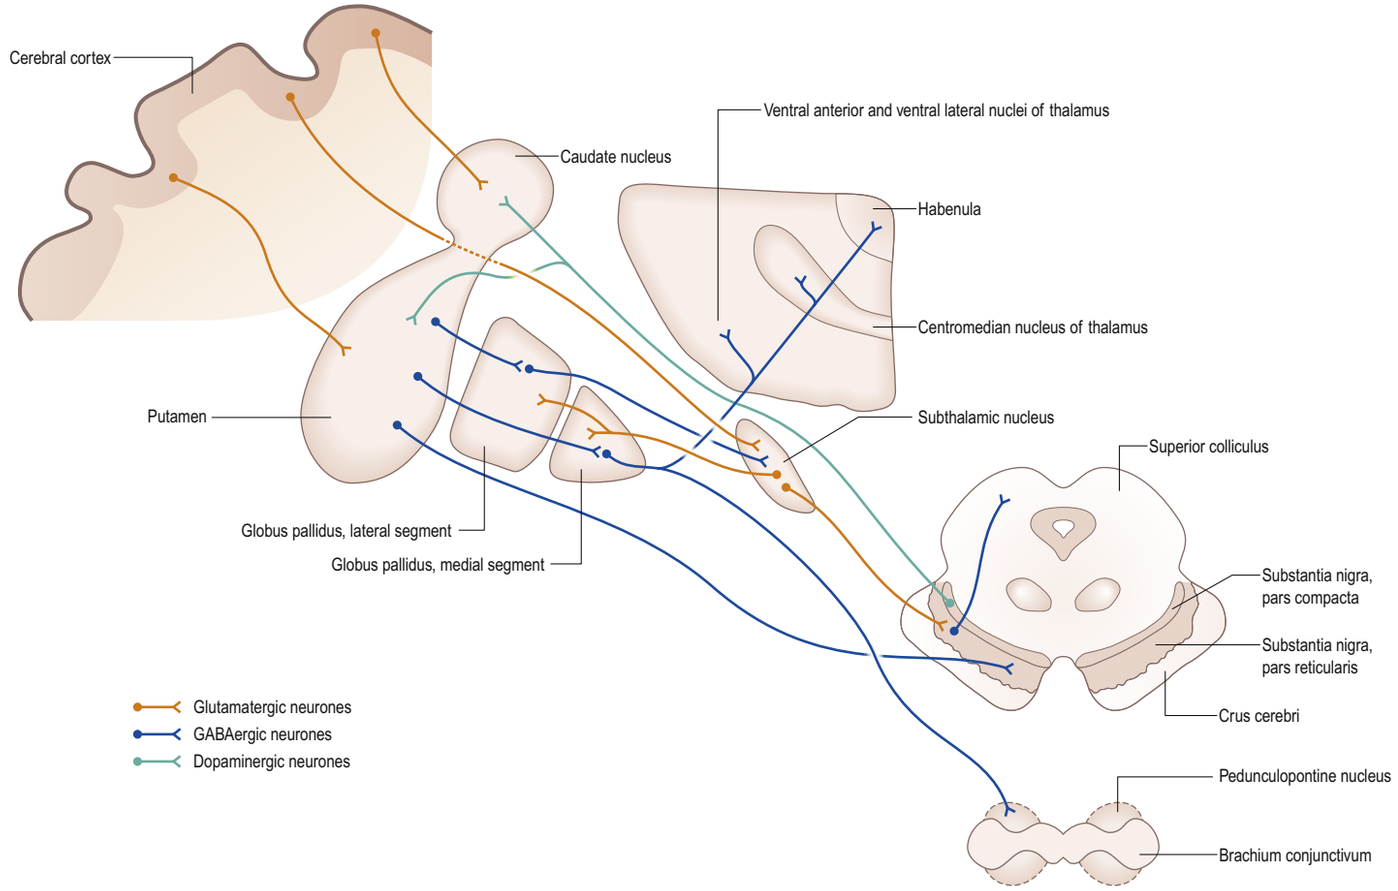

Fig. 31.10 Principal connections of the basal ganglia with the diencephalon and brainstem.

substantia nigra pars reticulata (see Figs 31.9–31.10). The connection with the substantia nigra is both direct and indirect, via the subthalamic nucleus. The projections from the pars reticulata are as described for the dorsal system, but axons from the ventral pallidum reach the thalamic mediodorsal nucleus (which projects to prefrontal association and cingulate cortices) and midline nuclei (which project to the hippocampus). Ventral pallidal axons also reach the habenular complex of the limbic system.

The brain areas beyond the basal ganglia, substantia nigra and subthalamic nucleus to which both ventral and dorsal systems appear to project are the prefrontal association and cingulate cortices and the deep superior colliculus.

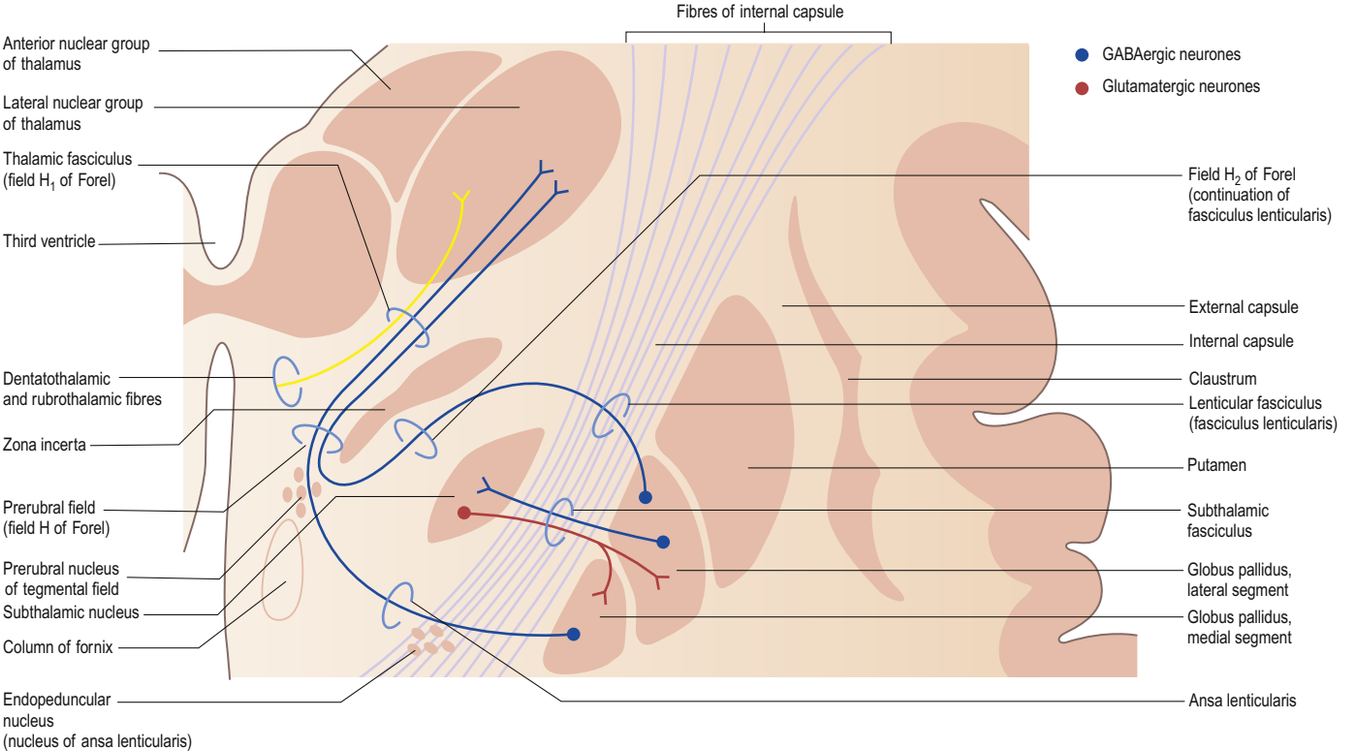

Fig. 31.11 Coronal section of the brain showing the major connections of the basal ganglia with the diencephalon.

GLOBUS PALLIDUS

The globus pallidus (pallidum) lies medial to the putamen and lateral to the internal capsule. It consists of lateral (external) and medial (internal) segments separated by an internal medullary lamina. Both segments receive large numbers of fibres from the striatum and subthalamic nucleus, but they have substantially different connections. The lateral segment projects to the subthalamic nucleus as part of the 'indirect pathway'. The medial segment is considered to be a homologue of the pars reticulata of the substantia nigra, with which it shares similar cellular and connectional properties. Together, the segments constitute the main output of the basal ganglia to other levels of the neuraxis, principally to the thalamus.

The cell density of the globus pallidus is less than one-twentieth that of the striatum. The morphology of the majority of cells is identical in the two segments, i.e. large multipolar GABAergic neurones which closely resemble the neurones in the substantia nigra pars reticulata. Their dendritic fields are discoid, with planes at right-angles to incoming striatopallidal axons, each of which, therefore, potentially contacts many pallidal dendrites *en passant*. This arrangement, coupled with the diameters of the dendritic fields (500 µm), suggests that a precise topographical organization is unlikely within the pallidum.

Striatopallidal fibres are of two main types. They project to either the lateral or the medial pallidum. Those projecting to the lateral segment constitute the beginning of the 'indirect pathway'. They utilize GABA as their primary transmitter and also contain enkephalin. Efferent axons from neurones in the lateral segment pass through the internal capsule in the subthalamic fasciculus and travel to the subthalamic nucleus (**Fig. 31.11**).

Striatopallidal axons destined for the medial pallidum constitute the 'direct pathway'. Like the indirect projection, these utilize GABA as their primary transmitter but they also contain substance P and dynorphin. Efferent axons from the medial pallidum project through the ansa lenticularis and fasciculus lenticularis (see Fig. 31.11). The former runs round the anterior border of the internal capsule and the latter penetrates the capsule directly. Having traversed the internal capsule, both pathways unite in the subthalamic region, where they follow a horizontal hairpin trajectory, and turn upwards to enter the thalamus as the thalamic fasciculus. The trajectory circumnavigates the zona incerta and creates the so-called 'H' fields of Forel (see Figs 31.5, 31.11). Within the thalamus, pallidothalamic fibres end in the ventral anterior and ventral lateral nuclei and in the intralaminar centromedian nucleus. These in turn project excitatory (presumed glutamatergic) fibres primarily to the frontal cortex, including the primary and supplementary motor areas. The medial pallidum also projects fibres caudally to the pedunculopontine nucleus, as described below (see Fig. 31.10).

SUBTHALAMIC NUCLEUS

The subthalamic nucleus is a biconvex, lens-shaped nucleus in the subthalamus of the diencephalon. It lies medial to the internal capsule, immediately rostral to the level at which the latter becomes continuous with the crus cerebri of the midbrain (see Figs 31.3, 31.5). Within the nucleus, small interneurones intermingle with large multipolar cells with dendrites that extend for about one-tenth the diameter of the nucleus. Dorsally, the nucleus is encapsulated by axons, many of which are derived from the subthalamic fasciculus and carry a major GABAergic projection from the lateral segment of the globus pallidus as part of the indirect pathway. The nucleus also receives afferents from the cerebral cortex. It is unique in the intrinsic circuitry of the basal ganglia in that its cells are glutamatergic and project excitatory axons to both the globus pallidus and substantia nigra pars reticulata. Within the pallidum, subthalamic efferent fibres end predominantly in the medial segment but many also end in the lateral segment.

The subthalamic nucleus plays a central role in the normal function of the basal ganglia and in the pathophysiology of basal ganglia-related disorders. Destruction of the nucleus, which occurs rarely as a result of stroke, results in the appearance of violent, uncontrolled involuntary movements of the contralateral side of the body, known as ballism (hemiballismus). The subthalamic nucleus is crucially involved in the pathophysiology of Parkinson's disease (Mitchell et al 1989) and is a target for functional neurosurgical therapy of the condition. (For a detailed description of the anatomical structure and variability of the subthalamic nucleus seen using high-field magnetic resonance imaging (MRI) with histological validation, see Massey et al (2012) and Massey and Yousry (2010).)

SUBSTANTIA NIGRA

The substantia nigra is a nuclear complex deep to the crus cerebri of the midbrain (see Fig. 28.16); its cytoarchitecture and connections are described in Chapter 28. Briefly, it consists of a pars compacta, a pars reticulata and a smaller pars lateralis. The pars compacta and pars lateralis correspond to the dopaminergic cell group A9. The pars compacta projects heavily to the caudate nucleus and putamen; smaller projections end in the globus pallidus and the subthalamic nucleus. The neurones of the pars reticulata and the medial pallidum collectively constitute the output neurones of the basal ganglia system. In Parkinson's disease, the levels of dopamine in the substantia nigra and striatum decrease dramatically as a result of the degeneration of pars compacta neurones and their terminals in the neostriatum.

PEDUNCULOPONTINE NUCLEUS

The pedunculopontine nucleus (nucleus tegmenti pedunculopontinus) lies in the dorsolateral part of the pontomesencephalic tegmentum (Hamani et al 2007). Anterograde tract-tracing studies in non-human primates and rodents have revealed multiple afferent and efferent connections between the pedunculopontine nucleus and the basal ganglia, cerebellum, substantia nigra, thalamus, cerebral cortex and spinal cord. The nucleus receives GABAergic efferent fibres from the globus pallidus and substantia nigra. In animal models of Parkinson's disease, these projections are overactive and the pedunculopontine nucleus is inhibited. Taken in conjunction with other experimental evidence, this suggests that the pedunculopontine nucleus is involved in the pathophysiology of disturbances of locomotion, gait and posture in Parkinson's disease (Mena-Segovia et al 2004). That said, the variation in nuclear connectivity between quadripedal and bipedal animals must be considered when evaluating evidence from any non-primate animal model (Alam et al 2011, Stein and Aziz 2012).

PATHOPHYSIOLOGY OF BASAL GANGLIA DISORDERS

The basal ganglia might be said to guide intention into action. As far as their role in movement control is concerned, they appear to promote and support patterns of behaviour that are appropriate in the prevailing circumstances and to inhibit unwanted or inappropriate movements. This is exemplified by disorders of the basal ganglia, which are characterized, depending on the underlying pathology, by either an inability to initiate and execute wanted movements (as in Parkinson's disease) or an inability to prevent unwanted movements (as in Huntington's disease).

Parkinson's disease is the most common pathological condition affecting the basal ganglia. It is characterized by akinesia, muscular rigidity and tremor due to degeneration of the dopaminergic neurones of the substantia nigra pars compacta (which project to the striatum in the nigrostriatal pathway). As a consequence, dopamine terminals are lost in the striatum and dopamine levels are severely depleted: dopamine receptors located on medium spiny neurones, which are the target of the nigrostriatal pathway, are spared.

Dopamine appears to have a dual action on medium spiny striatal neurones. It inhibits those of the indirect pathway and excites those of the direct pathway: when dopamine is lost from the striatum, the indirect pathway therefore becomes overactive and the direct pathway becomes underactive (**Fig. 31.12**). Overactivity of the striatal projection to the lateral pallidum results in inhibition of pallidosubthalamic neurones and, consequently, overactivity of the subthalamic nucleus. Subthalamic efferents mediate excessive excitatory drive to the medial globus pallidus and substantia nigra pars reticulata. This is exacerbated by underactivity of the GABAergic, inhibitory direct pathway. Overactivity of basal ganglia output then inhibits the motor thalamus and its excitatory thalamocortical connections. While this description is little more than a first approximation of the underlying pathophysiology, this model of the basis of parkinsonian symptoms has led to the introduction of new neurosurgical approaches to the treatment of Parkinson's disease, based upon lesioning and deep brain stimulation of the medial globus pallidus and subthalamic nucleus (see below).

The current medical treatment for Parkinson's disease largely relies on levodopa (L-DOPA; L-dihydroxyphenylalanine), the immediate metabolic precursor of dopamine, or on dopamine agonists. Whilst these usually provide good symptomatic relief for many years, eventually they lead to the development of side-effects, including dyskinesias. The involuntary movements that occur as a consequence of long-term treatment of Parkinson's disease resemble those seen in Huntington's disease, i.e. tardive dyskinesia and ballism. Experimental evidence suggests that these may share a common neural mechanism (Mitchell et al 1985, Mitchell et al 1992) (see Fig. 31.12). Thus, the indirect pathway becomes underactive, e.g. due to the effects of dopaminergic drugs in Parkinson's disease, or the degeneration of the striatopallidal projection to the lateral pallidum in Huntington's disease. This leads to physiological inhibition of the subthalamic nucleus by overactive pallidosubthalamic neurones. The involvement of the subthalamic nucleus explains why the dyskinetic movements of levodopa-induced dyskinesia and Huntington's disease resemble those of ballism produced by a lesion of the subthalamic nucleus. Underactivity of the subthalamic nucleus removes the excitatory drive from medial pallidal neurones, which are known

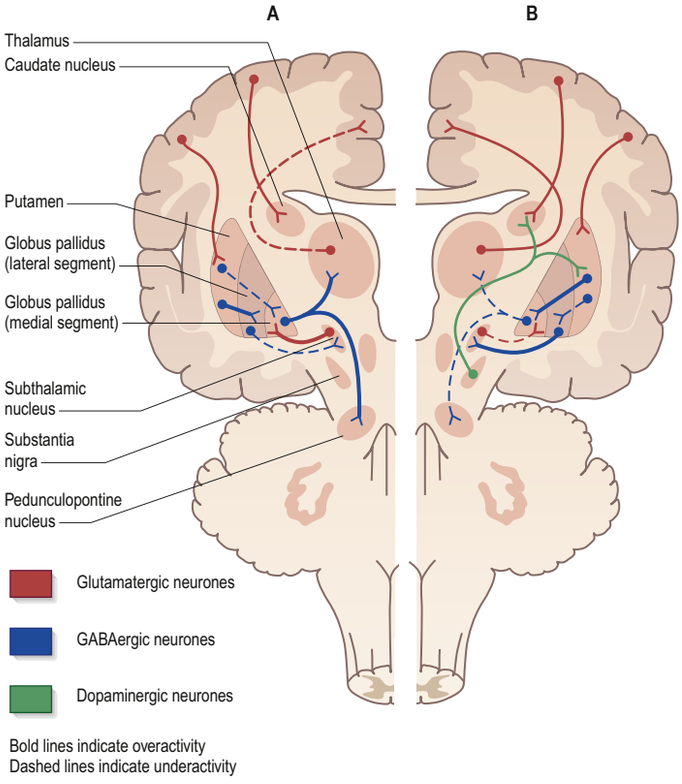

Fig. 31.12 The pathophysiology of Parkinson's disease (**A**) and dyskinesias (**B**). (Adapted with permission from Crossman AR, Neary D Neuroanatomy: An Illustrated Colour Text, 6th ed. Elsevier, Churchill Livingstone. Copyright 2019.)

to be underactive in dyskinesias (Crossman 1990). Once again, this anatomical model of basal ganglia function is an oversimplification. Whilst it is true that underactivity of the medial globus pallidus is associated with dyskinesias, it is also known that lesions of the globus pallidus alleviate them. This so-called 'pallidotomy paradox' suggests that the dynamic aspects of pallidal and nigral efferent activity are important factors in the generation of dyskinesia (Marsden and Obeso 1994). A more recent 'rate model' of basal ganglia function hypothesizes that specific components oscillate in neuronal synchrony at different frequencies to select specific voluntary motor patterns (Little and Brown 2014). Both rodent electrophysiology and recording from deep brain electrodes implanted in patients with Parkinson's disease suggest that neuronal activity suppression in the 8–30 Hz beta frequency band correlates with relief of parkinsonian akinesia and rigidity by both dopamine and subthalamic nucleus deep brain stimulation.

There is evidence that dysfunction of the basal ganglia is also involved in other complex, less well understood, behavioural disorders. In animal experiments, lesions of the basal ganglia, especially of the caudate nucleus, induce uncontrollable hyperactivity (e.g. obstinate progression, incessant pacing and other constantly repeated behaviours). This and other evidence has led to the notion that the corpus striatum enables an individual to make motor choices and avoid 'stimulus-bound' behaviour. Positron emission tomography (PET) studies in humans have shown that sufferers from obsessive–compulsive disorder (OCD), which is characterized by repeated ritualistic motor behaviour and intrusive thoughts, exhibit abnormal activity in the prefrontal cortex and caudate nuclei. There are similar suggestive observations in childhood attention deficit hyperactivity disorder (ADHD), Huntington's disease and Tourette's syndrome. In this respect, it may be significant that the basal ganglia, besides receiving connections from the frontal lobe and limbic cortices, also have an ascending influence on the prefrontal and cingulate cortices through the substantia nigra pars reticulata and dorsomedial and ventromedial thalamus in parallel, functionally segregated, cortico-striato-thalamic circuits that subserve locomotor, oculomotor, cognitive and affective behaviour (Alexander et al 1986; see Fig. 31.9).

Before the advent of levodopa therapy, neurosurgery for Parkinson's disease was commonplace. The medial globus pallidus and thalamus were favoured targets for chemical or thermal lesions. Pallidotomy and thalamotomy often improved rigidity and tremor, but they produced little consistent beneficial effect on akinesia. With the arrival of levodopa

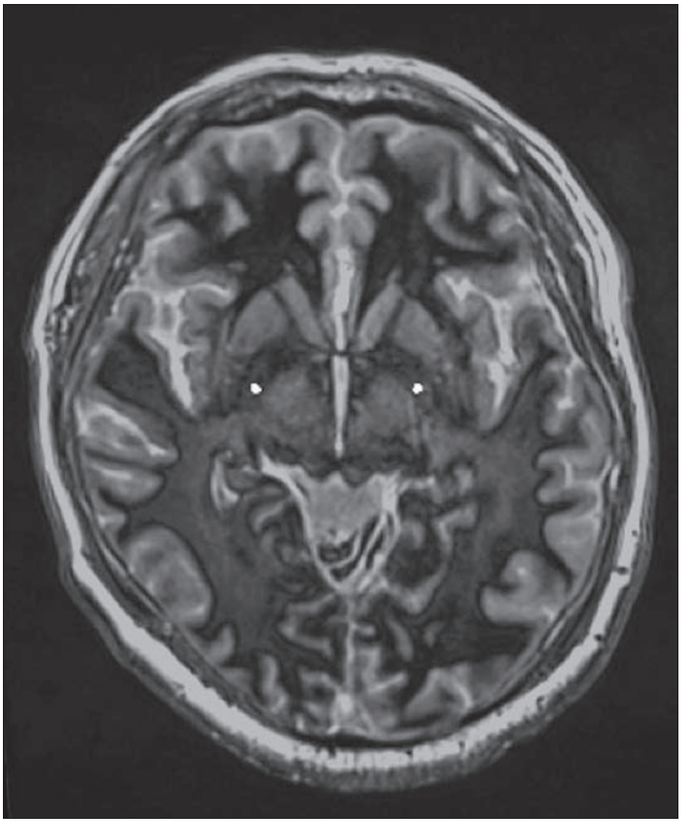

Fig. 31.13 Magnetic resonance image with CT overlaid showing the placement of deep brain stimulation electrodes (white dots) bilaterally in the globus pallidus of a patient with dystonia (Courtesy of Mr E Pereira, St George's, University of London.)

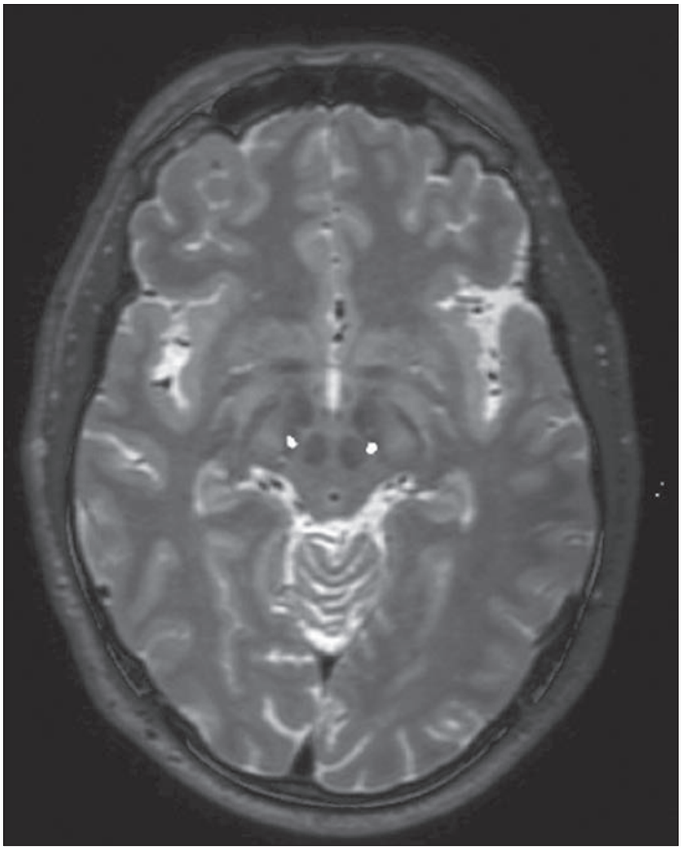

Fig. 31.14 Magnetic resonance image with CT overlaid showing the placement of deep brain stimulation electrodes (white dots) bilaterally in the subthalamic nucleus of a patient with Parkinson's disease. (Courtesy of Mr E Pereira, St George's, University of London.)

therapy, which very effectively alleviates akinesia, the surgical treatment of Parkinson's disease underwent a progressive decline. It soon became clear, however, that long-term use of levodopa was associated with a number of side-effects such as dyskinesias, 'wearing-off' and the 'on–off' phenomenon. More recent advances in understanding the pathophysiology of movement disorders, and of Parkinson's disease in particular, have stimulated a renaissance in the use of neurosurgery to treat movement disorders.

Lesioning the subthalamic nucleus in experimental primates made parkinsonian with the neurotoxin MPTP dramatically alleviated the parkinsonian symptoms, suggesting that the subthalamic nucleus might be an appropriate clinical target (Pereira and Aziz 2006). While therapeutic surgical lesions of the subthalamic nucleus can alleviate tremor, rigidity and bradykinesia in patients with Parkinson's disease, the risk of side-effects is not trivial: the subthalamic nucleus is a small structure wrapped by fibres of passage and close to the hypothalamus and internal capsule.

In 1992, Laitinen et al reintroduced pallidotomy for the treatment of end-stage Parkinson's disease, but confined the lesions to the posteroventral part of the medial pallidum. These lesions were found to be extremely reliable in abolishing contralateral rigidity and drug-induced dyskinesias, with slightly less efficacy on tremor and bradykinesia (Laitinen et al 1992).

Implantation of deep brain electrodes, through which high-frequency pulses generated by a pacemaker could inhibit cells in the vicinity, has been a concept since the early 1970s. It did not become a widespread reality until the late 1980s, when it was facilitated by technological advances. The introduction of the technique of deep brain stimulation (DBS), which avoids making permanent lesions, made bilateral surgery safer. There have been numerous reports of the effectiveness of both bilateral pallidal and subthalamic nucleus stimulation in Parkinson's disease (Rodriguez-Oroz et al 2012; **Figs 31.13–31.14**). Subthalamic nucleus stimulation is largely favoured for relieving akinesia and rigidity, with pallidal stimulation considered to ameliorate dyskinesias if cognition and speech are at risk. Subthalamic stimulation is more effective than pallidal stimulation in allowing patients to reduce their anti-parkinson medication. Isolated tremor syndromes are best relieved by stimulation of either the contralateral ventral intermediate thalamic nucleus or the zona incerta.

Another manifestation of basal ganglia dysfunction is dystonia, which is characterized by increased muscle tone and abnormal postures. Dystonia may occur as a consequence of levodopa treatment in Parkinson's disease or inherited disease (e.g. early-onset torsion, or Oppenheim's dystonia, an autosomal dominant disorder most commonly associated with a mutation in the *DYT1* gene that encodes torsin A). Although the pathophysiological basis of dystonia is unclear (Hallett 2006), it is probably caused by underactivity of basal ganglia output. The observation that painful dystonic posturing of the limbs in parkinsonian patients responds dramatically to bilateral pallidal stimulation led to the development of bilateral pallidal stimulation for dystonia. Intriguingly, in dystonia the pallidal neurones are believed to fire at rates below normal, and so it is open to question how this stimulation works. Moreover, while the effect of stimulation is immediate in the case of Parkinson's disease, in dystonia the improvement may take weeks to emerge, suggesting that the neural mechanism underlying the therapeutic effect of stimulation for this condition is different and implicating a role for neuroplasticity in dystonia. Targeting of the subthalamic nucleus and ventral intermediate thalamus for both phasic and tonic components of craniocervical dystonia has an immediate effect and shows great promise.

Another recent neurosurgical development in the therapy of Parkinson's disease has involved targeting the pedunculopontine nucleus, which both receives fibres from and sends fibres to basal ganglia and related nuclei. Recently, DBS of the pedunculopontine nucleus through implanted electrodes has been applied in drug-resistant akinetic parkinsonian patients. Low-frequency stimulation sometimes alleviates postural instability and on-medication gait freezing and falling, symptoms that conventional medication and surgery fail to improve (Garcia-Rill et al 2019).

The advent of novel DBS electrodes of longer contact span enabling dual targeting, for example of the ventral intermediate thalamus and either the subthalamic nucleus or zona incerta, has opened up increased treatment possibilities in movement disorders. Additionally, segmented directional electrodes enable current steering to reduce capsular or other side-effects from subthalamic or thalamic stimulation and increase the therapeutic window of stimulation. Future directions include miniaturization and 'closed loop' stimulation where neuronal oscillations are recorded from the deep brain electrodes and responded to, either for more effective stimulation in Parkinson's disease or for motor control via brain/computer interfaces in spinal cord injury or motor neurone disease (Lozano et al 2019).

CHAPTER
32

Cerebral hemispheres

The cerebral hemispheres are the largest part of the human brain: they consist of the telencephalon (cerebral cortex and underlying white matter), basal ganglia and diencephalon. Both hemispheres are interconnected by the corpus callosum and the anterior commissure. The cerebral cortex contains the motor and premotor regions, the highest level at which motor activities are controlled, and the primary sensory regions, which provide the first cortical level for the conscious experience of sensory stimuli and to which sensory organs project either directly (olfactory stimuli) or via specific thalamic nuclei. Cortical areas of higher levels are either modality-specific (higher unimodal cortices) or multimodal (association cortex), enabling complex analyses of the internal and external environments. The cortical part of the limbic system (hippocampal formation, amygdala, cingulate and retrosplenial cortex) is a multimodal region that is particularly concerned with memory and the emotional aspects of sensory experience and behaviour. It is also connected with subcortical areas such as the hypothalamus in integrating widespread physiological activities that include endocrine and vegetative reactions. Other association regions within the frontal, temporal and parietal lobes are concerned with the highest aspects of cognitive function, such as social communication, language and visuospatial attention. Anterior association regions of the frontal lobe contribute to personality, judgement, foresight and planning.

The white matter contains association fibres limited to each hemisphere; commissural fibres linking corresponding areas of both hemispheres; and projection fibres connecting the cerebral cortex with subcortical, brainstem and spinal cord nuclei. Some of these bundles (tracts, fasciculi) are relatively well defined and compact, while others fan out and are less easy to identify. A detailed knowledge of the three-dimensional anatomical interrelationships of white matter tracts is a requisite for the planning, intraoperative monitoring and execution of neurosurgical procedures for tumour surgery, resection of epileptic foci and deep brain stimulation. Current understanding of the fibre tracts owes much to the introduction of diffusion-weighted magnetic resonance imaging (dMRI), which enables both postmortem and *in vivo* visualization of the trajectory of the white matter tracts that connect distant regions (structural connectivity). Functional MRI (fMRI) defines the role of cortical areas by task-driven activation or resting state analyses of cortical networks, and thus allows the study of functional connectivity. Stereotaxic atlases in which data are registered to a reference brain are used to integrate different multimodal imaging findings and bridge between data acquired at different scales, from macroscopical *in vivo* MRI to microscopical postmortem anatomy (Eickhoff et al 2005, Van Essen 2005, Zilles and Amunts 2010, Catani and Thiebaut de Schotten 2012).

CEREBRAL HEMISPHERE SURFACES, SULCI AND GYRI

The external surface of each hemisphere is highly convoluted into a series of gyri, separated by sulci that represent extensions of the subarachnoid space (**Figs 32.1–32.3**). The term fissure is used for the deepest sulci, whereas incisures or notches are short, shallow indentations. The main sulci have depths of 1–3 cm, and may harbour small annectant gyri connecting the walls of two adjacent gyri. Most sulci are orientated towards the nearest ventricular cavity and for this reason the sulcal floor is often used by neurosurgeons as point of entry into the underlying ventricle. The sulci of the adult brain are highly variable between subjects, and can be long or short, branching, continuous or interrupted by short transitional gyri (Ono et al 1990, Ribas 2010, Catani and Thiebaut de Schotten 2012, Naidich et al 2012). All long primary sulci can be consistently identified in most human brains (e.g. lateral fissure, central, precentral, postcentral, calcarine, parieto-occipital, collateral, cingulate and callosal sulci). Among the short sulci, primary sulci such as the rhinal, olfactory, lateral and occipital sulci are consistently found in all brains, whereas other short sulci are highly variable and composed of several branches (e.g. orbital and subparietal sulci), or are sometimes absent and therefore indicated as supplementary (e.g. middle frontal sulcus).

Each gyrus is composed of two lateral walls, and a crown that is visible on the external surface. It is estimated that about two-thirds of the cerebral cortex lies along the gyral walls and is therefore buried in the depths of the sulci (Henneberg 1910, Zilles et al 1988). The majority of the sulci appear during postmenstrual weeks 18–21: cortical folding (gyrification) accelerates conspicuously from postmenstrual week 28 and reaches a transient maximum between the 7th and 13th months

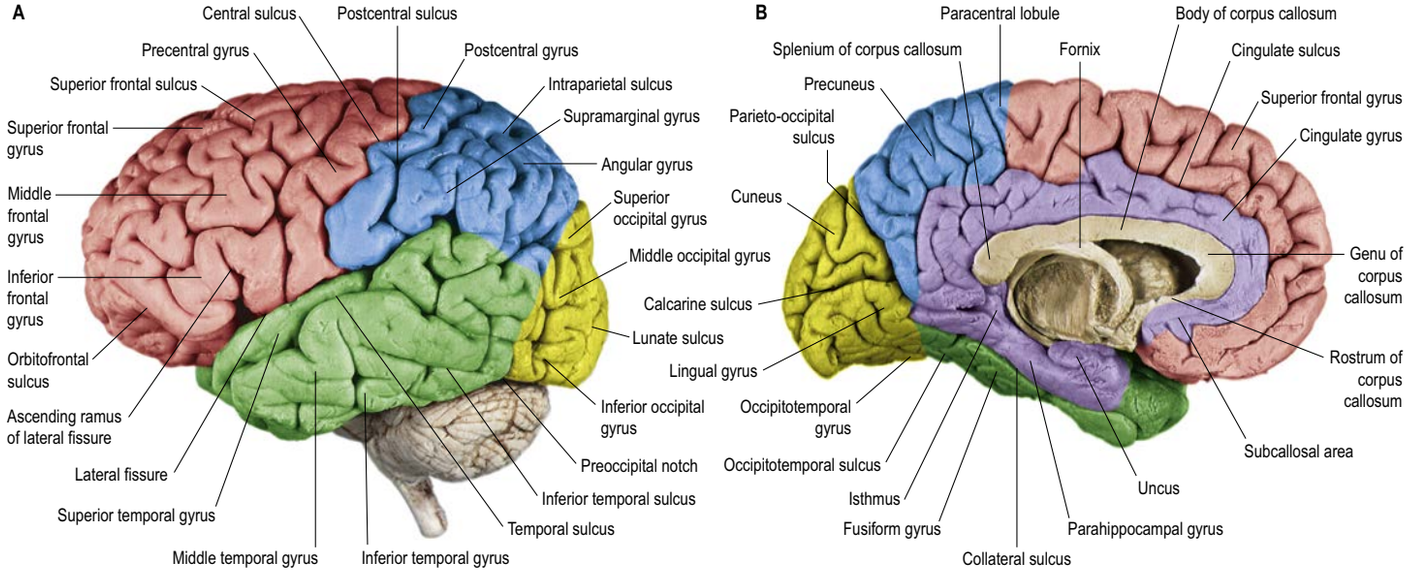

Fig. 32.1 Lateral (**A**) and medial (**B**) aspect of the left cerebral hemisphere, indicating the major gyri and sulci. The colours indicate the lobes: frontal (red), parietal (blue), temporal (green), occipital (yellow) and limbic (purple). (Dissected by EL Rees, photograph by Kevin Fitzpatrick on behalf of GKT School of Medicine, London; enhanced and labelled by M Catani and B Crossman.)

The process of fetal cortical development includes sequential neural cell proliferation at the ventricular zone, ventriculofugal migration of neuronal progeny to form the most recent outer layer of the cortex, and increases in cortical thickness and expansion of the cortical surface area (Ch. 14). The description of the external appearance of this process as a measurement of cerebral hemisphere growth and fetal age, i.e. the visualization of early surface ridges adjacent to neighbouring depressions, is fraught with limitations similar to those noted when describing the pre- and postnatal growth of individuals. Techniques to study hemispheric growth include examination of postmortem brains that have been fixed and removed from the cranium after spontaneous fetal death (Nishkuni and Ribas 2013); MR imaging of brains within the calvaria (Zhang et al 2013); and ultrasound examination of routine second and third trimester scans of live fetuses (Chen et al 2017, Husen et al 2019). These studies have noted different ages at which sulci first appear, reflecting the heterogeneous ethnic, gender and nutritional status of the fetuses: in the case of postmortem studies, there is also the possibility that underlying pathology might have affected cerebral growth.

postnatally. From this time on, the degree of folding declines by 18% until the adult value will be reached at an age of approximately 23 years (Armstrong et al 1995).

The main cerebral sulci divide the hemispheres into frontal, parietal, occipital, temporal, insular and limbic lobes (Fig. 32.1A,B). In the adult brain, the limbic lobe is visible on the medial surface of each hemisphere. Parts of the frontal, parietal and temporal lobes cover the insular lobe, which is present in the depth of the lateral fissure (opercularization). Each hemisphere has superolateral, medial and inferior (basal) surfaces and a frontal, temporal and occipital pole (see Fig. 32.1A,B).

The superolateral surface is convex and lies beneath the bones of the calvaria: the frontal, parietal, temporal and occipital lobes correspond approximately in surface extent to the overlying bones from which they take their names. The frontal and parietal lobes are separated by the central (Rolandic) sulcus and both are separated from the temporal lobe by the prominent lateral (Sylvian) fissure. Frontal and temporal regions are each composed of three horizontal gyri, the superior, middle and inferior frontal and temporal gyri, respectively. The central region is composed of two slightly oblique gyri, the frontal precentral gyrus and the parietal postcentral gyrus, that are separated by the central sulcus. The deep intraparietal sulcus divides the superior parietal lobule from the inferior parietal lobule (which is subdivided into supramarginal and angular gyri). The occipital region is composed of three horizontal gyri (superior, middle and inferior occipital gyri), which are highly variable between subjects. The insula lies deep in the floor of the lateral fissure and consists of 4–5 diagonal gyri, separated by the central insular sulcus into anterior short and posterior long insular gyri.

The inferior surface has a smaller anterior frontal orbital part and a larger posterior tentorial part that belongs to the temporal and occipital lobes. The orbital part rests on the floor of the anterior cranial fossa, and the posterior part rests on the floor of the middle cranial fossa and the upper surface of the tentorium cerebelli. The orbital part of the inferior surface is made up of the orbital gyri and the gyrus rectus. The tentorial part of the inferior surface is covered by the basal aspects of

the inferior temporal, inferior occipital and lingual gyri, and the fusiform gyrus.

The medial surface is flat and vertical, and is separated from the contralateral hemisphere by the longitudinal fissure and the falx cerebri. The medial surface of the hemisphere includes a C-shaped inner ring composed of two continuous gyri (the cingulate and parahippocampal gyri), surrounded by the gyrus rectus, superior frontal gyrus, paracentral lobule, precuneus, cuneus and lingual gyrus. Some details of the anatomy of the gyri and sulci of each lobe are illustrated in Figs 32.2–32.3.

NEURONAL TYPES IN THE CEREBRAL CORTEX

The cerebral cortex is an intricate complex of neuronal somata and fibres, neuroglia and blood vessels. The neocortex contains two major neuronal cell types: excitatory pyramidal cells with long axons (projection neurones) and stellate cells (**Fig. 32.4**). Pyramidal cells are the most abundant type and represent about 75% of the cortical neurones. Stellate cells have been subdivided into spiny stellate cells that express glutamate as neurotransmitter, and GABA-containing inhibitory aspinous interneurones with relatively short, locally terminating axons (Fig. 32.5). All types have been further divided on the basis of their size and shape, connectivity, neurotransmitter and gene expression, and electrophysiological characteristics.

Laminar organization

The most obvious microscopic feature of the cortex is its horizontal organization in layers or laminae that are visible to the naked eye or under the microscope after cell body or myelin staining. The isocortex has six layers in histological sections stained to show the somata (Nissl stain) (**Fig. 32.9**). The laminar pattern of the allocortex is heterogeneous, showing less or more layers depending on the allocortical region. The most important features of myeloarchitectonic lamination are given in **Table 32.2**.

The molecular layer I of the adult brain is cell-sparse and contains few scattered neurones. It consists mainly of the apical dendritic tufts of pyramidal neurones and horizontally orientated axons, as well as glial cells. Some spiny stellate, neurogliaform, horizontal and a few scattered Cajal–Retzius cells are found in this layer. Inputs to the apical tufts are thought to be of cortico-cortical origin, but thalamocortical axonal terminals also occur. There are several subtypes of Cajal–Retzius cells; they are numerous in the fetal brain, but most are eliminated during early postnatal stages. They release the neurotransmitter glutamate, but their precise function is not clear. They control the laminar organization of the developing cortex by releasing the glycoprotein Reelin which acts like a stop signal for the outwardly migrating neurones. A lack of Reelin or other molecules in its signalling pathway results in a severe impairment of laminar organization. Decreased Reelin has been associated with lissencephaly and major psychiatric disorders in the human brain. The horizontally running dendrites of Cajal–Retzius cells are embedded in a mass of tangentially running myelinated and unmyelinated axons and dendrites. These tangential fibres consist of afferent fibres that arise from outside the actual cortical area, fibres from cortical interneurones, and the apical dendritic arborizations of virtually all pyramidal neurones of layers III and V. In myelin stained sections, a narrow band of tangential fibres, the Cajal–Retzius stripe, is visible in the centre of layer I (see Fig. 32.9).

The external granular lamina II is dominated by the somata of small pyramidal and non-pyramidal cells ('granular' cells). Myelin staining shows mainly vertically orientated fibres traversing the layer. In many brain regions, tangentially orientated myelinated fibres are found in higher density at the border between layers II and III, the horizontal Exner stripe (see Fig. 32.9). This border is difficult to determine in those cortical regions where the neuronal density of layer II is low.

The external pyramidal layer III predominantly contains small and medium-size pyramidal cells, as well as non-pyramidal neurones with vertically orientated intracortical axons. Together with layers I and II, layer III is the main target of interhemispheric (callosal) cortico-cortical afferents, and the principal source of cortico-cortical efferents. Scattered interneurones are also found in this layer. The pyramidal cells are smallest in the most superficial part of the layer and their size increases towards its deeper part. Layer III can frequently be subdivided into IIIa, IIIb and IIIc, where IIIa is most superficial and IIIc is the deepest. As in layer II, myelin stains reveal a mostly vertical organization of fibres; a band of horizontally running and myelinated fibres, the outer Baillarger stripe, can be seen at the border between layer IIIc and IV in many isocortical regions (see Fig. 32.9).

The width of the internal granular layer IV varies according to area. In Nissl-stained preparations it is seen to consist mainly of small round granular cells, which are different types of spiny stellate and pyramidal neurones and various types of aspiny interneurones. Layer IV is the main target of thalamo-cortical afferents and intra-hemispheric cortico-cortical afferents. In myelin-stained sections, the outer band of Baillarger is seen in layer IV of the primary visual cortex. The band is so obvious in this cortical area that it can be detected with the naked eye in histological sections of unstained fresh or frozen brains. It was first observed by Francesco Gennari in the year 1776, and independently 10 years later, by Félix Vicq d'Azyr: the horizontal, myelin-rich band is, therefore, often named the stripe of Gennari or of Vicq d'Azyr. It subdivides layer IV of the primary visual cortex into three sublayers: IVa, IVb (where the stripe is found) and IVc.

The internal pyramidal layer V often contains the largest pyramidal cells of any cortical layer. However, actual sizes vary considerably from area to area; in some association areas, layer III pyramidal cells are larger than those of layer V (externopyramidization). Layer V pyramidal neurones give rise to axons that leave the cortex and run down to subcortical structures. Scattered non-pyramidal cells are also present in layer V. In many cortical areas, layer V can be subdivided into sublayers Va, Vb and

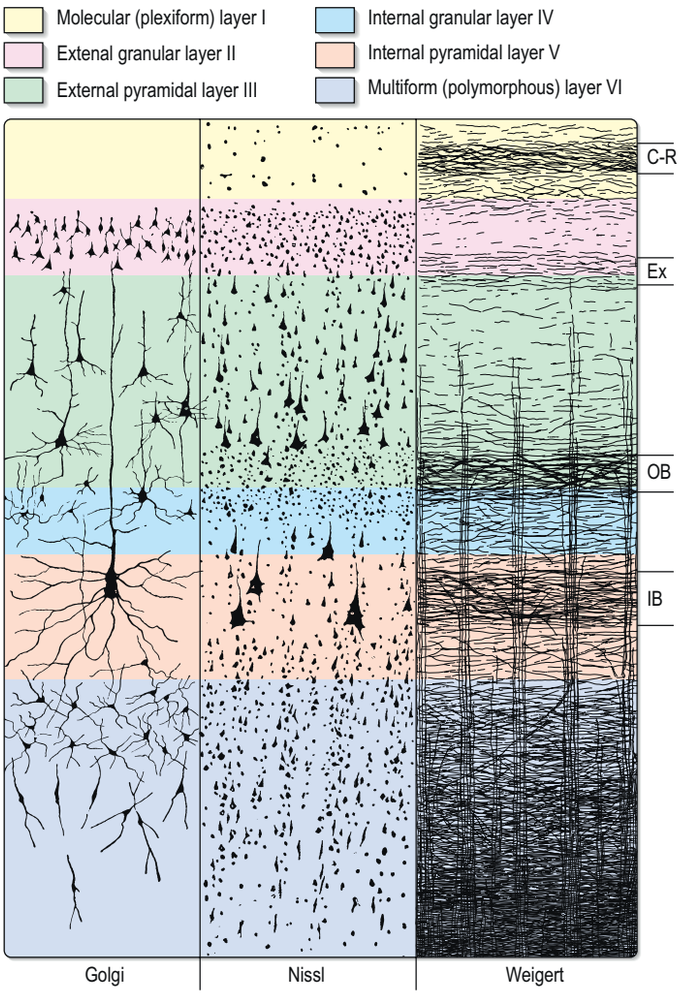

Fig. 32.9 The layers of the isocortex. The three vertical columns represent the distribution of cellular elements, as revealed by the techniques of Golgi (impregnating some complete neurones), Nissl (staining cell bodies) and Weigert (staining myelinated fibres). Horizontally running and densely packed myelinated fibres represent the Cajal–Retzius stripe (C–R) in layer I, the Exner stripe (Ex) at the layer II/III border, the outer band of Baillarger (OB) in deeper layer III or layer IVb of the primary visual cortex, and the inner band of Baillarger (IB) in layer V.

Pyramidal cells have a flask-shaped or triangular soma that ranges from 10 to 80 μm in diameter and gives rise to a single thick apical dendrite and multiple basal dendrites. The apical dendrite ascends towards the cortical surface, tapering and branching (see Fig. 32.4). Some dendrites end in the most superficial lamina, the molecular layer (layer I), others end at the level of the outer granular (layer II) or outer pyramidal layer (layer III). From the basal surface of the soma, dendrites spread horizontally or obliquely for distances up to 1 mm, depending on the size of the soma. Like apical dendrites, the basal dendrites branch profusely along their length. All pyramidal cell dendrites are studded with dendritic spines that become more numerous as the distance from the cell soma increases. A single slender axon arises from the axon hillock, which is usually situated centrally on the basal surface of a pyramidal neurone. For the vast majority, if not in all, pyramidal neurones, the axon leaves the cortical grey matter to enter the white matter. Before an axon reaches the white matter, it gives rise to a recurrent branch that terminates in the cortical region of origin of the parent axon. Pyramidal cells use an excitatory amino acid, either glutamate or aspartate, as neurotransmitter. Various types of pyramidal cells can be identified by their connectivity (e.g. axonal projections to the ipsi- or contralateral hemisphere, cortico-striate, cortico-thalamic, cortico-pontine and cortico-spinal projections), electrophysiological (e.g. regular fast or slow spiking, or intrinsically bursting types) and genetic characteristics. The giant Betz cells and the solitary Meynert cells are very large pyramidal cells with special morphological features.

The volume of the somata of Betz cells, located in lamina V of the primary motor cortex, is ten times larger than that of common layer V pyramidal cells. A Betz cell gives rise to a 10 μm thick myelinated axon that terminates on motor neurones in the brainstem and anterior horn of the spinal cord via the cortico-nuclear and cortico-spinal tracts, respectively. In contrast to common pyramidal cells, which have a single apical dendrite and dendritic arbors that exit the soma from basal angles, Betz cells have many dendrites that arise directly from the entire circumference of the soma. Meynert cells are located at the border between layers V and VI of the primary visual cortex; their somata are three times larger than those of common layer V pyramidal cells. In contrast to other pyramidal cells, most of their spines are found on the extensively arborized basal dendrites in layers V and VI, which extend below several blobs and interblobs (see below). Meynert cells are involved in motion detection, mediated via their connections with area MT/V5, and with the superior colliculus via axon collaterals. The von Economo neurone (spindle neurone) is a subtype of projection neurone that occurs preferentially in the deeper layer V of fronto-insular and anterior cingulate regions and has also been described in the entorhinal cortex, the hippocampal formation, and the dorsomedial Brodmann's area 9 (BA9). These neurones are characterized by a single apical dendrite, a single basal dendrite and a long projection axon and are probably glutamatergic: their selective degeneration is found in early stages of fronto-temporal dementia.

Spiny stellate cells (see Fig. 32.4) are the second most numerous cell type in the neocortex. They are found preferentially in lamina IV and are the major target of thalamo-cortical input. Their relatively small multipolar somata commonly measure 6–10 μm in diameter. Several primary dendrites, profusely covered in spines, radiate for variable distances from each soma. The axons ramify within the grey matter, predominantly in the vertical plane. Spiny stellate cells use glutamate as neurotransmitter. These morphological and chemical characteristics led some authors to classify spiny stellates as a variant pyramidal cell, but their locally terminating axons also argues for a classification as interneurone.

All aspiny or sparsely spinous stellate cells are GABAergic (γ-aminobutyric acid) inhibitory interneurones (see Fig. 32.6). Their axons are confined to grey matter and terminate on other interneurones and pyramidal cells. Interneurones form inhibitory synapses with pyramidal neurones, and can also receive inhibitory synapses from other interneurones, but such connections are sparse: most synapses on interneurones are excitatory. There are many different subtypes of interneurones, including basket, horizontal, chandelier, double bouquet, bipolar/fusiform, bitufted, neurogliaform and Martinotti cells, and layer I interneurones (see Fig. 32.5; **Fig. 32.6**). Each morphological interneurone type can display widely varying electrophysiological or molecular properties. GABAergic interneurones often co-express neuropeptides (neuropeptide Y (NPY), somatostatin (SOM), cholecystokinin (CCK), vasoactive intestinal polypeptide (VIP)) and/or calcium binding proteins (parvalbumin (PV), calbindin (CB), calretinin (CR)) in a cell-type specific manner. GABAergic interneurones can be subdivided into several non-overlapping types according to differences in their developmental origin, target cells, and molecular markers. The embryonic medial and caudal ganglionic eminences are the origin of three GABAergic interneuronal types that co-express PV, SOM, and the serotonin receptor 5-HT_{3A}. The PV type includes basket and chandelier cells: axons of PV basket cells terminate mainly in the perisomatic region, and chandelier cells co-express PV and CCK and terminate on the axon initial segment of pyramidal cells. The SOM type includes Martinotti cells that project to distal dendrites. The 5-HT_{3A} type includes bipolar cells that co-express VIP and can lead to disinhibition (interneurone-selective disinhibitory cells, **Fig. 32.7**); Reelin cells (including Cajal–Retzius cells; see Fig. 32.5 and Martínez-Cerdeño and Noctor 2014); and CCK-expressing small basket cells. Neuronal nitric oxide synthase (nNOS) is constitutively expressed in 2% of cortical interneurones and is co-localized with SOM or NPY: these interneurones have high numbers of glutamate receptors that mediate the glutamate-induced hyperexcitation that follows cerebral impairment.

The common PV basket cells (see Fig. 32.6) are found in layers II–VI. They never express Reelin. Small basket cells express SOM, CCK and VIP. All basket cells show a mostly multipolar dendritic arbor, and a short, vertical axon that rapidly divides into horizontal collaterals that typically end in large terminal sprays on the somata and proximal dendrites of pyramidal cells, and rarely on other PV-expressing interneurones. The synaptic outputs of the fast-spiking (common) basket cells are strongly depressing.

The cell bodies of horizontal cells (see Fig. 32.6) lie mainly at the border between layers I and II, occasionally deep in lamina I (molecular layer). They are small and fusiform, and their dendrites spread short distances in layer I in two opposite directions. Their axons often stem from a dendrite, then divide into two branches that travel away from each other for great distances in the same layer. The morphological subtype of horizontal cells is heterogeneous with respect to the co-expression of PV, Reelin, SOM, VIP and NPY. Layer I horizontal cells express PV and Reelin, which is particularly important for the development of the regular lamination of the cortex during development. Other horizontal cells also express VIP, NPY and SOM.

Chandelier cells (see Fig. 32.5) are frequently found at the border between layers I/II and layer VI. Some, but not all, express PV. They have a variable morphology, although most somata are ovoid. Their dendrites arise from the upper and lower poles of the cell body and the axon emerges from either the cell body or a proximal dendrite. The ascending or descending axons ramify close to the cell body and terminate in numerous vertically orientated strings that run alongside the axon initial segment of pyramidal cells, where they build very effective inhibitory synapses.

Double bouquet cells (see Fig. 32.6) are found in laminae II and III and their axonal arborization is predominantly perpendicular to the pial surface, traversing layers II and V. Generally, these neurones have two or three main dendrites that terminate in a superficial and deep dendritic tuft. A single axon arises usually from the oval or spindle-shaped soma and rapidly divides into ascending and descending branches that collateralize extensively; the axonal arbor is confined to a perpendicularly extended, but horizontally confined, cylinder.

The bipolar cell (see Figs 32.5–32.6) has a very small, ovoid soma with a single ascending and a single descending dendrite that arise from the upper and lower poles, respectively of the soma. Sixty per cent of these cells are located in layers II and III. They co-express VIP, PV, CCK and acetycholine. They receive GABAergic input from basket cells on their somata, and from layer V pyramidal cells on their proximal dendrites. The dendrites branch sparsely and run vertically to produce a narrow dendritic tree that may extend through most of the cortical layers. Commonly, the axon originates from one of the primary dendrites and branches into a vertically elongated and horizontally confined axonal arbor that closely parallels the dendritic tree. Since pyramidal cells represent a major target for the GABA/PV/VIP synapses, the activation of these synapses may lead to coherent oscillations that provide the necessary signal to synchronize pyramidal cell discharges across and within cortical columns.

Bitufted cells (see Fig. 32.6) have two tufts of dendrites that originate directly from the soma and extend in vertical directions through all layers. The somata of these interneurones are most frequently located in layers II–IV and express Reelin. Some bitufted cells also express SOM. Layer II–III bitufted interneurones receive excitatory input from pyramidal cells in the same layers. Depression can be observed at these excitatory synapses: it may be caused by exocytotic GABA release from dendrites (since GABA-activated presynaptic $GABA_B$ receptors are found on the glutamatergic terminals), causing a reduction of glutamate release, i.e. conditioning. The axons of bitufted cells generate inhibitory synapses with pyramidal cells of the same cortical column (feedback inhibition). Since the elongated dendritic arbors span the entire cortex, bitufted interneurones receive input from all cortical layers, which means that bitufted cells can control the excitability of cortical columns.

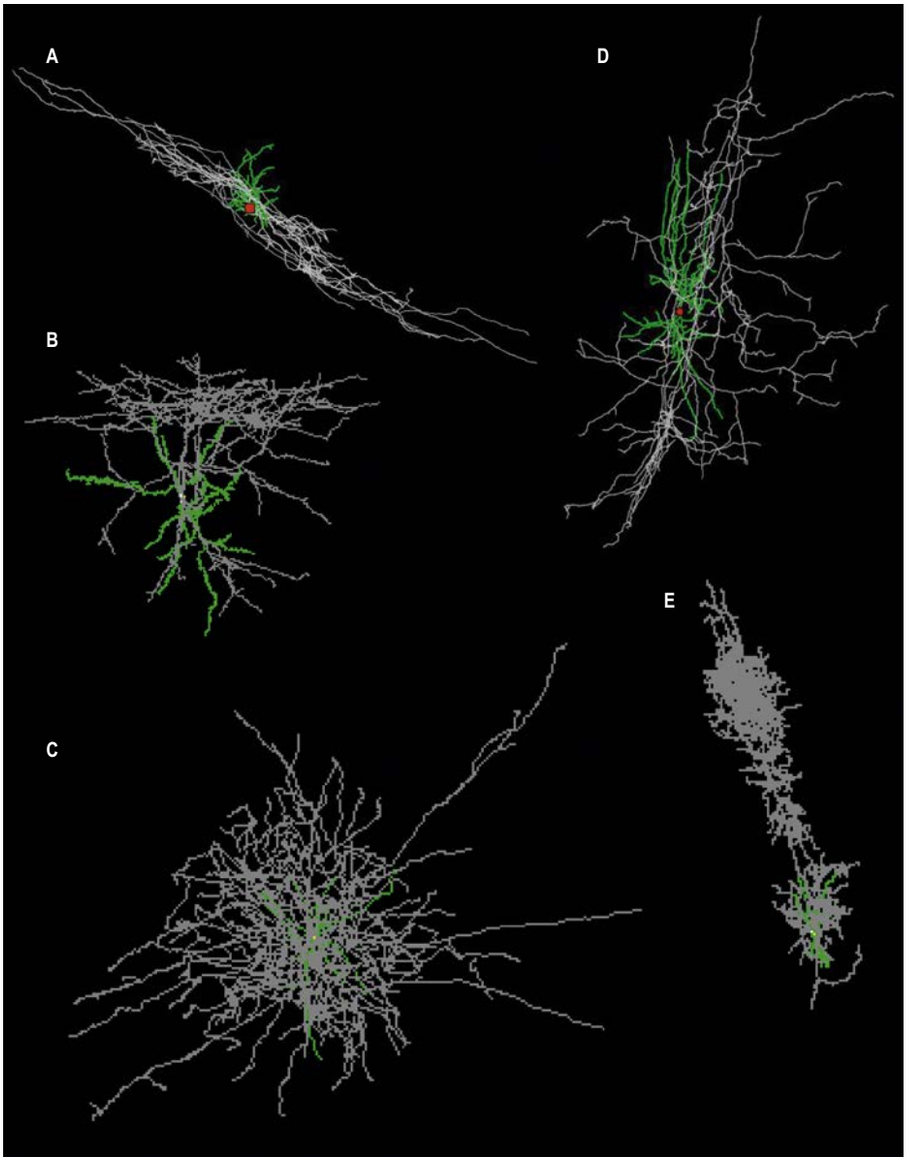

Fig. 32.6 A–E, Interneurones of the cerebral cortex. Grey, dendrites; green, axons; red, incomplete soma. **A**, Biocytin-stained horizontal cell in layer I of the primary somatosensory cortex (NMO_37241). **B**, Biocytin-stained Martinotti cell in layers II–III of the rat motor cortex (NMO_07436). **C**, Neurobiotin-stained basket cell in layers II–III of the macaque prefrontal cortex (NMO_01863). **D**, Biocytin-stained bitufted neurone in layer IV of the human temporal isocortex (NMO_97192). **E**, Neurobiotin-stained double bouquet cell in layers II–III of the macaque prefrontal cortex (NMO_01870). (All images are from NeuroMorpho.Org (Ascoli et al 2007), a central open resource for neuronal morphologies.)

The neurogliaform or spiderweb cell (see Fig. 32.5) is a small spherical cell found in layers I–IV. Most cells in layer I are neurogliaform cells that co-express PV, Reelin, NPY and VIP. Those in deeper layers also contain nNOS. Numerous short dendrites typically radiate out from their somata. The axon arises from the soma or a proximal dendrite and forms a wider, very dense axonal plexus composed of fine branches.

Most of the Martinotti cells (see Fig. 32.6) are located in supragranular layers II and III. They are more sparsely distributed throughout granular and infragranular layers. All express SOM and Reelin, but not all SOM-positive cells are Martinotti cells. They can also express CB, CR, CCK, VIP and NPY. The most striking feature of Martinotti cells in layers V–VI is their characteristic long ascending axon that spreads horizontally and arborizes extensively in layer I. Their bipolar or multipolar dendrites branch locally or down to deeper layers. **Table 32.1** provides a summary of GABAergic interneurones, main targets and anatomical signatures.

These interneurones build the microcircuitry of the cerebral cortex with other interneurones and pyramidal (projection neurones) cells (see Fig. 32.7). They synaptically connect neurones of the same and/or different layers. Various sequences of direct or indirect synaptic connections between inhibitory interneurones and excitatory pyramidal cells are the basis of the complex modulatory mechanism of cortical microcircuitry. If GABAergic interneurones receive an excitatory input, they will inhibit the excitatory output of those cells by a direct synaptic connection with pyramidal cells (feedforward inhibition; **Fig. 32.8**). However, they will excite pyramidal cells if they are indirectly connected with them via an interposed inhibitory GABAergic cell that contacts the pyramidal cell (disinhibition). A third principal type of connectivity in microcircuits occurs if GABAergic interneurones receive an excitatory input from a pyramidal cell and send back an inhibitory output to the pyramidal cell (feedback inhibition). Impaired microcircuitry can lead to synchronized excitatory activity in cases of epilepsy.

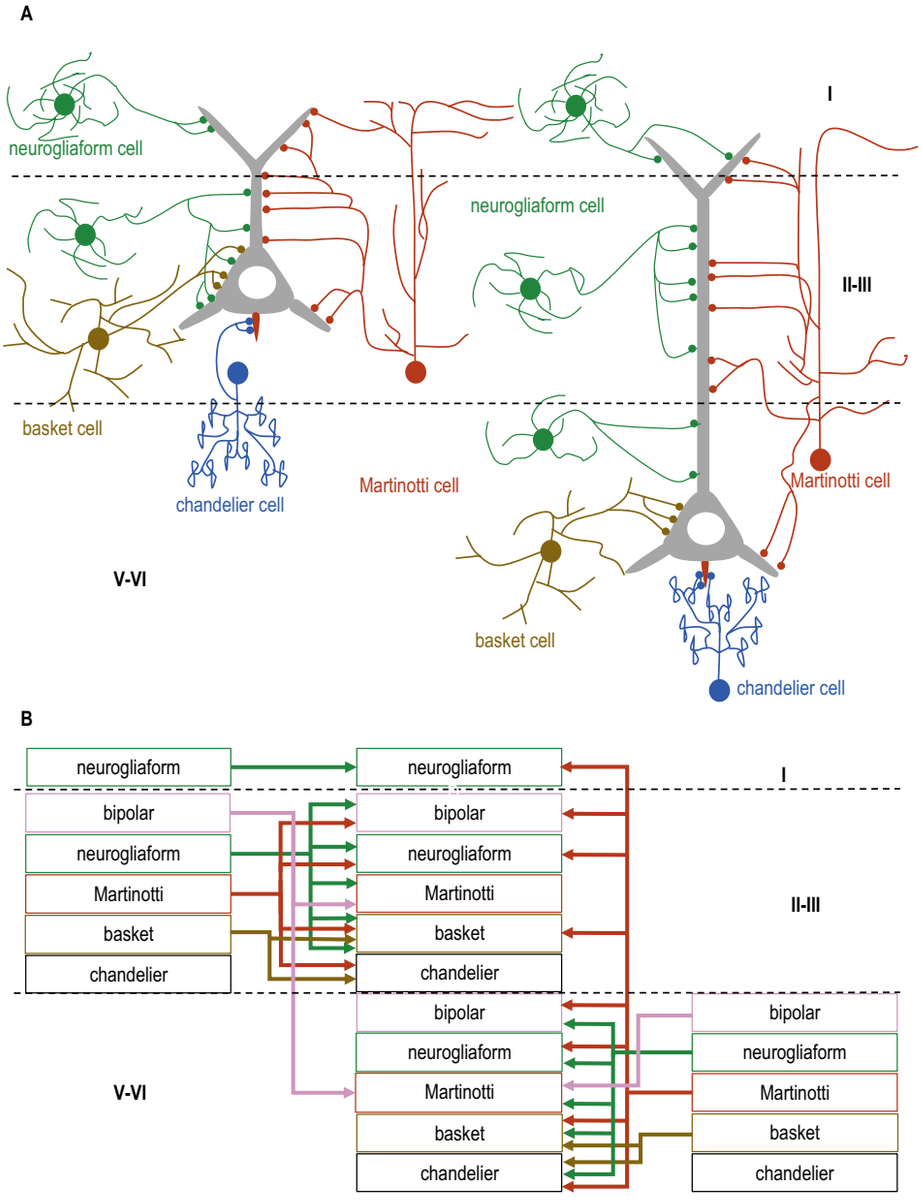

Fig. 32.7 **A**, Connections between GABAergic interneurones (examples are neurogliaform, basket, chandelier and Martinotti cells) and pyramidal cells of layers III and V. The neurogliaform cells of layer I contact the dendritic tufts in the same layer. The soma and the proximal dendrites of pyramidal cells of layers III and V receive input from neurogliaform cells of the respective layer, and from cholecystokinin- and parvalbumin-expressing basket cells. The chandelier cells contact the initial axon segment of pyramidal cells. Martinotti cells of layers III and V have axon terminals on basal, proximal, apical and dendritic tufts of pyramidal cells. **B**, Connections between different types of GABAergic interneurones in layers I–VI of the isocortex. (Adapted with permission from Tremblay R, Lee S, Rudy B 2016 GABAergic interneurones in the neocortex: from cellular properties to circuits. Neuron 20:260–92.)

TABLE 32.1 Isocortical GABAergic interneurones classified by their co-localization of parvalbumin, somatostatin and serotonin 5-HT$_{3A}$ receptors, morphological types, main targets and anatomical signatures

Main marker	Parvalbumin		Somatostatin		5-HT$_{3A}$					
% interneurones	40%		30%		30%					
Morphological type	Basket cell	Chandelier cell	Martinotti cell	Non-Martinotti cell	VIP cell			Non-VIP cell		
					40% of 5-HT$_{3A}$			60% of 5-HT$_{3A}$		
					Bipolar	CCK small basket	Multi polar	Small basket	CCK large basket	Neurogliaform cell
Main target	Soma and proximal dendrite	Only pyramidal cells; axon initial segment	Dendrites		Interneurones			Synaptic and volume transmission		
Anatomical signature	• Present in layers II–VI • Most prominent in layers IV–V • Multipolar dendritic arbor • Axonal arbor within and between layers and columns • Extensive connectivity with pyramidal cells and parvalbumin + interneurones	• Most frequent in layers II–VI • Multipolar dendritic arbor • Local axonal arbor	• Pesent in layers II–VI • Most prominent in layer V • Multipolar or bitufted dendritic arbor • Local axonal but transcolumnar arbor • No connections to other somatostatin neurones	• Present in layers IV–V • Multipolar or bitufted dendritic arbor • No axonal plexus in layer I	• Most frequent in layers II–III • Intracolumnar but interlayer vertical dendrites • Intracolumnar axonal arbor			• Present in layer I • Multipolar dendritic arbor • Short translaminar axon		• Present in layers I–VI • Small multipolar dendritic arbor • Dense axonal arbor

Adapted from Tremblay et al 2016.

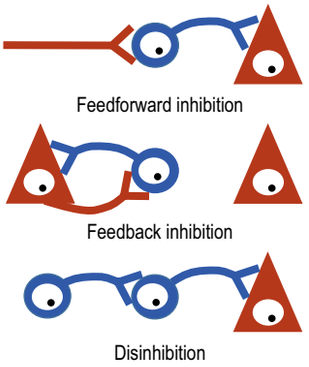

Fig. 32.8 Circuit motifs between excitatory glutamatergic pyramidal cells and inhibitory GABAergic interneurones. Feedforward inhibition is based on the excitation of an interneurone by an external input (e.g. thalamo-cortical input): the interneurone inhibits a cortical pyramidal cell. Feedback inhibition is based on the excitation of an interneurone by a cortical pyramidal cell and the recurrent inhibition of the pyramidal cell by an interneurone. Disinhibition occurs when an interneurone is excited and this interneurone gives rise to an inhibitory connection with another interneurone: in this case, the inhibition of the second interneurone leads to a decrease of its inhibitory action on a pyramidal cell. (Adapted with permission from Tremblay R, Lee S, Rudy B 2016 GABAergic interneurones in the neocortex: from cellular properties to circuits. Neuron 20:260–92.)

TABLE 32.2 Most important criteria for myeloarchitectonic descriptions (Vogt 1910, Vogt and Vogt 1919)

Presence of Baillarger (layers 4 and 5b) stripes		
	Astriate	Baillarger stripes cannot be delineated due to the very high fibre density in layers 5a and 6a[1] Occurrence: large parts of the precentral gyrus
	Propeastriate	A modification of the astriate type, because of a slight decrease of the fibre density in layers 5a and 6a,[1] i.e. the cortex is nearly astriate Occurrence: parts of the precentral gyrus, inferior parietal lobule, parts of the superior temporal gyrus
	Propeunistriate	The outer Baillarger stripe is well demarcated, the inner stripe is less obvious, but better visible than in the unistriate type, since layer 6a is less dense than 5b. Fibre density in layer 5a is slightly lower than in the propeastriate type Occurrence: dorsal part of the medial frontal gyrus, parts of transverse and superior temporal gyri
	Bistriate	Both Baillarger stripes clearly detectable because of lower fibre densities in layers 5b and 6a[1] Occurrence: frontal pole, medial frontal gyrus, parts of the transverse temporal gyrus, postcentral gyrus, superior parietal lobule, parts of extrastriate visual cortex
	Unistriate	A distinct outer Baillarger stripe is visible, but the inner stripe cannot be delineated from layer 6 due to high fibre density in sublayer 6a[1] Occurrence: superior frontal gyrus, parts of precentral gyrus, medial orbital region, anterior cingulate cortex, inferior temporal gyrus
	Unitostriate (conjunctostriate)	Both Baillarger stripes appear to be fused to a broad band, due to an increased fibre density in layer 5a (accompanied by a more or less prominent thinning of this layer) and a lightly stained layer 6a Occurrence: lateral orbital region, posterior part of the inferior frontal gyrus, parts of extrastriate visual cortex
	Singulostriate	The inner Baillarger stripe is lacking Occurrence: temporopolar region, primary visual cortex
Myelin density in Baillarger stripes		
	Equodensus	Both Baillarger stripes are equally dense
	Externodensior	Outer Baillarger stripe denser than inner stripe
	Internodensior	Inner Baillarger stripe denser than outer stripe
Intrusion depth of radiate bundles into the cortical ribbon		
	Euradiate	Radiate bundles reach upper border of layer 3b
	Infraradiate	Radiate bundles reach upper border of layer 5b
	Supraradiate	Radiate bundles extend into layers 1–2

From Zilles et al 2015c, modified

Vc. In myelin stained sections, the lamina is seen to be traversed by ascending and descending vertical fibres and to contain another prominent band of horizontal fibres, the inner band of Baillarger (see Fig. 32.9).

The multiform layer VI consists of excitatory cells (pyramidal neurones with dendrites and axons that branch and terminate in layers IV to V, spiny stellate cells with local dendritic branches and axons that terminate in layer VI, inverted pyramidal neurones, and bipolar/fusiform and other odd-shaped cells), and inhibitory interneurones. The upper part of this layer (layer VIa) has a higher cell density than its lower part (layer VIb), which blends gradually with the underlying white matter. A clear demarcation of layer VIb from the white matter is difficult in most brain regions. In some regions the cells of layer VIb can cover an area several times thicker than the cortex.

Cortical layers and their connections

Non-thalamic subcortical afferents to the neocortex from the basal forebrain (Ch1–4, cholinergic), pedunculopontine (Ch5, cholinergic) and laterodorsal tegmental (Ch6, cholinergic) nuclei, ventral tegmental area (A10, dopaminergic), raphe nuclei (B1–9, serotoninergic), and nucleus coeruleus (A6, noradrenergic), terminate throughout all cortical layers; the laminar pattern of the density of their endings varies considerably from area to area.

Thalamo-cortical afferent fibres are found particularly in layers III–IV, and to a lesser extent also in layers I–II. Cortico-cortical input projects as long-distance feedback input mainly to layers II–IIIa, and as short-distance feedforward connections to layers IIIb and IV. Cortico-cortical input from the contralateral hemisphere (callosal afferents) mainly ends in layer III. In general, the largest input to a cortical area tends to terminate mainly in layer IV. This pattern of termination is best seen in the major thalamic input to primary visual, auditory and somatic sensory areas (**Fig. 32.10**).

Supragranular pyramidal cells, predominantly layer III but also lamina II, give rise to both association and commissural cortico-cortical efferents. Generally, short cortico-cortical fibres arise more superficially, and long cortico-cortical (both association and commissural) axons come from cells in the deeper parts of layer III. The cortico-cortical long-distance feedforward fibres originate in layers II–III, and the long-distance feedback fibres from layers V and VI. Layer V also gives rise to cortico-striate (to the basal ganglia), cortico-thalamic, cortico-tectal, cortico-bulbar/nuclear (including cortico-pontine) and cortico-spinal fibres. Layer VI is the major source of cortico-thalamic and cortico-claustral fibres (see Fig. 32.10).

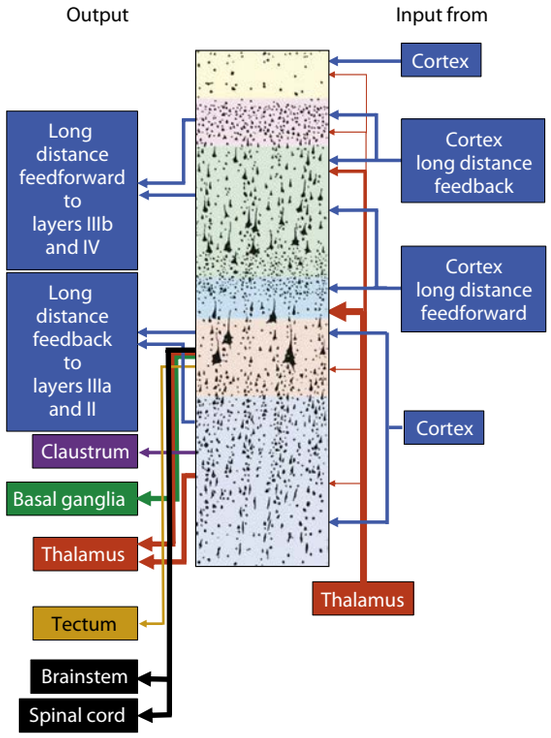

Fig. 32.10 Major afferent and efferent connections of the isocortical layers. Long-distance feedforward cortico-cortical output originates from supragranular layers; progressively more infragranular layers are recruited on approaching the target site and terminate in layers IV and IIIb. Long-distance feedback cortico-cortical output originates from the infragranular layers; progressively more supragranular layers are recruited on approaching the target site and terminate in layers IIIa and II.

Columns and modules

Experimental physiological and connectional studies have demonstrated an internal organization of the cortex that is at right-angles to the pial surface and the underlying layers, with vertical columns or modules running through the depth of the cortex (**Fig. 32.11**). The term 'column' refers to the observation that all cells encountered by a microelectrode penetrating and passing perpendicularly through the cortex respond to a single peripheral stimulus, a phenomenon first identified in the somatosensory and visual cortices (Mountcastle 1957, Hubel and Wiesel 1959, 1972). In the visual cortex, narrow (50 µm) vertical strips of neurones respond to a bar stimulus of the same orientation (orientation columns), and wider strips (500 µm) respond preferentially to stimuli detected by one eye (ocular dominance columns; see p. 531). Adjacent orientation columns aggregate within an ocular dominance column to form a hypercolumn, responding to all orientations of stimulus for both eyes for one point in the visual field. Similar functional columnar organization has been described in widespread areas of neocortex, including motor cortex and association areas.

MAPS OF THE HUMAN CEREBRAL CORTEX

The systematic study of variations in cortical layering across the cerebral mantle has produced several maps of the human and non-human brain. Currently, the most widely used map is the cytoarchitectonic map of Brodmann (1910) which segregates the human iso- and allocortex into approximately 50 areas or fields (**Fig. 32.12**). Brodmann's map lacks data on the areas buried within the intrasulcal surface and on interindividual variability in the extent and location of the areas. The Brodmann–Jülich map is shown in **Fig. 32.13** (with some examples of probabilistic maps in **Fig. 32.14**): functional specialization will be discussed in this chapter in the context of the cytoarchitectonic divisions of the cerebral lobes.

TRANSMITTERS IN THE HUMAN CEREBRAL CORTEX

Available with the *Gray's Anatomy* e-book

Glutamate

Glutamate is the ubiquitous major excitatory transmitter in the human cerebral cortex, found in pyramidal neurones and astrocytes. The latter rapidly take up synaptically released glutamate via specific transporter molecules and metabolize it into glutamine and water. Glutamine is discharged from astrocytes by transporters, enters nerve terminals by electrogenic transporters, and is converted back into glutamate which is used again for neuronal transmission or is assimilated into the neuronal Krebs cycle. This glutamate–glutamine shuttle is crucial for the function of glutamate: excessive activation by high glutamate concentrations leads to pathological conditions and cell death.

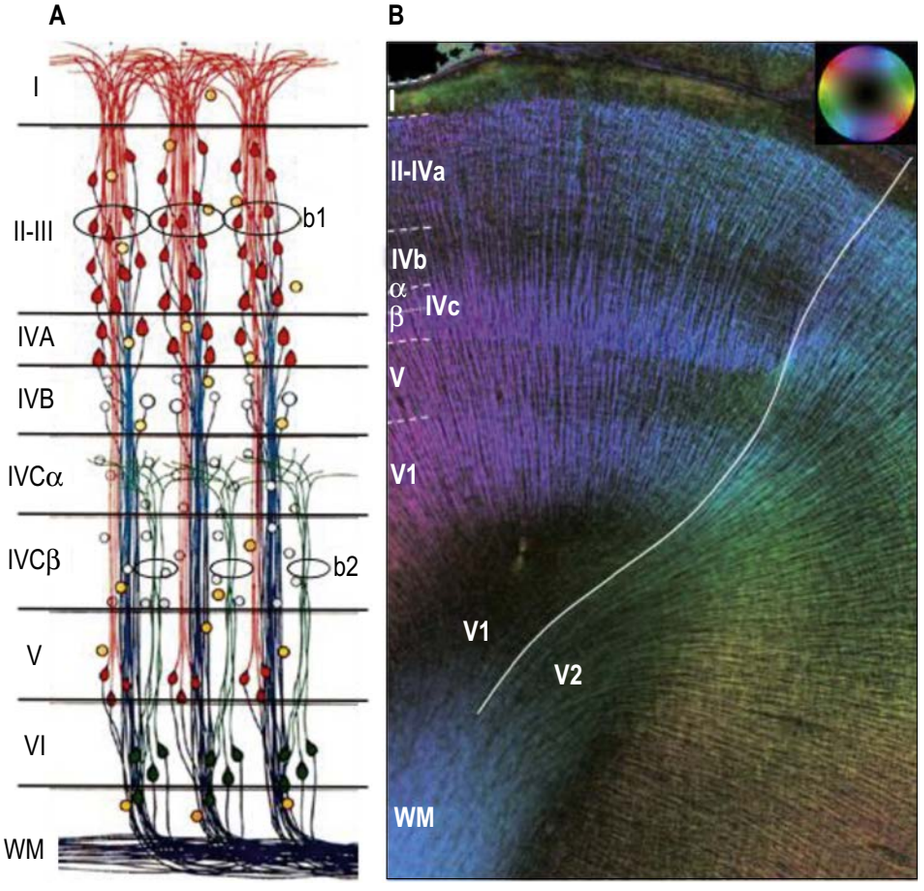
The minicolumn is a distinctive module in the neocortex (Buxhoveden and Casanova 2002). It is a highly repetitive cortical unit consisting of horizontal and vertical components. Minicolumns display a considerable structural and functional heterogeneity between areas. The potential impact of the minicolumn concept seems to be important for comparative neuroanatomy and brain pathology (Buxhoveden et al 2006).

Apical dendrites of layer V pyramidal cells form columnar structures called dendritic bundles (Fleischhauer et al 1972). Each bundle consists of several apical dendrites and extends through layer IV into layer III/II where the dendrites begin to ramify (see Fig. 32.11B). Within the bundle, some dendrites approach each other so closely as to be separated only by the extracellular space. Dendritic bundles and minicolumns of neuronal somata are spatially closely related. The dendritic bundles lie between the columns of cell bodies. The transverse diameter of both (about 50 μm) is roughly the same in the entire isocortex. Neurones in a minicolumn can send their apical dendrite to different bundles, some of them through bifurcating apical dendrites; neurones in separate minicolumns can send their dendrites to the same bundle. They might correspond to narrower assemblies of neurones with radially invariant activation/response to motion in the visual, motor and auditory areas. Electrophysiological studies suggest that the vertical bundles of dendrites are the morphological substrate of vertical functional units. Myelinated axons entering or leaving the cerebral cortex are also not distributed at random but are organized in axonal bundles (see Fig. 32.11B).

Similar criticisms apply to the more elaborate cytoarchitectonic map produced by von Economo and Koskinas (1925) (**Fig. 32.15**): **Tables 32.3–32.4** compare the parcellation in the maps of Brodmann (1909) and von Economo and Koskinas (1925). Ongoing work on a cytoarchitectonic map of the entire human cerebral cortex based on a quantitative, statistically testable parcellation method, and information on intersubject variability and the cortical areas within the intrasulcal surface, is presented here (see Fig. 32.14) in a map that is three-dimensional; the brain with the map can be tilted by the user into any direction of view.

Maps of cortical segregation using myeloarchitectonic criteria contained over 100 myeloarchitectonic areas (**Figs 32.16–32.18**) (Vogt and Vogt 1919, Hopf 1954) (**Fig. 32.19**; see Table 32.2). The various cyto- and myelo-architectonic maps that were produced using different staining methods were roughly comparable: one of Brodmann's areas (Brodmann 1910) contains several subdivisions represented in the maps of von Economo and Koskinas (1925) and of Vogt and Vogt (1919) and in the probability maps (Tables 32.3–32.4). However, some of the areas in Brodmann's map (e.g. BA19, BA37), particularly in the higher eulaminate regions, could not be corroborated using more observer-independent methods and comparison with functional observations (Zilles and Amunts 2010).

The development of *in vitro* tissue slice binding techniques and quantitative autoradiography has enabled the visualization and quantification of neurotransmitters and their receptors within individual cortical fields. Although a single receptor type can characterize the borders of functionally and cytoarchitectonically defined cortical regions, in most cases only the characterization of the expression patterns of multiple receptors in the same cortical region can provide the criteria for a multimodal parcellation. These multi-receptor expression patterns are the characteristic fingerprints of each cortical area (**Figs 32.20–32.22**). They facilitate detailed mapping of the human cerebral cortex and provide insight into the hierarchical relationships of these areas and the principles of their organization into structurally and functionally defined networks (Palomero-Gallagher and Zilles 2009, Palomero-Gallagher et al 2015, Zilles and Amunts 2010, Amunts and Zilles 2015, Zilles and Palomero-Gallagher 2017). Maps of cortical neurotransmitters are important for understanding the neuropathological signatures of neurological and psychiatric disorders and the development of new molecules that can selectively modulate the activity of individual areas.



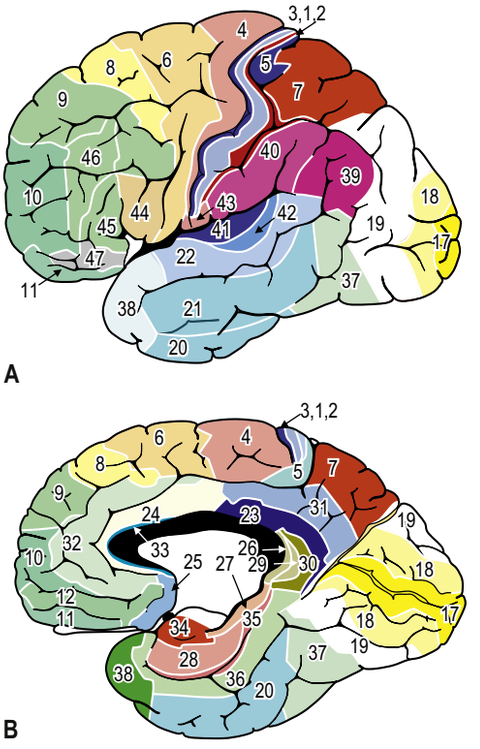


Fig. 32.11 A–B, Columns of dendritic bundles originating in layer V (b1) and layer VI (b2) pyramidal cells (modified after Mountcastle 1957). Dendritic bundles originating in layer V terminate in layer I (red fibres), those originating in layer VI terminate in layer IV (green fibres). **B**, Bundles of vertically orientated myelinated axons in the primary (V1) and secondary (V2) visual cortex. The myelinated fibers can be visualized with polarized light imaging because myelin is birefringent. The colour of fibres encodes for their spatial orientation according to the colour sphere (top right). Fibres running vertical to the image plane are hidden in the black regions. Roman numerals indicate cortical layers; V1, primary visual cortex (BA17); V2, secondary visual cortex (BA18); WM, white matter.

Fig. 32.12 Cytoarchitectonic parcellation of the cerebral cortex by Brodmann (1910). BA (Brodmann area) 3, represents the primary somatosensory cortex; BA17, primary visual cortex; BA41, primary auditory cortex. BA1 and BA2 are probably secondary somatosensory areas. BA18, secondary visual area; BA42, secondary auditory area; BA4, primary motor cortex; BA6, entire premotor cortex. BA8–BA12 represent the prefrontal; BA5, BA7, BA39 and BA40 the posterior parietal; and BA20, BA21, BA22 and BA38 the temporal association cortices. The Broca region consists of BA44, BA45 and probably BA47. BA23–BA25 and BA31–BA33 are parts of the cingulate cortex, whereas BA26, BA29 and BA30 are listed by Brodmann (1909) as retrosplenial cortex. BA27, presubiculum; BA28 and BA34, entorhinal cortex; BA35, perirhinal cortex, are parts of the hippocampal region: Brodmann did not completely map this region, because the subiculum, cornu Ammonis and dentate gyrus are not identified. **A**, lateral view, left side; **B**, medial view, right side. (Adapted from Brodmann 1910.)

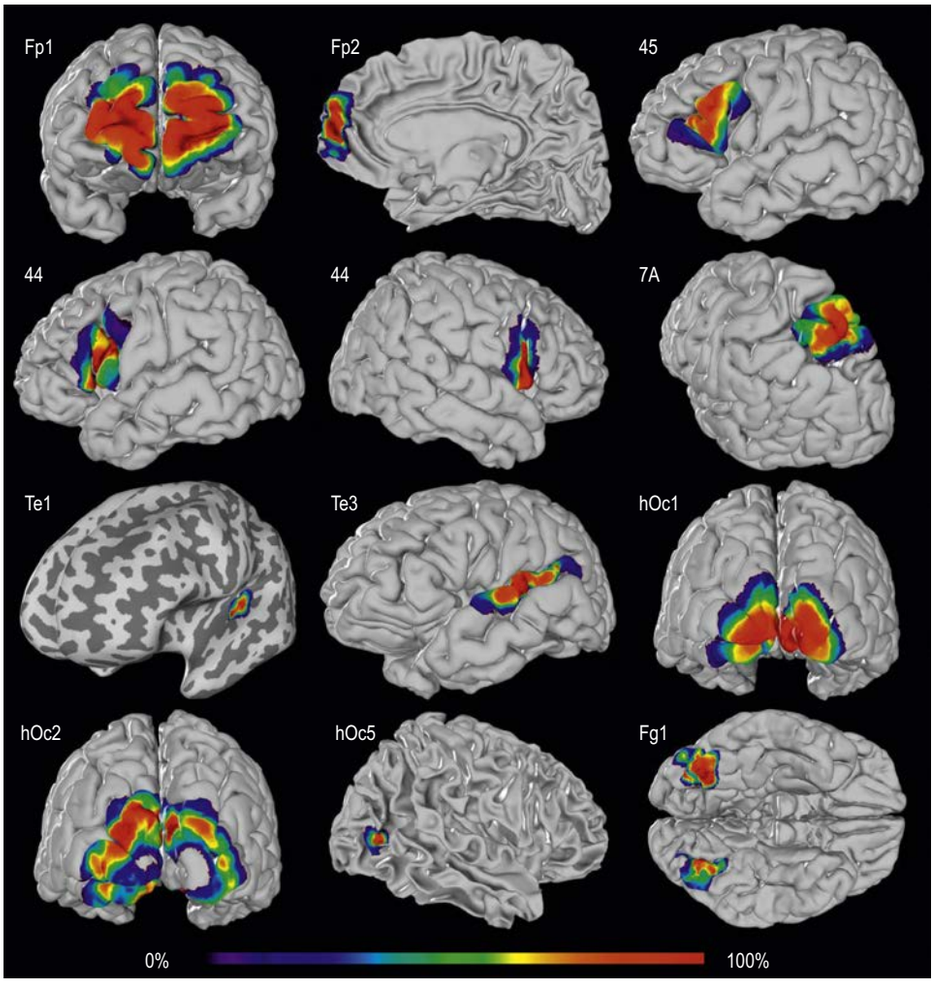

Fig. 32.14 Continuous probability maps provided by the Jülich/Düsseldorf group and publicly available under https://interactive-viewer.apps.hbp.eu. The probabilities from low (blue) to high (red) for each area are visualized separately. (From https://tinyurl.com/ydncaz7q.)

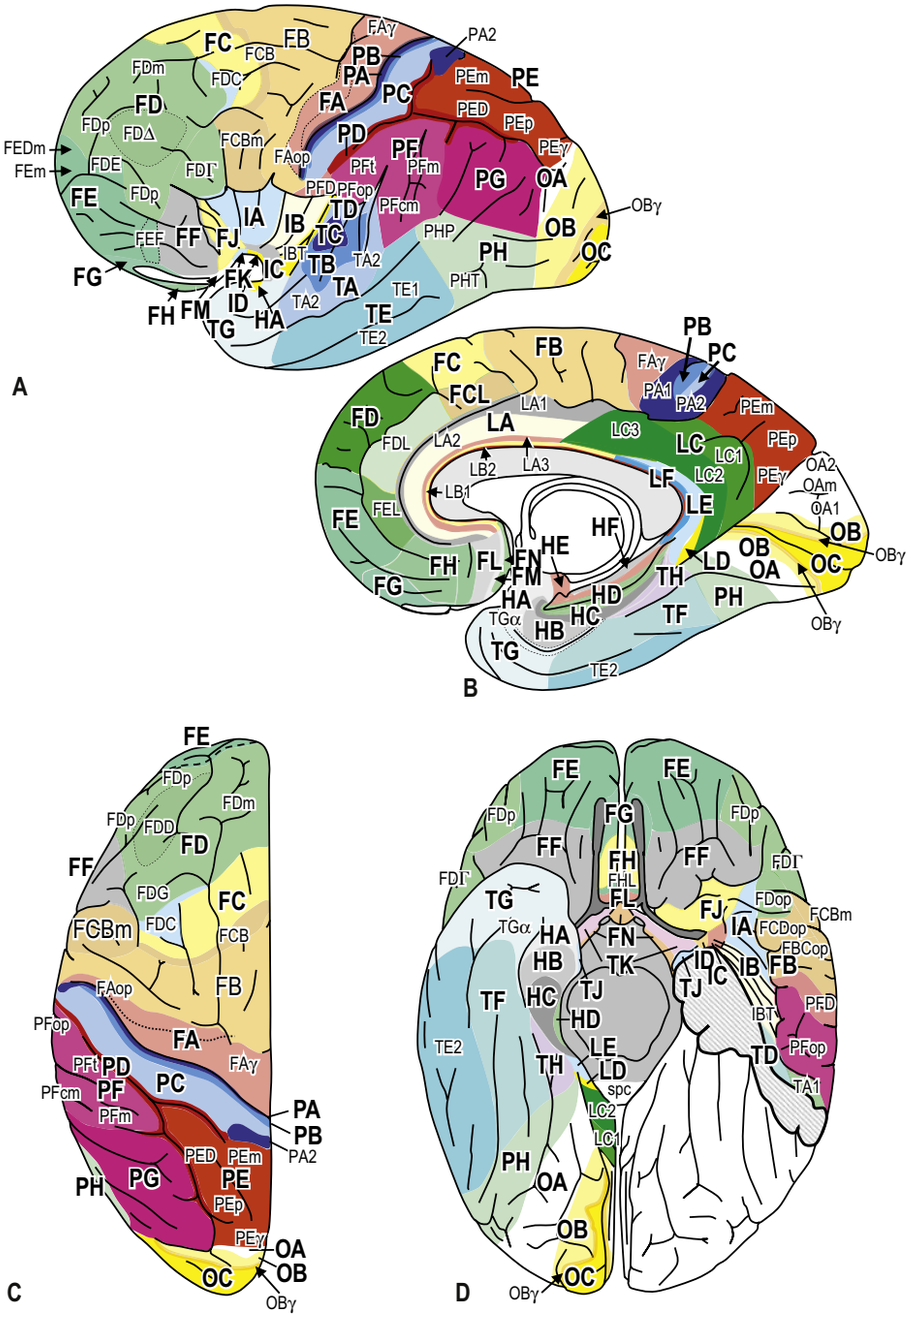

Fig. 32.15 Cytoarchitectonic parcellation of the cerebral cortex by von Economo and Koskinas (1925). Brodmann's (1910) map and this map have been compared and putative matches between both maps are given in Table 32.4, as well as by the same colour coding of comparable cortical areas in Fig. 32.12 (Brodmann's map) and this figure. **A**, lateral view, left side; **B**, medial view, right side; **C**, dorsal view; **D**, ventral view. (Modified after von Economo and Koskinas 1925.)

TABLE 32.3 Comparison between the map and nomenclature system used by Brodmann (1909, 1914) and those of Vogt (1910), Vogt and Vogt (1919) and the Jülich/Düsseldorf group (modified after Zilles et al 2015c)

	n.d.	VTb^1, VTb^2	n.d.

Abbbreviation: n.d., not determined.

The Vogt map is mainly based on myeloarchitectonic observations, but also includes comparisons with cytoarchitecture. The other maps are based on cytoarchitectonic observations.

The Düsseldorf/Jülich map is based on the following publications: Amunts et al 1999, Amunts et al 2010, Amunts et al 2012, Bludau et al 2014, Caspers et al 2013b, Caspers et al 2006, Eickhoff, Amunts et al 2006, Geyer et al 1996, Geyer et al 1999, Grefkes et al 2001, Kujovic et al 2013, Kurth, Eickhoff et al 2010, Malikovic et al 2007, Palomero-Gallagher 2008, Palomero-Gallagher et al 2013, Rottschy et al 2007, Scheperjans, Eickhoff et al 2008, Scheperjans, Hermann et al 2008.

Maps of the Jülich/Düsseldorf group are shown in the JuBrain Cytoarchitectonic Atlas Viewer atlas and the SPM Anatomy Toolbox.

TABLE 32.4 List of cytoarchitectonic areas according to (1) von Economo and Koskinas (1925), (2) Brodmann (1909) and (3) JuBrain (Amunts and Zilles 2015). The areas listed under Brodmann and JuBrain overlap completely or partially with those of von Economo and Koskinas. In (1), main areas (bold font) are distinguished from their subdivisions (normal font) as originally proposed by von Economo and Koskinas.

	1	Area name after von Economo and Koskinas	2	3
Frontal lobe (F)				
Prerolandic region				
1	**FA**	Precentral area	4	4a, 4p
2	FAγ	Giant pyramidal precentral area	4	4a, 4p
3	FAop	Opercular precentral area	4	4a, 4p
4	**FB**	Agranular frontal area	6	6
5	FBop	Opercular agranular frontal area	6	6

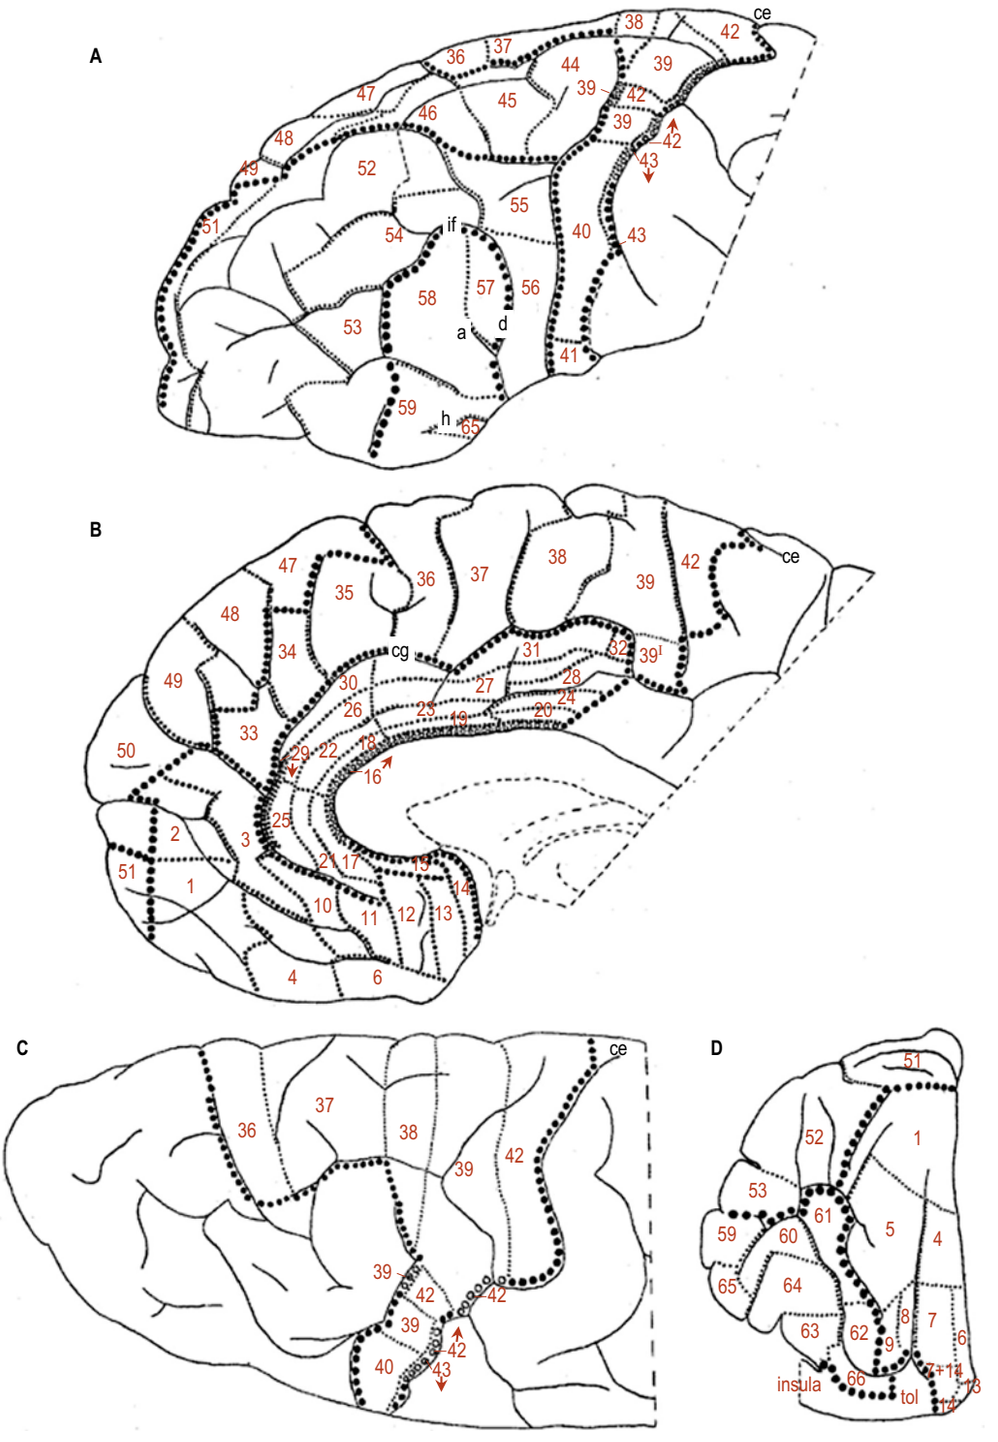

Fig. 32.16 A myeloarchitectonic map of the human frontal lobe after Vogt (1910). **A**, lateral view; **B**, medial view; **C**, dorsal view; **D**, ventral view. Prefrontal areas rostral to areas V36, V39 and V40 are not shown in the dorsal view. Arabic numbers indicate Vogt's myeloarchitectonically defined areas. Abbreviations: a, ascending branch of the lateral fissure; ce, central sulcus; cg, cingulate sulcus; d, diagonal sulcus; h, horizontal branch of the lateral fissure; if, inferior frontal sulcus; tol, olfactory tuberculum. (With permission from Zilles K, Palomero-Gallagher N, Bludau S Cytoarchitecture and maps of the human cerebral cortex. In: Toga AW (ed) Brain Mapping: An Encyclopedic Reference. Anatomy and Physiology. Elsevier, Academic Press. Copyright 2015.)

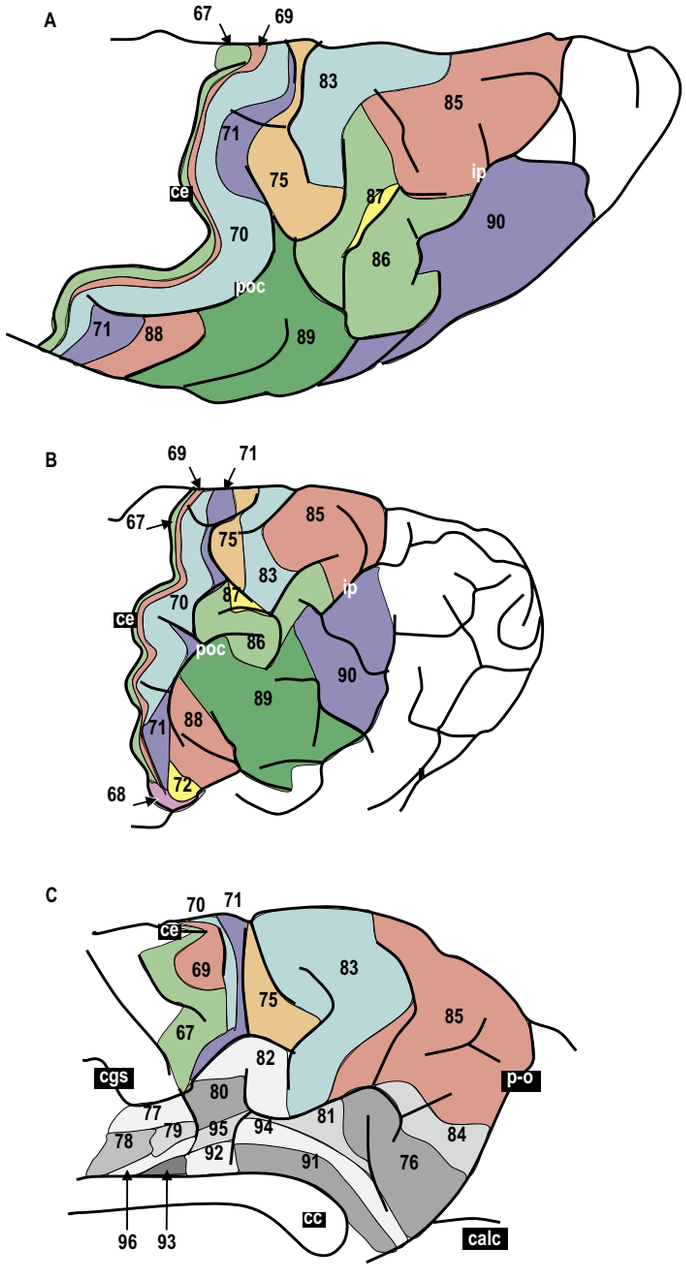

Fig. 32.17 Myeloarchitectonic maps of the human parietal cortex after Vogt (1911): **A**, dorsal view; **B**, lateral view; **C**, medial view. Arabic numerals indicate myeloarchitectonic areas. Abbreviations: calc, calcarine sulcus; cc, corpus callosum; ce, central sulcus; cgs, cingulate sulcus; ip, intraparietal sulcus; p-o, parieto-occipital sulcus; poc, postcentral sulcus. (With permission from Zilles K, Palomero-Gallagher N, Bludau S Cytoarchitecture and maps of the human cerebral cortex. In: Toga AW (ed) Brain Mapping: An Encyclopedic Reference. Anatomy and Physiology. Elsevier, Academic Press. Copyright 2015.)

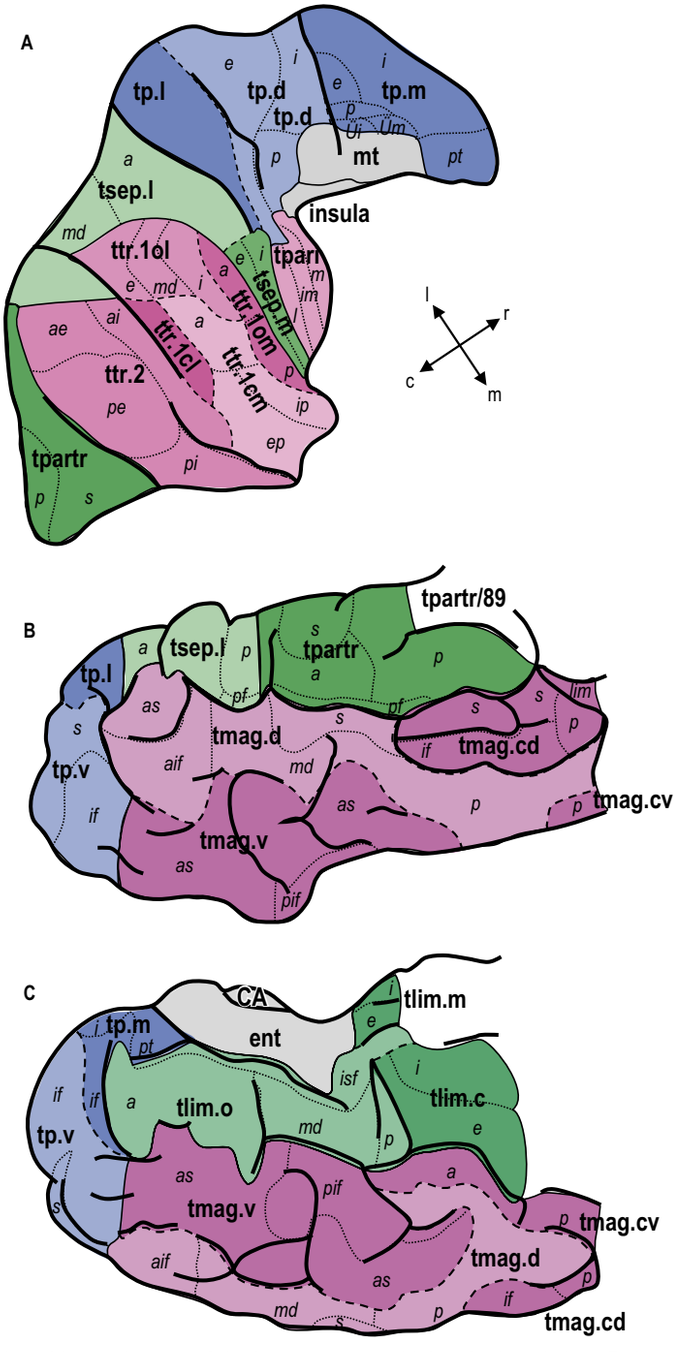

Fig. 32.18 A–C, A myeloarchitectonic map of the human temporal lobe: **A**, dorsal view; **B**, lateral view; **C**, medial view (modified from Hopf 1954). Bold letters are code names of regions and subregions, italics are code names of areas. Continuous lines surround the regions, dashed lines indicate subregional borders, and dotted lines areal borders. Orientations of the map in **A** are indicated. Abbreviations: c, caudal direction; m, medial direction; l, lateral direction; r, rostral direction; CA, cornu Ammonis region of the hippocampus; ent, entorhinal area; mt, mesocortex. The regio temporalis limitans (tlim) is subdivided into caudal (c), medial (m) and oral (o) subregions; tlim.c contains two areas (e, i), tlim.m two areas (e, i) and tlim.o four areas (a, isf, md, p). The regio temporalis magna (tmag) is subdivided into the caudodorsal (cd), caudoventral (cv), dorsal (d) and ventral (v) subregions. tmag.cd consists of four areas (lim, if, p, s), tmag.cv of two areas (a, p), tmag.d of five areas (aif, as, md, p, s), and tmag.v of two areas (as, pif). The regio temporopolaris (tp) is subdivided into the dorsal (d), lateral (l), medial (m) and ventral (v) subregions. tp.d consists of three areas (e, I, p), tp.l is not further subdivided, tp.m has seven areas (e, i, if, p, pt, Ül, Üm), and tp.v two areas (if, s). The regio temporalis parainsularis (tpari) contains three areas (im, l, m). The regio temporalis paratransversa (tpartr) contains four areas (a, p, pf, s). The regio temporalis separans (tsep) is subdivided into the lateral (l) and medial (m) subregions. tsep.l contains four areas (a, md, p, pf) and tsep.m two areas (e, i). The regio temporalis transversa (ttr) is subdivided into the prima caudolateralis (1cl), prima caudomedialis (1cm), prima orolateralis (1ol), prima oromedialis (1om) and secunda (2) subregions. ttr.1cl is not further subdivided, ttr.1cm has three areas (a, ep, ip), ttr.1ol three areas (e, I, md), ttr.1om two areas (a, p) and ttr.2 four areas (ae, ai, pe, pi). (C, Adapted from Hopf 1954, reproduced with permission from Zilles K, Palomero-Gallagher N, Bludau S Cytoarchitecture and maps of the human cerebral cortex. In: Toga AW (ed) Brain Mapping: An Encyclopedic Reference. Anatomy and Physiology. Elsevier, Academic Press. Copyright 2015.)

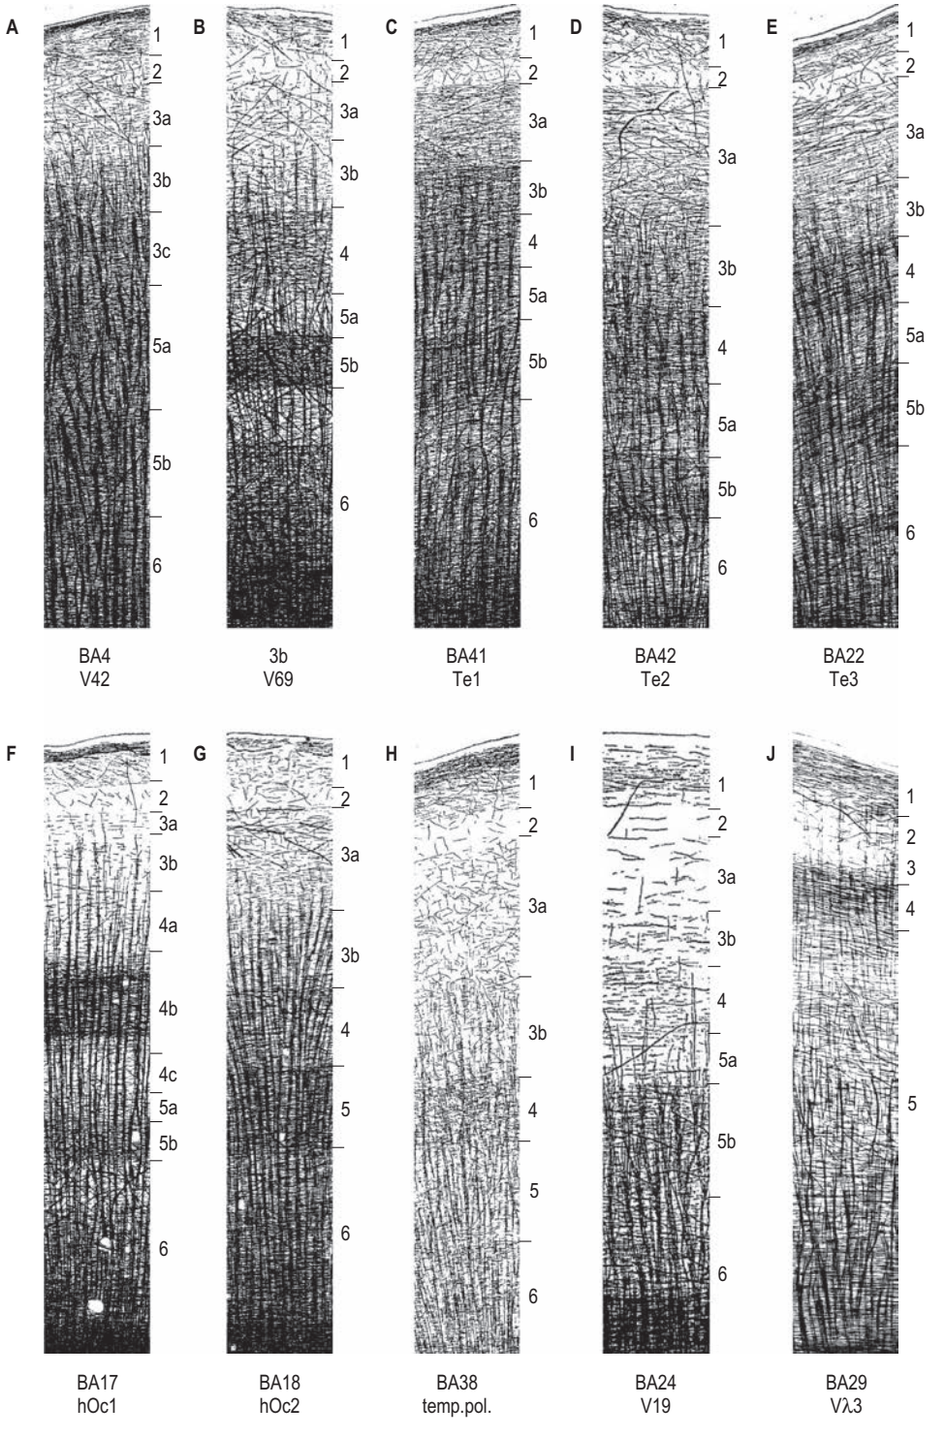

Fig. 32.19 Myelinated fibres and their lamination pattern in representative iso- and periallocortical areas. The cortical thickness of the different areas has been normalized. Arabic numerals indicate myeloarchitectonic layers. **A**, Primary motor cortex (BA4/V42). **B**, Primary somatosensory cortex (area 3b/V69). **C**, Primary auditory cortex (BA41/Te1). **D**, Secondary auditory cortex (BA42/Te2). **E**, Superior temporal gyrus (BA22/Te3). **F**, Primary visual cortex (BA17/hOc1). **G**, Secondary visual cortex (BA18/hOc2). **H**, Temporal pole (BA38/temp.pol.). **I**, Anterior cingulate cortex (BA24/V19). **J**, Retrosplenial cortex (BA29/Vλ3). Abbreviations: BA, Brodmann areas (Brodmann 1909); hOc1 and hOc2, cytoarchitectonically defined primary and secondary visual cortex as reported by Amunts et al (2000); Te1 and Te2, cytoarchitectonically defined primary and secondary auditory areas as reported by Morosan et al (2001); Te3, higher auditory area (part of BA22) as reported by Morosan et al (2005); V, Vogt areas (Vogt and Vogt 1919). (With permission from Zilles K, Palomero-Gallagher N, Amunts K Myeloarchitecture and maps of the cerebral cortex. In: Toga AW (ed) Brain Mapping: An Encyclopedic Reference. Anatomy and Physiology. Elsevier, Academic Press. Copyright 2015.)

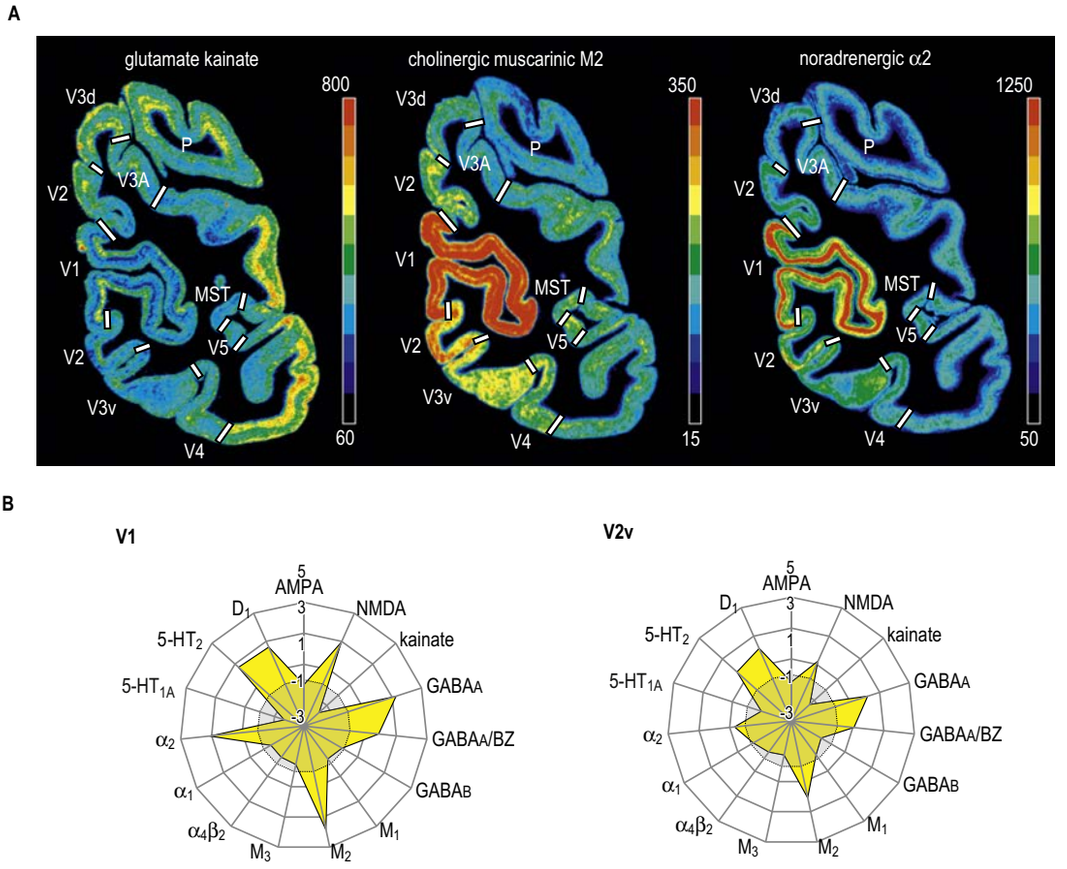

Fig. 32.20 Receptor analysis of the occipital areas. **A**, Distribution of three receptors in a coronal slice of the occipital cortex. **B**, Receptor fingerprints of areas V1 and V2. (Modified from Zilles and Palomero-Gallagher (2017).)

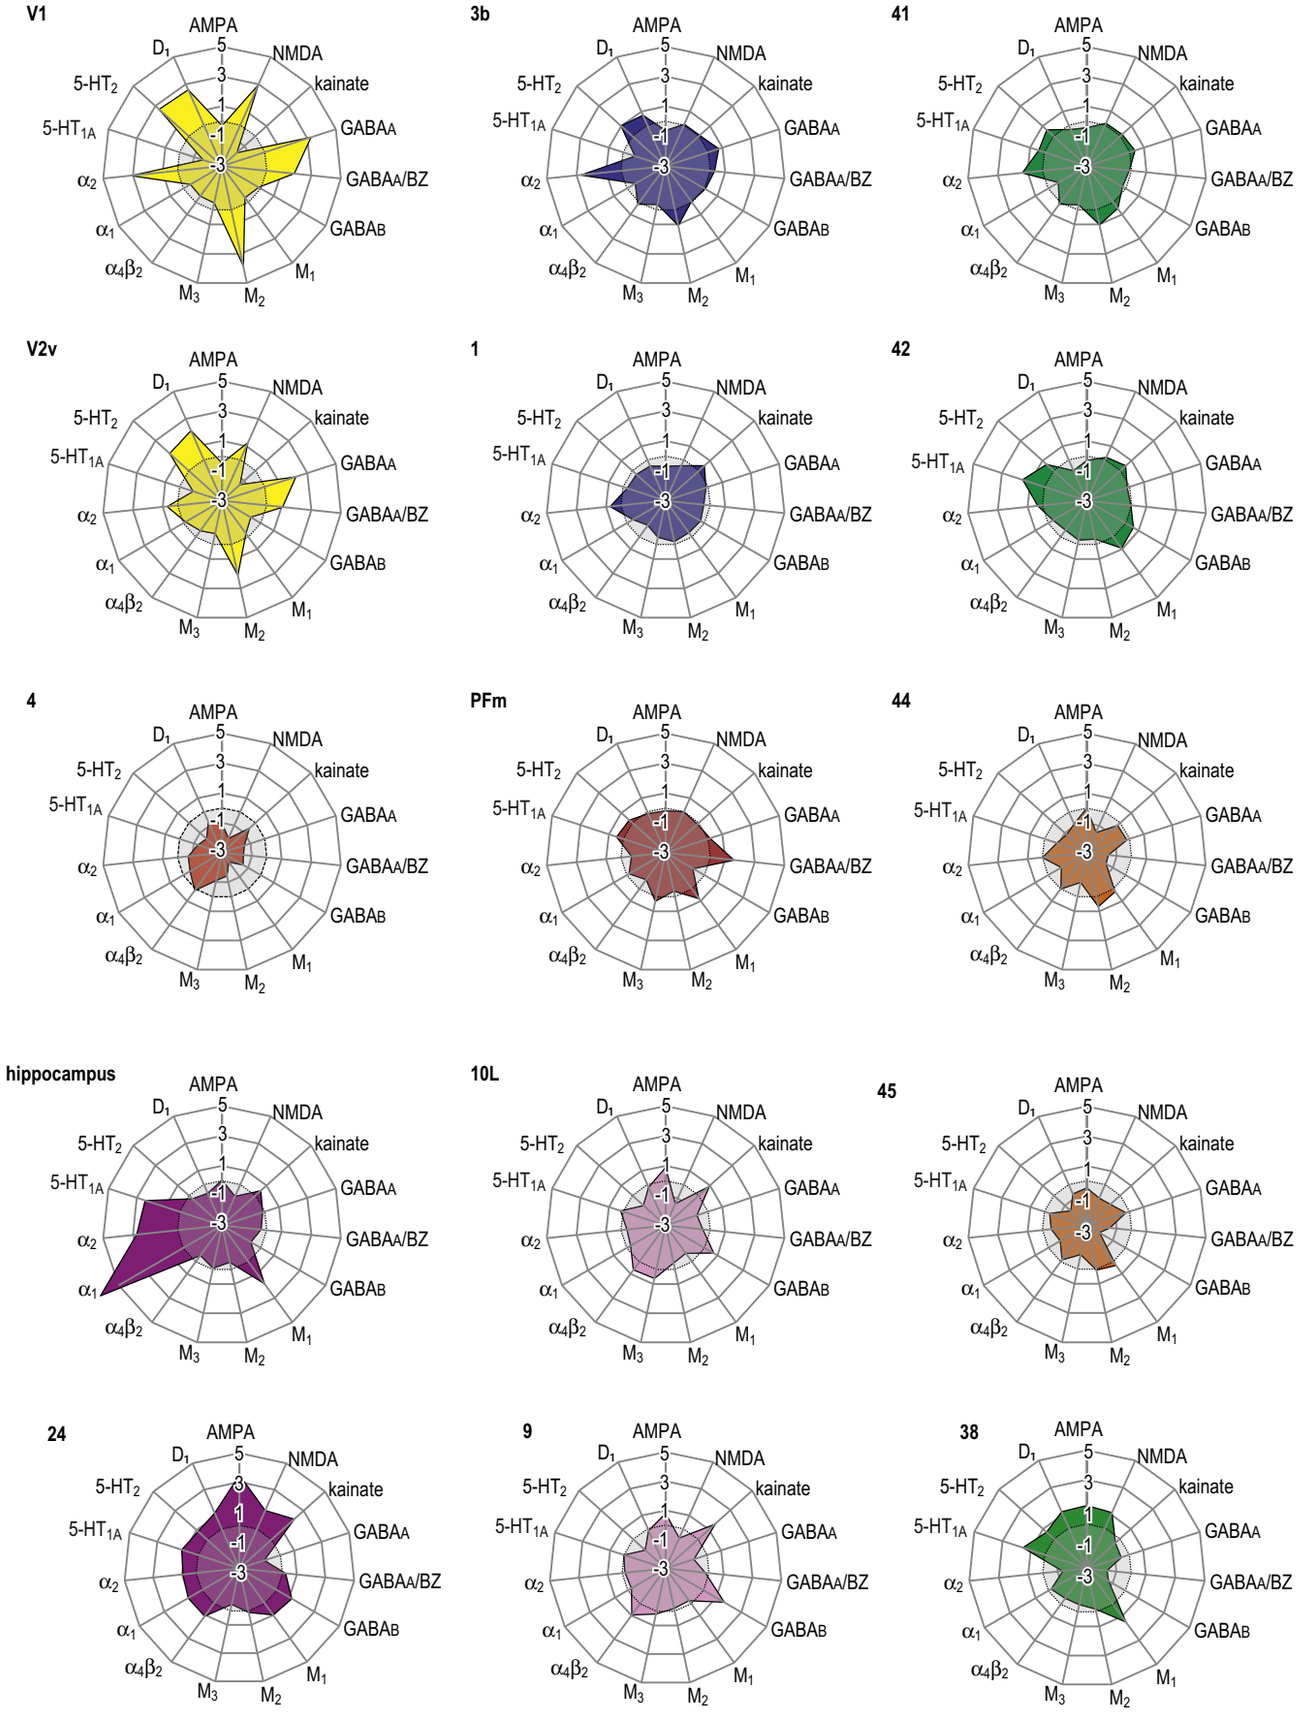

Fig. 32.21 Multi-receptor fingerprints of cortical areas of the human brain. V1, primary visual cortex; V2v, ventral part of the secondary visual cortex; 1, somatosensory system; 3b, BA1 and BA2 areas of the primary somatosensory cortex; 41 and 42, primary and secondary auditory cortex; 4, primary motor cortex; 44 and 45, areas of Broca's region; PFm, inferior parietal area; 10L, frontopolar area; 9, BA9; 24, BA24; 38, BA38. (Courtesy of Karl Zilles, unpublished data.)

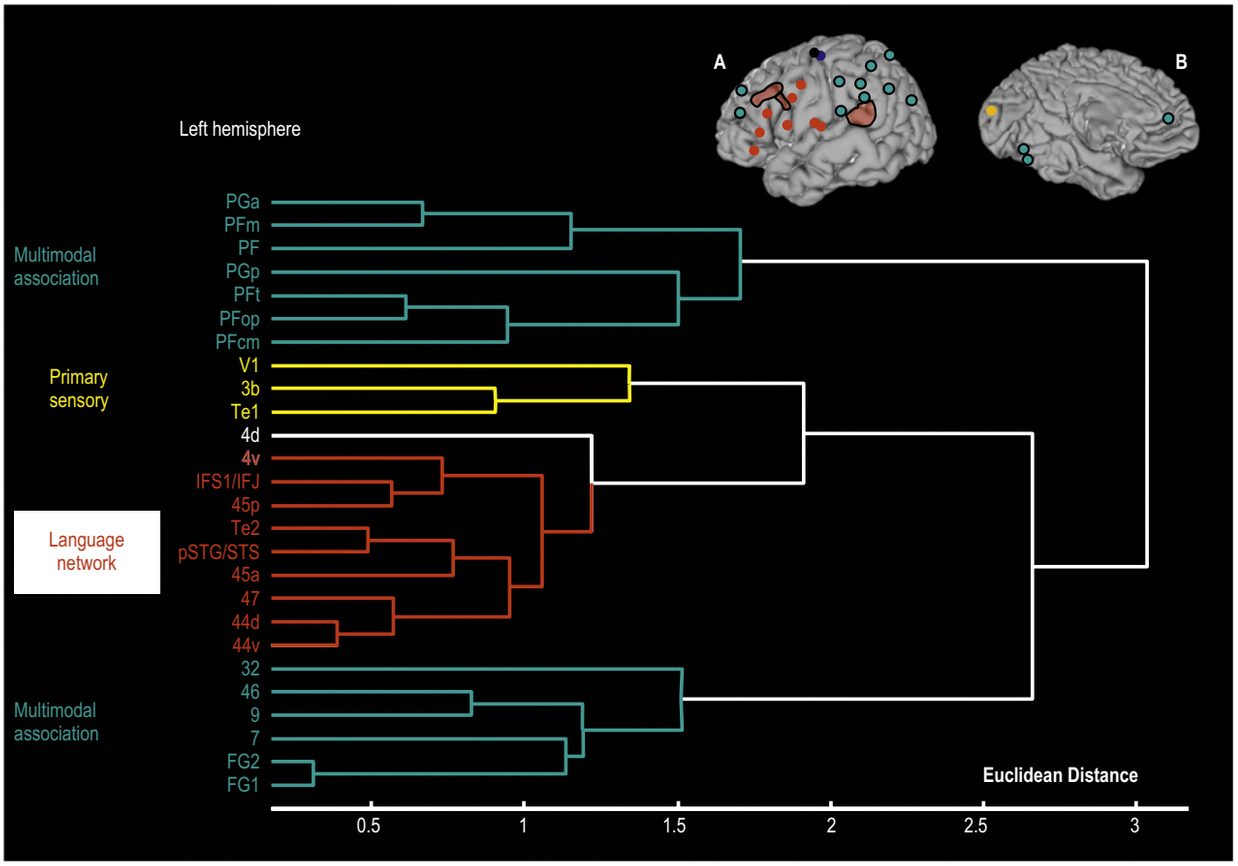

Fig. 32.22 Hierarchical Cluster Analysis of receptor fingerprints in the left (**A**) and right (**B**) hemispheres. (Adapted with permission from Zilles K, Bacha-Trams M, Palomero-Gallagher N et al 2015 Common molecular basis of the sentence comprehension network revealed by neurotransmitter receptor fingerprints. Cortex 63:79–89.)

A single receptor type can characterize the borders of functionally and cytoarchitectonically defined cortical regions. Prominent examples are the M_2 receptor and the delineation of BA17, area 3 and BA41 from surrounding cortical areas, or the identification of mossy fibre terminations on kainate receptors in the hippocampus. However, in many cases only the comparative evaluation of the expression patterns of multiple receptors in the same cortical region provides the criteria for a multimodal parcellation, which cannot be achieved by a single receptor type analysis. These multireceptor expression patterns, the characteristic fingerprints of each cortical area (see **Figs 32.20–32.22**), allow a detailed mapping of the human cerebral cortex and the identification of cortical networks. The analysis of receptor fingerprints reveals cortical regions that belong to the same functional network. For example, analysis of receptor fingerprints in the cingulate cortex has revealed four regions that are differentially involved in emotional processing, mediation of motor and cognitive processes via premotor planning with motivational characteristics, spatial orientation, memory and visuospatial functions (Palomero-Gallagher et al 2009).

The fingerprints of BA44 and BA45 are more similar to each other than they are to those of the ventral premotor cortex or the ventrally adjacent BA47, often interpreted as part of Broca's region. Subsequent analysis of many functionally identified language and non-language regions revealed that the receptor fingerprints of BA44 and BA45 belong to a complex system of language-related areas in the left hemisphere that consists of the subdivisions of BA44 and BA45, BA47, the secondary auditory area BA42, and a region in the posterior part of the superior temporal gyrus and sulcus within Wernick's area (Amunts et al 2010, Zilles et al 2015b; see Fig. 32.22). The fingerprints of the areas in this functional system clearly differ from those of primary sensory cortical areas, multimodal areas of the inferior and superior parietal lobules, higher extrastriate visual areas, BA32 and the primary motor cortex. A separate analysis of the fingerprints of the right and left hemispheres revealed a notable interhemispheric difference that underlines the lateralized language function.

Fingerprint analysis of the different areas of the inferior parietal lobule demonstrated a very close relation between BA39 and the extrastriate area V3v (Caspers et al 2013b), supporting the notion that at least the posterior part of BA39 is a hub in the ventrodorsal visual stream (Pisella et al 2006). Hierarchical cluster analysis of the receptor fingerprints of fusiform areas FG1 and FG2 argues for their position between the ventral visual stream and multimodal association areas of the inferior parietal lobule (Caspers et al 2013a). FG1 and FG2 differ from the early visual areas of the ventral stream: a principal component analysis found that all visual areas were separated from nearly all other cortical areas studied, but FG1 and FG2 were segregated from early visual areas, indicating their close association with multimodal association areas of the inferior parietal lobule (Caspers et al 2013b).

Numerous glutamatergic pathways can be identified in the forebrain (see Fig. 32.7; **Figs 32.23–32.24**). Axons of glutamatergic pyramidal neurones in layers II and III project to cortical neurones of layers IV (short distance cortico-cortical feedforward projections) and V–VI (long distance cortico-cortical feedforward projections), and reciprocally from layers V and VI to layer II and superficial part of layer III (feedback projections): these are cortico-cortical pathways. Axons in layer VI project to the claustrum (cortico-claustral pathway). Axons in layer V excite GABAergic medium-spiny neurones (principal neurones) in the caudate nucleus and putamen via asymmetric synapses on their dendritic spines (cortico-striatal pathway). Axons in layers V and VI are connected via the internal capsule with neurones in the thalamus (cortico-thalamic pathway). Axons of neurones in thalamic nuclei mainly terminate on neurones in layer IV (thalamo-cortical pathway) and can extend to various degrees into layer III. Axons in layer V terminate on dopaminergic and GABAergic neurones in the substantia nigra (SN)/ventral tegmental area (VTA) (cortico-nigral/VTA pathway). Axons in layer V descend via the internal capsule and crus cerebri to multipolar cells of the pontine nuclei (cortico-pontine pathway), which in turn project as mossy fibres to the cerebellar cortex. Axons in layer V terminate via the internal capsule and crus cerebri on multipolar cells of the motor nuclei of the brainstem and tectum (cortico-nuclear and cortico-tectal pathways). Axons in layer V terminate via capsula interna, crus cerebri and pyramidal tract on motoneurones of the anterior horn of the spinal cord (cortico-spinal pathway). Axons in layer III terminate as commissural fibres via the corpus callosum on neurones of homologous or heterologous cortical areas of the contralateral hemisphere (callosal pathway).

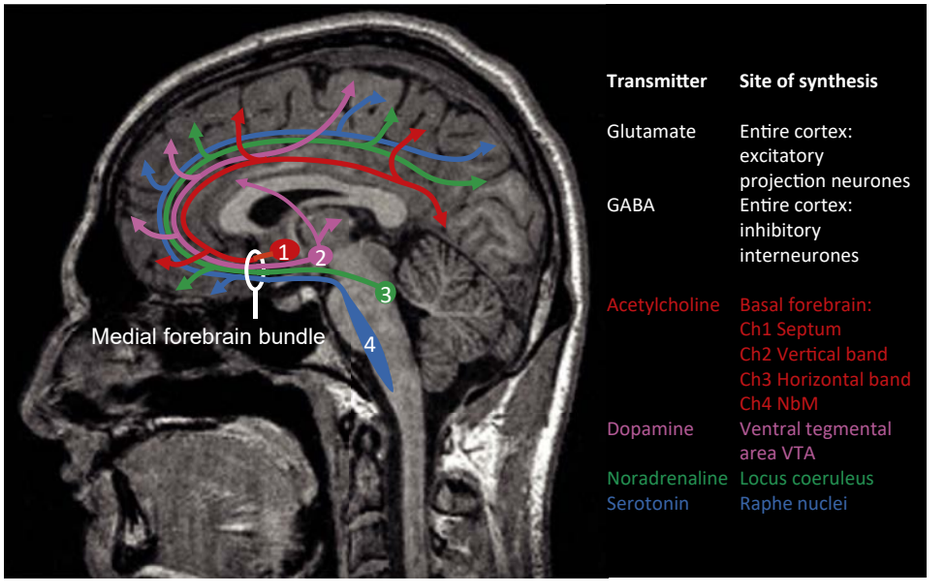

Fig. 32.23 Transmitter systems in the cerebral cortex and sites of transmitter synthesis. Key: 1, basal forebrain; 2, ventral tegmental area; 3, locus coeruleus; 4, raphe nuclei. Abbreviation: NbM, nucleus basalis Meynert.

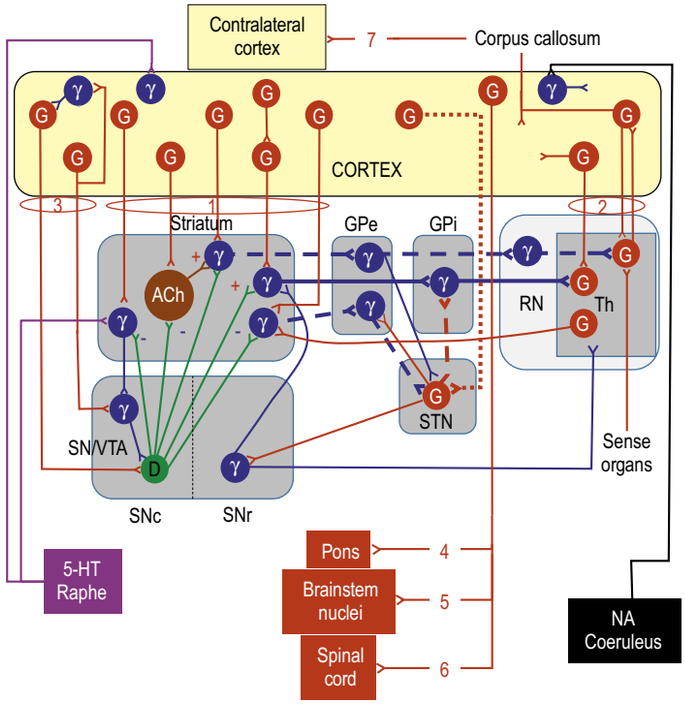

Fig. 32.24 Efferent and afferent pathways of the cerebral cortex and their transmitters. Dashed thick blue lines label the indirect pathway, continuous thick lines label the direct pathway and the pointed line indicates the hyperdirect pathway. Key: 1, cortico-striatal pathway; 2, cortico-thalamic and thalamo-cortical pathways; 3, cortico-nigral pathway; 4, cortico-pontine pathway; 5, cortico-nuclear pathway; 6, cortico-spinal pathway; 7, callosal connections. Afferent fibres from the raphe nuclei (serotonin, 5-HT) and from the locus coeruleus (noradrenaline, NA) run in the medial forebrain bundle. ACh, cholinergic neurones; D, dopaminergic neurones; G, glutamatergic neurones; γ, GABAergic neurones; GPe, lateral (external) part of the globus pallidus; GPi, medial (internal) part of the globus pallidus; NA, noradrenaline (norepinephrine); RN, reticular nucleus; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; SN/VTA, substantia nigra/ventral tegmental area; STN, subthalamic nucleus; Th, thalamus.

GABA is the ubiquitous major inhibitory neurotransmitter in the human cerebral cortex. However, it can also have an excitatory effect under certain conditions. GABA-induced depolarization occurs in the developing cortex, and in mature cortical neurones following dendritic $GABA_A$ receptor activation. All cortical interneurones, with the notable exception of the spiny stellate cells, are GABAergic. Ninety-five per cent of cortical interneurones co-express GABA and calcium-binding proteins (CBPs): parvalbumin (PV), calbindin (CB), and calretinin (CR). Most of these cells are located in layers II–III. In the primary visual cortex of the macaque monkey, the majority of interneurones (97%) express only one of the three CBPs (**Fig. 32.25**): about half of the cells are positive for PV, nearly one-third for CB and the rest are positive for CR. The three interneuronal subtypes also differentially express glutamate receptors (Kooijmans et al 2014). The fast-spiking PV cells show high expression of the GluA2 and GluA3 subunits, whereas the intermediate spiking CB and CR cells show high expression of the GluA1 and GluA4 glutamatergic AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) receptor subunits (Kooijmans 2016). Interneurones can be categorized according to their co-expression of the GluN2 subunits of the glutamatergic NMDA (N-methyl-D-aspartate) receptor. PV-IR cells show a low expression of the receptor, largely confined to their somata, whereas CB and CR expressing cells also express high levels of GluN2 subunits, both on their somata and in their dendrites (Kooijmans 2016).

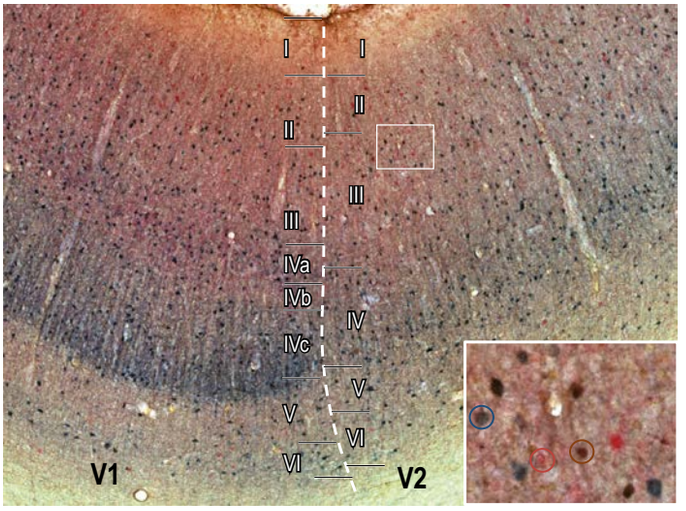

Fig. 32.25 Neurones expressing calcium-binding proteins at the border (dashed line) between human V1 and V2. Parvalbumin in blue, calbindin in magenta and calretinin in brown (see inset). Roman numerals indicate cortical layers. (Courtesy of Dr RN Kooijmans, NIN/KNAW Amsterdam.)

The neuromodulatory transmitters of the cortex are acetylcholine, dopamine, noradrenaline and serotonin. Neurones that synthesize these neuromodulators are all located in subcortical regions and send long projection axons to the cerebral cortex. These transmitters can positively or negatively modulate the excitability of cortical neurones by binding to numerous different receptor subtypes linked to multiple signal transduction mechanisms: they enhance the signal-to-noise ratio of cortical responses and modify the threshold for activity-dependent synaptic modifications.

Acetylcholine is synthesized in large multipolar neurones in various regions of the basal forebrain (Ch1–Ch4) (**Fig. 32.26**). Their axons reach the entire cortex: cholinergic synapses are found on dendritic shafts, apical dendrites, the somata of pyramidal cell dendrites and of non-pyramidal cells. The density and laminar distribution pattern of cholinergic fibres differ significantly between different cytoarchitectonic areas. In the primary visual cortex, cholinergic fibres are particularly dense in layers I–IIIa, followed by layer IIIb, layers IVA and IVB, and alternating patches in layer IVC display a higher density of cholinergic fibres than layers IVB and V. Most but not all cholinergic synapses are symmetric.

Dopamine-containing neurones located in the dorsal parts of the substantia nigra (A9), ventral tegmental area (A10) and the retrorubral area (A8) send axons to the entire cortex (see Fig. 32.23). The whole frontal lobe receives dopaminergic afferents from these three sites (Björklund and Dunnet 2007). Dopamine interneurones (A16) are present in the glomerular layer of the olfactory bulb. The densities and laminar distribution patterns of dopaminergic terminals differ between cortical areas: the primary motor cortex is densely innervated, the primary sensory cortices are sparsely innervated. In the motor cortex, dopaminergic fibres are evenly distributed throughout the different layers, other cortical regions show higher densities in layers I–IIIa and V–VI than in the middle layers. Dopaminergic terminals form symmetric synapses with dendritic shafts and spines, somata and axons. Direct local dopaminergic modulation of the excitability of cortical neurones is thought to be mediated via asymmetric membrane specializations of dopaminergic afferents on dendrites and dendritic spines, i.e. via the postsynaptic targets of both dopaminergic and excitatory input (synaptic triads) (Jacob and Nienborg 2018).

Noradrenaline (norepinephrine) is synthesized in the locus coeruleus (see Fig. 32.23): the efferent projections reach the entire cortex via the medial forebrain bundle. Noradrenaline-containing axons are found in all cortical areas. There are differing regional and laminar densities, for example, in the human primary visual cortex, axon terminals are most dense in layer V, followed by layer VI, and relatively sparse in other layers. Noradrenaline is particularly important for the developmental plasticity of the cortex: it facilitates activity-dependent synaptic modifications in the cortex. Noradrenaline-containing varicosities form either symmetric or asymmetric synapses mainly on spines and dendritic shafts. Axosomatic synapses on pyramidal and non-pyramidal neurones are rare.

Serotonin (5-hydroxytryptamine, 5-HT) innervation of the entire cortex originates from either the dorsal raphe nucleus (see Fig. 32.23), via thin fibres with small varicosities, or the median raphe nucleus, via thick fibres with large spherical varicosities: the efferent projections from both raphe nuclei reach the entire cortex via the medial forebrain bundle. 5-HT axon terminals are present in all cortical areas and layers. 5-HT fibres synapse with pyramidal neurones and GABAergic interneurones, preferentially on spines and dendritic shafts, but also on somata.

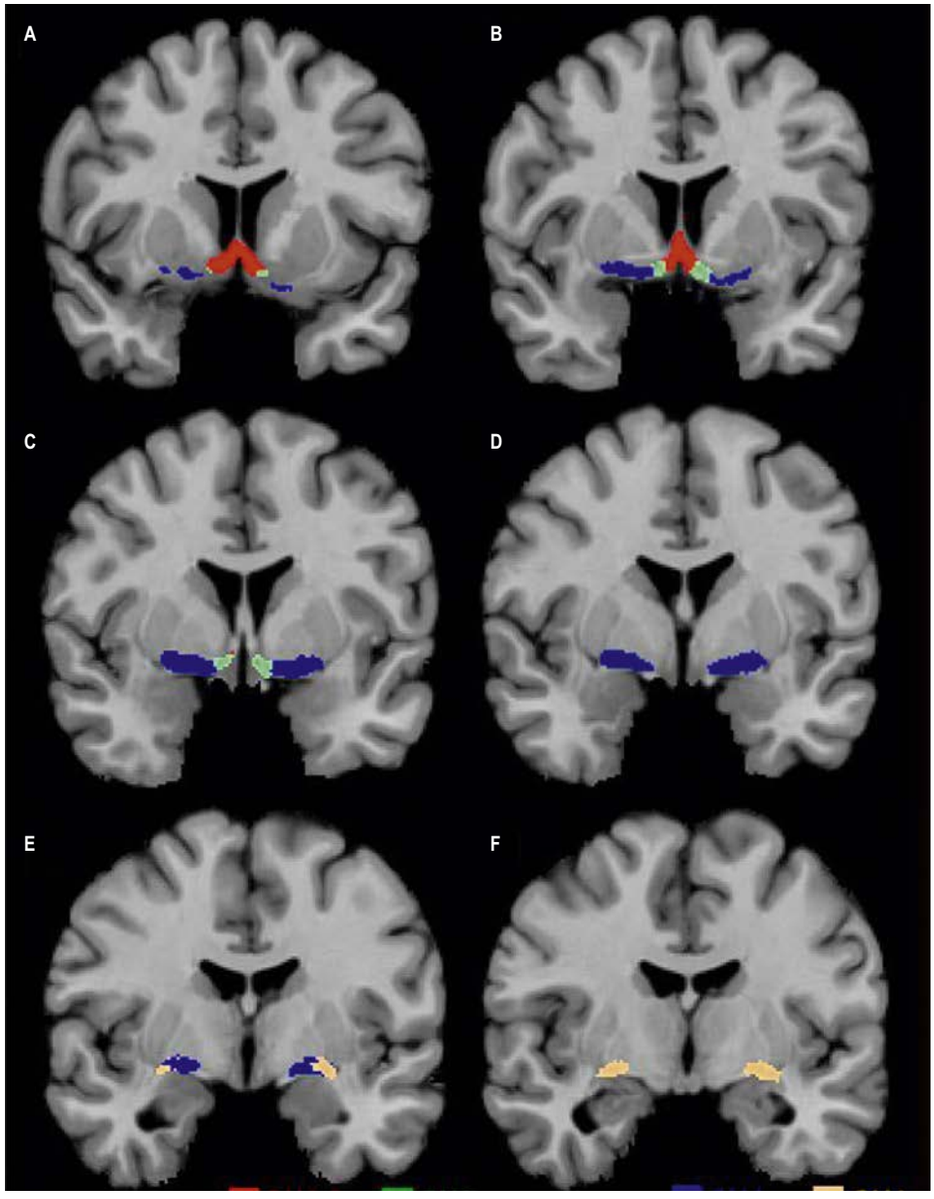

Fig. 32.26 A–F, Magnocellular cholinergic cell groups Ch1 to Ch4 in the basal forebrain and their maximum probability maps in the anatomical MNI space in rostral to caudal coronal planes (A, rostral; F, caudal). In the MPM each voxel is assigned to the cytoarchitectonic compartment that showed the greatest overlap among ten brains. Red, Ch1–2 cell groups (septum + vertical limb of Broca); green, Ch3 (horizontal limb of Broca); blue, Ch4 (Ncl. basalis Meynert); beige, Ch4p.

Neuropeptides are small proteins or polypeptides that are synthesized by neurones and serve as modulatory neurotransmitters. They act in or out of the central nervous system via G protein and second messenger systems, and increase or decrease the functional impact of co-released neurotransmitters in the brain. More than 100 different neuropeptides have been identified, and only a selection of the most abundant types can be described here. Vasoactive intestinal polypeptide (VIP), neuropeptide Y (NPY), somatostatin (SOM), substance P (SP) and cholecystokinin (CCK) are among the frequently occurring neuropeptides in the human cerebral cortex. Many of the neuropeptide-containing neurones are interneurones. VIP is synthesized in bipolar interneurones and plays an important role in the local regulation of metabolism in the cerebral cortex by stimulating glycogenolysis and altering cortical blood flow. VIP inhibitory cells receive long range projections and inhibit SOM inhibitory interneurones. Dendrites of VIP cells most extensively branch in layers I and deep IV to superficial V. The density of their axons is highest in layers II–IV. NPY can be co-released with GABA and glutamate, reduces pain perception and voluntary alcohol intake, and controls epileptic seizures. Impairment of NPY functions also seems to play a role in obesity, anxiety, and neurodegenerative disorders. All SOM-expressing neurones of the cortex are a subset of GABAergic inhibitory interneurones (Martinotti cells, bitufted interneurones and basket cells). Basket cells are particularly abundant in the frontal or entorhinal cortices. SOM, NPY, SP and calbindin are often co-expressed in the same cell. The somata of such neurones occur mainly in the infragranular layers, or in the subcortical white matter. The activity of SOM cells is regulated by changes in brain state, during learning and reward: they undergo long-lasting structural and functional changes during experience-dependent plasticity of the cortical network. SOM cells play a role in schizophrenia and epilepsy. Only a few pyramidal cells of the isocortex contain SP, which is often co-localized with serotonin or noradrenaline. CCK can be co-localized with glutamatergic, GABAergic, dopaminergic and serotoninergic neurones that project to the cortex: it plays a role in regulating satiety and appetite, thermoregulation, sexual behaviour and memory. The cell bodies of CCK-containing neurones are frequently observed in the supragranular layers. Cell bodies of SP- and SOM-containing neurones prevail in the temporal lobe, those of CCK- and NPY-containing neurones in the frontal lobe. Axons containing NPY, SOM and SP are present in all cortical layers, particularly as horizontally orientated fibres in layer I, and randomly orientated fibres in the supra- and infragranular layers, but they are sparse in the inner granular layer IV.

Transmitter receptors are key molecules of signal processing in the nervous system. The functional receptors are homomeric or heteromeric proteins in the cell membrane of neurones or glial cells (Table 32.5). The effects of transmitters are defined by the receptors to which they bind after release from the presynaptic neurone. One transmitter can bind to multiple receptor types. This non-covalent binding leads to local changes of the membrane potential that may be fast (via ionotropic receptors, which are ligand-controlled ion channels) or slow (via metabotropic receptors, coupled to G-proteins that control the activation of second messengers). These changes are either excitatory or inhibitory depending on the actual receptor type. Receptors are located postsynaptically or presynaptically as heteroreceptors, i.e. receptors that regulate the synthesis and/or the release of transmitters other than their own transmitter, or as autoreceptors, i.e. receptors located on the terminal of a presynaptic cell. Autoreceptors are usually G protein-coupled receptors and only respond to the same transmitter released by the presynaptic neurone: they are located in the dendrites, soma, axon, or axon terminals, and act as part of a negative feedback loop in signal transduction.

The heterogeneous regional and laminar expression patterns of each receptor type indicate a parcellation of the cerebral cortex on a molecular basis. The regional segregation of transmitter receptors (Fig. 32.27) can be demonstrated *in vivo* by positron emission tomography (PET) or single photon emission tomography (SPECT). Both methods are clinically important, but their spatial resolution does not enable an analysis of the laminar or cellular localization of receptors. *In vitro* demonstration of receptors at high spatial resolution and receptor type specificity is possible with immunohistochemistry, in situ hybridization or quantitative receptor autoradiography (see Fig. 32.27).

TABLE 32.5 Receptor subtypes of the cerebral cortex and their subunit composition, genes, ion effects and function

Transmitter and receptor type	Subunits	Genes	Ion	Function
Glutamate				
Subtypes				
Ionotropic AMPA receptor	GluA1-GluA4	*GRIA1-GRIA4*	Ca^{2+}	Fast excitation
Ionotropic NMDA receptor	GluN1	*GRIN1*	Na^{+} and Ca^{2+}	Slow excitation
	GluN2A-D	*GRIN2A-D*		-
	GluN3A-B	*GRIN3A-B*	K^{+} (out)	
Ionotropic kainate receptor	GluR5-GluR7	*GRIK1-GRIK3*	Na^{+} and Ca^{2+}	Excitation (postsynaptic)
	KA1, KA2	*GRIK4-GRIK5*	K^{+} (out)	Inhibition (presynaptic)
Metabotropic GluR2/3 receptor		*GRM2, GRM3*	K^{+} activation	Inhibit release of glutamate, GABA
G-protein-coupled receptor			Ca^{2+} inactivation	Noradrenaline, dopamine; pre-, post-, and extrasynaptic inhibition via cAMP inhibition
GABA				
Subtypes				
Ionotropic $GABA_A$ receptor	α_1–α_6, β_1–β_3	*GABRA1-6*	Cl^{-} (in)	Fast inhibition
	γ_1–γ_3, δ, ε, π,	*GABPB1–3*		$\alpha + \gamma$ provide benzodiazepine binding sites
	θ	*GABRC1-3*		
Metabotropic $GABA_B$		*GABBR1-2*	K^{+}	Slow inhibition G-protein-coupled receptor pre-, post-, and extrasynaptic
Acetylcholinesterase				
Subtypes				
Ionotropic nicotinic $\alpha_4\beta_2$ receptor				Post- and presynaptic excitation
Metabotropic muscarinic M_1 receptor				Excitation
Metabotropic muscarinic M_2 receptor				Inhibition
Metabotropic muscarinic M_3 receptor				?
Dopamine				
Subtypes				
Metabotropic D_1 receptor				Excitation
Metabotropic D_2 receptor				Inhibition
Noradrenaline (Norepinephrine)				
Subtypes				
Metabotropic α_1 receptor				Excitation
Metabotropic α_2 receptor				Inhibition
Serotonin (5-hydroxytryptamine)				
Subtypes				
Metabotropic 5-HT_{1A} receptor				Inhibition
Metabotropic 5-HT_{2A} receptor				Excitation/Inhibition

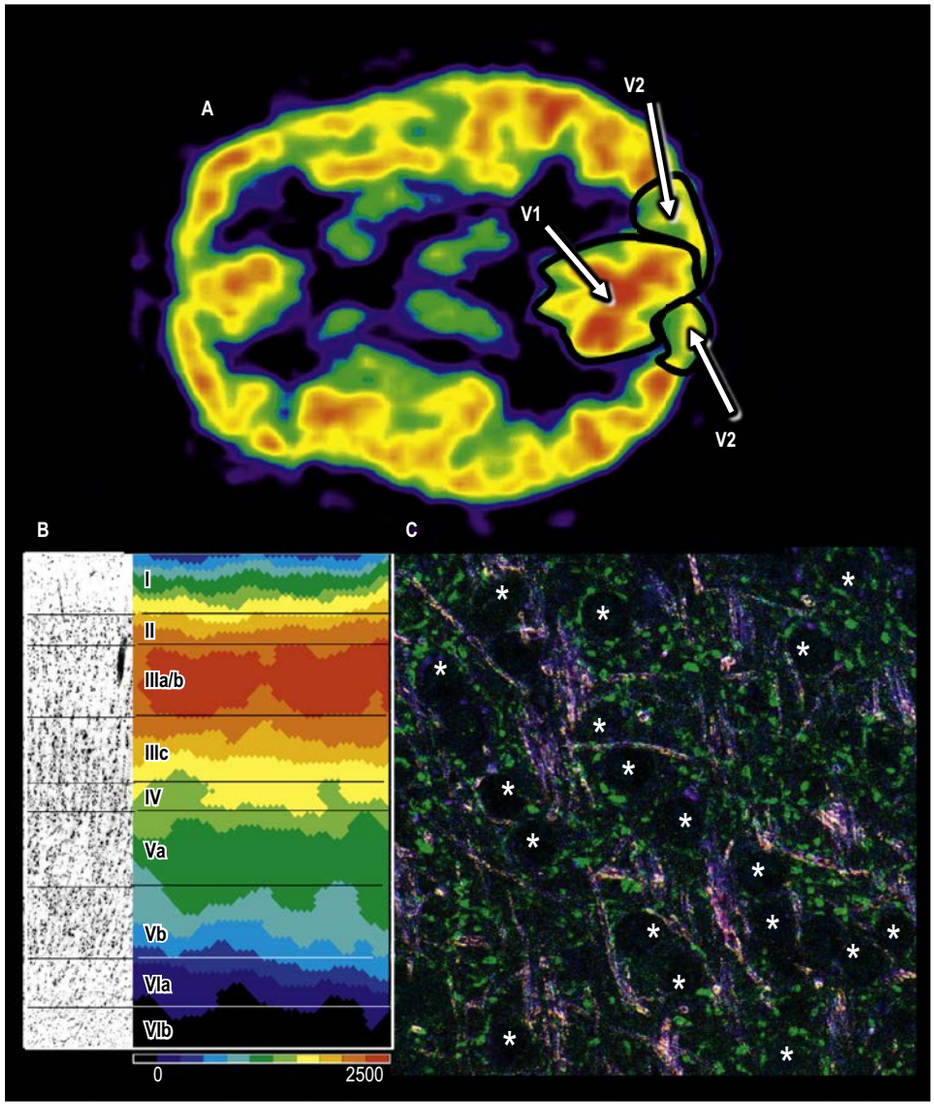

Fig. 32.27 A, Visualization of the regional distribution of serotonin 5-HT_2 receptors with PET in a horizontal section through the human brain. **B**, Laminar distribution of the density (colour scale in fmol/mg protein) inhibitory $GABA_A$ receptor in the human superior parietal cortex (area 7a) visualized with quantitative *in vitro* receptor autoradiography. **C**, Cellular (macaque cortex, immunohistochemistry) distributions of transmitter receptors in the cerebral cortex. Green, vesicular glutamate transporter (VGluT2, thalamo-cortical glutamatergic boutons); red, NMDA glutamate receptor subunit (GluN2A); blue, NLGN 1 (neuroligin 1, postsynaptic partner of transsynaptic scaffolding complex). Asterisks = cell bodies. (Courtesy of Dr RN Kooijmans, NIN/KNAW Amsterdam.)

Glutamate receptors are either ionotropic receptors (AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid; NMDA, N-methyl-D-aspartate; and kainate receptors), which control ion channels, or metabotropic receptors which act through second messenger systems. All glutamate receptor types are expressed by neurones and astrocytes. Activated AMPA and kainate receptors lead to fast excitatory synaptic signal transmission.

The highest densities of the ionotropic glutamate AMPA receptor (Figs 32.28–32.29) are found in the orbitofrontal (BA11) and lateral prefrontal (BA8–10, 46, 47), temporal (BA20, 21, 36, 38), early and higher visual (V3A, FG1, FG2) and part of the insular cortical areas. Lowest densities are found in the motor (BA4, 6), somatosensory (BA1, area 3b), parietal (BA5, PGa, PGp), early visual (V2, V4v), and anterior and posterior cingulate (BA23, 31, 32) cortices. Preferential cellular localizations are the dendritic spines of pyramidal cells in the supragranular layers.

The ionotropic glutamate NMDA receptor (Figs 32.28–32.29) is a heterotetrameric protein complex consisting of subunits NR1–NR3. It has a cation channel that enables sodium and calcium ions to move from extracellular space into a neurone after binding of glutamate and glycine. The current through the channel is voltage-dependent, since magnesium ions block the channel for the influx of sodium and calcium

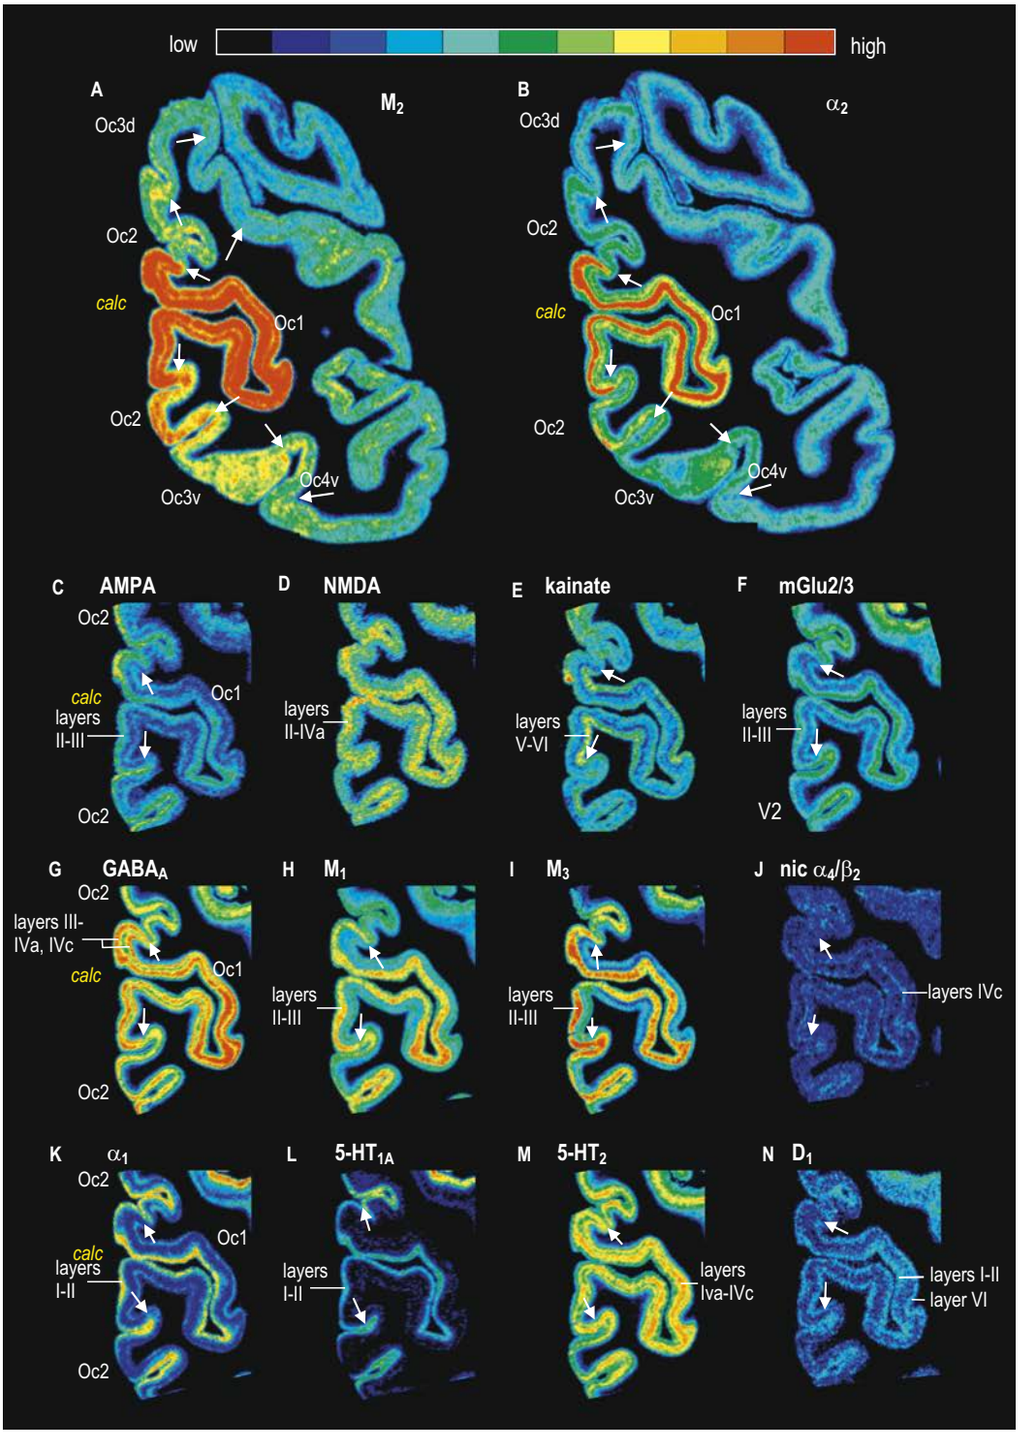

Fig. 32.28 A–B, Regional and laminar distribution of acetylcholine muscarinic M_2 (**A**), and adrenergic α_2 (**B**) receptors in coronal section through the occipital lobe of a human brain. M_2 and α_2 receptors delineate the primary visual area Oc1 by their distinctly higher densities compared to the secondary visual area Oc2 (BA18, V2). The borders of the early visual areas Oc3v (V3v), Oc4v (V4v) and Oc3d (V3d) are also visible by differences in their higher or lower regional and laminar receptor densities (arrows). **C–N**, The layer-specific localization of low or high densities of glutamate (**C**, glutamate AMPA; **D**, glutamate NMDA; **E**, glutamate kainate; **F**, glutamate mGluR 2/3; **G**, $GABA_A$; **H**, acetylcholine muscarinic M_1; **I**, acetylcholine muscarinic M_3; **J**, acetylcholine nicotinic $\alpha_4\beta_2$; **K**, noradrenaline α_1; **L**, serotonin 5-HT_{1A}; **M**, serotonin 5-HT_2; **N**, dopamine D1). Arrows indicate the border between Oc1 (BA17, V1) and Oc2 (BA18, V2). Colour scale indicates relative density of each receptor.

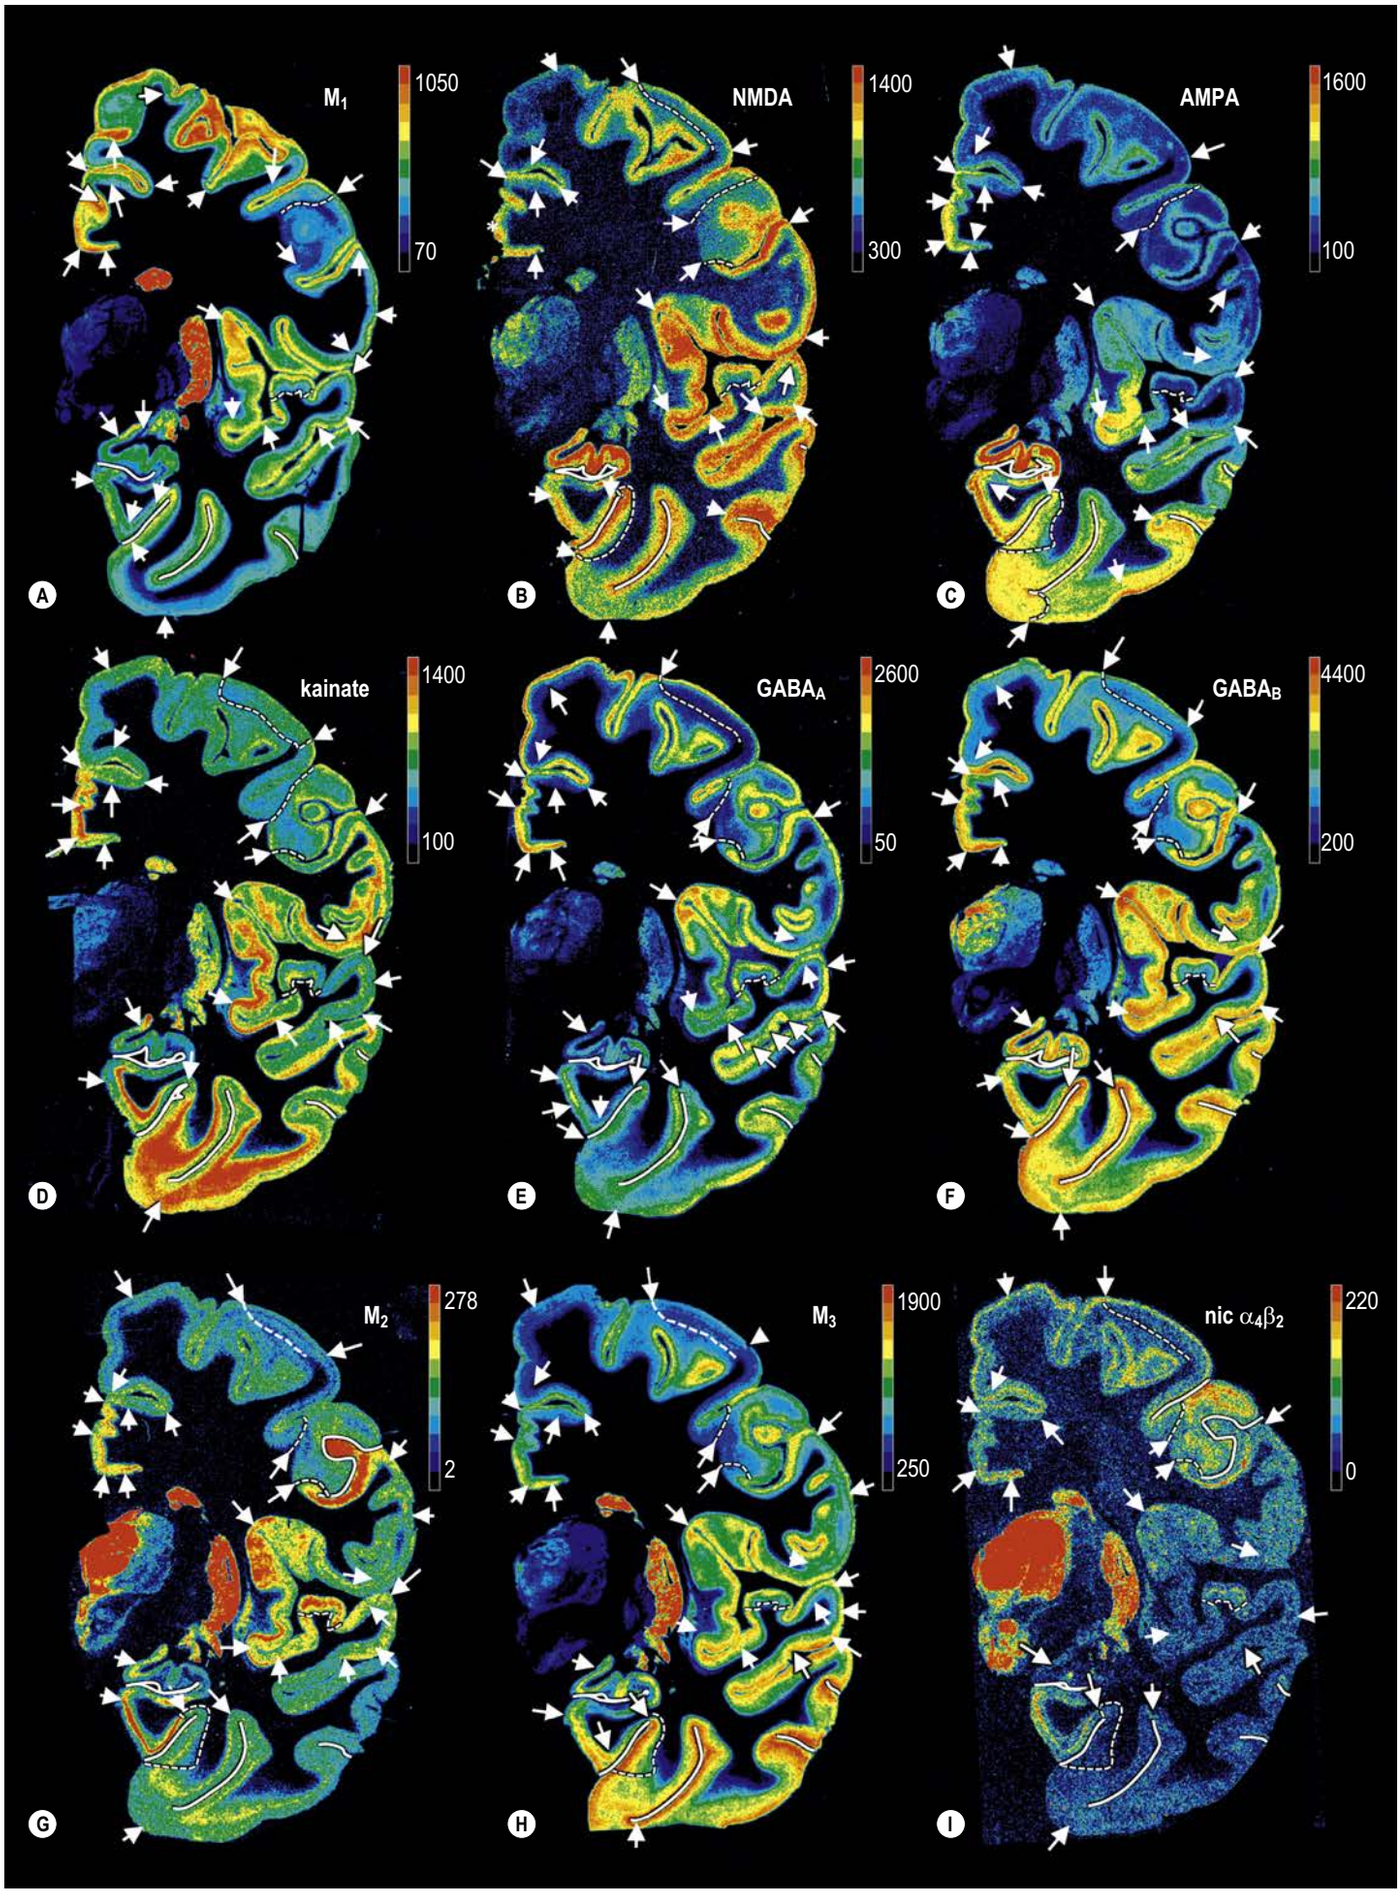

Fig. 32.29 A–R, Regional and laminar distribution of various neurotransmitter receptors of the human brain visualized with colour-coded quantitative receptor autoradiography. Each image, obtained from nine contiguous coronal slices at the level of the central sulcus, shows the distribution of the following receptors: **A**, Acetylcholine muscarinic M_1 receptor; **B**, glutamate NMDA receptor; **C**, glutamate AMPA receptor; **D**, glutamate kainate receptor; **E**, $GABA_A$ receptor; **F**, $GABA_B$ receptor; **G**, acetylcholine muscarinic M_2 receptor; **H**, acetylcholine muscarinic M3 receptor; **I**, acetylcholine nicotinic $\alpha_4\beta_2$ receptor;

Arrows label boundaries of cortical areas. Colour scales indicate densities of receptors in fmol/mg protein.

ions at resting membrane potential, i.e. the cell must be depolarized to remove magnesium ions from the channel before the influx of sodium and calcium ions can occur. Calcium ions are important for synaptic plasticity (long-term potentiation, LTP), a cellular mechanism for learning and memory. Since the effects of those synapses are potentiated, because the postsynaptic part is already depolarized by another channel, i.e. by AMPA receptors, the NMDA receptor is the molecular basis of Hebb synapses. Whereas LTP is caused by synaptic NMDA receptors, long-term depression (LTD) seems to be linked to extrasynaptic NMDA receptors. Excessive influx of calcium ions mainly via extrasynaptic NMDA receptors leads to excitotoxicity, found in Alzheimer's, Parkinson's and Huntington's diseases, amyotrophic lateral sclerosis (ALS), stroke and epilepsy. Blocking of NMDA receptors by antagonists (e.g. memantine) is thought to be potentially helpful in the therapy of Alzheimer's disease. Most NMDA receptors are preferentially expressed by pyramidal neurones and are localized postsynaptically on dendrites and dendritic spines in the supragranular layers II–III of the isocortex: their distribution is much sparser in layer IV. The glutamatergic thalamo-cortical input, which largely terminates in layer IV, is largely mediated by non-NMDA receptors. Relatively few NMDA receptors are presynaptic auto- and heteroreceptors. The highest NMDA receptor densities are found in parts of the insular, temporal (BA21, 36, 38), occipito-temporal (BA37), visual (V1, V2, V3v, V3A, V3d, FG1, FG2) and anterior cingulate (BA24, 32) cortices and the lowest densities are found in the motor (BA4, 6), part of the lateral prefrontal (BA9, 10, 46, 47), Broca's (BA44, 45), parietal (BA5, PFt) and posterior cingulate (BA23) cortices.

The ionotropic kainate receptors (see Figs 32.28–32.29) are preferentially found in the anterior cingulate (BA24, 32), orbitofrontal (BA11), lateral prefrontal (BA8–10), somatosensory (BA2) and temporal (BA42, 20–22, 36) regions, and the lowest densities are found in the motor (BA4, 6), part of Broca's region (BA45), superior parietal (BA5), occipito-temporal (BA37) and visual (V1, V2, V3A, Vd, V4v, FG1, FG) cortices. In the isocortex, kainate receptors are found with highest densities in the infragranular layers.

The metabotropic mGluR2/3 receptor (see Figs 32.28–32.29) reaches higher densities than any of the ionotropic glutamate receptors. The highest densities occur in the inferior temporal, anterior cingulate and entorhinal cortices. The vast majority of mGluR2/3 receptors occur as presynaptic autoreceptors in axonal terminals. The metabotropic mGluR1 receptor occurs only at very low concentrations in the cerebral cortex. The metabotropic mGluR5 receptor reaches highest densities in the cingulate and insular cortices.

GABA receptors are either ionotropic or metabotropic. The highest densities of the inhibitory ionotropic $GABA_A$ receptor (see Figs 32.28–32.29) occur on somata and initial axonal segments in the supragranular layers of the primary and early visual cortex (V1, V2, V3v, V4v, V3d, V3A) followed by the primary somatosensory (area 3b), inferior parietal (PFm, PGp, PGp), posterior cingulate (BA31) and primary auditory (BA41) cortices. The lowest densities occur in the motor (BA4, 6), lateral prefrontal (BA8–10), anterior cingulate (BA24, 32), inferior parietal (PFt) and ectorhinal (BA36) areas, as well as part of Broca's region (BA44).

The metabotropic $GABA_B$ receptor (see Figs 32.28–32.29) reaches generally higher densities than the $GABA_A$ receptor in the cerebral cortex. The highest densities are found in the orbitofrontal (BA11), lateral prefrontal (BA8–10, 47), primary somatosensory (BA2), superior parietal (BA5), anterior cingulate (BA24, 32), ectorhinal (BA36), insular and temporal (BA20, 21, 42) regions, and the lowest densities in the motor (BA4, 6) cortex, Broca's region (BA44, 45), inferior parietal (PFm, PGa), temporo-polar (BA38), early visual (V2, V3d, V3A, V4v) and posterior cingulate (BA23) regions.

Acetylcholine receptors are either ionotropic or metabotropic. The metabotropic muscarinic receptors (mAChRs) occur at considerably higher densities than the ionotropic nicotinic receptors (nAChRs). Five subtypes of mAChRs have been identified (M_1–M_5). The excitatory M_1, M_3 and M_5 receptors are coupled to Gq proteins which activate phospholipase C leading to influx of calcium ions and activation of intracellular signalling cascades. The inhibitory M_2 and M_4 receptors are coupled to $G_{i/o}$ proteins that inhibit the enzyme adenylyl cyclase and so reduce the production of cAMP.

The metabotropic excitatory M_1 receptor has seven transmembrane domains and suppresses potassium ion channels through G_q protein coupling. The receptor mediates slow excitation. It reaches generally higher densities than the M_2, but lower densities than the M_3 receptor (see Figs 32.28–32.29). The M_1 receptor plays a major role in learning and attention and the pathogenesis of amyloid plaques in Alzheimer's disease: high receptor densities favour the non-amyloidogenic pathway in the metabolism of the amyloid precursor protein, whereas low expression of this receptor seems to favour the amyloidogenic pathway. Highest densities of M_1 receptors are found in the lateral prefrontal (BA46, 47), occipito-temporal (BA37), primary and secondary auditory (BA41, 42), temporal (BA21, 22), temporo-polar (BA38), ectorhinal (BA36), inferior parietal (PFm, PFt) and cingulate (BA24, 31) regions: nearly all of these regions are found in the default mode network. Motor (BA4, 6), lateral prefrontal (BA10), orbitofrontal (BA11), somatosensory (area 3a), early and higher visual (V2, V3A, V3d, V3v, FG1, FG2) and superior parietal (BA5) regions have the lowest densities.

The inhibitory M_2 and M_4 receptors have seven transmembrane domains, which act via $G_{i/o}$ proteins that lead finally to opening of potassium ion and closing of calcium ion channels. The M_2 receptor (see Figs 32.28–32.29) is located pre- and postsynaptically. Highest densities are found in layers III and IV of the primary sensory cortices, i.e. area 3b as part of the primary somatosensory cortex, BA41 (primary auditory cortex) and BA17 (primary visual cortex), where it improves the signal-to-noise ratio. Early visual areas (V2, V3v, V4v, V3d), Broca's region (BA44, 45), lateral prefrontal (BA46), inferior parietal (PGa, PGp) and anterior cingulate (BA24, 32) areas also show high receptor densities, whereas the primary sensory areas of the isocortex, the motor cortex (BA4, 6), orbitofrontal (BA11), somatosensory (BA2), parietal (BA5, PFt), temporal (BA20–22), ectorhinal (BA36), occipito-temporal (BA37) and hippocampal areas show a distinctly lower M_2 receptor density.

The cholinergic excitatory metabotropic M_3 receptor also has seven transmembrane domains and acts via G_q proteins. They upregulate phospholipase C and, therefore, inositol trisphosphate and intracellular calcium as a signalling pathway. Highest densities of this receptor (see Figs 32.28–32.29) are found in the supragranular layers of superior and inferior parietal (BA5, PGa, PGp, P, Pft), medial temporal (BA21), occipito-temporal (BA37), posterior cingulate (BA31), fronto-polar (BA10), lateral prefrontal (BA9, 46) and orbitofrontal (BA11) regions and lowest densities are seen in Broca's region (BA44, 45), motor (BA4, 6), somatosensory (area 3a, BA1), temporo-polar (BA38), anterior cingulate (BA32) and visual (V2, V3A, V3d, V3v, V4v) cortices.

The neuronal nicotinic acetylcholine receptors consist of five subunits, of which each has four tansmembrane domains. The subunits are symmetrically arranged around the cation channel. Cations cause a

depolarization: calcium ions act on different intracellular signal cascades that can lead to the gene regulation or release of transmitters. The nicotinic receptors are either homomeric or heteromeric (at least one α and one β subunit) combinations of 12 different subunits (α2–α10 and β2–β4). The excitatory nicotinic $\alpha_4\beta_2$ acetylcholine receptor (see Figs 32.28–32.29) reaches highest densities in the layer IV of the primary visual (V1), auditory (BA41) and somatosensory (areas 3a and 3b) cortices and layer III of the primary motor cortex (BA4). Relatively high densities are also found in the supragranular layers of the frontopolar (BA10), orbitofrontal (BA11), lateral prefrontal (BA8, 9, 46, 47), cingulate (BA24, 23, 32), higher visual (FG1) and entorhinal (BA28) cortices. Lowest densities occur in the premotor (BA6), somatosensory (BA1, 2), inferior parietal (PFm, PFt), temporal (BA20–22), occipitotemporal (BA37), early visual (V2, V3d) and ectorhinal (BA36) areas.

Noradrenaline (norepinephrine) improves the signal-to-noise ratio in the processing of sensory stimuli and enhances consolidation of long-term memory. It is also important for regulating the working memory and attention functions of the prefrontal cortex. Moderate levels of noradrenaline enhance prefrontal cortical functions via postsynaptic α_2 adrenoceptors under normal conditions; high levels of noradrenaline during stress impair prefrontal cortical functions via α_1 receptors.

The excitatory metabotropic α_1 adrenoceptor (see Figs 32.28–32.29) is coupled to the G_q protein, which causes an increase of intracellular calcium ions (via second messenger pathways), followed by a slow depolarization. Highest α_1 receptor densities are found in the supragranular layers of the cingulate (BA24, 31, 32), premotor (BA6), orbitofrontal (BA11), lateral prefrontal (BA8), somatosensory (BA2), inferior parietal (PFm), temporal (BA20–22), secondary visual (V2) and ectorhinal (BA 36) areas, whereas lowest values are found in the Broca region (BA44, 45) and the primary motor (BA4), somatosensory (area 3b, BA1), auditory (A41)and visual (V1) cortices. Low densities are also seen in posterior cingulate (BA23), inferior parietal (PFt) and early as well as higher visual areas (V3d, V3A, V4v, FG1, FG2).

Inhibitory metabotropic α_2 adrenoceptors (see Figs 32.28–32.29) is coupled to the G_i protein. This causes a low cAMP level. The α_2 adrenoceptors are generally rarer than the α_1 adrenoceptors in the cerebral cortex. The α_2 adrenoceptors are found post- and presynaptically with highest densities in the supraganular layers. The presynaptic α_2 subtype occur as autoreceptors on noradrenaline-containing neurones and terminals and cause negative feedback on noradrenaline release, while both α subtypes are found post-synaptically. Like the cholinergic muscarinic M_2 receptor, by far the highest densities of the α_2 receptors are found in the primary sensory areas (V1, area 3a, 3b, 1, 2, BA41). This is in sharp contrast to the low densities of the expression of the α_1 receptor in these regions. High densities are also present in lateral prefrontal (BA8), anterior cingulate (BA24, 32), and early visual areas (V2, V3d, V3A, V3v). Lowest densities are found in the motor (BA4, 6), superior (BA5) and inferior (PFm, PFt, PGa) parietal, temporo-polar (BA38), occipito-temporal (BA37), higher visual (FG1, FG2), and posterior cingulate (BA23, 31) areas.

The excitatory metabotropic β_1 and β_2 adrenoceptors occur at lower densities than the α subtypes in the isocortex. They are coupled to a G protein, which causes high cAMP levels. Highest β adrenoceptor densities are found in the motor and layers III and IV of the temporal cortex, whereas lowest concentrations are located in the occipital pole.

Serotonin (5-hydroxytryptamine, 5-HT) modulates the excitability of cortical neurones by binding to 14 different receptor subtypes, mainly the 5-HT_{1A}, 5-HT_{1B} and 5-HT_2 subtypes. Serotonin influences sleep and arousal processes, executive functions of the prefrontal cortex, affective behaviour, aggression, learning and memory, and modulation of pain. 5-HT receptors are localized on GABAergic interneurones or projection neurones, and on axon terminals, dendrites and the somata of glutamatergic neurones as well as on cells that modulate noradrenergic, dopaminergic and cholinergic neurones.

The inhibitory metabotropic 5-HT_{1A} receptor (see Figs 32.28–32.29) binds to G_i proteins and thus inhibits adenylate cyclase, opens potassium channels, closes calcium channels and inhibits phosphatidylinositol (PI) turnover. This receptor is a somatodendritic autoreceptor on serotoninergic neurones of the raphe nuclei throughout the brainstem and modulates the pacemaker role of these neurones in a negative feedback loop. 5-HT_{1A} receptors are predominantly found in layers I to upper III of the isocortex, localized mainly in somata and dendrites of pyramidal cells in the most superficial layers, and at a much lower level on the initial axonal segment of layer V and VI pyramidal cells. The highest densities of these receptors are seen in the most posterior part of lateral prefrontal (BA46, 47), orbitofrontal (BA11), somatosensory (BA2), inferior parietal (PFt), secondary auditory (BA42, auditory belt), temporal (BA20–22), temporo-polar (BA38), occipito-temporal (BA37), anterior cingulate (BA24), ecto- (BA36) and entorhinal (BA28) cortices. The lowest densities are found in motor (BA4, 6), primary somatosensory (area 3b) and visual (V1) regions, as well as the BA44 in the Broca region, PGa in the inferior parietal, early and higher visual (V2, V3d, V3A, V3v, FG1, FG2), and posterior cingulate (BA 23) areas.

The inhibitory metabotropic 5-HT_{1B} receptor is almost always postsynaptically localized. It is found at high density in the primary visual cortex.

The excitatory metabotropic 5-HT_2 receptors are coupled to Gq proteins; their activiation ultimately leads to an increase in the concentration of intracellular calcium ions and PI hydrolysis. The highest densities of the 5-HT_2 receptor (see Figs 32.28–32.29) are found in layers III and IV of primary sensory areas (area 3b, BA2, BA17, BA41), posterior parietal (BA5, PGa), secondary auditory (BA42), early visual (V2, V3v), middle temporal (BA21), temporo-polar (BA38), early visual (V3v), and anterior and posterior cingulate (BA24, 23, 31) regions. The lowest concentrations have been reported in the motor cortex (BA4, 6), Broca's region (BA44, 45), lateral prefrontal (BA8–10), somatosensory (BA1), inferior parietal (PGp), occipito-temporal (BA37) and higher visual (FG1 and FG2) regions. 5-HT_{2A} receptors play a major role in the psychotomimetic effects of serotoninergic hallucinogens, e.g. LSD; they are localized postsynaptically on layer II, III and V pyramidal cells, GABAergic interneurones and glial cells.

5-HT_3, 5-HT_4 and 5-HT_7 receptors are present at very low densities in the cerebral cortex. The 5-HT_3 receptor, the only ionotropic 5-HT receptor, is a ligand-gated sodium channel, found in calbindin-, calretinin- and CCK-containing interneurones. The excitatory metabotropic 5-HT_4 and 5-HT_7 receptors are coupled to G_s proteins and activate adenylate cyclase. In the isocortex, the 5-HT_4 receptor occurs at low levels and the highest densities of the 5-HT_7 receptor occur in the infragranular layers.

Dopamine receptors are represented by five metabotropic receptor subtypes each with seven transmembrane domains. The two D1-like receptor subtypes (D_1 and D_5) are coupled to the adenylate cyclase-activating G_s protein, and the three D2-like receptors (D_2, D_3, and D_4) are G_i protein-coupled receptors that inhibit adenylyl cyclase and activate potassium channels. Dopamine receptors are involved in locomotion, cognition, emotion and affect as well as neuroendocrine secretion. Both D1-like receptor subtypes are expressed in layer V pyramidal neurones of the prefrontal, premotor, cingulate and entorhinal cortex, and are localized pre- and postsynaptically on dendritic spines and shafts. Highest densities of the excitatory D_1 receptor (see Figs 32.28–32.29) are present in the primary somatosensory (area 3b, BA2), fronto-orbital (BA11), inferior parietal (PGp), occipito-temporal (BA37), primary visual (V1), early visual (V2, V3v, V3d, V3A, V4v), temporopolar (BA38) and anterior cingulate (BA24) regions. Lowest densities are found in the motor cortex (BA4, 6), Broca's region (BA44, 45), somatosensory (area 3a), inferior parietal (PGa), temporal (BA20–22, 42), ectorhinal (BA36) and higher visual (FG 1, FG2) regions.

D_2 receptors are present at very low density in the deeper layers of the entire iso- and allocortex. The relatively highest D_2 densities are found in the prefrontal and temporal regions, and the glomerular and internal plexiform layers of the olfactory bulb, hippocampus and amygdala.

D_4 receptors are present in the hippocampus and isocortical regions in pyramidal cells and GABAergic interneurones.

FUNDAMENTAL SEGREGATION OF CORTICAL STRUCTURES

The two major architectonic types in the cerebral cortex are the isocortex and the allocortex. Isocortex is also called neocortex because it developed late during brain evolution, coinciding with the appearance of the first mammalian species. All areas of isocortex have a six-layered structure that emerges during the late fetal period. Isocortex forms the largest part of the human cortex (Fig. 32.30). It is described as homogenetic because of its uniform pattern of lamination (Brodmann 1909): adult isocortex is either homotypical (eulaminate) or heterotypical (koniocortical or dysgranular/agranular). Allocortex is heterogenetic (Brodmann 1909) and is distinguished developmentally by the fact that it does not develop through the cortical plate. In general, allocortex is composed of fewer layers than the isocortex (e.g. in the hippocampus and olfactory cortex), although the entorhinal cortex has more than six layers. Allocortex is subdivided into paleocortex and archicortex (hippocampus and part of the cingulate cortex). Transition zones, where the number and thickness of cortical layers vary, occur between the allo- and isocortex and are called peripaleo-, periarchi- and proisocortex, depending on the adjoining parts of allo- and isocortex (Fig. 32.31).

Eulaminate isocortex retains the six-layered structure with a well-defined layer IV and is found in most of the prefrontal, parietal, temporal and occipital cortices. Heterotypical koniocortical cortex is found in the primary somatosensory (area 3b), visual (BA17) and auditory (BA41) areas that are characterized by the presence of layer IV granule cells in the more superficial layers (granularization). Heterotypical dysgranular/agranular cortex is observed in cortical

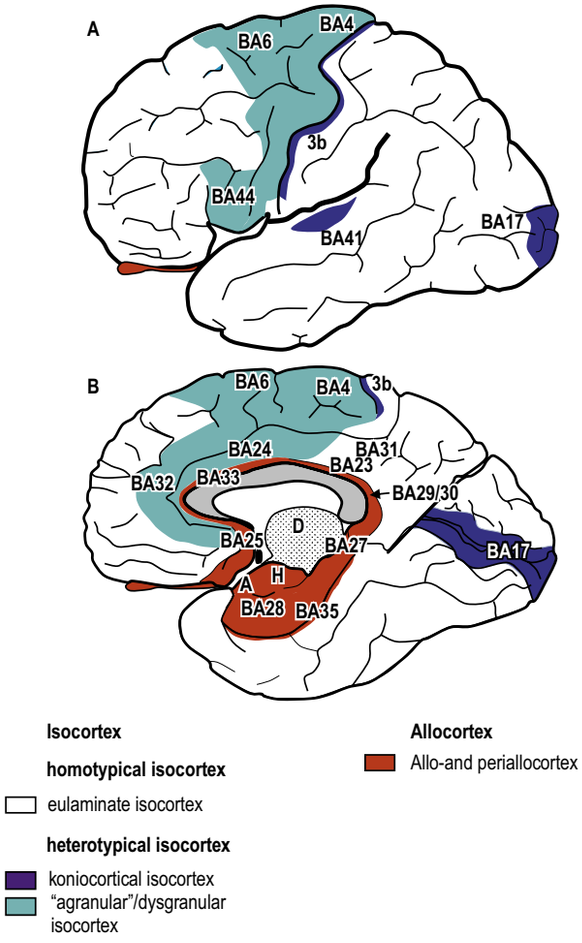

Fig. 32.30 The principal cortical types in lateral (**A**) and medial (**B**) views of the human brain. The eulaminate (white, most areas of the isocortex), koniocortical (blue, areas 3b, BA17, BA41) and 'agranular'/dysgranular regions (turquoise, BA4, BA6, BA44, BA32) of the iso- and proisocortex, as well as the allo- and periallocortex (orange) are shown. Abbreviations: A, amygdala; D, diencephalon, H, hippocampus retrocommissuralis.

areas where layer IV appears to be invaded by pyramidal cells from layers III and V to varying degrees, so that layer IV appears very thin and sometimes interrupted (dysgranular) or is not visible as a distinct layer (agranular) in Nissl-stained sections. The motor cortex (BA4 and BA6), prefrontal area BA8, anterior part of the insular lobe, posterior part of Broca's language region (BA44), and the rostral area 32 of the anterior cingulate cortex have a dysgranular or agranular cytoarchitectonic appearance.

Paleo- and peripaleocortex

The paleocortex consists of the olfactory bulb, the area retrobulbaris (anterior olfactory nucleus), the tuberculum olfactorium and the area prepiriformis. The peripaleocortex is found in the most anterior part of the insular cortex adjacent to the paleocortex (Fig. 32.31).

The olfactory nerves arise from olfactory receptor neurones in the olfactory mucosa. The axons collect into numerous small bundles ensheathed by glia and surrounded by layers of meninges and enter the anterior cranial fossa by passing through the foramina in the cribriform plate of the ethmoid bone. They are attached to the inferior surface of the olfactory bulb lying at the anterior end of the olfactory sulcus on the orbital surface of the frontal lobe, and terminate in the olfactory bulb.

Olfactory bulb

The olfactory bulb is continuous posteriorly with the olfactory tract, through which the output of the bulb projects directly to the ipsilateral retrobulbar area (anterior olfactory nucleus), olfactory tubercle, prepiriform area, amygdala and rostral entorhinal cortex. There is a clear laminar structure in the olfactory bulb (Fig. 32.32A). From the surface inwards, the laminae are the olfactory nerve layer, glomerular layer, external plexiform layer, mitral cell layer, internal plexiform layer and granule cell layer (Fig. 32.32B). The olfactory nerve layer is formed by the unmyelinated axons of the olfactory receptor neurones. These axons divide and synapse on terminal dendrites of secondary olfactory neurones (mitral, tufted and periglomerular cells) forming glomeruli. The external plexiform layer contains the principal and secondary dendrites of the mitral and tufted cells. The mitral cell layer is a thin sheet composed of the cell bodies of mitral cells, each of which sends a single principal dendrite to a glomerulus, secondary dendrites to the external plexiform layer and a single axon to the olfactory tract. It also contains a few granule cell bodies. The internal plexiform layer contains recurrent and deep axon collaterals of mitral and tufted cells and granule cell somata. The granule cell layer contains the majority of the granule cells and their superficial and deep processes; numerous centripetal and centrifugal fibres pass through the layer.

Different odour molecules are represented by different patterns of spatial activity in the olfactory bulb (Shepherd 2006). The axons of the principal neurones in the olfactory bulb (the mitral and tufted cells) form its output via the olfactory tract. These cells are morphologically similar and probably use glutamate or aspartate as their neurotransmitter. Mitral cells span the layers of the bulb and receive the sensory input at their glomerular tufts. The axons of mitral and tufted cells are parallel output pathways from the olfactory bulb. Periglomerular and granule cells are the main types of interneurones in the olfactory bulb. The majority of periglomerular cells are dopaminergic (cell group A15), but some are GABAergic. Granule cells are similar in size to periglomerular cells; they lack an axon and therefore resemble amacrine cells in the retina. Granule cells are GABAergic and have two principal spine-bearing dendrites that pass radially in the bulb. They are likely to be a powerful inhibitory influence on the output neurones of the olfactory bulb. D_1 receptors are present mainly in the internal granular and plexiform layers. The highest densities of D_2 receptors are found in the glomerular and internal plexiform layers of the olfactory bulb.

Neurones of the retrobulbar area and collaterals of pyramidal neurones in the olfactory cortex project to the granule cells of the olfactory bulb. Cholinergic neurones in the horizontal limb nucleus of the diagonal band of Broca, which is part of the basal forebrain cholinergic system, project to the granule cell layer and to the glomerular layer. Other afferents to the granule cell layer and the glomeruli arise from the noradrenergic pontine locus coeruleus and the serotonergic mesencephalic raphe nucleus.

Retrobulbar area

The granule cell layer of the olfactory bulb extends into the olfactory tract with scattered medium-sized multipolar neurones that constitute the retrobulbar area (see Fig. 32.31; 32.32C). This area extends from the caudal part of the olfactory bulb to the point where the olfactory peduncle joins the cortex of the frontal lobe. Many centripetal axons from mitral and tufted cells relay to this area, and axons from the retrobulbar area join the remaining direct fibres from the bulb and continue into the olfactory tract.

As the olfactory tract approaches the anterior perforated substance, it flattens and splays out as the olfactory trigone. Fibres of the tract continue from the caudal angles of the trigone as diverging medial and lateral olfactory tracts that border the anterior perforated substance (see Fig. 32.31). The lateral olfactory tract follows the anterolateral margin of the anterior perforated substance to the insula, where it bends posteromedially to merge with an elevated region, the gyrus semilunaris, at the rostral margin of the uncus in the temporal lobe. The tenuous grey layer that covers the lateral olfactory tract merges laterally with the gyrus ambiens. The grey layer over the lateral olfactory tract and the gyrus ambiens form the prepiriform area, which extends caudally into the entorhinal area of the parahippocampal gyrus. The prepiriform area, periamygdaloid regions and the entorhinal area (BA28) together make up the piriform cortex. The anterior perforated substance is continuous laterally with the peduncle of the temporal stem and the amygdaloid complex, and medially with the septal region.

The main targets of the lateral olfactory tract are the prepiriform area, amygdala and rostral entorhinal cortex. Neurones in the prepiriform area project to targets that include the orbitofrontal and agranular insular cortex, thalamus (especially the medial dorsal thalamic nucleus), hypothalamus, amygdala and hippocampal formation.

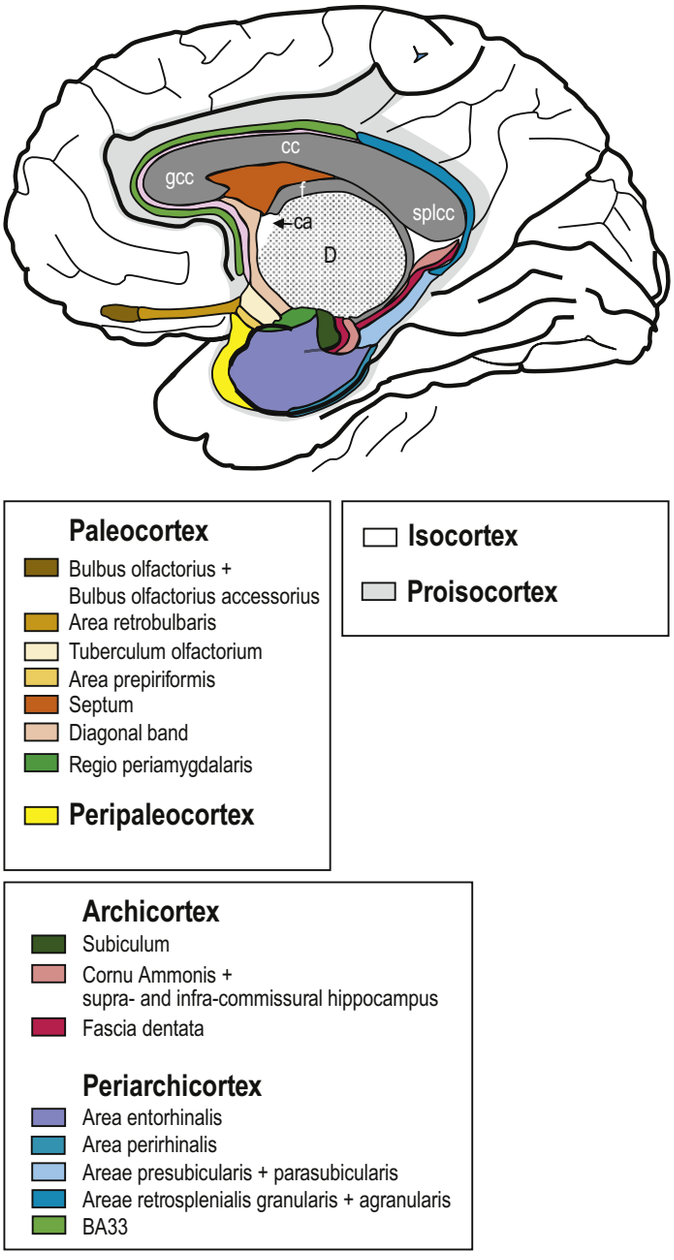

Fig. 32.31 The paleo-, peripaleo-, archi-, periarchi-, proiso- and isocortical regions of the human brain. Abbreviations: Ca, anterior commissure; cc, corpus callosum; D, diencephalon; f, fornix; gcc, genu of the corpus callosum; splcc, splenium corporis callosi of the corpus callosum.

Prepiriform area

The prepiriform area (BA51, primary olfactory cortex) is the largest olfactory cortical area and extends from the lateral olfactory tract to the limen insulae and temporal cortex (Fig. 32.33). This paleocortical area can be subdivided into a frontal portion at the base of the frontal lobe, and a temporal portion in the region between the frontal and temporal lobes. It is partly underlain by a ventral extension of the claustrum (endopiriform nucleus) and shows the prototypical three-layered structure of the paleocortex, i.e. a superficial molecular layer, thin intermediate densocellular layer and a deep multiform layer. The superficial molecular layer is differentiated into three sublayers: an outermost, cell-poor sublayer (a), an intermediate sublayer (b) which contains many glial cells and the fibres of the lateral olfactory tract; and the deepest sublayer (c) which has a lower cell density. The intermediate densocellular layer varies in thickness and appears to be interrupted; it contains pyramidal and polymorphic cells with dendrites that extend in the first layer. The deep multiform layer consists of the largest cells in the prepiriform area with an intermediate packing density. A very thin, nearly cell-free sheet (external capsule) separates the multiform layer from the underlying claustrum.

The prepiriform area receives afferents from the olfactory bulb, retrobulbar area, olfactory tubercle, septum, amygdala, orbitofrontal cortex, and the contralateral prepiriform area (via the anterior commissure). Efferent reciprocal connections are found in all these areas, and in the anterior insular and hippocampal cortices, claustrum and ventral putamen.

Neuroimaging studies in humans demonstrate activity in the prepiriform cortex during olfactory learning and memory tasks as well as in olfactory-induced motivational and cognitive states: olfactory dysfunction is a major finding in anhedonia.

Olfactory tubercle

The olfactory tubercle is located caudal to the retrobulbar area and medial to the prepiriform area in the anterior perforated substance. Its three-layered structure is poorly differentiated in the human brain (see Figs 32.31, 32.33C). Numerous islands of Calleja, consisting of very small and densely packed granule cell neurones, are found in all layers of the tubercle and between the tubercle and the ventral striatum. The olfactory tubercle receives input from the olfactory part of the amygdala and from the olfactory bulb via the lateral olfactory tract and sends efferents to the ventral pallidum. Medium spiny cells are the dominant cell type; they resemble neurones in the striatum.

Periamygdaloid cortex

The periamygdaloid cortex (see Figs 32.31, 32.33) is located ventral to the prepiriform area and medial to the entorhinal area. It is a cytoarchitectonically heterogeneous region with several subdivisions, all of which receive olfactory input from the olfactory bulb and other paleocortical regions. The periamygdaloid cortex is therefore considered part of the olfactory cortex.

Between the piriform cortex and the laterally adjoining insular cortex, a peripaleocortical transition zone (BA16, Brodmann 1905) (see Fig. 32.31) can be demonstrated in non-human primate brains that has been called the peripaleocortical claustral region by Stephan (1975), because of its close topographical relation to the claustrum. BA16 is the least differentiated area in the insular cortex and shows an agranular architecture. It seems to be comparable with the areas ID and TI of von Economo and Koskinas (1925) and shows a four-layered type (for details see Stephan 1975).

Connections of the peripaleocortical claustral region with the prepiriform cortex, amygdala, adjoining isocortex, claustrum and contralateral BA16 have been described in primates. The strong connections with the piriform cortex make an olfactory function of the peripaleocortical insular cortex probable, but a definite statement about the function of area 16 in the human brain is presently not possible.

Amygdala

The amygdala is located in the rostral part of the temporal lobe at the transition between the piriform cortex, ventral striatum and claustrum dorsally, the entorhinal cortex ventrally and the hippocampus posteriorly (Fig. 32.34). It forms the ventral, superior and medial walls of the tip of the temporal (inferior) horn of the lateral ventricle, and neighbours the inferomedial margin of the claustrum. Fibres of the external capsule and basal forebrain, including the cholinergic magnocellular nucleus basalis of Meynert, partially separate the amygdala from the putamen and globus pallidus. Laterally, the amygdala lies close to the optic tract. The rostral portions of the amygdala are bordered medially by the piriform cortex. The amygdala reaches the medial surface of the temporal lobe by forming the semilunar gyrus, which is separated from the ventrally located entorhinal cortex by the semi-anular sulcus. At a caudal level, the amygdala is surrounded laterally by the temporal horn of the lateral ventricle. The head of the hippocampus is interposed between the amygdala and entorhinal cortex. Transition zones are present between the amygdala and the surrounding structures.

The amygdala is composed of numerous nuclei that have different cyto-, myelo- and receptor architectonics: they can be assigned to three major groups named superficial, basolateral and centromedial (Heimer et al 1999).

The superficial (cortex-like) group consists of the anterior amygdaloid area, amygdalopiriform transition area, amygdalohippocampal transition area, posterior cortical nucleus and ventral cortical nucleus. All parts of this group have a superficial molecular layer, which is characteristic of the cerebral cortex, overlying a densely packed cellular layer, and so resemble a two-layered cortex (cortex-like nuclei). The term

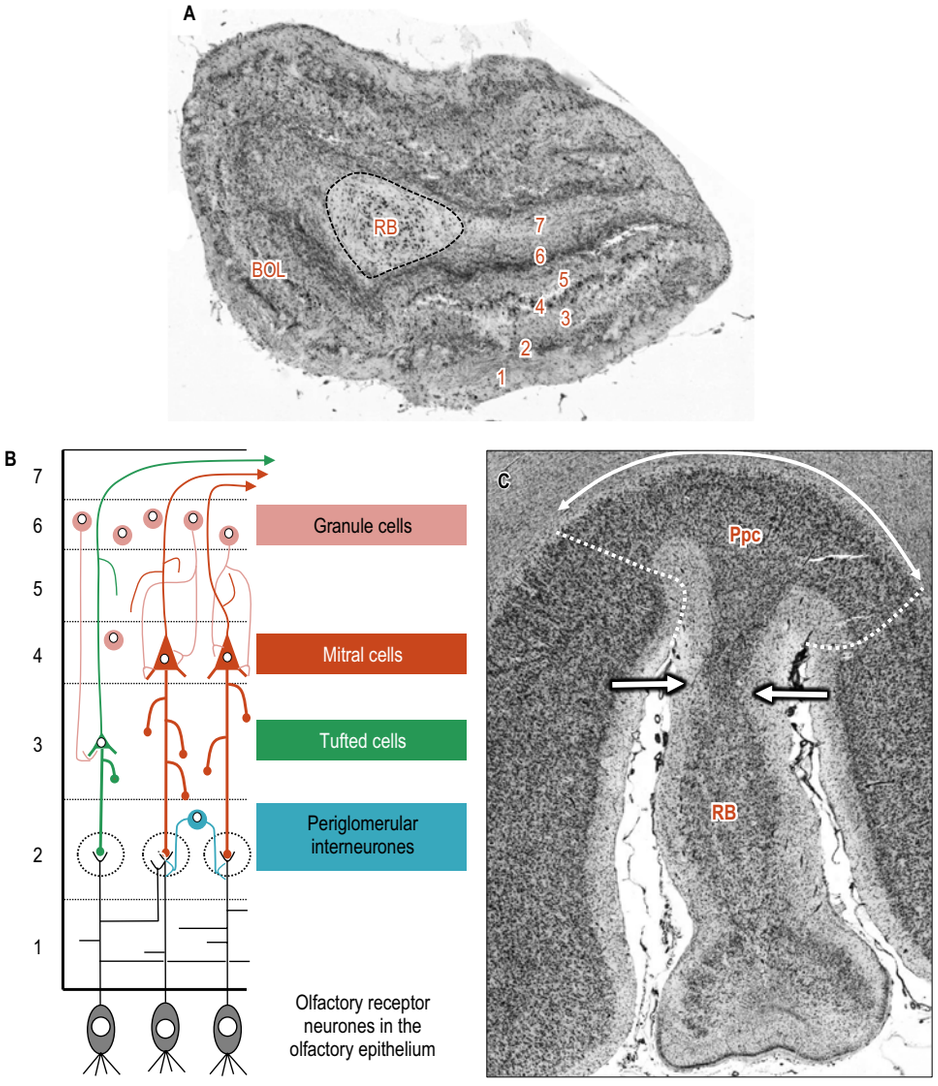

Fig. 32.32 The paleocortical areas of the human brain. **A**, Olfactory bulb (bulbus olfactorius, BOL) with the most rostral part of the retrobulbar area (area retrobulbaris, RB). **B**, Major cell types and connections in the olfactory bulb. **C**, Retrobulbar area (area retrobulbaris, RB) and peripaleocortex (Ppc). Layers of the olfactory bulb: 1, stratum fibrosum externum (olfactory nerve layer); 2, stratum glomerulosum; 3, stratum plexiforme externum; 4, stratum mitrale; 5, stratum plexiforme internum; 6, stratum granulosum internum; 7, tractus olfactorius.

nucleus is therefore misleading, because these nuclei possess a cortical architecture. However, this group develops in an outside-in manner typical of non-cortical structures, whereas isocortex develops in a characteristic inside-out manner. Comparative anatomical studies suggest that this part of the amygdala should be classified as paleocortex. The anterior amygdaloid area is found in the dorsal lip of the entorhinal sulcus (see Fig. 32.34). Most of the loosely packed neurones of this area are small and spindle-shaped. Magnocellular neurones of the basal nucleus of Meynert are visible adjacent to the anterior amygdaloid area and the central and medial nuclei. The amygdalopiriform transition area, which borders the entorhinal area dorsally and the prepiriform cortex ventrally, contains cell clusters (medial) and loosely packed neurones (lateral) of varying shapes. The amygdalohippocampal transition area contains darkly stained and densely packed neurones. The ventral cortical nucleus consists of fork-shaped neurones (dorsal) and radially arranged and densely packed neurones (ventral).

The basolateral group consists of lateral, basolateral, basomedial and paralaminar nuclei. This group contains a high density of neurones of variable size. The lateral nucleus has dorsomedial and ventrolateral subnuclei. The basolateral nucleus contains the largest cells of the amygdala: it is commonly divided into dorsal magnocellular and intermediate parvocellular basal nuclei and a ventral band of darkly staining and densely packed cells, the paralaminar nucleus, which borders the basolateral and lateral nuclei. It has been suggested that the basolateral nuclear complex should be considered as a quasicortical structure because it shares several characteristics with the cortex. Although it lacks a laminar structure, it has direct, often reciprocal, connections with adjacent temporal and other areas of cortex, and it projects to the motor or premotor cortex. It receives direct cholinergic and non-cholinergic inputs from the magnocellular system in the basal forebrain and has reciprocal connections with the mediodorsal thalamus. The distribution of small peptidergic neurones in the basolateral nuclear group, e.g. those containing neuropeptide Y (NPY), somatostatin (SOM) and cholecystokinin (CCK), are also similar in form and density to those found in the adjacent cortex of the temporal lobe. Projection neurones from this part of the amygdala appear to utilize, at least in part, the excitatory amino acids glutamate or aspartate as transmitters. Moreover, they project to the ventral striatum rather than to hypothalamic and brainstem sites. Thus, it may be appropriate to consider this part of the amygdaloid complex as a polymodal cortex-like area, separated from the cerebral cortex by fibres of the external capsule. The vast majority of projection neurones in the basolateral group are excitatory spiny pyramidal and modified pyramidal neurones, intermingled with nonpyramidal interneurones. Nonpyramidal projection neurones in the basolateral group that target the mediodorsal nucleus of the thalamus also point to a position of the basolateral group between the cerebral cortex and noncortex-like deeper nuclei.

The neocortex-like centromedial group consists of medial and central nuclei. The basal nucleus of Meynert is a dorsal neighbour. The centromedial group contains mainly GABAergic and peptidergic projection neurones: small neurones are densely packed in the medial nucleus and sparse in the central nucleus. The bed nucleus of the stria terminalis at the frontal (anterior) horn of the lateral ventricle is surrounded medially by the lateral septum and fornix, and medially by the striatum. It is connected with the central and medial nuclei of the amygdala by the sublenticular extended amygdala (heterogeneous cell groups in the substantia innominata) that is often referred to as the anterior amygdaloid area. Whereas the central nucleus projects to areas that are involved in fear and stress responses, the medial nucleus mainly modulates food intake and sexual behaviour: both nuclei play a major role in endocrine homeostasis.

A consistent feature of the intrinsic connections among amygdaloid nuclei is that they arise primarily in the lateral and basal nuclei, and terminate in the central and medial nuclei, suggesting a largely unidirectional flow of information. The lateral nucleus projects to all divisions of the basal nucleus, accessory basal nucleus, paralaminar and anterior cortical nuclei, and less heavily to the central nucleus; it receives few afferents from other nuclei. The magnocellular, parvocellular and intermediate

parts of the basal nucleus project to the accessory basal, central (especially the medial part) and medial nuclei, as well as to the periamygdaloid cortex and the amygdalohippocampal area. The accessory basal nucleus projects densely to the central nucleus, especially its medial division, as well as to the medial and cortical nuclei. Its major intra-amygdaloid afferents arise from the lateral nucleus. The medial nucleus projects to the accessory basal, anterior cortical and central nuclei, as well as to the periamygdaloid cortex and amygdalohippocampal area, while afferents arise especially from the lateral nucleus. The intrinsic connections of the cortical nucleus are not well understood. The posterior part of the cortical nucleus projects to the medial nucleus but it has been difficult to differentiate this projection from that arising in the amygdalohippocampal area. The central nucleus projects to the anterior cortical nucleus and the various cortical transition zones and forms an important relay for afferents from many of the amygdaloid nuclei, especially the basal and accessory basal nuclei; it has major extrinsic connections.

The amygdala is connected with both cortical areas of the telencephalon and subcortical structures. Bidirectional amygdalo-cortical connections are established with the iso- and pro-isocortex of the temporal, prefrontal, cingulate and insular areas. They run in the external capsule, whereas the allocortical connections with the entorhinal cortex, posterior parahippocampal gyrus, Ammon's horn and subiculum are located in the white matter between the entorhinal cortex and amygdala. The subcortical connections of the amygdala are mediated by the stria terminalis, the ventral amygdalofugal pathway and the medial forebrain bundle. The stria terminalis runs parallel to the fornix and medial to the body and tail of the caudate nucleus; it connects the caudal medial regions of the amygdala to the bed nucleus of the stria terminalis, hypothalamus and nucleus accumbens. Some projections of the stria terminals terminate in the olfactory cortex. The ventral amygdalafugal pathway is a shorter pathway running parallel and inferior to the anterior commissure and connecting the amygdala to the hypothalamus.

The medial forebrain bundle contains many fibres that connect the amygdala to the brainstem. Noradrenergic fibres arise primarily from the locus coeruleus; serotoninergic fibres arise from the dorsal and, to some extent the median, raphe nuclei; dopaminergic fibres arise primarily in the midbrain ventral tegmental area (A10). The basal and parvocellular accessory basal nuclei, the amygdalohippocampal area and nucleus of the lateral olfactory tract receive a very dense cholinergic innervation that arises from the magnocellular nucleus basalis of Meynert.

The amygdala plays a role in a variety of functions, including arousal and attention, goal-directed behaviour, fear responses, adaptation to stress, social behaviour, olfaction, food intake and sexual behaviour (see also the limbic system). Damage to the amygdala is often due to neurodegenerative disorders including Alzheimer's, Parkinson's and Huntington's disease, encephalitis, temporal lobe epilepsy and autism. The anatomical basis for these functions and dysfunctions is the multimodal input converging from many cortical and subcortical regions to the amygdala. Functional analyses using imaging also show an activation of the amygdala by faces and emotional stimuli. Bilateral complete calcification of the amygdala is characteristic of the rare Urbach–Wiethe syndrome (Fig. 32.36), which is associated with impaired emotional processing of both negative and positive stimuli.

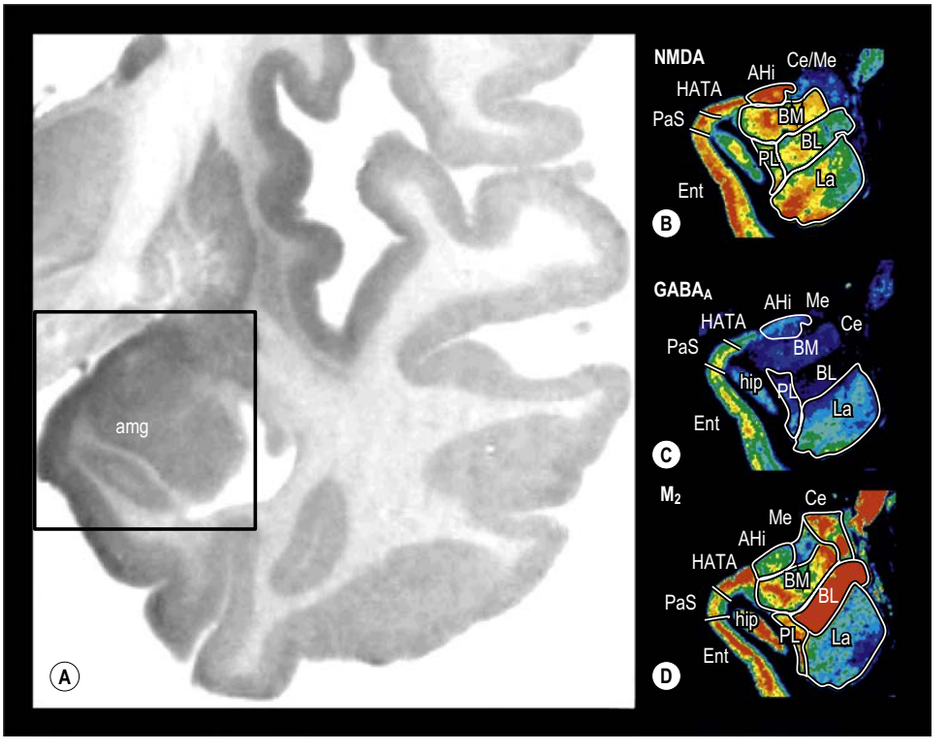

Fig. 32.35 The distribution of receptors in the human amygdala. **A**, Magnetic resonance image (4 Tesla, spatial resolution 350 mm isotropic). **B**, Glutamate NMDA receptor. **C**, $GABA_A$ receptor. **D**, Acetylcholine muscarinic M_2 receptor. Abbreviations: Ahi, amygdalo-hippocampal transition area; amg, amygdala; BL, basolateral nucleus; BM, basomedial nucleus; Ce, central nucleus; Ent, entorhinal cortex; HATA, hippocampal–amygdaloid transition area; hip, hippocampus; La, nucleus lateralis; Me, medial nucleus; PaS, parasubiculum; PL, paralaminar nucleus.

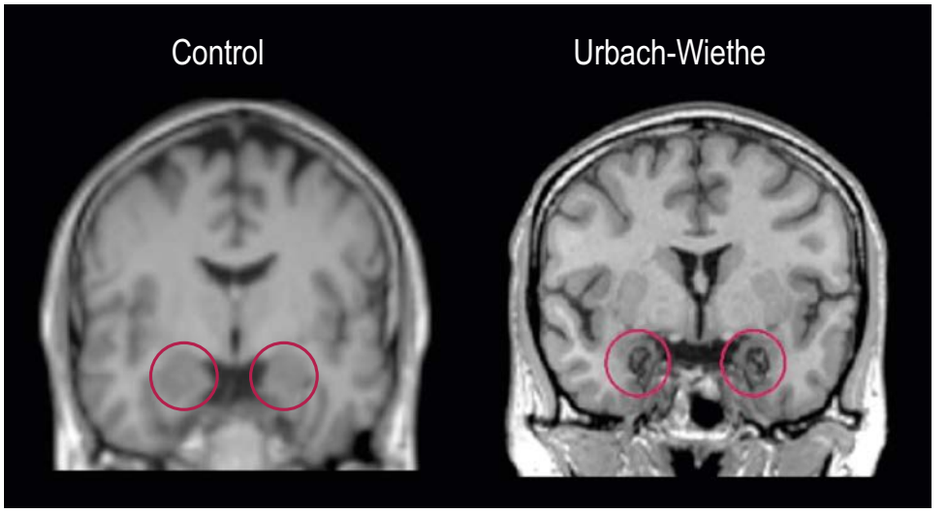

Fig. 32.36 Magnetic resonance imaging of the amygdala in a healthy control subject (left) and the Urbach–Wiethe syndrome (right). (Adapted with permission from Hurlemann R, Schlaepfer T, Matusch A et al 2009 Reduced 5-HT_{2A} receptor signaling following selective bilateral amygdala damage. Social Cogn Affect Neurosci 4:79–84.)

Differences in transmitter receptor densities support the cytoarchitectonic subdivision of the amygdala and its functional specializations (Fig. 32.35). The amygdalohippocampal transition area shows the highest α_1 and α_2 adrenoceptor densities in the amygdala. The amygdalopiriform transition area has the highest serotoninergic 5-HT_{1A} receptor density. The border of the ventral cortical nucleus with the medial nucleus is marked by higher densities of cholinergic (except for M_2), glutamatergic, serotoninergic and GABAergic receptors when compared to its neighbours. Densities of α_1 and 5-HT_{1A} receptors are higher in the ventral cortical nucleus than in the adjacent basomedial nucleus. There are higher densities of muscarinic M_2, nicotinic $\alpha_4\beta_2$, α_1 and α_2 receptors in the anterior amygdaloid area than in the neighbouring basomedial nucleus. The central nucleus has the highest kainate receptor densities. The medial nucleus has relatively low receptor densities, but its border with the anterior amygdaloid area is highlighted by higher densities of benzodiazepine binding sites and $GABA_B$ receptors in the medial nucleus. Lower M_1, M_3 and higher α_1 receptor densities in the medial nucleus mark its border with the central nucleus. The lateral nucleus displays the highest $GABA_A$ receptor density in the amygdala. The basolateral nucleus has higher M_2 and lower $GABA_A$ receptor and benzodiazepine binding site densities as compared to the lateral nucleus. The basomedial nucleus has higher α_1 receptor densities than the basolateral nucleus. The paralaminar nucleus is demarcated by the highest density of M_1 receptors in the amygdala and also has higher 5-HT_{1A} receptor densities than the dorsally adjacent nuclei. Its border with the basolateral nucleus is clearly delineated by the higher AMPA, kainate, M_1, M_3 receptor and benzodiazepine binding site densities in the paralaminar nucleus.

Archi- and peri-archicortex and the concept of the limbic system

The limbic system is composed of interconnected cortical and subcortical regions (**Fig. 32.37**) dedicated to memory, and linking visceral states and emotion to cognition and behaviour (Mesulam 2000; Heimer and Van Hoesen 2006). The Latin term *limbus* means border and was originally used by Thomas Willis (1664) to describe the parahippocampal and cingulate gyri encircling the thalamus. Paul Broca suggested that the limbic structures might be associated mainly with olfaction and for many years the term *rhinencephalon* ('olfactory brain') was used synonymously with limbic lobe. With the identification of extensive connections between limbic cortical regions and subcortical structures in the diencephalon (mammillary bodies, anterior thalamic nuclei) and the clinical description of syndromes associated with damage to its single constituents, the functions of the limbic system were extended to social interactions and behaviour (Brown and Schäfer 1888), consolidating memories (Bechterew 1900) and forming emotions (Cannon 1927) (for a review see Catani et al 2013). Currently the limbic system includes two divisions (**Fig. 32.37A–B**): a network including the amygdala and orbitofrontal cortex connected by the uncinate fasciculus (Yakovlev's circuit) involved in emotion, reward and social behaviour; and a network including the hippocampus, parahippocampal cortex, mammillary bodies, anterior thalamus, ventromedial frontal and cingulate cortices, connected by the fornix, mammillo-thalamic tract and anterior thalamic projections involved in episodic memory. This second network is commonly referred to as the Papez circuit (1937), although its constituents were already anatomically defined by early anatomists, including Bechterew (1900) and Jakob (1906). Both divisions are extensively connected to the cingulate cortex and nuclei of the septum, hypothalamus, striatum (nucleus accumbens) and midbrain (ventral tegmental area) (Mesulam 2000).

The cortical components of the limbic system include the archicortex of the hippocampus proper, and the periarchicortex of the parahippocampal gyrus, retrosplenial region and cingulate gyrus (**Fig. 32.37C**). The parahippocampal and cingulate gyri contact each other in the region behind the splenium of the corpus callosum (retrosplenial cortex) and form the so-called great limbic lobe of Broca. These two gyri are outwardly delimited by the subcallosal, cingulate, subparietal, anterior calcarine, collateral and rhinal sulci which are collectively considered to form the limbic fissure.

At its anterior end, the parahippocampal gyrus folds back on itself to form the uncus, which is bordered superiorly by the most lateral aspect of the frontobasal region via a peduncle anterior to the temporal horn of the lateral ventricle. The anteromedial surface of the uncus region faces the carotid cistern and its posteromedial surface borders the crural cistern and the cerebral peduncle. The semilunar gyrus, a lateral extension of the lateral olfactory stria, and the ambient gyrus form two small prominences on its medial and anterior surface (see Fig. 32.37C). Both gyri cover the amygdala and are separated by the semi-anular sulcus, which harbours the anterior choroidal artery. The most rostral and anterior aspects of the uncus correspond to the entorhinal cortex (see Fig. 32.37C). The

Abbreviations: A, ambiens gyrus; acal, anterior calcarine sulcus; Aps, anterior perforate substance; AR, gyri of Andreas Retzius; bG, bandaletta Giacomini; ca, commissura anterior; cc, corpus callosum; cing, cingulate sulcus; Cing, cingulate gyrus; col, collateral sulcus; D, diencephalon; Ec, entorhinal cortex; f, fornix; Fus, fusiform gyrus; Hp, hippocampus precommissuralis; Hr, hippocampus retrocommissuralis (cornu Ammonis red, dentate gyrus blue); Hs, hippocampus supracommissuralis; Ist, isthmus; OFC, orbitofrontal cortex; Parh, parahippocampal gyrus; ppir, area prepiriformis; ppo, posterior parolfactory sulcus; Pt, paraterminal gyrus; rh, rhinal sulcus; rhi, intrarhinal sulcus; Rsp, retrosplenial region; sann, semiannular sulcus; sc, subcallosal sulcus (anterior parolfactory sulcus); Sc, subcallosal gyrus; Sl, semilunar gyrus; sp, subparietal sulcus; spell, septum pellucidum; u, uncal sulcus; U, uncinate gyrus; Ua, uncinate apex. (A, B, With permission from Catani M, Thiebaut de Schotten M 2012 Atlas of Human Brain Connections. Oxford: Oxford University Press; C, with permission from Duvernoy HM 1998 The Human Hippocampus. Functional Anatomy, Vascularization and Serial Sections with MRI. Berlin: Springer.)

posterior half of the uncus contains the head of the hippocampus and is separated inferiorly from the parahippocampal gyrus by the uncal sulcus. Its inferior surface is hidden inside the uncal sulcus, in which the posterior half of the uncus region harbours the uncinate gyrus anteriorly and the uncal apex (intralimbic gyrus, hippocampus inversus) posteriorly, separated by the band of Giacomini (see Fig. 32.37C). Collectively, these structures correspond to the extraventricular part of the head of the hippocampus. The band of Giacomini corresponds to the tail of the dentate gyrus, which vanishes on the medial aspect of the uncus.

On its lateral aspect, the parahippocampal gyrus is delimited by the collateral sulcus that separates it from the fusiform gyrus, and more anteriorly by the rhinal sulcus, which is occasionally continuous with the collateral sulcus. The latter is a long, deep sulcus that extends along the basal temporal and occipital surface, with multiple side branches (see Figs 32.3C,D,F, 32.37C). Its temporal segment bulges into the ventricular floor as the collateral eminence, located lateral to the hippocampus. Its occipital segment corresponds to the collateral trigone that forms the triangular, flat surface of the ventricular atrium and occipital (posterior) horn. The rhinal sulcus, which is not always readily identifiable, separates the uncus from the rest of the temporal pole. Medially, it lies under the thalamus along the choroidal fissure. Superiorly, it is attached along the inferior aspect of the insular lobe via fibres that cover the inferior horn. The choroidal fissure extends between the entire fornix and thalamus, from the head and the body of the hippocampus to the interventricular foramen. Anteriorly, the anterior and mesial parts of the temporal lobe and the parahippocampal gyrus merge with the basal and lateral aspect of the frontal lobe through a neural peduncle that constitutes the so-called temporal stem (limen insulae). Posteriorly, the choroidal fissure lies within the inferior horn between the fimbria of the fornix and the inferior aspect of the thalamus, along the parapeduncular space that harbours the ambient cistern. More superiorly and anteriorly, the choroidal fissure lies between the body of the fornix and the superior surface of the thalamus.

The hippocampal gyrus folds medially where it harbours the hippocampus proper. The latter encircles the corpus callosum and is divided into precommissural, supracommissural and retrocommissural parts, according to its relation to the anterior commissure (see Fig. 32.37C). The retrocommissural hippocampus is a major part of the limbic lobe, and is separated from the parahippocampal gyrus by the hippocampal fissure. The parahippocampal gyrus includes Brodmann's periarchicortical areas BA27 (presubiculum), BA28 (entorhinal cortex) and BA35 (perirhinal cortex). In primates, areas of the parahippocampal gyrus project to virtually all multimodal association areas of the cortex, and it also provides the major funnel through which multimodal inputs converge on the hippocampus.

Posteriorly, the parahippocampal gyrus is continuous with the lingual gyrus and the cingulate gyrus along its isthmus. Buried within the posterior wall of the callosal sulcus, the retrosplenial cortex occupies the anterior region of the isthmus cinguli. The retrosplenial cortex is microstructurally different from the cingulate cortex and functionally is closer to the posterior parahippocampal place area (see below). At its rostral extension, the cingulate gyrus ends in the subcallosal gyrus below the genu of the corpus callosum (see Figs 32.1, 32.3C–D). The anterior and posterior paraolfactory gyri lie anterior to the paraterminal gyrus, separated by the anterior para-olfactory sulcus (see Figs 32.1, 32.2C–D). Anteriorly, a fold connects the most basal portion of the cingulate gyrus with the gyrus rectus, encircling the posterior end of the superior rostral sulcus (the cingulate pole). The paraterminal gyrus lies on the medial wall of the cerebral hemisphere posterior to the paraolfactory gyri, immediately facing the lamina terminalis, and delineated anteriorly by the short, vertical posterior olfactory sulcus. Inferiorly, the paraterminal gyrus extends along the diagonal band of Broca and the lateral olfactory stria. The cingulate gyrus includes Brodmann's periarchicortical areas BA26 (area ectosplenialis; hidden in the callosal sulcus at the level of splenium), BA25 (area subgenualis or preterminalis), BA29 (granular retrosplenial cortex), BA30 (agranular retrosplenial cortex), BA33 (area pregenualis) as well as the proisocortical areas BA23 (area cingularis posterior) and BA24 (area cingularis anterior). Area 24 is surrounded by the isocortical BA32, and BA23 is bordered by the isocortical BA31.

Hippocampal formation

The hippocampal formation consists of the archicortical hippocampus proper (cornu Ammonis, dentate gyrus and subiculum) and the periarchicortical presubiculum (BA27) and parasubiculum (BA26), as well as the entorhinal (BA28) and perirhinal (BA35) cortices (**Table 32.6**). The

entorhinal cortex is laterally confined by the collateral sulcus, in which most of the perirhinal cortex is buried. Except for the most rostral parts of BA28 and BA35 in the gyrus ambiens, the periarchicortical cortex of the hippocampal formation is located in the parahippocampal gyrus.

Hippocampus proper

The retrocommissural part of the hippocampus proper is a convex elevation, approximately 5 cm long, within the parahippocampal gyrus and neighbouring the temporal (inferior) horn of the lateral ventricle. It can be macroscopically divided into a head, a body and a tail (**Fig. 32.38**). The surface of the hippocampus, the alveus, is covered by ependyma inside the ventricular cavity. On the surface of the dentate gyrus, small cortical prominences form a chain along the medial aspect of the hippocampus. Along its medial margin, the hippocampus is separated from the subiculum of the parahippocampal gyrus by the shallow hippocampal sulcus that usually terminates anteriorly within the uncus. The dentate gyrus is separated from the fimbria of the fornix by the fimbriodentate sulcus which lies parallel with the hippocampal sulcus (**Fig. 32.39**).

The large retrocommissural part of the hippocampus proper is a three-layered archicortical structure (**Figs 32.40–32.41**) that continues as the supracommissural hippocampus, lying as the indusium griseum on the corpus callosum, and a thin vertical structure rostral to the septum and the genu of the corpus callosum. The indusium griseum is a thin layer of grey matter lying over the whole length of the dorsal surface of the corpus callosum, and covered by medial and lateral longitudinal striae that run within the callosal sulcus beneath each cingulate gyrus. Anteriorly, the indusium griseum is connected to the paraterminal gyrus; posteriorly, it circles the splenium of the corpus callosum and runs along the fasciolar gyrus on each side. The retrocommissural hippocampus (hippocampus proper) consists of Ammon's horn (cornu Ammonis), the fascia dentata and the subiculum. Ammon's horn and the fascia dentata are distinguished on the basis of their principal excitatory neurones, which are pyramidal and granule cells, respectively.

The archicortical fascia dentata is located in the dentate gyrus and consists of three layers: a superficial molecular layer containing the dendrites of the granule cells, an intermediate granular layer with densely packed somata of the granule cells, and an internal, relatively cell-sparse multiform layer surrounding a continuation of the cornu Ammonis, the CA4 region of the hilus. The multiform layer contains cells that give rise primarily to ipsilateral association fibres that remain within the dentate gyrus and do not extend into other hippocampal fields. The hilus and fascia dentata together form the dentate gyrus. The cortex of the dentate gyrus is the least complex of the hippocampal formation (see Figs 32.40–32.41). The outer two-thirds of its molecular layer receive most of the afferent projections to the dentate gyrus, primarily from the entorhinal cortex via the perforant path, whereas the inner third is a termination field for commissural and associational projections.

The cornu Ammonis can be subdivided into four regions, CA1–CA4 (see Fig. 32.40). CA1 is the largest region in the hippocampus proper, and is the most complex of the hippocampal subdivisions: its appearance varies along its extent. CA1 is bordered laterally by the prosubiculum, which is a subfield of the subiculum, and medially by CA2. The most caudal portion of CA1 is located on Retzius's gyrus beneath the splenium of the corpus callosum. Approximately 10% of neurones in CA1 are interneurones, and 90% are glutamatergic projection neurones (pyramidal cells). CA2 has the most compact layer of pyramidal cells. Like CA1, it lacks a mossy fibre input from dentate granule cells and receives a major input from the supramammillary region of the hypothalamus. CA3 borders the hilus of the dentate gyrus at one end, and CA2 at the other. CA3 pyramidal cells are the largest in the hippocampus and receive a mossy fibre input from dentate granule cells on their proximal dendrites. The whole pyramidal cell layer in this field is about 10 cells thick. CA4 is not universally accepted as a distinct region but considered to be a mere continuation of CA3 within the hilus of the dentate gyrus: it merges with the multiform layer of the fascia dentata. The cornu Ammonis (see Fig. 32.41) consists of three layers: the thin, cell-sparse stratum oriens contains intrahippocampal association fibres, the basal dendrites and axons of pyramidal neurones and some interneurones; the pyramidal layer contains the somata of pyramidal cells and interneurones; and a wide, cell-sparse layer, the stratum radiatum-lacunosum-moleculare, contains the apical dendrites of the pyramidal cells and the perforant path, Schaffer collaterals, septal and commissural fibres. CA3 and CA2 cells in the stratum radiatum and stratum oriens receive associational connections from other rostrocaudal levels of the hippocampus, and afferents from subcortical structures such as the septal nuclei and supramammillary region. Schaffer collaterals, the projections from pyramidal cells in CA3 and CA2 to CA1, terminate in the stratum radiatum and stratum oriens. The projections from the entorhinal cortex to

the dentate gyrus (perforant path) travel in the stratum lacunosum-moleculare, where they make synaptic contact *en passant* with the distal apical dendrites of hippocampal pyramidal cells. The stratum lucidum between the pyramidal and radiatum layers contains the terminals of mossy fibres that make contact with the proximal dendrites of pyramidal cells in CA: it is not present in CA1 and CA2. The alveus between the stratum oriens and the ventricular surface consists of subicular and hippocampal pyramidal cell axons converging on the fimbria of the fornix

The archicortical subiculum is located between CA1 and the periarchicortical presubiculum (see Figs 32.39–32.40). It can be subdivided into the prosubiculum medially and the subiculum proper laterally. In addition to the molecular and pyramidal layers of the cornu Ammonis, a variable number of layers from surrounding fields are found in the subiculum, producing an intricate lamination pattern. The subiculum consists of a superficial molecular layer containing apical dendrites of subicular pyramidal cells, a pyramidal cell layer and a deep polymorphic layer. The stratum radiatum of CA1 stops abruptly at the border with the prosubiculum, where pyramidal neurones build a denser outer stripe, a less dense intermediate stripe and a denser inner stripe in the subiculum. The border between the prosubiculum and subiculum proper is difficult to identify. Compared with the prosubiculum, the cell packing density of the pyramidal layer is lower in the outer stripe but higher in the inner stripe of the subiculum. The major subcortical projections of the hippocampal formation to the septum, mammillary nuclei, nucleus accumbens, anterior thalamus and entorhinal cortex, all arise from pyramidal neurones of the subicular complex. The subiculum receives numerous direct cortical inputs, e.g. from the temporal polar and perirhinal cortices and the parahippocampal and superior temporal gyri.

The border between the archicortical subiculum and the periarchicortical presubiculum is characterized by particularly small neurones in the prosubiculum that form a parvocellular layer (see Figs 32.39–32.40). The pyramidal and multiform layers of the subiculum continue into the pyramidal-multiform layer of the presubiculum, where a plexiform layer is interleaved between the pyramidal-multiform and parvocellular layers. The presubiculum projects to the anterior thalamic nuclear complex (anteromedial, anteroventral and laterodorsal nuclei).

The parasubiculum (see Figs 32.39–32.40) can be delineated from the presubiculum by the abrupt appearance of large, loosely packed cells in the parvopyramidal layer, and by large, densely packed cells in the pyramidal-multiform layer of the parasubiculum. Its lateral border is formed by the entorhinal cortex. The parasubiculum is always present in the hippocampal head; it extends into the hippocampal tail in only 20% of human brains. The border between the parasubiculum and the entorhinal cortex is delineated by the increase in the number of cortical layers from four (parasubiculum) to eight (entorhinal cortex).

The hippocampal formation and its connections via the fornix are thought to be responsible for the formation of autobiographical (episodic) memory. Bilateral damage to the hippocampal formation as a result of neurodegeneration (Alzheimer's disease), infection (encephalitis), or bilateral removal of larger parts of the mesial temporal cortex because of epilepsy, is associated with an inability to learn new information (anterograde amnesia) or remember experiences in the relatively recent past (retrograde amnesia).

Neurotransmitters of the hippocampal formation

Available with the *Gray's Anatomy* e-book

Entorhinal cortex

The entorhinal cortex extends rostrally to the anterior limit of the amygdala and caudally overlaps a portion of the hippocampal fields. It can be subdivided into various subfields on the basis of differences in cyto- and myeloarchitecture (see Figs 32.34, 32.42). It receives input from the olfactory, piriform and periamygdaloid cortices; more caudal portions of entorhinal cortex do not generally receive olfactory inputs, but collect input from numerous neocortical regions. The entorhinal cortex provides the main input to the hippocampal formation via the perforant path.

The entorhinal cortex consists of eight layers (see Fig. 32.34B) which are quite distinct from those of the neocortex. Molecular layer 1 is nearly devoid of cell bodies. Layer 2 (pre-α) is a narrow cellular layer consisting of islands of densely packed large pyramidal and stellate cells. These islands are a hallmark feature of entorhinal cortex. They form small bumps (verrucae entorhinalis, previously called verrucae hippocampi) on the surface of the brain that can be seen by the naked eye or in magnetic resonance images, where they indicate the entorhinal cortex (Augustinack et al 2012). Notably, these verrucae disappear in Alzheimer's disease, and are signs of a general reduction of this area caused by the disease. Layer 3 (pre-β) consists of medium-sized pyramidal cells and continues into layer 4 (pre-γ) with a somewhat higher cell packing density. There is no internal granular layer; in its place, there is an acellular region of dense fibres called the lamina dissecans (a distinctive feature of entorhinal cortex), or layer 5. Layers 4 and 6 (pri-α) are apposed in regions where the lamina dissecans is less obvious. Layer 6 consists of large pyramidal cells five or six rows deep. Layer 7 (pri-β) is a cell sparse cleft and only distinguishable from layer 6 close to the border with the perirhinal cortex. Layer 8 (pri-γ) consists of large cells that are relatively densely packed and continue around the angular bundle (subcortical white matter deep to the subicular complex made up largely of perforant path axons) to lie beneath the pre- and parasubiculum.

The entorhinal cortex has reciprocal connections with the hippocampus and numerous neocortical regions. It receives afferents from many areas, including other areas of the parahippocampal gyrus and dorsal bank of the anterior portion of the superior temporal gyrus, as well as from the perirhinal (BA35), temporal polar, agranular insular, posterior orbitofrontal, dorsolateral prefrontal (BA9, BA10, BA46), medial frontal (BA25, BA32), cingulate (BA23, BA24) and retrosplenial cortices. It projects to the perirhinal and temporal polar cortices and the caudal parahippocampal and cingulate gyri. Evidence from clinical and experimental animal studies suggests that the reduction of the entorhinal cortex plays an important role in Alzheimer's disease because it is involved in the frontotemporal cortical memory network.

Septum

The septum is a midline and paramedian structure. It is listed here as part of the periarchicortex, which is much more differentiated in lower primates and insectivores: comparative neuroanatomical studies argue for this classification (Stephan 1975). The septum must not be confused with the septum pellucidum, which separates the lateral ventricles. The septal complex is composed of different nuclei (**Fig. 32.43**). Four main groups, dorsal, ventral, medial and caudal, have been identified. The dorsal group is the dorsal septal nucleus, the ventral group consists of the lateral septal nucleus, the medial group encompasses the medial septal nucleus and the vertical part of the diagonal band of Broca and the caudal group contains the fimbrial and triangular septal nuclei.

The major input to the septum terminates primarily in the lateral septal nuclei. It includes fibres of the fornix that arise from CA3 and CA1, the subiculum and afferent fibres arising from the preoptic area, anterior, paraventricular and ventromedial hypothalamic nuclei, and the lateral hypothalamic area. The lateral septum also receives a rich monoaminergic innervation, including a noradrenergic input from the locus coeruleus and the medullary cell groups (A1, A2), a serotoninergic input from the midbrain raphe nuclei, and a dopaminergic input from the ventral tegmental area (A10).

The output of the lateral septum reaches the medial and lateral preoptic areas, anterior hypothalamus, supramammillary and midbrain ventral tegmental area via the medial forebrain bundle, and the medial habenular nucleus and midline thalamic nuclei via the stria medullaris thalami. Efferent fibres from the medial septal and vertical limb nuclei of the diagonal band travel dorsally via the fornix, fimbria, striae longitudinales, and ventrally via the amygdaloid complex. While these projections reach all hippocampal fields, the most prominent terminations are in the dentate gyrus, CA3, presubiculum, parasubiculum and entorhinal cortex. Many are GABAergic or cholinergic.

Retrosplenial region

The retrosplenial region consists of the periarchicortical areas B26, BA29 and BA30. In the human brain, most of this small region is hidden in the callosal sulcus behind the splenium. Only a part of area 30 reaches the medial surface of the hemispheres on the posterior cingulate sulcus (**Fig. 32.44**; see Fig. 32.13). The retrosplenial cortex is implicated in working and long-term memory and visuospatial functions. This region is part of a network that mediates topokinetic navigation and memory, i.e. the retrosplenial cortex is activated when memory for previously learned routes is required for movement in space.

Area 26 and the posterior part of area 33 are located in the callosal sulcus. Area 26 extends rostrally above the splenium and reaches the level of the midcingulate cortex. Both areas have a poorly differentiated cortical structure with an external granular layer and almost no deep pyramidal layers. Area 29 follows area 26 medially and can be divided into medial and lateral subfields. It is characterized by a second layer of densely packed small neurones that look like granular cells, below the molecular layer, particularly at its rostral levels (granular retrosplenial cortex). Pyramidal and multiform layers follow. The stream of gradually increasing laminar differentiation (see Fig. 32.44L) from the poorly laminated area 33 to area 26, followed by area 29, is continued

Glutamate is the major excitatory transmitter of the hippocampal pyramidal cells and of their connections, namely, the perforant pathway that arises in the entorhinal cortex and terminates in the dentate gyrus and the CA1 region; mossy fibres that run from the dentate granule cells to the pyramidal cells of the CA3 field; and Schaffer collaterals that arise as axonal collaterals of CA3 pyramidal cells and terminate on CA1 pyramidal cells. In addition to the principal pyramidal neurones, various inhibitory, mostly GABAergic, interneurones are found in the CA regions and the fascia dentata. They often co-localize CCK, SOM, VIP and other neuropeptides. For example, the axon terminals of GABAergic chandelier cells in the granule cell layer of the fascia dentata and the pyramidal layer of the CA region end on proximal axonal segments of pyramidal cells. GABAergic basket cells are found mainly in the granule cell layer of the dentate gyrus, but also in the hilar region. Both cell types receive local, commissural and entorhinal afferents. Basket cells are present in the pyramidal and oriens layers of the CA region, and occasionally in the stratum radiatum-lacunosum-moleculare. Most of the neocortical interneurones are also found in the hippocampal formation (for details see Freund and Buzsáki 1996).

There are many peptide-containing neurones in the hippocampal formation. Granule cells in the dentate gyrus contain the opioid peptide dynorphin, which is also present in mossy fibres. Enkephalin, or a related peptide, may be present in fibres arising in the entorhinal cortex. There is a dense plexus of somatostatin-immunoreactive fibres in the molecular layer of the fascia dentata and in the stratum lacunosum-moleculare of the CA regions. Somatostatin-immunoreactive interneurones are found in the multiform layer of the fascia dentata, the stratum oriens of the CA regions, and the deep layers of the entorhinal cortex. VIP-immunoreactive interneurones are numerous in many hippocampal fields. CCK-immunoreactive cells are found in the hilar region of the dentate gyrus, in all strata of the CA regions, particularly in the pyramidal cell layer, and also throughout the subicular complex and entorhinal cortex. There are substantial plexuses of CCK-immunoreactive fibres in the stratum lacunosum-moleculare, and the subiculum. CCK-immunoreactive cells may give rise to extrinsic projections, e.g. to the lateral septum and medial mammillary nucleus, because CCK-immunoreactive fibres are found in the fimbria/fornix.

The medial septal complex and the supramammillary area of the posterior hypothalamus are two major sources of subcortical afferents to the hippocampal formation. There are also projections from the amygdaloid complex and claustrum (to the subicular complex and entorhinal cortex), as well as monoaminergic projections from the ventral tegmental area, the mesencephalic raphe nuclei and the locus coeruleus. Noradrenergic and serotoninergic projections reach all hippocampal fields. Neurones in the supramammillary area project to the hippocampal formation via the fornix and terminate most heavily in the dentate gyrus and fields CA2 and CA3 of the cornu Ammonis. All divisions of the anterior thalamic nuclear complex and associated lateral dorsal nucleus project to the hippocampal formation, predominantly to the subicular complex. Some midline thalamic nuclei, particularly the parataenial, central medial and reuniens nuclei, project especially to the entorhinal cortex.

The highest density of glutamate AMPA receptors are found in the molecular and pyramidal strata of the hippocampus proper and the prosubiculum (**Fig. 32.42A**). NMDA receptors are mainly concentrated in the pyramidal layer of CA1 and the prosubiculum, as well as in the molecular layer and hilus of the dentate gyrus (**Fig. 32.42B**). Kainate receptors show a particular distribution pattern: they are very densely packed in the stratum lucidum of CA3 and the hilus (**Fig. 32.42C**). The highest concentration of $GABA_A$ receptors is found in the molecular layer of the fascia dentata and the pyramidal layer of the CA regions (**Fig. 32.42D**). In the human hippocampus, about 60% of the cholinergic muscarinic receptors are of the M_1, 20% of the M_2, 15% of the M_4 and roughly 5% of the M_3 subtypes. M_1 receptors are widely distributed within the hippocampus (**Fig. 32.42E**) and expressed in somata and dendrites of pyramidal and granule cells: they show a similar distribution to that of the AMPA receptors and are mainly responsible for the modulation of pyramidal cell excitability. The M_2 receptor is restricted to interneurones. M_4 receptors are mainly located in glutamatergic terminals and mediate cholinergic presynaptic inhibition of Schaffer collaterals. The predominant cholinergic nicotinic receptor (nAChR) subtype in the CA and dentate gyrus (DG) is the homomeric α_7 receptor; there are also heteromeric $\alpha_4\beta_2$ and $\alpha_3\beta_4$ receptor subtypes. nAChRs are found in granular cells of the dentate gyrus and pyramidal cells of the CA regions: in CA3, they can enhance the release of glutamate from mossy fibres via activation of protein kinase A. An impaired cholinergic function is a characteristic marker of Alzheimer's disease. These alterations not only pertain to concentrations of the neurotransmitter; cholinergic nicotinic receptors of granule cells of the dentate gyrus, presubiculum and parahippocampal gyrus are also reduced by 30% in Azheimer's patients relative to age-matched control subjects. The noradrenergic α_1 receptors are highly concentrated in all layers of the dentate gyrus and in the stratum lucidum (**Fig. 32.42F**). The α_2-adrenoceptors display a highly restricted maximal density in the radiatum-lacunosum layer of CA1 (**Fig. 32.42G**). β-adrenergic receptors are expressed by hippocampal neurones and play important roles in gating long term depression (LTD). Their density is higher in the fascia dentata than in the CA regions. The serotoninergic $5\text{-}HT_{1A}$ receptor, which hyperpolarizes CA1 and CA3 pyramidal cells, is most densely distributed in the pyramidal and lacunosum strata of CA1 (**Fig. 32.42H**): the hyperpolarizing effects parallel the depolarizing effects induced by $5\text{-}HT_{2A}$ receptors. The $5\text{-}HT_3$ receptor is present at high densities in interneurones of the lacunosum-molecular layer of the CA1 region, as well as in entorhinal, piriform and cingulate areas. The $5\text{-}HT_4$ receptor occurs at highest levels in the hippocampus and potentiates the excitation on dendrites of CA1 pyramidal cells in the stratum radiatum by stimulating Schaffer collaterals. The density of post synaptic excitatory $5\text{-}HT_7$ receptors is highest in the hippocampus and anterior cingulate cortex, increasing the excitability of CA3 pyramidal cells and suppressing the perforant path input to CA1 pyramidal cells. Dopamine D_1/D_5 receptors support long-lasting and learning-related forms of synaptic plasticity at the mossy fibre synapses in CA3 and provide evidence for a neuromodulatory role of this receptor in experience-dependent synaptic encoding in the hippocampal subfield CA3.

The regional and laminar distribution of transmitter receptors in the retrosplenial cortex is inhomogeneous and supports its cytoarchitectonic parcellation (see Fig. 32.44A–J). The densities (averaged over all cortical layers) of glutamate AMPA, kainate and to a lesser degree, of NMDA receptors as well as those of the noradrenergic α_1 and α_2 receptors, increase from area 26 to area 23 of the posterior cingulate cortex and thus parallel the direction of cytoarchitectonic differentiation. The densities of $GABA_A$ and $GABA_B$ receptors in the deeper layers of retrosplenial areas 29 and 30 are lower than those in area 23. The distribution of $GABA_B$ receptors also confirms the subdivision of area 29 into lateral 29l and medial 29m parts: $GABA_A$ receptor densities are lower in the upper layers of the lateral part than they are in the medial subdivision. Area 30 has the highest M_3 receptor densities of the cingulate cortex. Area 29 contains higher densities of muscarinic M_1 and nicotinic $\alpha_4\beta_2$ receptors than area 30. The concentration of $5\text{-}HT_{1A}$ receptors is slightly higher in area 29 than in area 30.

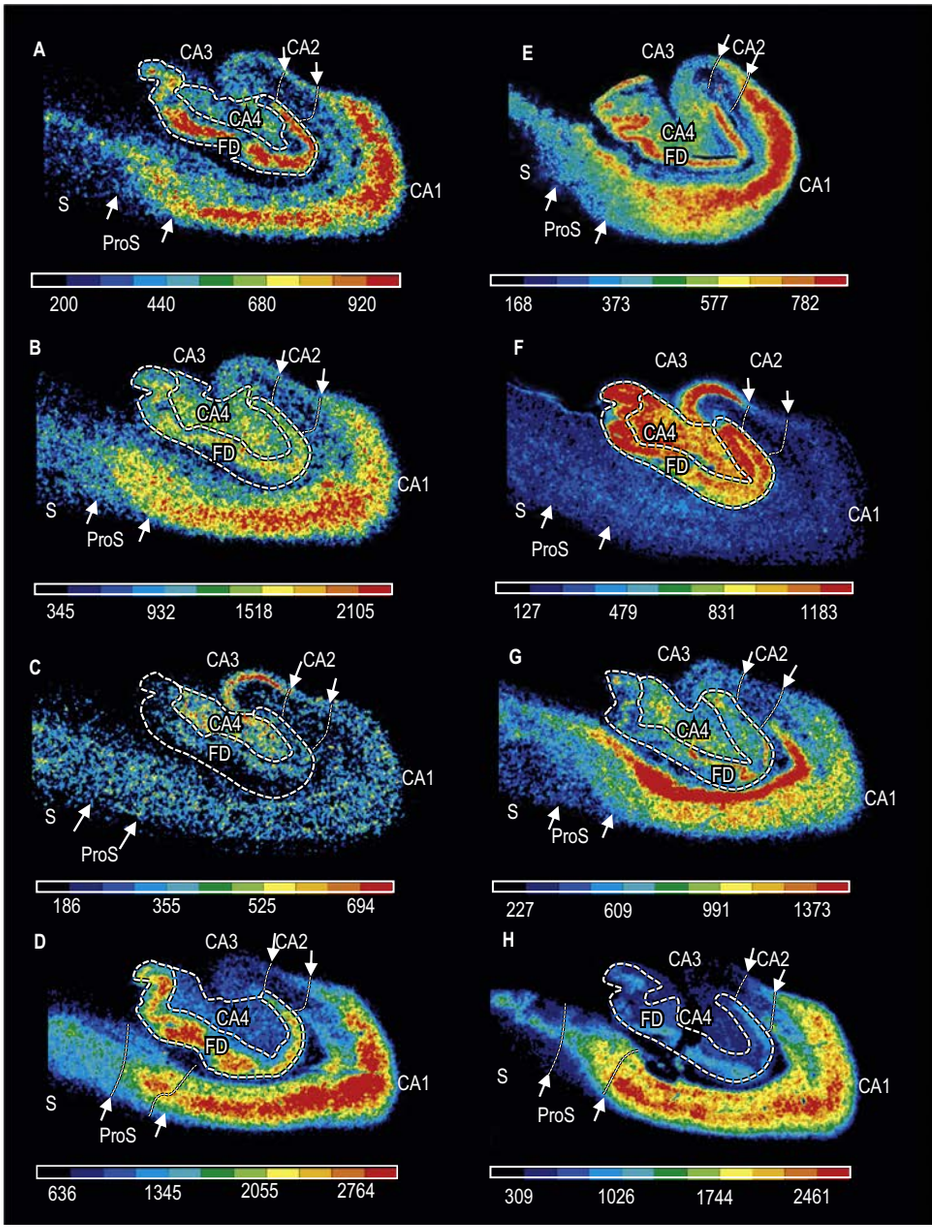

Fig. 32.42 The distribution of transmitter receptors in the human hippocampus. **A**, Glutamate AMPA receptor; **B**, glutamate NMDA receptor; **C**, glutamate kainate receptor; **D**, $GABA_A$ receptor; **E**, acetylcholine muscarinic M_1 receptor; **F**, noradrenaline α_1 receptor; **G**, noradrenaline α_2 receptor; **H**, serotonin 5-HT_{1A} receptor. Abbreviations: CA1–CA4, regions of cornu Ammonis FD, fascia dentata; ProS, prosubiculum; S, subiculum. Arrows and dashed lines label boundaries of hippocampal subdivisions. Colour scales indicate densities of receptors in fmol/mg protein.

Copyright 2012.)

medially in area 30. This latter area shows a more differentiated laminar pattern with molecular (I), outer granular (II) and pyramidal (III) layers, followed by an inconspicous and fragmented inner granular layer (IV), an inner pyramidal (V) and a multiform (VI) layer. Because the inner granular layer is barely visible, area 30 is often designated as agranular retrosplenial cortex.

Cingulate cortex

Within the inner aspect of the medial surface of each cerebral hemisphere, the cingulate gyrus wraps around the corpus callosum. Lying above the callosal sulcus and below the cingulate sulcus, the cingulate gyrus starts anteriorly within the subcallosal area below the rostrum of the corpus callosum and ascends around the genu of the corpus callosum. It borders the medial aspect of the superior frontal gyrus, the paracentral lobule, and more posteriorly the precuneus and the anterior cuneus. Anteriorly and basally, the cingulate sulcus may be continuous with the anterior para-olfactory sulcus under the rostrum of the corpus callosum and the subcallosal gyri. It may be double and parallel, the additional superior sulcus being the paracingulate sulcus. Architectonically, the cingulate cortex is a transition region between allocortex and isocortex and therefore includes periarchi-, proiso- and isocortical areas organized into four major divisions.

The original Brodmann's (1909) division of the cingulate cortex into anterior (BA24, BA25, BA32, BA33) and posterior (BA23 and BA31) regions has been replaced by a four region model that encompasses the anterior cingulate, midcingulate, posterior cingulate and retrosplenial cortices (**Fig. 32.45**) (Palomero-Gallagher et al 2009). These regions can be further subdivided using a multimodal approach informed by cyto- and receptor-architectonical, connectional and functional analyses.

The anterior cingulate cortex includes subgenual (areas 25, s24, s32, 33) and pregenual areas (p24, p32). The periarchicortical areas 25 and 33 display a laminar differentiation that is reduced compared to pro-isocortical agranular areas s24 and p24, and dysgranular isocortical areas s32 and p32 (see Fig. 32.45). Area 33 has the least differentiated lamination, whereas areas s32 and p32 are the most evolved and five layers can be recognized. Layers II–III as well as V–VI cannot be separated from each other in some of the anterior cingulate cortex areas, particularly in area 33.

Area 25 is of particular interest because of its projections to autonomic brainstem nuclei and its role in the regulation of visceromotor functions.

The most rostral portion of area 24 in the cingulate sulcus (subfield 24c) contains the face region of the rostral cingulate premotor area (Morecraft et al 2007). Von Economo and Koskinas (1929) first described a unique neuronal type, the spindle cell of Von Economo, in the anterior cingulate cortex (ACC), anterior insula and orbitofrontal cortices. These neurones have fusiform somata and vertically orientated cell processes and occur mainly in layer V (Nimchinsky et al 1995).

The midcingulate cortex (MCC) is divided into anterior (a24′, 24c′ and 32′) and posterior (p24′ and 24d) parts (see Fig. 32.45). Response selection, including the possibility of generating coordinated and context-dependent movements, is a characteristic function of the midcingulate cortex. Gyral and intrasulcal portions of midcingulate cortex differ in their cytoarchitecture, for example, layer V of the intrasulcal areas contain large pyramidal cells. The gyral cortex of the midcingulate cortex is thicker and has much broader layers than its intrasulcal part. Area 24c′ and ACC area p24c contain large pyramidal cells that represent the functionally defined rostral cingulate premotor area (see Fig. 32.45; Vogt 2016). In area 24d, the gigantopyramidal field of Braak (Braak 1976) contains extremely large pyramidal cells resembling Betz cells. The intrasulcal areas 24d and 23c of the posterior cingulate cortex (PCC) represent the functionally defined caudal cingulate premotor area (see Fig. 32.45; Vogt 2016). The latency of the onset of movements in the caudal cingulate premotor area, which codes for direction, force, target acquisition and orienting movements in space, is shorter than

The layer below lamina I (molecular layer) is broad and fused with layer III and contains scattered aggregations of evenly distributed pyramidal cells. Anterior and posterior divisions of area 25 have been described (Palomero-Gallagher et al 2008). There are cytoarchitectonic differences between the subgenual and pregenual components of area 24 as follows: layer II of area s24 is thinner and less cell dense than that of p24, and the neurones form aggregates only in s24; layer III of area s24 contains pyramidal cells that are larger in its upper than its lower portion, and it is thinner than in p24a; layer V is thinner in area s24 than p24, and layer VI is thinner and more cell sparse in area s24 than in p24.

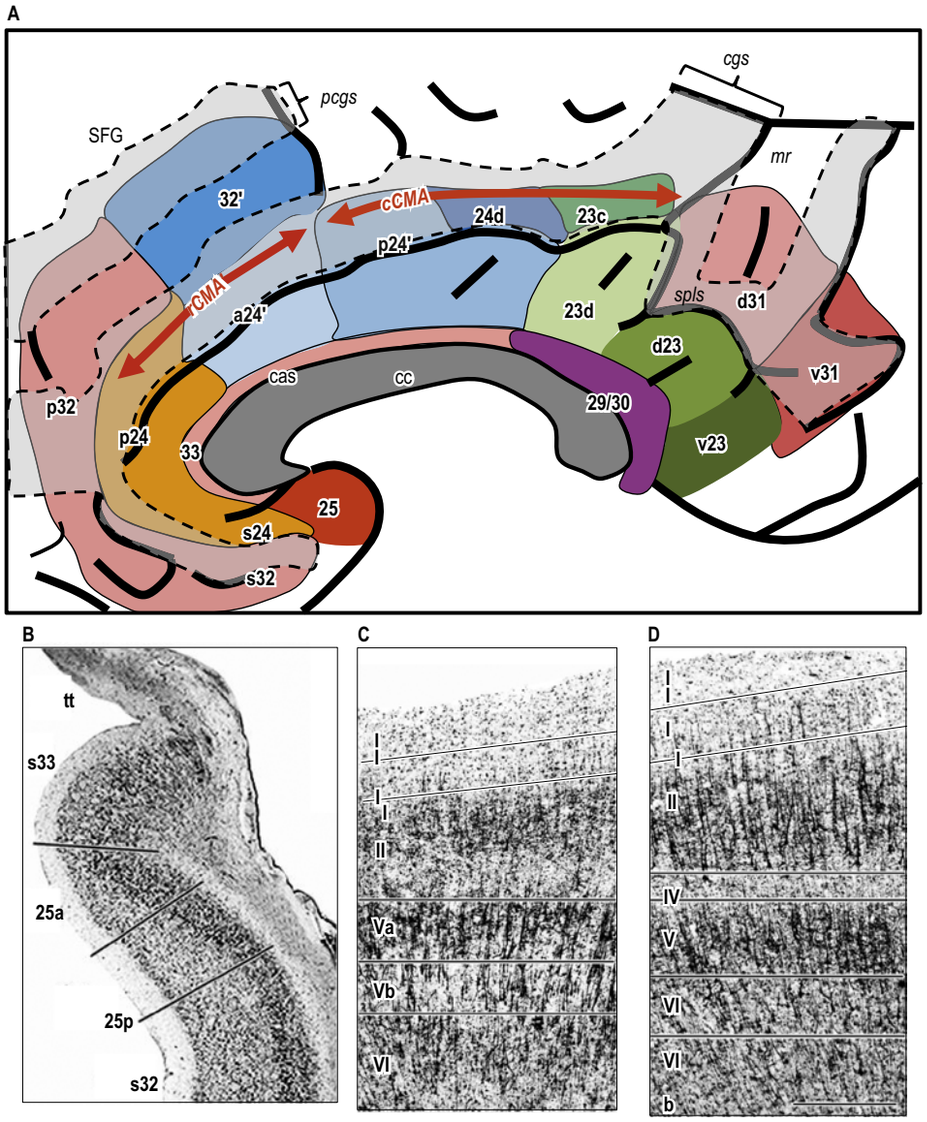

Fig. 32.45 The cytoarchitecture of anterior cingulate areas. **A**, The anterior cingulate cortex comprises areas s24, p24, 25, p32, s32, and the most anterior portion of area 33. The midcingulate cortex encompasses areas a24′, p24′, 24d, 32′ and the underlying portion of area 33. The posterior cingulate cortex contains areas 23c, 23d, d23, v23, d31 and v31. The retrosplenial region is represented by areas 29 and 30. Abbreviations: cas, callosal sulcus; cc, corpus callosum; cCMA, caudal cingulate premotor area; cgs, intrasulcal part of the cortex in the cingulate sulcus; mr, marginal ramus of the cingulate sulcus; pcgs, intrasulcal part of the cortex in the paracingulate sulcus; rCMA, rostral cingulate premotor area; SFG, superior frontal gyrus; spls, splenial sulcus. **B**, Coronal section through areas tt (taenia tecti), s33, anterior part of area 25 (25a), posterior part of area 25 (25p), subgenual part of area 32 (s32). Cell body stain. **C**, Laminar differentiation of area p24. SMI-32 ir stain. **D**, Laminar differentiation of area p32. SMI-32 ir stain. (A, Adapted with permission from Vogt BA, Palomero-Gallagher N Cingulate cortex. In: Mai JK, Paxinos G (eds) The Human Nervous System. Elsevier, Academic Press. Copyright 2012; D, adapted with permission from Palomero-Gallagher N, Mohlberg H, Zilles K et al 2008 Cytology and receptor architecture of human anterior cingulate cortex. J Comp Neurol 508:906–26.)

that of the rostral cingulate premotor area, which is involved in self-initiated movements. The characteristic gigantopyramidal cells of area 24d may indicate its involvement in skeletomotor functions. It mainly regulates the motor activity of the fore- and hindlimbs and that of the trunk. Isocortical area 32′ is also a transitional dysgranular region to the granular isocortical area BA9 and the premotor area 6aβ.

The posterior cingulate cortex consists of isocortical areas 23c, 23d, d23, v23, d31 and v31 (see Fig. 32.45). Area 23d is dysgranular and the remaining subdivisions of BA23 and BA31 are granular. An increasing packing density of granular cells in layer IV can be observed along a gradient from area 23d (low density) to areas v23 and 31 (high density).

The amygdala has reciprocal connections with the cingulate cortex that define the borders of emotion-specific cingulate areas. The basolateral and accessory basal nuclei of the amygdala are preferentially connected with area a24′ (part of the midcingulate region), which is specifically involved in emotion, emotional awareness and facial expressions associated with fear. In contrast, the posterior part of the midcingulate, the posterior cingulate and the retrosplenial cortices and retrosplenial cortices have no direct connections with the amygdala. Their involvement in emotion is related to selecting input from various sensory cortices (Vogt et al 2006). Areas BA25 and BA32, but not a24′ of the midcingulate cortex, are connected with autonomic regulatory nuclei of the brainstem: for example, they regulate gastric motility. These autonomic connections include major projections to the central nucleus of the amygdala, lateral hypothalamus, periaqueductal grey, and parabrachial nucleus. There are additional, though smaller, projections to the nucleus of the solitary tract and the dorsal motor nucleus of the vagus. BA25 also has reciprocal connections with the entorhinal cortex and the anterior cingulate area. Dense reciprocal connections between the posterior cingulate and inferior parietal cortices determine the posterior border of the anterior cingulate cortex (there are fewer connections with the midcingulate cortex and no connections with the anterior cingulate cortex). The cingulospinal projection system originates mainly in areas 24d (the gigantopyramidal caudal cingulate motor area (Braak 1976), which is buried in the cingulate sulcus) and a24′ of the midcingulate cortex, but not in areas 24, 25 or 32 of the anterior cingulate cortex (Dum and Strick 1991).

Chemoarchitecture of the cingulate cortex

Available with the *Gray's Anatomy* e-book

Isocortex

The isocortex and its parcellation into cortical areas will be separately described for each lobe in terms of its external sulci and gyri, internal cortical structure, connectivity and function. The subdivisions of the cerebral cortex as described in the different lobes is mainly based on the cytoarchitectonic parcellation schemes of Brodmann (1909) and von Economo and Koskinas (1925), and recent observer-independent cytoarchitectonic and multimodal parcellation methods (Schleicher et al 1999, Amunts et al 2007, 2014, Zilles and Amunts 2010, 2012, Amunts and Zilles 2015, Palomero-Gallagher et al 2015, Zilles et al 2015c, Palomero-Gallagher and Zilles 2018). Myeloarchitectonic findings will be included as appropriate (for review, see Zilles et al 2015a).

Frontal lobe

The frontal lobe contains numerous cortical areas for motor and cognitive functions, and is the largest lobe of the human forebrain. Its prefrontal cortex developed during the evolution of the brain to an absolute and relative size that is not attained by other primates.

NMDA receptors have the highest densities of the three ionotropic glutamate receptor subtypes in the cingulate cortex (Fig. 32.46). The balance between different glutamate receptor subtypes differs between the ACC and PCC. AMPA and kainate receptors have the second highest density in the ACC and PCC, respectively. They also present a rostrocaudal density gradient, the highest concentrations of both receptor types are in the ACC, and the lowest densities are in the PCC, suggesting that the ACC may work on a higher glutamatergic excitation level via AMPA and kainate receptors than MCC and PCC areas. Additionally, the ACC may be more susceptible to pathological processes that are characterized by increased glutamate levels and hyperexcitation. AMPA receptor densities are lower in area 25 than in the isocortical area 32. Conversely, the lowest NMDA receptor densities occur in the ACC, with the exception of area 25, which contains the highest NMDA receptor densities measured in the entire cingulate cortex. The lower kainate receptor density in s33 demarcates this area from s24. Area 24d, which projects to the spinal cord, contains very low kainate receptor densities. AMPA and NMDA receptors are characterized by higher concentrations in the supragranular than in the infragranular layers, whereas the opposite holds true for the kainate receptors.

The expression of GABA receptor subtypes varies along the rostrocaudal extension of the cingulate cortex. PCC shows higher densities of the inhibitory $GABA_A$ receptors and their benzodiazepine binding sites (BZ) than ACC and MCC. Very low levels of BZ densities occur in panic disorder and suggest a lower GABAergic inhibition of PCC under pathological conditions. PCC also contains higher $GABA_B$ receptor densities than MCC, from which is appears that PCC works on a higher GABAergic inhibition level than ACC and MCC: activation mediated by the glutamate receptors may be counterbalanced by fast inhibition via $GABA_A$ receptors in the PCC rather than in the ACC.

Choline acetyltransferase is synthesized by cholinergic neurones of the basal forebrain and is the most specific marker of cholinergic innervation. Axons of these neurones terminate throughout the cerebral cortex. Mapping of choline acetyltransferase reveals comparable densities of this enzyme in the ACC and PCC. Receptor analysis provides a more nuanced image. Lower nicotinic $\alpha_4\beta_2$, muscarinic M_1, M_2 and M_3 receptor densities are found in ACC than in PCC. This gradual increase in cholinergic receptors along the rostral-to-caudal extension of cingulate areas matches that of GABA receptors, and is the opposite of the observed decrease of the glutamate AMPA and kainate receptor densities. Thus, excitatory neurotransmission in the PCC is not only more strongly countered by GABA inhibition than in the ACC, but it is also subject to a stronger modulation via the cholinergic system. The densities of nicotinic $\alpha_4\beta_2$ receptors are lowest in the ACC and highest in the PCC and the retrosplenial cortex.

The α_1 adrenoceptor is the prevailing α receptor subtype in the cingulate cortex. The density of $5\text{-}HT_{1A}$ receptors is highest in area 25, and it is the prevailing serotonin receptor subtype in ACC. The proiso- and isocortical cingulate areas 23, 24, 31 and 32 contain higher $5\text{-}HT_{1A}$ receptor densities than the periallocortical areas. The $5\text{-}HT_2$ receptor shows higher densities in the PCC than in the ACC.

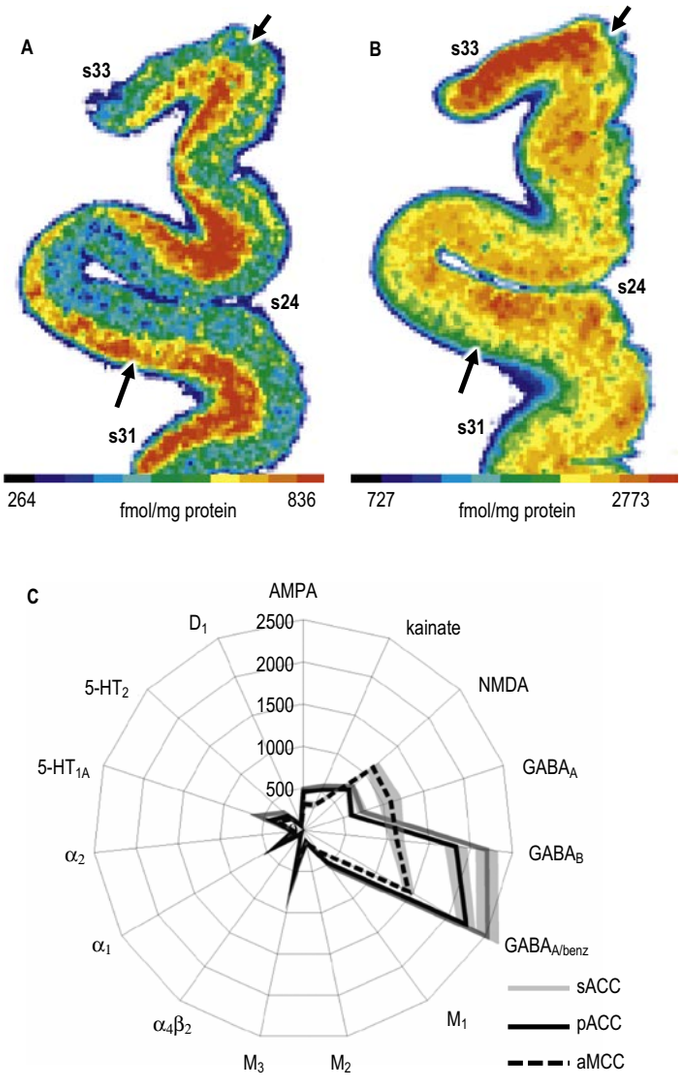

Fig. 32.46 Transmitter receptors in the human cingulate cortex. Coronal sections showing colour-coded regional and laminar densities of various receptors. **A**, Kainate receptors in areas of ACC. **B**, $GABA_B$ receptors in areas of ACC. **C**, Receptor fingerprint (glutamate: AMPA, kainate, NMDA subtypes; GABA: $GABA_A$, $GABA_B$ subtypes and $GABA_A$ benzodiazepine binding site; acetylcholine: muscarinic M_1, M_2, M_3 subtypes and nicotinic $\alpha_4\beta_2$ subtype; noradrenaline: α_1 and α_2 subtypes; serotonin: $5\text{-}HT_{1A}$ and $5\text{-}HT_2$ subtypes; dopamine: D1 subtype) of the entire anterior cingulate cortex. Densities correspond to the average of each receptor over all areas for a given region. sACC encompasses areas 25a, 25p, s33, s24a, s24b, and s32; pACC includes areas p33, p24a, p24b, pv24c, pd24c; aMCC encompasses areas 33, a24a′, a24b′, a24c′ and 32′. Receptor densities range from 0 to 2500 fmol/mg protein. (Adapted with permission from Palomero-Gallagher N, Mohlberg H, Zilles K et al 2008 Cytology and receptor architecture of human anterior cingulate cortex. J Comp Neurol 508:906–26.)

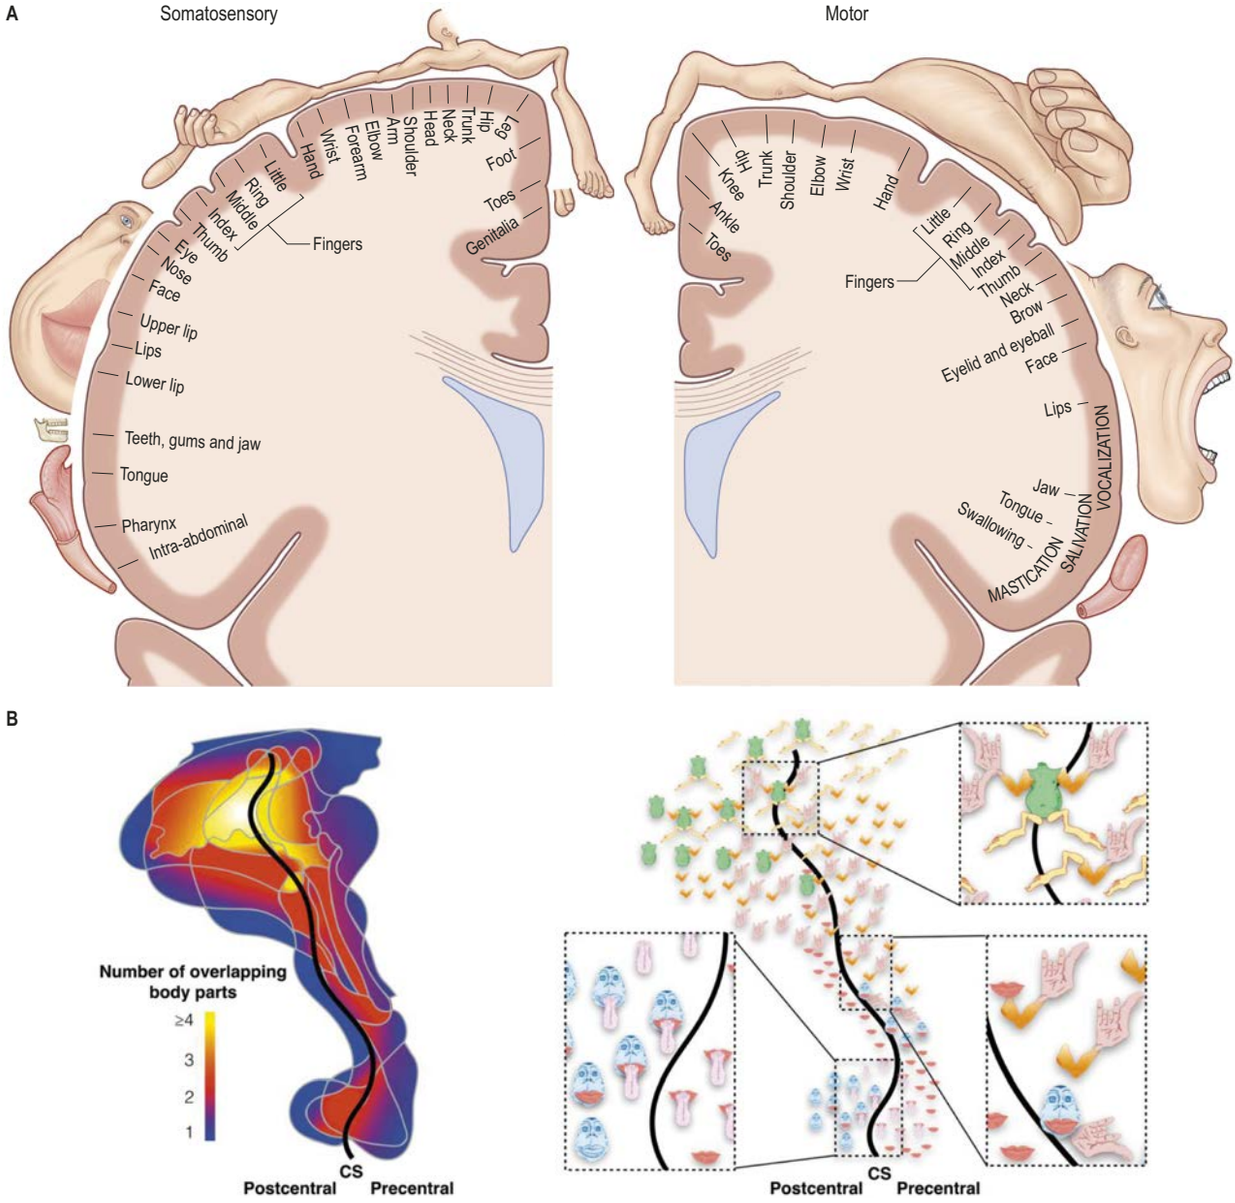

Fig. 32.49 The homunculus in the human brain. **A**, Diagram of the somatosensory (left) and motor (right) homunculi of the postcentral and precentral gyri, respectively. The homunuclus was originally created by Penfield and Boldrey (1937) to indicate two fundamental aspects of the organization of the pericentral cortex: the topographical order of body part representations and their altered proportions, reflecting the amount of cortex dedicated to a particular function. **B**, A modern appraisal of the homunculus indicates an overlap between different body parts. Left: Heat map of the degree of overlap ranging from blue (one body part) to yellow (four or more body parts). Right: Map indicating the overlapping body parts of the homunculus. Note that the overlap is between body parts that cooperate for specific functions, such as neurones of the central area that control the mouth, arm and hand for feeding. Abbreviation: CS, central sulcus. (B, Adapted with permission from Catani M 2017 A little man of some importance. Brain 140:3055–61.)

The frontal lobe is delimited posteriorly by the central sulcus, medially by the cingulate sulcus and inferolaterally by the lateral fissure. The precentral gyrus is delimited by the central sulcus posteriorly and the precentral sulcus anteriorly. Anterior to the precentral gyrus the superior, middle and inferior frontal gyri converge anteriorly where they form the frontal pole. Its dorsal surface is covered by the frontal bone, and its ventral surface lies over the orbital part of the frontal bone and the cribriform plate of the ethmoid bone, and displays the orbital and rectus gyri. Its medial surface faces the falx cerebri.

The frontal lobe contains the primary motor area (BA4) in the anterior wall of the central sulcus; the supplementary motor area (SMA) and pre-supplementary motor area (pre-SMA) on its dorsomedial surface (medial part of BA6); premotor areas (lateral part of BA6) on its dorsolateral surface; the medial prefrontal (BA32) and lateral prefrontal (BA8–BA10 and BA44–BA47) cortex rostral to the precentral gyrus; and the fronto-orbital region (BA11–BA12) on its baso-rostral surface (see Fig. 32.13).

Frontal lobe sulci and gyri

Available with the *Gray's Anatomy* e-book

Frontal lobe internal structure and connectivity

The primary motor cortex (BA4) corresponds to a largely intrasulcal part of the precentral gyrus and is visible on the cortical surface only at its most superior level. BA4 has the lowest threshold for eliciting contralateral muscle contraction by electrical stimulation. It contains a topographically organized map ('motor homunculus') of the opposite body half, where the head is represented most laterally and inferiorly, the hand is represented in the central region, and the leg and foot are represented on the medial surface of the hemisphere in the paracentral lobule (Fig. 32.49). A striking feature of this map is the disproportionate representation of body parts in relation to their physical size: large areas represent the muscles of the face and hand, which are capable of finely controlled or fractionated movements (Penfield and Boldrey 1937; for a recent review of the homunculus, see Catani 2017).

In the adult stage, layer IV of BA4 and BA6 is difficult to identify in Nissl-stained sections (Fig. 32.50A), and both areas were traditionally classified as agranular cortex. A distinct inner granular layer IV is visible in fetal brains, but disappears during the first year of life (Amunts et al 1995). The typical small cells of layer IV have been demonstrated at the

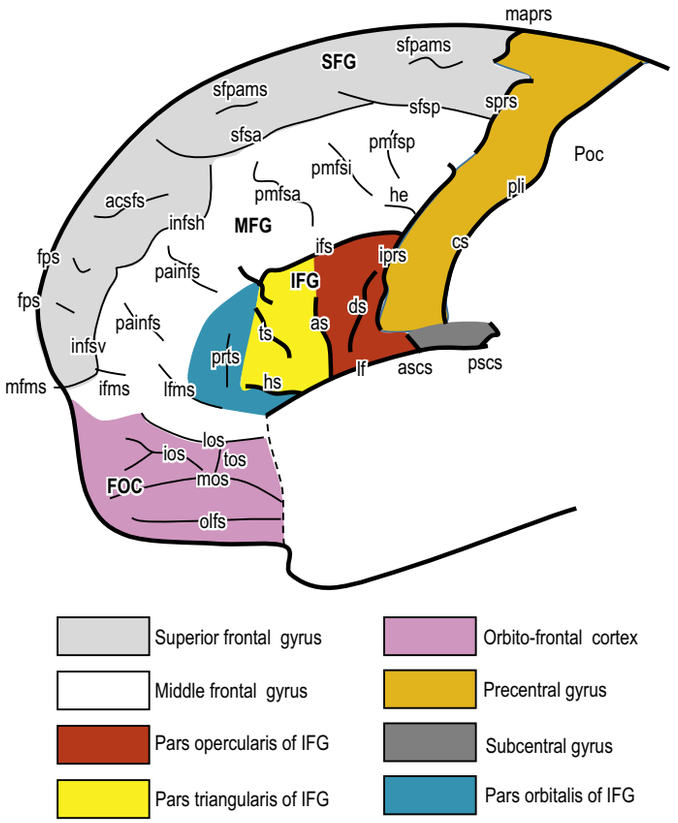

Fig. 32.47 Sulcal and gyral patterns of the frontal lobe. (Adapted with permission from Petrides M, Pandya DN 2012 The frontal cortex. In: Mai JK, Paxinos G (eds) The Human Nervous System. Elsevier, Academic Press. Copyright 2010.)

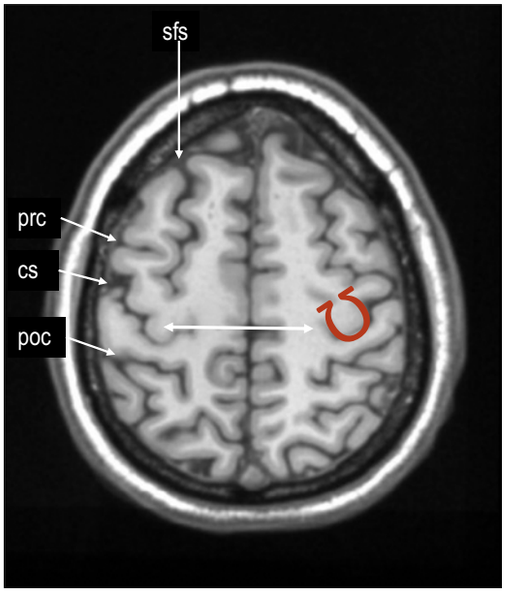

Fig. 32.48 Representation of the hand in the precentral gyrus. Abbreviations: cs, central sulcus; poc, postcentral sulcus; prc, precentral sulcus; sfs, superior frontal sulcus. Ω, hand-knob of the precentral gyrus. (Adapted with permission from Yousry TA, Schmid UD, Alkadhi H et al 1997 Localization of the motor hand area to a knob on the precentral gyrus: a new landmark. Brain 120:141–57.)

The central sulcus demarcates the primary motor (BA4) and somatosensory (BA1–BA3) cortical areas located in the precentral and postcentral gyri, respectively. The central sulcus starts in or near the interhemispheric fissure, a little behind the midpoint between the frontal and occipital poles, and runs in a letter S shape ventrally and rostrally, to end usually shortly above the lateral sulcus: it is mostly continuous in both hemispheres (**Fig. 32.47**).

The precentral gyrus lies over the dorsolateral and lateral surface of the cerebral hemisphere, its upper aspect extending onto the medial surface. It is continuous medially and inferiorly with the postcentral gyrus along connections that encircle both extremities of the central sulcus. The inferior connection corresponds to the subcentral gyrus, delineated anteriorly and posteriorly by the anterior and posterior subcentral rami of the lateral fissure. They can be situated either completely over the lateral fissure, or in part internal to the fissure. The superior connection corresponds to the paracentral lobule that is located on the medial surface of the hemisphere inside the interhemispheric fissure, and delineated anteriorly by the paracentral sulcus and posteriorly by the ascending marginal ramus of the cingulate sulcus. Some brains show a middle connection between the pre- and postcentral gyri (*pli de passage moyen* of Broca), which is usually hidden within the central sulcus: when this middle connection reaches the brain surface, it interrupts the central sulcus. The motor hand area has been localized by fMRI to an Ω-like protrusion of the precentral gyrus directed to the postcentral gyrus (**Fig. 32.48**) that is found at the level of the middle genu of the central sulcus (Yousry et al 1997). The precentral gyrus is delimited anteriorly by the precentral sulcus, itself divided into superior and inferior precentral sulci by a connection between the middle frontal gyrus and the precentral gyrus. The superior part of the precentral sulcus is very often interrupted superiorly by a connection between the superior frontal and precentral gyri, producing a more medial segment, the medial precentral sulcus. More dorsally, within the precentral region, the marginal precentral sulcus (see Fig. 32.47) may merge with the superior precentral or central sulci.

The superior frontal gyrus is continuous anteriorly and inferiorly with the rectus gyrus, and may also be connected to the orbital gyri and the middle frontal gyrus. Posteriorly, it is connected to the precentral gyrus (see Fig. 32.47). Usually the superior frontal gyrus is subdivided by an intermediate frontal sulcus into a lateral and a medial portion. The middle frontal gyrus is usually the largest of the frontal gyri, and is frequently connected posteriorly to the precentral gyrus. It harbours a complex of multiple shallow sulcal segments known collectively as the middle or intermediate frontal sulcus (Petrides and Pandya 2012).

The inferior frontal gyrus is subdivided by small sulci into a posterior pars opercularis, an intermediate pars triangularis and an anterior pars orbitalis (see Fig. 32.47). The opercular part is rostrally bordered by the ascending ramus of the lateral fissure, and posteriorly by the precentral sulcus. A diagonal sulcus is occasionally visible in the pars triangularis. The triangular part extends between the ascending and horizontal rami of the lateral fissure, and continues with the lateral orbital part. The frontomarginal sulcus is often a short branching sulcus that separates the frontal pole into different portions.

The olfactory sulcus lies longitudinally in a paramedian position on the frontobasal (orbital) surface of the frontal lobe (see Fig. 32.47). It underlies the olfactory tract and bulb. Posteriorly, the olfactory tract is divided into medial and lateral striae that delineate the most anterior aspect of the anterior perforated substance. The narrow gyrus rectus, medial to the olfactory sulcus, is considered to be the most anatomically constant of the cerebral gyri. The orbital gyri, lateral to the olfactory sulcus, account for the greatest proportion of the frontobasal region. The orbital gyri are delineated by the lateral, medial and transverse orbital sulci that together form a characteristic H shape. The posterior orbital gyrus lies anterior to the anterior perforated substance and typically presents a configuration similar to a tricorn hat, a feature that may facilitate its identification in anatomical specimens where the H-shaped orbital sulcus is less obvious.

On its medial surface, the frontal lobe is limited inferiorly by the cingulate sulcus, which starts within the subcallosal region and extends over the cingulate gyrus. The cingulate sulcus may occasionally be

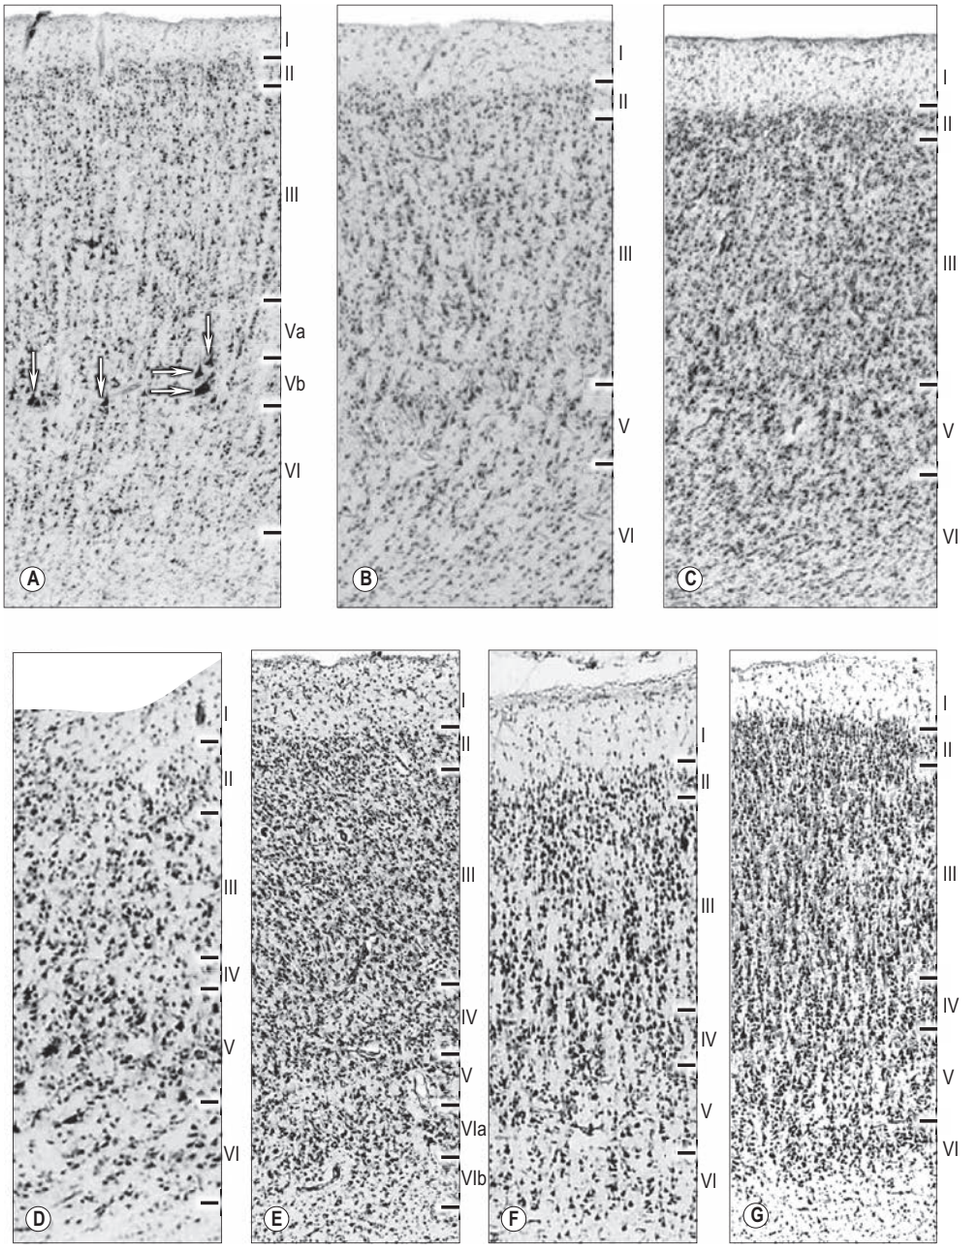

Fig. 32.50 A–C, Nissl stained sections through the human motor and somatosensory cortex. **A**, Primary motor cortex (BA4); arrows indicate Betz cells in layer Vb. **B**, Premotor cortex, area PMdc (dorso-caudal part of BA6). **C**, Premotor cortex, area PMdr (dorso-rostral part of BA6). **D–G**, Nissl staining of the human anterior parietal cortex. **D**, Area 3a (transition area between the primary motor and primary somatosensory cortex). **E**, Primary somatosensory cortex (area 3b). **F**, Primary somatosensory area 1 (BA1), and **G** primary somatosensory area 2 (BA2).

double in its anterior portion, when the more rostrally and dorsally situated sulcus is called the paracingulate sulcus (see Fig. 32.2).

The paracentral lobule contains the distal part of the central sulcus and, inferior to it, the paracentral fossa (see Fig. 32.2). The gyrus rectus is bounded superiorly by the superior rostral sulcus and accommodates the shallower inferior rostral sulcus along its medial surface.

border region between layers III and V in the adult stage (Barbas and Garcia-Cabezas 2015). The most characteristic feature of BA4 are the somata of extremely large pyramidal cells (Betz cells) in lamina V (**Fig. 32.50**). These cells are 80–100 μm in diameter, and their axons form the corticospinal and corticonuclear tracts. BA4 contains a very high density of myelinated axons in the lower half of its cortical depth. It also has the lowest concentration of most transmitter receptor types across all cortical areas (**Fig. 32.51**), presumably because most receptors are found pre- and post-synaptically and myelin sheaths prevent the building of synapses.

The major thalamic connections of BA4 are with the posterior part of the ventral lateral nucleus, which receives afferents from the deep cerebellar nuclei and contains a topographic representation of the contralateral half of the body that is preserved in its projection to BA4. The anterior part of the ventral lateral nucleus projects to the premotor and supplementary motor areas of the cortex. Other thalamic connections of BA4 are with the centromedian and parafascicular thalamic nuclei. Apart from the corticospinal tract and thalamic projections, the motor cortex has extensive subcortical connections with the striatum, subthalamic nucleus, pontine nuclei and all the somatomotor nuclei in the brainstem (oculogyric, facial and hypoglossal nuclei).

BA4 is the origin of polysynaptic descending pathways to the spinal cord that relay in the reticular formation, red nucleus, superior colliculus, vestibular nuclei and inferior olivary nucleus. BA4 is also connected with the ipsilateral somatosensory cortex through short U-fibres, which are topographically organized according to the homuncular principle, i.e. the largest projections are observed for the hand and there are progressively smaller projections for the tongue/mouth and foot areas (Catani et al 2012). These projections to the motor cortex arise mainly in BA1 and BA2, with minor contribution from area 3b. Fibres from the somatosensory cortex terminate in layers II and III of BA4: neurones in the motor cortex that can be activated from the somatosensory cortex tend to have a late onset of activity, mainly during the execution of movement. Connections between motor and somatosensory homunculi may play a role in precision grasping and motor learning. Additional ipsilateral corticocortical fibres to BA4 posterior to the central sulcus come from the opercular part of the somatosensory area (SII). Neurones in BA4 are responsive to peripheral stimuli and have receptive fields similar to those in the primary somatosensory cortex. Cells located posteriorly in the motor cortex (area 4p) have cutaneous receptive fields, whereas more anteriorly situated neurones (in area 4a) respond to stimulation of deeper tissues (Geyer et al 1996).

The motor cortex receives inputs from the lateral premotor cortex, supplementary motor area and insula. Most of these connections are short U-shapes that modulate motor cortical activity in relation to the preparation, guidance and temporal organization of movements. BA4 sends fibres to, and receives fibres from, its contralateral counterpart, and also projects to the contralateral supplementary motor cortex.

Brodmann's 'agranular' area 6 (see Fig. 32.13) lies immediately in front of the primary motor cortex on the precentral gyrus and extends superiorly into the lateral and medial portions of the superior frontal gyrus (Geyer et al 2012). BA6 is subdivided into the lateral premotor cortex and the supplementary motor (SMA proper) and presupplementary motor (pre-SMA) cortices on the medial hemispheric surface (**Fig. 32.52**). The lateral premotor cortex is segregated into a dorsal and a ventral area on cytoarchitectonical, connectional and functional grounds; both dorsal and ventral areas contribute to the corticospinal tract. Further anterior and posterior subdivisions of the dorsal and ventral lateral premotor cortex can be identified (see Fig. 32.50B–C).

The major thalamic connections of the premotor cortex are with the anterior division of the ventrolateral nucleus and with the centromedian, parafascicular and centrolateral components of the intralaminar thalamic nuclei. Subcortical projections to the striatum and pontine nuclei are prominent, and it projects to the superior colliculus and the reticular formation. Commissural connections are with the contralateral premotor, primary motor and superior parietal (BA5) cortices. Ipsilateral corticocortical connections with BA5 are common to both dorsal and ventral subdivisions of the premotor cortex, and both send a major projection to the primary motor cortex. The dorsal premotor area receives fibres from the posterior superior temporal cortex and projects to the supplementary motor cortex. The dorsal subdivision of the lateral premotor area receives projections from the frontal eye field. Perhaps the greatest functionally significant difference in connectivity between the dorsal and ventral subdivisions of the lateral premotor area is that the dorsal premotor area receives fibres from the dorsolateral prefrontal cortex, whereas the ventral subdivision receives fibres from the ventrolateral prefrontal cortex. All of these association connections are reciprocal.

Direction selectivity for movement is a common feature of many premotor neurones. Neurones in the dorsal premotor cortex show anticipatory activity and task-related discharge as well as direction selectivity, but little or no direct stimulus-related activity. Together with the posterior parietal cortex, the dorsal premotor cortex is important in establishing a motor programme or intention, thus contributing to motor preparation in relation to internally guided movement. In contrast, the ventral premotor cortex is related more to the execution of externally guided movements in relation to a specific stimulus, especially visually guided movements.

The supplementary motor area (SMA proper) is found within the medial portion of BA6 (see Fig. 32.52A). An additional functional subdivision, the pre-supplementary motor area (pre-SMA), lies anterior to the supplementary motor area on the medial surface of the cortex. The portion of area 24 buried in the cingulate sulcus and adjacent to BA6 contains two motor areas, the anterior and posterior cingulate motor areas (see Fig. 32.52). SMA proper and pre-SMA are 'agranular' cortices, because a layer IV is not clearly definable in Nissl stained sections of this area (see Fig. 32.52B).

SMA receives its major thalamic input from the anterior part of the ventral lateral thalamic nucleus, which in turn is the major recipient of input from the internal segment of the globus pallidus. Additional thalamic afferents are from the ventral anterior nucleus, intralaminar nuclei (notably the centrolateral and centromedial nuclei) and the mediodorsal nucleus. The connections with the thalamus are reciprocal. SMA makes a substantial contribution to the corticospinal tract. It contains a homuncular representation of the body in which the leg is posterior, the face anterior and the upper limb is represented between them. Its role in the control of movement is primarily in complex tasks that require temporal organization of sequential movements and in the retrieval of motor memory. Stimulation of SMA elicits the sensation of an urge to move, or of anticipation that a movement is about to occur.

Pre-SMA receives connections from widespread regions of the ipsilateral frontal lobe, including the primary motor cortex, dorsal premotor area, dorsolateral and ventrolateral prefrontal, medial prefrontal, fronto-orbital cortices and the frontal eye field. These connections are reciprocal, but the major ipsilateral efferent pathway is to the motor cortex. Parietal lobe connections of pre-SMA are with the superior parietal area BA5 and inferior parietal lobule. Contralateral connections are with SMA and contralateral premotor cortices. Further subcortical connections pass to the striatum, subthalamic and pontine nuclei, the brainstem reticular formation and the inferior olivary nucleus.

The frontal eye field (FEF) is an important area for the control of eye movements. It is located near the junction of the middle frontal and precentral sulci: activation studies in humans indicate a more posterior localization (BA6) compared to monkeys (BA8). It receives its major thalamic projection from the parvocellular mediodorsal nucleus, with additional afferents from the medial pulvinar, ventral anterior nucleus, suprageniculate–limitans complex and the paracentral nucleus of the intralaminar group. The thalamocortical pathways to FEF are part of pathways from the superior colliculus, substantia nigra and the dentate nucleus of the cerebellum. The FEF has extensive ipsilateral corticocortical connections, and receives input from several visual areas in the occipital, parietal and temporal lobes, including the middle temporal area (V5). There are also projections from the auditory superior temporal gyrus and the ventrolateral and dorsolateral prefrontal cortices. The FEF projects to the dorsal and ventral premotor cortices and to a medial motor area, probably the supplementary eye field adjacent to the supplementary motor area proper. The FEF projects prominently to the superior colliculus, the pontine gaze centre within the pontine reticular formation, and oculogyric-related nuclei in the brainstem.

The prefrontal cortex on the dorsolateral surface of the hemisphere consists predominantly of Brodmann's areas 8, 9, 10, 46, 47 and language areas 44 and 45. All prefrontal areas except area 44 have a layer IV, and thus are granular cortices; area 44 is dysgranular (**Fig. 32.53C–D**). These areas receive their major thalamic afferents from the mediodorsal nucleus, with additional contributions from the medial pulvinar and ventral anterior and paracentral nuclei of the anterior intralaminar group. The dorsolateral region receives long association fibres from the posterior and middle superior temporal gyri (including auditory association areas) and from the posterior parietal and much of the middle temporal cortices. It also receives projections from the frontal pole (BA10), and from the medial prefrontal cortex (BA32). It projects to SMA, the dorsal premotor cortex and the frontal eye field. All these thalamic and corticocortical connections are reciprocal. Commissural connections are with the homologous areas and with the contralateral inferior parietal cortex. The ventrolateral prefrontal region receives long association fibres from the inferior parietal lobule, auditory association

Roman numerals indicate cortical layers. **E–F**, Distribution of glutamate kainate (**E**) and $GABA_B$ (**F**) receptors in Broca areas BA44 and BA45. Abbreviations: ifj1, area in the inferior frontal sulcus (ifs) at the junction with the precentral sulcus (prcs); ifs1, area in the inferior frontal sulcus; ins, insular cortex; op, frontal opercular region. The colour scales indicate low and high receptor densities.

areas of the temporal operculum, the insula and the anterior part of the ventral bank of the superior temporal sulcus. It also receives input from the anterior fronto-orbital cortex and projects to the frontal eye field and the ventral premotor cortex. It is reciprocally connected with the contralateral homologous area via the corpus callosum.

The granular cortex of the frontal pole (BA10) has greatly expanded in humans compared to other species. It receives thalamic inputs from the mediodorsal nucleus, medial pulvinar and paracentral nucleus and is reciprocally connected with the cortex of the temporal pole, the anterior fronto-orbital cortex and the dorsolateral prefrontal cortex. Within the frontal lobe, BA10 has connections with BA32, the ventrolateral prefrontal cortex, and premotor areas on the medial surface of the hemisphere. Commissural connections to the homologous area of the contralateral hemisphere are extensive. BA10 is segregated into lateral (Fp1) and medial (Fp2) areas on cytoarchitectonic, genetic and functional grounds (see Figs 32.13, 32.53C–D) (Bludau et al 2014, 2018). The lateral area is involved in working memory, episodic memory retrieval and attending environmental stimuli, whereas the medial frontal pole region is engaged in self-generated stimuli (i.e. the 'thoughts in our head'). The interaction between the two areas mediated by the fronto-marginal tract determine whether signals from the internal (mental) or external (sensory) world dominate ongoing behaviour and cognition (Burgess et al 2011, Catani et al 2012).

The fronto-orbital cortex is connected with the mediodorsal, anteromedial, ventral anterior, medial pulvinar, paracentral and midline nuclei of the thalamus. Three areas are cytoarchitectonically identified in the fronto-orbital cortex (**Fig. 32.54A**): the granular area Fo1, mainly on the rostral gyrus rectus and medial of the olfactory sulcus; the granular to dysgranular area Fo2, mainly on the posterior part of the ventromedial gyrus rectus and the medial and lateral banks of the olfactory sulcus; and the granular area Fo3 between the olfactory and medial or intermediate orbital sulci. Fo3 is bordered medially by Fo1 and Fo2. The posterior part of the fronto-orbital cortex extends to the olfactory and insular cortices and is partly covered by the temporal lobe. The parolfactory sulcus often marks the border between the medial part of the fronto-orbital cortex and BA25. The medial fronto-orbital cortex has reciprocal connections with various limbic structures including the anterior cingulate, insula, amygdala and entorhinal cortices, hippocampus, diagonal band of Broca, midline thalamic nuclei and the magnocellular sector of the mediodorsal thalamic nucleus. The fronto-orbital cortex is involved in a variety of functions associated with pleasant as well as painful perceptions and reward processing (see limbic lobe). Olfactory and gustatory stimuli elicit activations in the fronto-orbital cortex that are often associated with hedonistic aspects, and is also involved in touch and pain processing.

The language area of Broca consists of BA44 and BA45 in the opercular and triangular parts of the inferior frontal gyrus, respectively. BA44 is found immediately anterior to the most inferior aspect of the precentral gyrus (**Fig. 32.54B**). Both areas are involved in speech production and show considerable inter-individual variability in size and relationship to gyri. Volumes of left BA44 are always larger than those of the right hemisphere. Thus, interhemispheric differences in the volume of BA44 may be interpreted as anatomical correlates of language dominance. Volumes of BA45 do not differ significantly between the hemispheres. BA44 is involved more in syntactic processes, and BA45 more in semantic processes. The borders between these areas are not consistently defined by sulcal landmarks (Amunts et al 1999). BA47, or at least its most posterior part, should also be considered as part of the Broca region for functional reasons. The cytoarchitecture of BA44 and BA45 is characterized by very large pyramidal cells, sometimes clustered, in deeper layer III, and large pyramidal cells in upper layer V (**Fig. 32.53A–B**). The size of cells in layer III increases from its border with layer II to the layer III/IV border. The most important difference between BA44 and BA45 is found in layer IV, which is dysgranular and invaded by pyramidal cells of layers III and V in BA44. In contrast, layer IV of BA45 is seldom invaded by layer III or layer V pyramidal cells, i.e. BA45 is a granular cortical area. Both areas can be further subdivided on the basis of regional and laminar densities of multiple receptors (**Fig. 32.53E–F**).

Parietal lobe

The parietal lobe lies posterior to the central sulcus on the superolateral and medial surfaces of the cerebral hemisphere. The anterior part of the human parietal cortex comprises somatosensory areas 3a, 3b, BA1 and BA2 in the postcentral gyrus, and the parietal operculum (OP1–OP4). The posterior parietal cortex contains multimodal areas in both the superior (BA5, BA7) and inferior (BA40, BA39) parietal lobules, as well as areas in the intraparietal sulcus that were not described by Brodmann (see Fig. 32.13). The posterior parietal cortex is a key node in networks connecting visual occipital and auditory temporal areas with premotor and prefrontal cortices. The superior parietal lobule (SPL) encompasses parts of the lateral as well as the medial surface, the latter including the precuneus.

Parietal lobe sulci and gyri

Available with the *Gray's Anatomy* e-book

Parietal lobe internal structure and connectivity

All parietal areas have a six-layered eulaminate cortex, with the exception of areas 3a and 3b of the primary somatosensory cortex. The molecular layer (layer I) does not differ between the various areas, but differences in layers II to VI help to parcellate the parietal cortex. The basic myeloarchitectonic organization of the isocortex, with radiate fibre bundles reaching the superficial parts of cortical layer III, can be found in all parietal areas, although the preponderance and extent of the inner and outer stripes of Baillarger differ.

The primary somatosensory cortex (SI) located in the postcentral gyrus includes areas 3a, 3b, BA1 and BA2. Area 3a lies in the depth of the central sulcus and is contiguous to area 4p whereas area 3b is in the posterior wall of the central sulcus. BA1 is on the crown of the postcentral gyrus, and BA2 occupies its posterior cortex (see Fig. 32.13). Area 3a has a low cell packing density, with a few larger pyramidal cells in deep layer III, and an incipient layer IV (see Fig. 32.50D). In contrast, area 3b has a very high cell packing density in the supragranular layers, particularly layer IV, and the cells in layer III are homogeneously distributed: this led to the classification of area 3b as koniocortical (see Fig. 32.50E). BA1 is characterized by an obvious layer IV, and a pronounced columnar arrangement of typically large and numerous pyramidal cells in layers III and V, with a marked superficial-to-deep increase in cell size across layer III (see Fig. 32.50F). BA2 also has an obvious layer IV, fewer pyramidal cells in layer III, large pyramidal cells only appearing deep in layer III and a sharp layer VI–white matter border (see Fig. 32.50G).

The primary somatosensory cortex contains a topographical map of the contralateral half of the body. The face, tongue and lips are represented inferiorly, the trunk and upper limb are represented on the superolateral aspect, and the lower limb is represented on the medial aspect of the hemisphere. The function of SI depends on its thalamic input from the ventral posterior nucleus. This nucleus is divided into a ventral posterolateral part, which receives information from the trunk and limbs, and a ventral posteromedial part, in which the head is represented. Within the ventral posterior nucleus, neurones in the central core respond to cutaneous stimuli and those in the most dorsal anterior and posterior parts, which arch as a 'shell' over the central core, respond to deep stimuli. This is reflected in their differential projections to the cortex: the cutaneous central core projects to 3b, the deep tissue-responsive neurones send fibres to areas 3a and 2, and an intervening zone projects to area 1. Within the ventral posterior nucleus, anteroposterior rods of cells respond with similar modality and somatotopic properties. They appear to project to restricted focal patches in the primary somatosensory cortex of approximately 0.5 mm width. The laminar termination of thalamocortical axons from the ventral posterior nucleus is different for the separate cytoarchitectonic subdivisions of the primary somatosensory cortex. In 3a and 3b, these axons terminate mainly in layer IV and the adjacent deep part of layer III, whereas in BA1 and BA2 they end in the deeper half of layer III, avoiding layer IV. Additional thalamocortical fibres to primary somatosensory cortex arise from the intralaminar system, notably the centrolateral nucleus.

There is a complex internal local connectivity among the primary somatosensory areas with a stepwise hierarchical progression of information from area 3b through BA1 to BA2. Short U-fibres connect the primary somatosensory areas with ipsilateral BA4 and parietal areas in the superior and inferior parietal lobule, and the parietal operculum. The primary somatosensory cortex has reciprocal commissural connections with its contralateral homologue, except that the cortices containing the representation of the distal extremities are relatively devoid of such connections. Callosal fibres in the primary somatosensory areas arise mainly from the deep part of layer III and terminate in layers I–IV. Pyramidal cells contributing callosal projections receive monosynaptic thalamic and commissural connections.

The primary somatosensory area has reciprocal connections with subcortical structures that include the claustrum (which in turn receives afferents from the nucleus basalis of Meynert), the locus coeruleus and the midbrain raphe. Corticostriatal fibres originating in layer V project mainly to the ipsilateral putamen. Other projections from layer V of the primary somatosensory cortex terminate in the main pontine nuclei, the nucleus reticularis tegmenti pontis (pontine tegmental reticular nucleus) and the spinal cord. The topographical representation in the cortex is preserved in terms of the spinal segments to which different

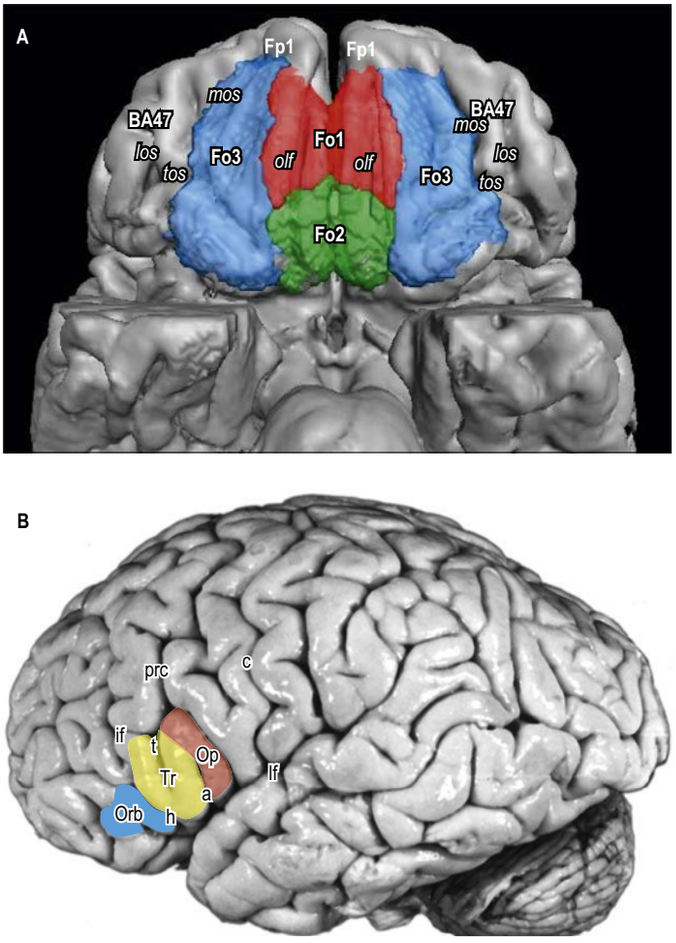

Fig. 32.54 A, A cytoarchitectonical map of the fronto-orbital cortex showing areas Fo1–Fo3. Abbreviations: los, lateral orbital sulcus; mos, medial orbital sulcus; olf, olfactory sulcus; tos, transverse orbital sulcus. **B**, Broca's language region areas BA44 on the opercular part, BA45 on the triangular and area 47 on the orbital part of the inferior frontal gyrus. Abbreviations: a, ramus ascendens of the lateral fissure; c, central sulcus; h, ramus horizontalis of the lateral fissure; if, inferior frontal sulcus; lf, lateral fissure; Op, opercular part of the inferior frontal gyrus; Orb, orbital part of the inferior frontal gyrus; prc, precentral sulcus; t, triangular sulcus; Tr, triangular part of the inferior frontal gyrus.

Anteriorily, the parietal lobe is delimited by the central sulcus. Posteriorly, it is well delineated on the medial aspect by the parieto-occipital sulcus, and on the dorso-lateral aspect by a line that can be drawn running from the point where the parieto-occipital sulcus reaches its most superior extremity at the edge of the hemisphere to the occipito-temporal incisure. The inferior boundary is defined by the lateral fissure and its imaginary prolongation to the line connecting the parieto-occipital sulcus and the occipito-temporal incisure.

The lateral aspect of the parietal lobe is divided into three regions by the postcentral and intraparietal sulci. The intraparietal sulcus, which originates from around the midpoint of the postcentral sulcus, is prominent on the superolateral surface of the parietal lobe, running parallel with the superior margin of the hemisphere (see Figs 32.2, 32.3). Anteriorly, the intraparietal sulcus is usually continuous with the inferior portion of the postcentral sulcus and posteriorly it passes into the occipital lobe as the superior occipital sulcus, which continues posteriorly into the transverse occipital sulcus. The intraparietal sulcus delineates the superior parietal lobule, continuous medially with the precuneus, and the inferior parietal lobule, made up of the supramarginal and angular gyri and a more posterior convolution continuous with the occipital lobe. The superior vertical branch of the intraparietal sulcus (transverse parietal sulcus) divides the SPL into an anterior and posterior portion, whereas the inferior vertical branch (intermediate sulcus of Jensen) separates the supramarginal gyrus anteriorly from the angular gyrus posteriorly. The inferior aspect of the supramarginal gyrus within the inferior parietal lobule of the dominant hemisphere corresponds to Wernicke's area, which extends along the posterior aspect of the superior temporal gyrus.

The postcentral gyrus is usually narrower than the precentral gyrus. Both gyri are located obliquely on the superolateral surface of the hemisphere, just superior to the lateral fissure. The superior portions of the pre- and postcentral gyri, which constitute the paracentral lobule on the medial surface of the cerebral hemisphere, are topographically related to the ventricular atrium, situated posterior to the thalamus. The inferior portions of both gyri cover the posterior half of the insula and are topographically related to the body of the lateral ventricle, situated superior to the thalamus. The portion of the subcentral gyrus corresponding to the base of the postcentral gyrus consistently lies over the transverse gyri of Heschl, situated on the opercular surface of the temporal lobe.

The supramarginal gyrus surrounds the distal portion of the lateral fissure (its posterior ascending branch) and becomes continuous with the posterior portion of the superior temporal gyrus. Above the distal end of the lateral fissure, the supramarginal gyrus is connected anteriorly to the postcentral gyrus through a fold that runs underneath the inferior aspect of the postcentral sulcus. Posteriorly, it occasionally rounds the inferior extremity of the intermediate sulcus and connects to the angular gyrus. The angular gyrus is a curved gyrus and always surrounds one of the distal segments of the superior temporal sulcus, usually the middle one (angular sulcus or t2 in Fig. 32.2H); its most inferior portion is continuous with the middle temporal gyrus. The configuration of the angular gyrus is defined by the distal branching of the superior temporal sulcus, which typically ends as three continuous or interrupted caudal branches.

The most superior distal branch of the superior temporal sulcus has an ascending course; it may either penetrate the supramarginal gyrus or coincide with the intermediate sulcus of Jensen separating the supramarginal and angular gyri. The second branch (t2) is usually more horizontal and enters the angular gyrus as the angular sulcus. The most inferior caudal branch (t3) of the superior temporal sulcus is less evident and less constant. It courses underneath a posterior fold that frequently connects the angular gyrus and the most lateral aspect of the occipital lobe, and is usually continuous with the anterior occipital sulcus, lying predominantly vertically along the anterior edge of the middle occipital gyrus.

On the medial surface of each hemisphere, the precuneus lies posterior to the paracentral lobule as a medial extension of the superior

parietal lobule. The precuneus is quadrangular, delineated anteriorly by the marginal branch of the cingulate sulcus, posteriorly by the parieto-occipital sulcus and inferiorly by the subparietal sulcus. Inferior to the subparietal sulcus, the precuneus is connected to the isthmus of the cingulate gyrus, which is continuous with the parahippocampal gyrus. The parieto-occipital sulcus separating the precuneus from the cuneus is deep and contains many small sulci and gyri.

parts of the postcentral gyrus project. Thus, the arm representation projects to the cervical enlargement, the leg representation to the lumbosacral enlargement, and so on. Within the grey matter of the spinal cord, fibres from the somatosensory cortex terminate in the dorsal horn, in Rexed's laminae 3–5; fibres from 3b and BA1 end more dorsally, and those from BA2 more ventrally.

The rostral part of the parietal operculum can be subdivided into four areas, i.e. areas OP1–OP4 (Eickhoff, Schleicher et al 2006), which reflect the subdivision of this region into a secondary somatosensory region (SII; OP1, 3, 4) and a putative vestibular cortex (OP2). The parietal opercular areas are characterized by a columnar arrangement. While OP1 has a pronounced superficial-to-deep increase in cell size in layer III, area OP2 appears more homogeneous, but with additional very large pyramidal cells in deep layer III. In area OP3, layer III, V and VI have considerably lower cell packing densities. Area OP4 is characterized by smaller cells throughout, with only medium-sized pyramids in deep layer III, and layer IV is difficult to visualize. The secondary somatosensory region lies along the upper bank of the lateral fissure, posterior to the central sulcus. It contains a somatotopic representation of the body, with the head and face most anterior, adjacent to SI, and the sacral regions most posterior. The secondary somatosensory region is reciprocally connected with the ventral posterior nucleus of the thalamus in a topographically organized fashion. Some thalamic neurones probably project to both primary and secondary somatosensory regions via axon collaterals. Other thalamic connections of the secondary somatosensory region are with the posterior group of nuclei and with the intralaminar central lateral nucleus. The secondary somatosensory region also projects to laminae IV–VII of the dorsal horn of the cervical and thoracic spinal cord, the dorsal column nuclei, the principal trigeminal nucleus and the periaqueductal grey matter of the midbrain. Within the cortex, SII is reciprocally connected with SI in a topographically organized manner and projects to the primary motor cortex. SII also projects in a topographically organized way to the lateral part of PPC, and makes connections with PCC. Both right and left SII areas are interconnected across the corpus callosum, although distal limb representations are probably excluded. Neurones in SII respond particularly to transient cutaneous stimuli, e.g. brush strokes or tapping, which are characteristic of the responses of Pacinian corpuscles in the periphery: they show little response to maintained stimuli.

The superior and inferior parietal lobules are each composed of seven cytoarchitectonically distinct areas (**Fig. 32.55**). The major difference in cytoarchitecture between the areas of the two lobules is that the pyramidal cells in layers IIIc and V are larger in the superior parietal lobule. Using modern quantitative cyto- and receptorarchitectonic methods, BA5 and BA7 in the superior lobule have been subdivided into areas 5L, 5M and 5Ci, and areas 7A, 7P, 7M and 7PC, respectively (Scheperjans et al 2005, Scheperjans, Hermann et al 2008). Using the same methodological approach for the inferior parietal lobule, areas PFop, PFcm, PFt, PF and PFm were identified within BA40, and areas PGa and PGp within BA39 (Caspers and Zilles 2018) (**Fig. 32.56**).

BA5 receives a dense feed-forward projection from all cytoarchitectonic areas of primary somatosensory cortex in a topographically organized manner. The thalamic afferents to this area come from the lateral posterior nucleus and from the central lateral nucleus of the intralaminar group. Ipsilateral corticocortical fibres from BA5 go to BA7, the premotor and supplementary motor cortices, the posterior cingulate gyrus and the insular granular cortex. Commissural connections between BA5 on both sides tend to avoid the areas of representation of the distal limbs. The response properties of cells in BA5 are more complex than in SI, with larger receptive fields and evidence of submodality convergence. BA5 also contributes to the corticospinal tract.

The areas of the inferior parietal lobule are reciprocally connected to adjacent areas in the intraparietal sulcus, the superior parietal lobule, the ventrolateral premotor and prefrontal cortex as well as posterior temporal and occipital areas. These connections are mediated by short U-fibres (Catani et al 2017) and long association fibres of the arcuate fasciculus, and superior and middle longitudinal fasciculi.

Functional anatomy of the superior and inferior parietal lobules

Occipital lobe

On the superolateral cerebral surface, the occipital lobe is situated posterior to a virtual line connecting the point of emergence of the parieto-occipital fissure on the superomedial border of the cerebral hemisphere with the incisura occipito-temporalis. On the medial surface, the occipital lobe is limited anteriorly by the parieto-occipital sulcus and by its prolongation towards the tentorium cerebelli. Along the inferior cerebral surface, the base of the occipital lobe is continuous with the base of the temporal lobe. The sulci and gyri of the occipital lobe, especially of its superolateral surface, exhibit a greater degree of anatomical variation than is seen in the other lobes. Regarding the major named sulci, there appears to be reasonable consensus that the parieto-occipital, calcarine, paracalcarine, lingual, transverse occipital, inferior lateral occipital and anterior occipital sulci, together with the occipital parts of the collateral and lateral occipitotemporal sulci, are constant features of the surface of the occipital lobe, whereas the superior occipital, superior lateral occipital, inferior occipital, lunate and occipitopolar sulci are less constant.

Occipital lobe sulci and gyri

Available with the *Gray's Anatomy* e-book

Occipital lobe internal structure and connectivity

The occipital lobe is composed of Brodmann's areas BA17, BA18 and BA19 and part of BA37. However, Brodmann's delineation of BA19 and BA37 has not been replicated using modern quantitative approaches and the whole region covered by these two areas has been re-defined (see Fig. 32.13).

BA17, the striate cortex, is the primary visual cortex (V1) and is located mostly on the medial aspect of the occipital lobe: it occupies the upper and lower lips and depths of the calcarine sulcus and extends onto the cuneus and lingual gyrus. V1 receives visual afferent fibres from the lateral geniculate nucleus via the optic radiations. The retina of each eye can be divided into a nasal (medial) and temporal (lateral) half, and the left and right visual fields of each eye are composed of a lateral and medial half, the latter partially overlapping in the midline. Each lateral visual field is perceived by the ipsilateral nasal retina and each medial visual field is perceived by the ipsilateral temporal retina. The fibres from the nasal retinae form the medial half of the optic nerve and decussate in the optic chiasma to form the optic tract with the temporal fibres of the contralateral retina. Projections of the ipsilateral and contralateral retinae reach the lateral geniculate nucleus where representations of the visual hemifields remain segregated in the magnocellular (layers 1–2) and parvocellular layers (layers 3–6). The fibres of the optic radiations originating from the lateral geniculate nucleus terminate in strict retinotopic fashion in the ipsilateral striate area. The cortex of each hemisphere receives impulses from two hemi-retinae, which represent the contralateral half of the binocular visual field. Superior and inferior retinal quadrants are connected with corresponding areas of the striate cortex. According to Elze (1928), Flechsig, in 1896, called attention to the peculiar course of the ventral fibres of the optic radiations, and named the sharp turn made by these fibres the 'temporal knee' (later referred to as Meyer's loop). The superior retinal quadrants (representing the inferior half of the visual field) are connected with V1 above the calcarine sulcus, and the inferior retinal quadrants (representing the upper half of the visual field) are connected through the Meyer's loop with the V1 below the calcarine sulcus. The peripheral nasal parts of the retinae (monocular periphery of the visual field) projects on the most anterior parts in the visual cortex near to the splenium of the corpus callosum: this is the small monocular part of V1. The fovea of the retina concerned with central vision impinges on a disproportionately large posterior part (binocular part of V1) around the occipital pole.

Area V1 is koniocortical (**Fig. 32.57**): in contrast to most of the isocortical areas where layer III is dominated by pyramidal cells, layers II/III of V1 is populated by small, densely packed granule cells. Layers II/III consist of excitatory pyramidal cells and receive massive inputs from layer IVc neurones but only a few thalamic inputs. They are also connected through reciprocal projections with layer V neurones. The neurones of layers II/III have cortico-cortical projections to the extrastriate regions V2, V3, V4 and V5. About 20% of the cells in layers II/III are GABAergic inhibitory interneurones. Layer IV of V1 is divided into three sublayers: IVa, IVb (which harbours the heavily myelinated stria of Gennari and contains a few cells, mainly interneurones), and IVc (**Fig. 32.57B**). Layer IV plays a major role in the M-pathway that originates from magnocellular (M) cells of the lateral geniculate nucleus. After receiving information through the M-pathway in layer IVcα, IVB projects to cytochrome oxidase-positive blobs (see below) in layers II/III, to areas V3 and V5/MT and the superior colliculus. The densely cellular IVc is further subdivided into a superficial IVcα and a deep IVcβ. The input to area 17 from the lateral geniculate nucleus terminates predominantly in layers IVa and IVc. Other thalamic afferents, from the inferior pulvinar nucleus and the intralaminar group, terminate in layers I and VI. Layer V neurones project primarily to III, provide strong feedback to layer VI neurones, and receive feedback via projections from

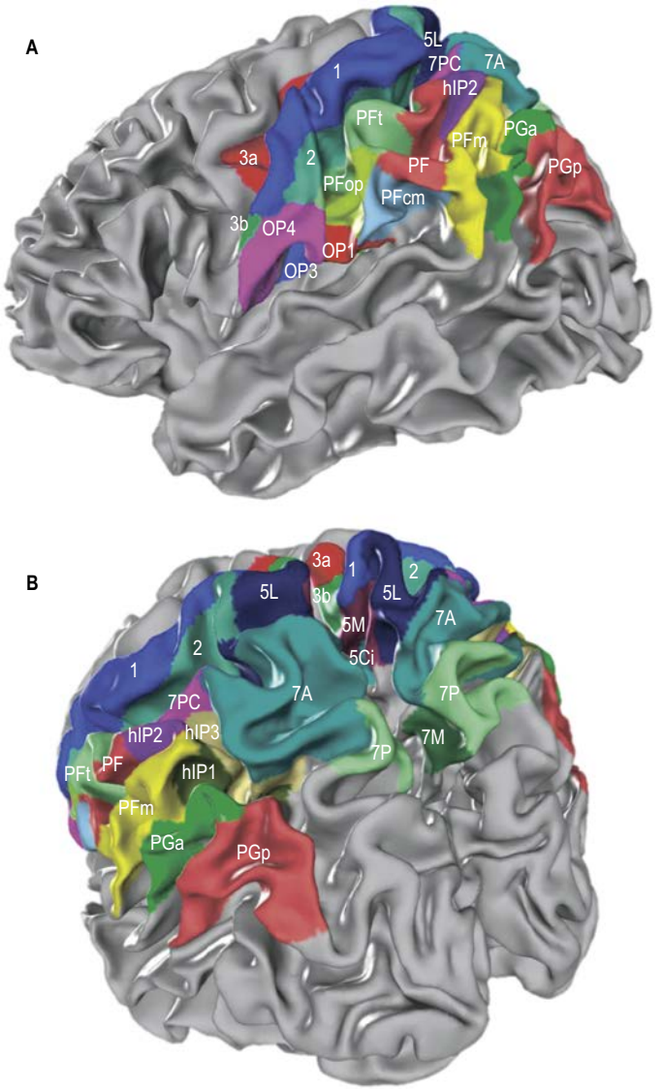

Fig. 32.55 A, Lateral view, left hemisphere, showing maximum probability maps of the parietal cortical areas. **B**, Oblique dorsal view on both hemispheres with maximum probability maps of the parietal cortical areas. (Adapted with permission from Caspers S, Zilles K Microarchitecture and connectivity of the parietal lobe. In: Vallar G, Coslett HB (eds) The Parietal Lobe. Handbook of Clinical Neurology, Vol. 151. Elsevier. Copyright 2018.)

Studies of the regional and laminar distribution patterns of multiple neurotransmitter receptors supported the parcellations found by quantitative cytoarchitectonic observations. In SI, area 3b had the highest densities of GABAergic $GABA_A$, cholinergic muscarinic M_2, noradrenergic α_2, and serotoninergic 5-HT_2 receptors than BA1 and BA2 (see Fig. 32.51). Additionally, areas 3b and BA2 had higher concentrations of cholinergic muscarinic M_1 receptors than areas 3a and BA1. In both the IPL and SPL, decreasing concentrations of glutamatergic AMPA receptors and increasing concentrations of serotonergic 5-HT_{1A} and 5-HT_2 receptors were observed along caudal-to-rostral gradients, respectively. Caudal as compared to rostral and middle areas of IPL were additionally characterized by higher concentrations of GABAergic $GABA_A$ and $GABA_B$ receptors and lower concentrations of benzodiazepine binding sites of the $GABA_A$ receptor, while middle areas as compared to rostral and caudal areas had higher concentrations of glutamatergic kainate and cholinergic nicotinic receptors (Caspers et al 2013a). In the SPL, rostral as compared to caudal areas additionally expressed higher concentrations of adrenergic α_2 receptors and lower concentrations of cholinergic nicotinic receptors (Scheperjans et al 2005).

There are two or three gyri (superior, middle and inferior) on the superolateral cerebral surface of the occipital lobe that converge posteriorly to form the occipital pole (see Figs 32.2–32.3). The superior occipital gyrus is always well defined, and is continuous along the superomedial margin of the hemisphere with the cuneus. Superiorly, it is delimited by the depth of the parieto-occipital fissure on the superolateral hemispheric surface. It is continuous with the SPL through the parieto-occipital 'pli de passage' of Gratiolet. Laterally, the superior occipital gyrus may be delimited by either the intra-occipital, transverse occipital or superior occipital sulci. The inferior occipital gyrus lies horizontally along the inferolateral margin of the hemisphere. Anteriorly, it is usually continuous with the inferior temporal gyrus; posteriorly, it can extend medially around the occipital pole, becoming continuous with the lingual gyrus on the medial surface of the hemisphere; superiorly, it is delimited by the lateral or inferior occipital sulcus. The superior lateral occipital sulcus is a horizontal sulcus. Anteriorly, it is frequently connected to the inferior temporal sulcus; inferiorly, it may be accompanied by a shorter inferior lateral occipital sulcus. Both of these sulci may be connected with a sulcal complex known as the anterior occipital sulcus, which, when present, lies along the anterior aspect of the middle occipital gyrus.

The intraparietal sulcus extends longitudinally and inferiorly into the occipital lobe, where it becomes the intra-occipital sulcus. The latter may occasionally descend to the occipital pole but it usually terminates on reaching the transverse occipital sulcus, dividing it into lateral and medial parts that penetrate the superior occipital gyrus. The lunate sulcus, although conspicuous in monkeys and apes, is only sometimes identifiable in human brains, when it appears as a well-defined vertical and backward-curved sulcus anterior to the occipital pole.

Despite significant anatomical variation, the superolateral occipital convolutions are connected to the parietal and temporal convolutions by consistent cortical folds. Four folds connect the parietal and temporal lobes with the occipital lobe: the superior parieto-occipital fold (parieto-occipital arcus) connects the SPL with the superior occipital gyrus; the inferior parieto-occipital fold, a posterior extension of the angular gyrus, connects with the middle occipital gyrus and occasionally also with the superior occipital gyrus; the first temporo-occipital fold is the continuation of the middle temporal gyrus with the inferior occipital gyrus; and the second temporo-occipital fold is the continuation of the inferior temporal gyrus with the inferior occipital gyrus.

The medial surface of the occipital lobe is separated from the parietal lobe by the parieto-occipital sulcus and dominated by the calcarine sulcus. The dorsal part of this region, above the calcarine sulcus and posterior to the parieto-occipital sulcus, is the cuneus. The ventral part of this region, lying below the calcarine sulcus and extending as far as the occipital extension of the collateral fissure, is the lingual gyrus. The calcarine sulcus starts anteriorly beneath the splenium of the corpus callosum, delineating the inferior aspect of the isthmus of the cingulate gyrus, and runs posteriorly just above the inferomedial margin of the hemisphere. The parieto-occipital sulcus separates the cuneus from the precuneus, and divides the calcarine sulcus into an anterior and a posterior part. The parieto-occipital and calcarine sulci appear continuous on the surface, but when their borders are retracted it becomes obvious that they are separated by one or more small gyri. The anterior part of the calcarine sulcus is classified as a complete sulcus because its depth creates an elevation (calcar avis) in the medial wall of the occipital horn of the lateral ventricle. The posterior part of the calcarine sulcus is considered an axial sulcus, given that its axis runs along the visual cortex. Only the posterior part includes the primary visual cortical areas, which are located on its superior (cuneal) and inferior (lingual) surfaces: this part of the calcarine sulcus frequently harbours the cuneolingual gyrus that links both gyri.

At the level of the occipital pole, the calcarine sulcus usually branches in a T or Y shape as the retrocalcarine sulcus. The gyrus descendens of Ecker lies posterior to and along the retrocalcarine sulcus and is occasionally bounded posteriorly by the occipitopolar sulcus. The retrocalcarine sulcus and its variations are sometimes referred to as external calcarine sulci.

Given the anatomical constancy of the calcarine and parieto-occipital sulci on the medial occipital surface, the cuneus is always a well-defined wedge-like convolution. The real anterior border of the cuneus is the cuneal limiting sulcus within the parieto-occipital fissure. Posteriorly, the cuneus rests over the posterior part of the calcarine sulcus and over the posterior aspect of the lingual gyrus. Superior to the posterior part of the calcarine sulcus, the cuneus harbours the paracalcarine or cuneal sulcus (the inferior sagittal sulcus of the cuneus of Retzius) and, further dorsally, the occipital paramedial sulcus (the paramesial sulcus of Elliot Smith or superior sagittal sulcus of Retzius). The basal or inferior surface of the occipital lobe is continuous with the basal surface of the temporal lobe. It is formed, from medial to lateral, by the lingual (also known as the medial occipito-temporal gyrus), fusiform (also known as the lateral occipito-temporal gyrus), and inferior occipital gyri respectively. The lingual gyrus lies inferiorly along the entire length of the calcarine sulcus, forming the mediobasal portion of the occipital lobe. It is continuous anteriorly with the parahippocampal gyrus and its basal surface rests on the tentorium cerebelli. Posteriorly, it is frequently divided into a superior and inferior part by an intralingual sulcus, which may be a posteromedial ramus of the collateral sulcus.

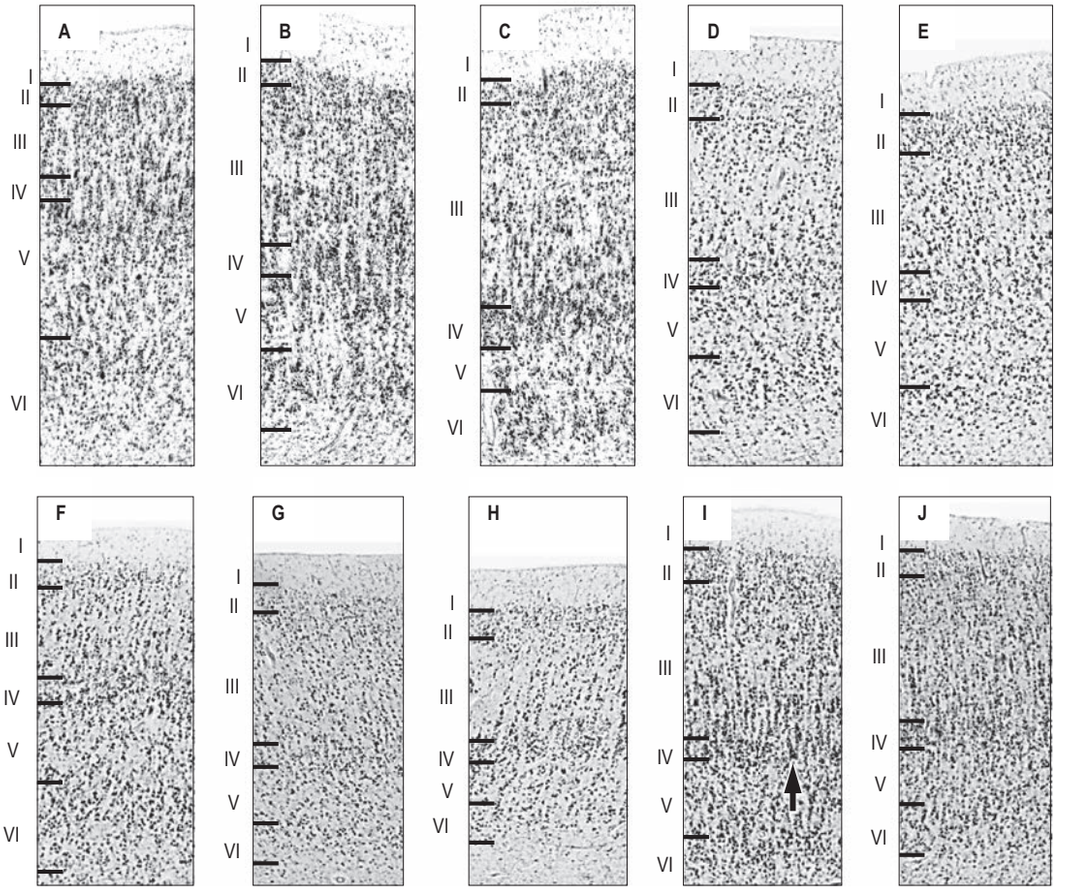

Fig. 32.56 A–J, The cytoarchitecture of cortical areas in the superior (**A–C**) and inferior (**D–J**) parietal lobules. Areas 5L (**A**), 7A (**B**), 7P (**C**) are parts of the superior parietal lobe. Areas PGa (**D**), PGp (**E**) are parts of BA39. Areas PFop (**F**), PFt (**G**), PFcm (**H**), PF (**I**) and PFm (**J**) are parts of BA40. Roman numerals indicate cortical layers.

The fusiform gyrus lies along the temporo-occipital transition. Its posterior or occipital part is bounded medially by the collateral sulcus and laterally by the occipito-temporal sulcus; hence it lies between the lingual gyrus medially and the inferior occipital gyrus laterally. The occipital part of the fusiform gyrus lies over the tentorium cerebelli just posterior to the petrous part of the temporal bone. Topographically, it corresponds to the floor of the ventricular atrium; the temporal part of the gyrus lies beneath the temporal horn of the lateral ventricle. The posterior portion of the fusiform gyrus contains the midfusiform sulcus lying between the collateral and occipito-temporal sulci (Weiner and Zilles 2016). The midfusiform sulcus is of functional importance, because it points to cortical areas involved in object recognition, face perception and reading.

The occipitotemporal sulcus rarely extends posteriorly as far as the occipital pole; both the collateral and occipitotemporal sulci frequently have secondary side branches and merge anteriorly. The inferior or basal aspect of the inferior occipital gyrus lies lateral to the fusiform gyrus and constitutes the most inferior portion of the lateral aspect of the occipital lobe. Along the inferolateral border of the hemisphere, the inferior temporal gyrus is continuous with the inferior occipital gyrus over the occipito-temporal incisure (preoccipital notch), and the inferior occipital gyrus is continuous with the lingual gyrus along the occipital pole. Along the parietal and occipital aspects of the superomedial border of the hemisphere, the superior parietal lobule is continuous with the precuneus, and the superior occipital gyrus is continuous with the cuneus above the calcarine sulcus and with the lingual gyrus below the calcarine sulcus.

Scales indicate absolute receptor densities in fmol/mg protein. Roman numerals indicate cortical layers.

II/III neurones. Very large pyramidal cells, Meynert cells, found at the V/VI border and within layer VI, project to both area MT and the superior colliculus.

The projections of the right and left retinae remain segregated in the lateral geniculate nucleus, where layers 2, 3 and 5 receive information from the ipsilateral eye, and layers 1, 4 and 6 from the contralateral eye. The magnocellular layers 1 and 2 of the lateral geniculate nucleus are important relay stations of the M-pathway from the retina to the visual cortex, whereas the parvocellular layers 3–6 are a relay station in the parallel P-pathway. The M-pathway mainly conveys motion information, the P-pathway information on shape and colour. The optic radiation consists of the geniculo-cortical projections to layer IV of V1, which terminate in alternating cell strips for each eye separately. Thus, the neurones within layer IV are monocularly driven. This horizontal, strip-like segregation is the anatomical basis of ocular dominance columns (Hubel and Wiesel 1977) (**Fig. 32.58**). Neurones encountered in vertical strips from pia to white matter exhibit a preference for stimulation of one or other eye, although binocularly driven neurones are found in the other layers of V1. In the human V1, ocular dominance columns are orientated vertical to the V1/V2 boundary and are about 0.5 mm wide with quite distinct functional borders.

Orientation columns in V1 are based on the finding that all neurones orientated in a column extending from pia to white matter and vertical to the cortical surface, respond preferentially to either a stationary or a moving line of a given orientation (see Fig. 32.58). Cells with simple, complex and hypercomplex receptive fields are found in V1. Simple cells are mainly in layer IV and respond optimally to lines in a narrowly defined position. Complex cells occur in layers II and III or layers V and VI, and respond to stimuli within a receptive field, but with a specific orientation. Hypercomplex cells are also found in layers II and III or layers V and VI: their response is similar to that of complex cells, but the length of a line is critical. The borders of orientation and ocular dominance columns intersect at right-angles.

Cytochrome oxidase (CO) blobs are found in V1 (see Fig. 32.58). They are regions of high staining for the metabolic enzyme cytochrome oxidase (Wong-Riley 1989) in layers II/III and V/VI. Interleaved 'interblob' regions form discrete structures between CO blobs. Layer II/III neurones in the CO blob region receive direct affrents from the interlaminar cells of LGN (I-pathway). Although CO blobs have often been associated with colour vision, their function remains elusive. Direct connections from the blob areas of V1 pass to V4. Output from V1 terminates in the claustrum, lateral geniculate nucleus, superior colliculus, pretectum and parts of the brainstem reticular formation; efferents to the striatum and pontine nuclei are sparse.

The human extrastriate visual cortex covers the remainder of the occipital lobe and extends into the temporal and parietal lobes, which means that about 20% of the entire cerebral cortex is covered by the visual system.

Area V2, which overlaps in part with BA18, contains a complete retinotopic representation of the visual hemifield, which is a mirror image of that in V1, with the vertical meridian along the border between areas V1 and V2. Within area V2 (**Fig. 32.57H–N**), functional modules called thin stripes, thick stripes, and interstripes are present. The blob areas of V1 project to the colour-sensitive neurones of the thin stripes, and those of the interblob regions of V1 terminate in the interstripe regions of V2. The thin stripes of V2 project to V4. The thick stripes of V2 receive input from layer IVb of V1. The neurones in the thick stripes are orientation- and direction-selective, and are also sensitive to binocular disparity, which allows them to code depth information. Reciprocal projections from V2 pass to several other visual areas, including V3 and its subdivisions (V3/V3d, VP/V3v, V3a; see Fig. 32.57O–Q), V4, V5 and areas in the temporal and parietal association cortices and frontal eye field. Afferents to V2 arrive from the lateral geniculate nucleus, inferior and lateral pulvinar nuclei and parts of the intralaminar thalamic nuclei. Subcortical efferents of V2 arise in layers V and VI and pass to the striatum, thalamus, claustrum, superior colliculus, pretectum, brainstem reticular formation, and pons. The reciprocal callosal connections of V2 are restricted to regions with the representation of the vertical meridian.

Area V3 (see Fig. 32.57O–Q) is a narrow strip adjoining the anterior margin of V2 and has been subdivided into two dorsal (V3/V3d; V3A) and a ventral (VP/V3v) regions on the basis of its afferents from area V1, myelo- and receptor architecture, and callosal and receptive field properties. V3d receives input from V1, whereas V3v does not. V3d shows less colour selectivity and greater directional selectivity than V3v. Both areas receive projections from V2 and are interconnected. A further visual area, area V3a, lies anterior to V3d and receives afferents from V1, V2, V3d and V3v. All V3 subdivisions project to diverse visual areas in the parietal, occipital and temporal cortices, and to the frontal eye field.

Area V4 lies within BA19 anterior to V3 (see Fig. 32.57O–Q). It receives afferents from V2, and is colour- and orientation-selective. Bilateral damage, e.g. caused by localized ischaemia, leads to achromatopsia. V4 is also involved in orientation, form and movement selectivity. It projects reciprocally to the inferior temporal cortex and also connects with other visual areas in the temporal and parietal lobes and with the pulvinar and intralaminar thalamic nuclei. Visual processing in the inferior temporal and temporoparietal lobes is realized via the dorsal and ventral visual streams that emanate from the occipital lobe. The dorsal pathway, concerned primarily with visuospatial discrimination, projects from V1 and V2 to the temporal and parietal cortices and enables sensory-motor transformations for visually guided actions directed at an object. V4 is an important relay station for the ventral stream, which is related to the perceptual identification of various classes of objects (see below). It is connected along the inferior temporal gyrus with the posterior, intermediate and anterior parts of the inferior temporal cortex, which feed into the temporal polar and medial temporal areas of the language and limbic networks.

The motion-selective area V5 (also called hMT+) (see Fig. 32.57O–Q) is located close to the junction of the occipital, temporal and parietal lobes and can be identified by its intense myelination. It receives input from layer IVb of V1 and the thick stripes of V2, forming a further M-pathway. Its cells are direction- and motion-sensitive. It is surrounded by the areas MST and FST that process higher-order aspects of stimulus motion. Bilateral lesions of V5 cause akinetopsia, a severe impairment in detecting the movements of objects.

Higher-order visual areas, selective for specific objects such as faces, words or buildings, are localized lateral to the collateral sulcus in the fusiform gyrus around the midfusiform sulcus. Best known is the posterior face recognition area. Lesions of this area cause prosopagnosia, the inability to recognize faces. Recognition of faces, numbers and words are associated with a central visual field bias, whereas the recognition of buildings depends on peripheral vision. Several cyto- and receptor architectonic areas (FG1–FG4) of the fusiform gyrus have been identified (Caspers et al 2013b, Lorenz et al 2017). FG1 and FG3 are medial to the midfusiform sulcus, and FG2 and FG4 are lateral to this sulcus on the fusiform gyrus (**Fig. 32.59**). Combined functional and cytoarchitectonic studies have shown that these areas subserve face, word form (characters), place and object (body) recognition (Weiner et al 2017). FG1 corresponds to the face-selective area in the posterior fusiform gyrus (area pFus-faces); FG2 to the posterior visual word form area (VWFA-1); FG3 to the parahippocampal place area (PPA); and FG4 to the medial face-selective area (mFus-faces), fusiform body area (FBA) and anterior visual word form area (VWFA-2).

Temporal lobe

The lateral surface of the temporal lobe is inferior to the lateral fissure and lies beneath the squamous portion of the temporal bone. The basal surface lies over the floor of the middle cranial fossa posterior to the greater wing of the sphenoid bone. The opercular surface lies inside the lateral fissure. (For the definition of the posterior limit of the temporal lobe, see the occipital lobe). The isocortical part of the temporal lobe is related with auditory functions and, in the dominant hemisphere, mostly with language. It also comprises parts of the visual system in the inferior temporal region (higher visual areas). The medial side of the temporal lobe belongs to the limbic system (see archicortex and periarchicortex).

Temporal lobe sulci and gyri

Available with the *Gray's Anatomy* e-book

Temporal lobe internal structure and connectivity

The superior, middle and inferior temporal gyri correspond to BA22, BA21 and BA20, respectively, and the temporal pole corresponds to BA38 (see Fig. 32.13).

The primary auditory cortex (BA41 or A1) covers a major part of Heschl's gyrus/gyri, and is surrounded by the secondary auditory cortex (BA42). BA41 corresponds to the functionally and connectionally defined core region of the primary auditory cortex, and BA42 to the belt region. BA41 is reciprocally connected with the medial geniculate nucleus via the acoustic radiation. The ventral division of the medial geniculate nucleus mainly projects to BA41, which receives additional projections from the medial pulvinar. The architectonically defined primary auditory cortex does not extend medially into the insular cortex, and does not reach the lateral bulge of the superior temporal gyrus. Posteriorly, it never extends beyond the second transverse temporal gyrus although Heschl's sulcus does not indicate precisely the border between BA41 and BA42.

The lateral surface is composed of the superior, middle and inferior temporal gyri, separated by the superior and inferior temporal sulci, all lying parallel to the lateral fissure. Anteriorly, the middle temporal gyrus is generally shorter, and the superior and inferior gyri fuse to form the temporal pole (see Figs 32.2–32.3).

The superior temporal sulcus terminates within the inferior parietal lobule, posterior to the end of the lateral fissure, by branching into an ascending sulcal segment and an inferior branch that runs towards the occipital lobe. The superior temporal gyrus continues posteriorly to the supramarginal gyrus encircling the terminal portion of the lateral fissure. The middle temporal gyrus is connected to the angular gyrus beneath the distal and horizontal portion of the superior temporal sulcus. The inferior temporal gyrus is continuous posteriorly with the inferior occipital gyrus over the preoccipital notch (occipito-temporal incisure). Both superior and inferior temporal sulci start at the most anterior aspect of the temporal pole and end posterior to the arbitrary border of the temporal lobe, and both have their depths directed towards the temporal horn of the lateral ventricle. Topographically, the depth of the posterior part of the superior temporal sulcus is particularly related to the ventricular atrium.

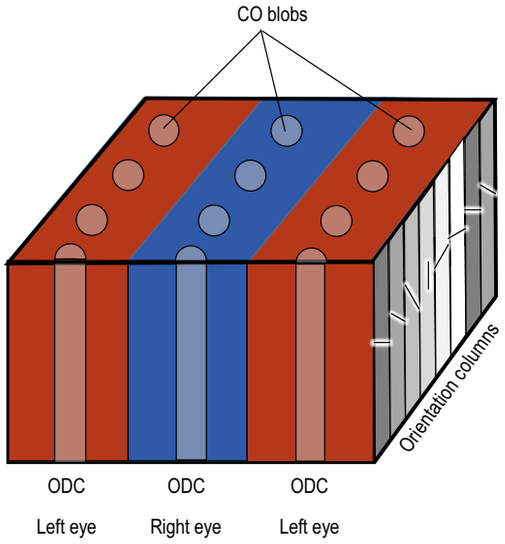

Fig. 32.58 Functional modules in V1. Abbreviation: CO blobs, cytochrome oxidase blobs; ODC, ocular dominance column.

The basal surface of the temporal lobe is composed laterally by the inferior surface of the inferior temporal gyrus and medially by the anterior or temporal portion of the fusiform or lateral temporo-occipital gyrus; the gyri are separated by the temporo-occipital sulcus. Medially, the fusiform gyrus is delimited by the collateral sulcus, which separates it from the parahippocampal gyrus. Although not extensive, the fusiform gyrus has an anterior or temporal part between the inferior temporal and parahippocampal gyri, and a posterior or occipital part between the inferior occipital and lingual gyri. The anterior part of the fusiform gyrus is typically curved or pointed, resembling an arrow; its anterior border usually lies close to the level of the cerebral peduncle. The temporal portion of the fusiform gyrus lies over the posterior aspect of the floor of the middle fossa and the upper surface of the petrous part of the temporal bone. The occipital part of the fusiform gyrus lies underneath the ventricular atrium.

Anterior to the fusiform gyrus, the collateral sulcus may be continuous with the rhinal sulcus. More frequently, these sulci are separated by the so-called temporolimbic passage. The rhinal sulcus separates the entorhinal cortex of the uncus medially from the isocortex of the temporal pole laterally.

The superior or opercular surface of the temporal lobe is formed by the superior surface of the superior temporal gyrus, which lies within the lateral fissure and is composed of multiple transverse gyri, one or two of which are the transverse gyrus/gyri of Heschl. The opercular surface originates around the midpoint of the superior temporal gyrus and is orientated diagonally towards the posterior vertex of the floor of the lateral fissure, with its longest axis orientated towards the ventricular atrium. Heschl's gyrus/gyri is/are bounded anteriorly by the first transverse sulcus and posteriorly by the second transverse sulcus (sulcus of Heschl), and divide the temporal

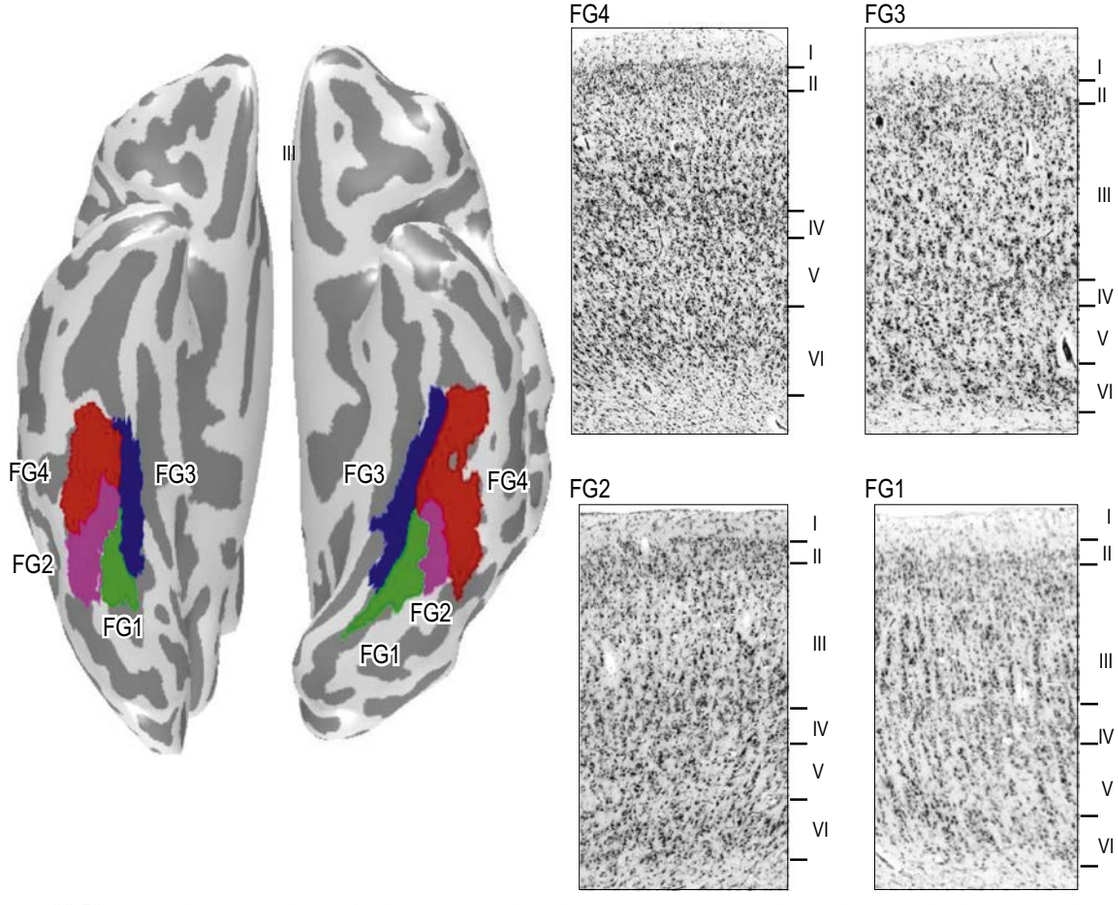

Fig. 32.59 Localization and cytoarchitectonic organization of higher visual areas in the ventral occipito-temporal cortex. (Adapted with permission from Weiner KS, Barnett MA, Lorenz S et al 2017 The cytoarchitecture of domain-specific regions in human high-level visual cortex. Cereb Cortex 27:146–61.)

opercular surface into an anterior polar plane, and a posterior temporal plane.

The surface of the polar plane shows several small transverse gyri directed obliquely towards the inferior part of the insular circular sulcus (inferior limiting sulcus) (see Fig. 32.2). The temporal plane is flat and triangular in shape and is usually larger in the dominant hemisphere, supposedly reflecting its association with language functions. Heschl's gyrus underlies the opercular surface of the postcentral gyrus, and the flat surface of the temporal plane underlies the opercular surface of the supramarginal gyrus.

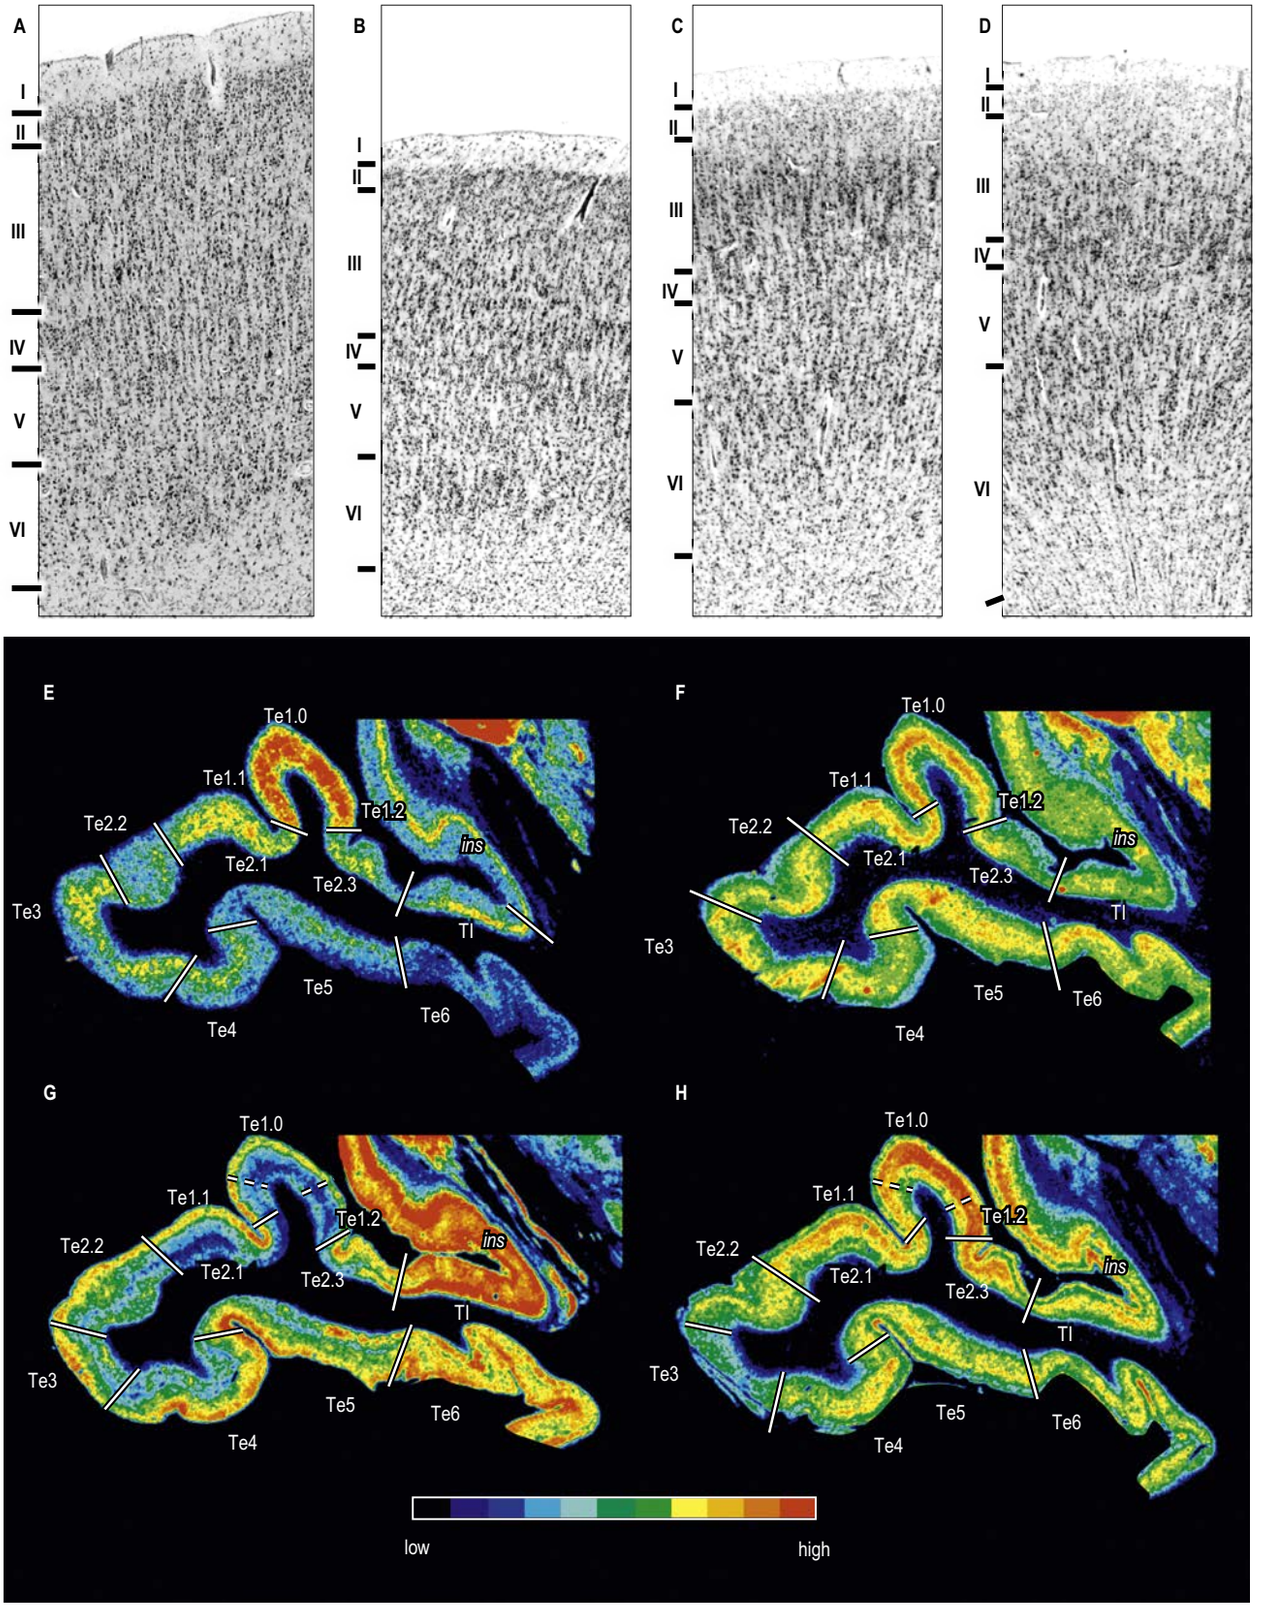

Fig. 32.61 A–D, The cytoarchitecture of the temporal cortical areas: **A**, Te1.0–Te1.2, primary auditory cortex (BA41); **B**, Te2.1–Te2.3, secondary auditory cortex (BA42); **C**, area Te3 (part of BA22 on the superficially exposed part of the superior temporal gyrus); **D**, BA21 on the middle temporal gyrus. **E–F**, Receptor distribution in the superior temporal gyrus (coronal sections): **E**, cholinergic muscarinic M_2 receptor; **F**, serotoninergic 5-HT_2 receptor; **G**, noradrenergic α_1 receptor; **H**, noradrenergic α_2 receptor. Lines indicate the positions of borders between areas. Laminar differentiation is indicated by Roman numerals. Te1, primary auditory cortex; Te2.1, Te2.2 and Te2.3 are subdivisions of the auditory belt region (comparable to BA42); Te3, Te4, Te5 and Te6 are parts of BA22 and belong at least partly to the auditory parabelt. TI is the transition area to the adjacent insular cortex (ins), which can be subdivided by Va2 receptors into TI1 and TI2.

The primary auditory cortex is koniocortical, like parietal area 3b and occipital area V1 (Fig. 32.60). Layer III mainly contains small to medium-sized pyramidal cells arranged in radial columns that extend partially into the neighbouring layers: this arrangement is known as the 'rain shower formation' of the primary auditory cortex (von Economo and Koskinas 1925). The geniculocortical fibres from the medial geniculate nucleus terminate densely in layer IV (Fig. 32.61). Te1 is also characterized by a very high density of cholinergic muscarinic M_2, GABAergic $GABA_A$, and noradrenergic α_2 receptors. The serotoninergic 5-HT_2 receptor has a slightly higher density in Te1. A high density of these receptors also occurs in the primary somatosensory (area 3b) and primary visual (BA17) areas, whereas the noradrenergic α_1 receptor has

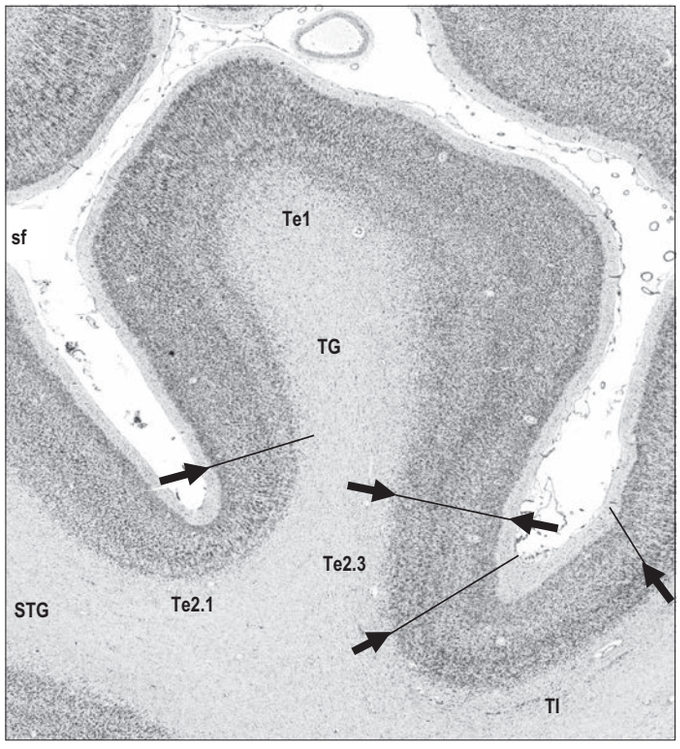

Fig. 32.60 Primary and secondary auditory cortical areas. Te1, primary auditory cortex (BA41); Te2.1 and Te2.3, lateral and medial parts of the secondary auditory cortex; TI is a transition area to the adjacent insular cortex and probably resembles Brodmann's BA52. Abbreviations: sf, Sylvian fissure; STG, superior temporal gyrus; TG, transverse gyrus of Heschl. Arrows indicate major areal borders.

a distinctly low density in the deeper layers of Te1 (see Fig. 32.61E–H). Dense myelination and strong expression of acetylcholine esterase and cytochrome oxidase are further characteristics of the primary auditory cortex. The neurones within the primary auditory cortex are spatially organized according to their response to sounds of different frequency (tonotopy) or intensity (ampliotopy) (Talavage et al 2004, Schreiner and Malone 2015). Using observer-independent cytoarchitectonic and multimodal parcellation methods, the primary auditory cortex (indicated as Te1) can be further subdivided into areas Te1.0, Te1.1 and Te1.2. Whether and how tonotopic fields relate to the architectonic subdivisions of Te1 is not known.

The secondary auditory area Te2 (BA42) is found anteriorly, laterally and caudally to Te1, and occupies the largest portion (>90%) of the temporal plane. Te2 does not extend onto the insular cortex medially nor does it extend on the convexity of the superior temporal gyrus laterally. The medial and the lateral borders are not precisely associated with sulcal landmarks. The koniocortical structure of Te1 disappears in Te2. The packing density of neurones in layer V increases from Heschl's gyrus through the planum temporale to the superior temporal gyrus. The pyramidal cells in layer III of Te2 are also arranged in vertical columns, referred to by von Economo and Koskinas (1925) as the 'organ pipe formation'. $GABA_B$, α_1 and $5\text{-}HT_{1A}$ receptors show higher densities in Te2 than in Te1.

The temporo-insular area TI differs from Te2: it has prominent and cell-dense infragranular layers, and there are differences in the regional and laminar receptor densities (see Fig. 32.61E–H). The border between the transitional area TI and the insular cortex can be defined on the basis of cytoarchitectonic differences and the distribution of cholinergic muscarinic M_2 receptor.

The auditory area Te3 occupies approximately the posterior two-thirds of the free surface of the superior temporal gyrus. Thus, Te3 corresponds to large parts of BA22, and is part of the auditory belt. It has a high density of IIIc pyramidal cells of prominent size and a rather cell-dense layer V. The layer VI/white matter boundary is less sharp than in Te2. Compared to Te2, Te3 has lower densities of M_2, and also slightly lower densities of M_1, NMDA and $GABA_A$ receptors. Compared to the areas (Te4 and Te5; see Fig. 32.61) located ventrally in the upper bank of the superior temporal sulcus, Te3 has lower densities of α_1, $5\text{-}HT_{1A}$, and AMPA receptors, particularly in the infragranular layers. The secondary and higher areas of the auditory cortex are involved in the perception of complex sounds, including frequency-modulated tones, harmonic complexes, amplitude modulations, spectrally dynamic sounds and sound sequences.

Direct corticofugal projections link the auditory cortex with the medial geniculate nucleus and the inferior colliculus. The auditory cortex interconnects with the prefrontal cortex, and posterior parts of the operculum project to areas 8 and 9. Central parts project to areas 8, 9 and 46. More anterior regions project to areas 9 and 46, to area 12 on the latero-orbital surface of the hemisphere, and to the anterior cingulate gyrus on the medial surface. Callosal connections are with the same and adjacent regions in the other hemisphere.

The functionally defined Wernicke's area is not clearly delineated anatomically, but corresponds to BA22 in the middle and posterior third of the superior temporal gyrus. It has a prominent role in comprehension of language, in particular sentences, syntactic processing and auditory working memory.

Temporal lobe areas connect via a 'dorsal' or a 'ventral' pathway with separate regions of the frontal lobe. The 'dorsal' pathway connects posterior temporal areas with the posterior dorsolateral prefrontal cortex; the 'ventral' pathway terminates in the anterior prefrontal cortex. In this context, the arcuate fascicle and the extreme capsule are particularly important for the impairment in Wernicke's aphasia. Considering that the dorsal and ventral prefrontal regions are characterized by spatial and non-spatial functional domains, it has been proposed that auditory information is channelled into at least two parallel processing streams: a dorsal or 'where' stream that subserves spatial localization, and a ventral or 'what' stream that subserves auditory object or pattern recognition. It has been shown that the anterior belt is responsive to the spectrotemporal features of a sound that code object identity, whereas neurones in the caudal belt are more sensitive to the spatial properties of a sound. It thus appears that object and spatial information is transmitted in different pathways beyond the auditory cortex.

BA21 on the middle temporal cortex is multimodal. It establishes reciprocal connections with early auditory, somatosensory and visual areas and connects to frontal areas according to an anterior–posterior gradient: posterior BA21 with BA8 and BA9, intermediate BA21 with BA9 and BA46, and anterior BA21 with BA10, BA46 and fronto-orbital areas. BA21 also projects to the temporal pole and the entorhinal cortex. Thalamic connections are with the pulvinar nuclei and the intralaminar group. Other subcortical connections with the ventral tegmental area, locus coeruleus and raphe nuclei follow the general pattern for all cortical areas.

The inferior temporal cortex, area 20, is, to a large extent, a higher visual association area. The posterior inferior temporal cortex receives major ipsilateral corticocortical fibres from V4. It contains a coarse retinotopic representation of the contralateral visual field and sends a major feed-forward pathway to the anterior part of the inferior temporal cortex. The anterior part of BA20 projects onto the temporal pole and the medial surface of the temporal lobe. Additional ipsilateral connections are with the parieto-temporal region. BA20 is also connected to BA46, the fronto-orbital cortex and the frontal eye field. Reciprocal thalamic connections are with the pulvinar and the intralaminar nuclei. Callosal connections are between corresponding areas and the adjacent higher visual areas of each hemisphere.

The cortex of the temporal pole receives feed-forward projections from widespread areas of temporal association cortex that are immediately posterior to it. The dorsal part receives predominantly auditory input from the anterior part of the superior temporal gyrus. The inferior part receives visual input from the anterior area of the inferior temporal cortex. Other ipsilateral connections are with the anterior insular, posterior and medial orbitofrontal, and medial prefrontal cortices. The temporal pole projects onwards into limbic and paralimbic areas. Thalamic connections are mainly with the medial pulvinar and with intralaminar and midline nuclei. Physiological responses of cells in this and more medial temporal cortex correspond particularly to behavioural performance and to the recognition of high-level aspects of social stimuli. Bilateral lesions of the temporopolar cortex cause retrograde amnesia (loss of all remote memories, but sparing learning and recent memory). Patients with these lesions suffer from a loss of autobiographical memories and the ability to recognize faces and names. The awareness of consolidated recognition of objects thus seems to occur in the temporo-polar cortex.

Insular lobe

The roughly triangular-shaped insular lobe (island of Reil) forms the base of the Sylvian cistern and lies between the frontal and temporal lobes (see Fig. 32.1). It is hidden in the depths of the lateral sulcus and covered by the opercular parts of the frontal, parietal and temporal lobes in the adult human brain.

The insular cortex subserves an extremely wide array of functions. It comprises such diverse functions such as olfaction, gustation, interoception, vestibular functions, general somatosensation, pain, cognition, attention, working memory, emotion including empathy, willed action, addictive behaviour and language. The insula seems to play a major role as a convergence zone and is implicated in the coordination between internal and external information through emotional subjective awareness. If the various functions are classified as larger functional domains, the sensorimotor domain is in the midposterior insula and forms the region posterior to the most posterior gyri breves; the cognitive domain is in the anterior-dorsal part of anterior and middle short gyri; the olfacto-gustatory domain is on the right middle insular gyrus; and the emotional domain is in the anterior-ventral part around the insular pole (**Fig. 32.62**).

Insular lobe sulci and gyri

Available with the *Gray's Anatomy* e-book

Insular lobe internal structure and connectivity

Cytoarchitectonically, four major zones are recognized within the insula. Starting from an allocortical small centre, a peri- to pro-isocortical semicircular zone is surrounded by a dysgranular to eulaminate isocortical zone. Most posteriorly, a relatively small granular isocortical zone follows to the caudal limit of the insula (see Fig. 32.62).

Thalamic afferents to the insula come from subdivisions of the ventral posterior nucleus and of the medial geniculate nucleus, from the oral and medial parts of the pulvinar, the suprageniculate/nucleus limitans complex, the mediodorsal nucleus and the nuclei of the intralaminar and midline groups. It appears that the anterior (agranular) cortex is connected predominantly with the mediodorsal and ventroposterior nuclei, while the posterior (granular) cortex is connected predominantly with the pulvinar and the ventral posterior nuclei.

Ipsilateral cortical connections of the insula are diverse. There are somatosensory connections with S1, S2 and surrounding areas, and the anterior part of the superior parietal lobule. The insular cortex also has connections with the orbitofrontal cortex, and several auditory regions

The insular surface is delineated peripherally by the circular sulcus of Reil, which is interrupted by the transverse insular gyrus running across the limen insulae. The anterior surface of the insula is covered by the fronto-orbital operculum (the posterior portion of the posterior orbital gyrus and the orbital part of the inferior frontal gyrus). Its lateral surface is covered superiorly by the frontoparietal operculum (triangular and opercular parts of the inferior frontal gyrus, subcentral gyrus, and anterior and basal part of the supramarginal gyrus) and inferiorly by the temporal operculum (polar plane of the superior temporal gyrus). Its anteroinferior vertex is the limen insulae, a narrow strip of olfactory cortex that extends along the lateral aspect of the lateral olfactory stria, conjoining the insular cortex and anterior perforate substance. The surface of the insula is divided into anterior and posterior parts by a deep central insular sulcus that courses obliquely from the limen insulae towards the central sulcus between frontal and parietal lobes. The anterior part of the insular surface is composed of short insular gyri (anterior, middle and posterior short insular gyri). The transverse insular gyrus runs along the limen insulae, connecting the anterior insula with the posteromedial part of the fronto-polar cortex. The latter is the connection between the posterior portion of the medial orbital gyrus and the posterior orbital gyrus, and is located anterior to and along the lateral olfactory stria. The accessory gyrus extends from the anterior portion of the anterior short gyrus superiorly to the transverse insular gyrus, beneath the fronto-orbital operculum. Both gyri constitute the insular pole within the anterior aspect of the insula. The posterior part of the insula is located behind its central sulcus and is composed of anterior and posterior insular long gyri. Both of these gyri are separated by the postcentral insular sulcus; the anterior long gyrus is usually larger, and may be single or divided at its upper end (see Fig. 32.62).

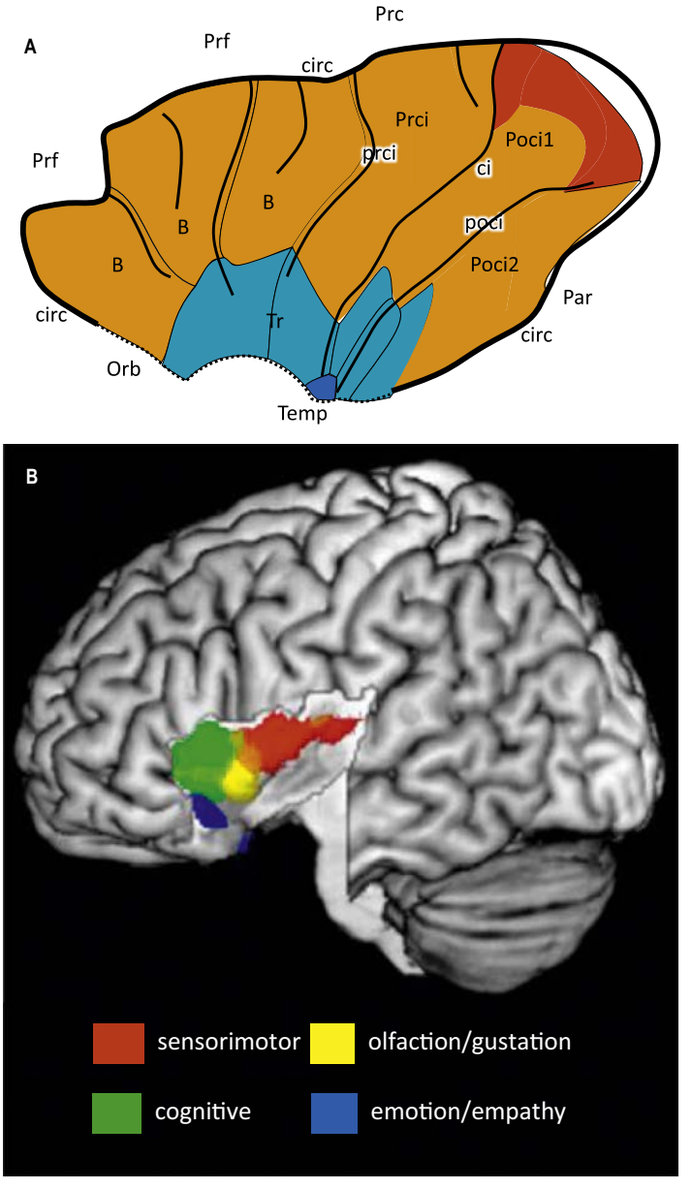

Fig. 32.62 Cortical regions and types (**A**) and functional domains (**B**) in the human insula. **A**, A cytoarchitectonic map of the insular cortex modified after Brockhaus (1940). Red, granular isocortical areas; orange, eulaminate to dysgranular isocortical areas; light blue, proiso- and periallocortical areas; dark blue, allocortical areas. **B**, Maps of functional domains. Abbreviations: B, short insular gyri; ci, central insular sulcus; circ, circular sulcus of the insula; Orb, adjoining fronto-orbital cortex; Par, adjoining parietal cortex; Poci1, first postcentral insular gyrus; Poci2, second postcentral insular gyrus; poci, postcentral sulcus of the insula; Prc, adjoining precentral cortex; Prci, precentral insular gyrus; prci, precentral sulcus of the insula; Prf, adjoining prefrontal cortex; Temp adjoining temporal cortex; Tr transverse orbital gyrus. Brain Struct Funct 214:519–34.)

in the temporal lobe interconnect with the posterior granular and dysgranular insular cortex. Connections with visual areas are virtually absent. The periallo- and allocortical insula has connections primarily with olfactory, limbic and paralimbic structures, including, most prominently, the amygdala.

WHITE MATTER OF THE CEREBRAL HEMISPHERES

The white matter of the cerebral hemispheres is composed of long myelinated axons grouped into larger white matter tracts (fasciculi). According to their origin, course and termination, white matter tracts can be classified into association, commissural or projection pathways (Fig. 32.63). The course of the large white matter tracts of the human brain can be studied using postmortem blunt dissections of brains prepared using Klingler's technique or *in vivo* with diffusion imaging tractography (Video 32.1).

Association tracts

Association tracts connect cortical areas in the same hemisphere and can be divided into short U-fibres linking adjacent gyri and long association tracts connecting distant gyri (Fig. 32.64). Most of the U-shaped fibres connect gyri within the same lobe (intralobar) whereas most of the long association fibres connect gyri of different lobes (interlobar). There is a relationship between the length of the fibres and the depth of their course within the white matter of the cerebral hemispheres: short U-fibres run more superficially, closer to the cortex of the gyri and sulci, whereas longer fibres group together deeper in the white matter of each gyrus and in the centrum semiovale. Association tracts are composed of both feed-forward and feed-back fibres that enable rapid feed-forward propagation of sensory input and top-down modulation of sensory processing.

Most of the intralobar tracts have been recently described and classified for the first time in humans with diffusion tractography.

In the frontal lobe, the frontal aslant tract is a short intralobar connection between the regions of the superior medial frontal lobe (supplementary and presupplementary motor areas, medial prefrontal cortex) and Broca's region (see Fig. 32.64; Fig. 32.65). The fronto-orbitopolar tract connects the posterior orbitofrontal, olfactory cortex and nucleus accumbens with the anterior orbitofrontal cortex and inferior frontal pole regions (see Fig. 32.64; Fig. 32.66). The superior and inferior frontal longitudinal fasciculi run underneath the superior and inferior frontal sulci, respectively and connect the posterior premotor cortex to the anterior prefrontal cortex (Fig. 32.67) (Catani et al 2012). The hand-knob region in the precentral gyrus is particularly rich in short U-fibres that are concentrically arranged around the origin of the corticospinal projections that are directed to the cervical spinal cord controlling finger movements (Fig. 32.68). The frontomarginal tract runs underneath the frontomarginal sulcus and connects medial and lateral frontal pole regions (see Fig. 32.66). The fronto-insular tracts are U-fibres connecting different areas of the inferior frontal and precentral gyri to the anterior gyri of the insula (Fig. 32.69). In the parietal lobe, short intralobar tracts connect the superior and inferior parietal lobules (intraparietal tract) and the post-central gyrus to the inferior parietal lobule (Fig. 32.70) (Catani et al 2017). In the temporal lobe, the temporal longitudinal fasciculus runs along the white matter of the superior, middle and inferior temporal gyri and connects anterior to middle and posterior temporal regions (Fig. 32.71). In the occipital lobe, the vertical occipital bundle of Wernicke links the regions of the superior, middle and inferior occipital gyri whereas the medial occipital longitudinal tract connects early visual areas to the parahippocampal place area (Figs 32.72–32.73).

Long interlobar association tracts have been originally described using postmortem blunt dissections in humans and axonal tracing studies in non-human primates. They include the arcuate fasciculus, superior, middle and inferior longitudinal fasciculi, inferior fronto-occipital fasciculus, uncinate fasciculus and cingulum. Individual variability in both the three-dimensional topography and size of these tracts has been reported in the healthy population, especially between hemispheres (interhemispheric asymmetry) or between male and female brains. The terminology used to indicate the association tracts often refers to their shape (e.g. the uncinate from the Latin *uncinatus* meaning 'hook-like'), their origin and termination (e.g. inferior fronto-occipital fasciculus), or their course, location and orientation within the cerebral hemispheres (e.g. inferior longitudinal fasciculus).

Arcuate fasciculus

The arcuate fasciculus is a dorsal association tract connecting perisylvian regions of the frontal, parietal and temporal lobe (see Fig. 32.64). In humans, two parallel pathways have been distinguished within the arcuate fasciculus (Catani et al 2005) (Fig. 32.74). The medial direct pathway (i.e. the arcuate fasciculus *sensu strictu* or direct long segment) connects Wernicke's region in the temporal lobe (BA41, 42, 22, 37) with Broca's region in the frontal lobe (BA6, 44, 45). The indirect pathway runs more laterally compared to the direct pathway and is composed of two separate segments: the anterior segment links Broca's region in the frontal lobe to Geschwind's region in the inferior parietal lobule (BA39, 40); the posterior segment links Geschwind's to Wernicke's region (Catani et al 2005). The direct long segment of the arcuate fasciculus is larger on the left hemisphere compared to the right in about 80% of the population; the remaining 20% shows a bilateral distribution

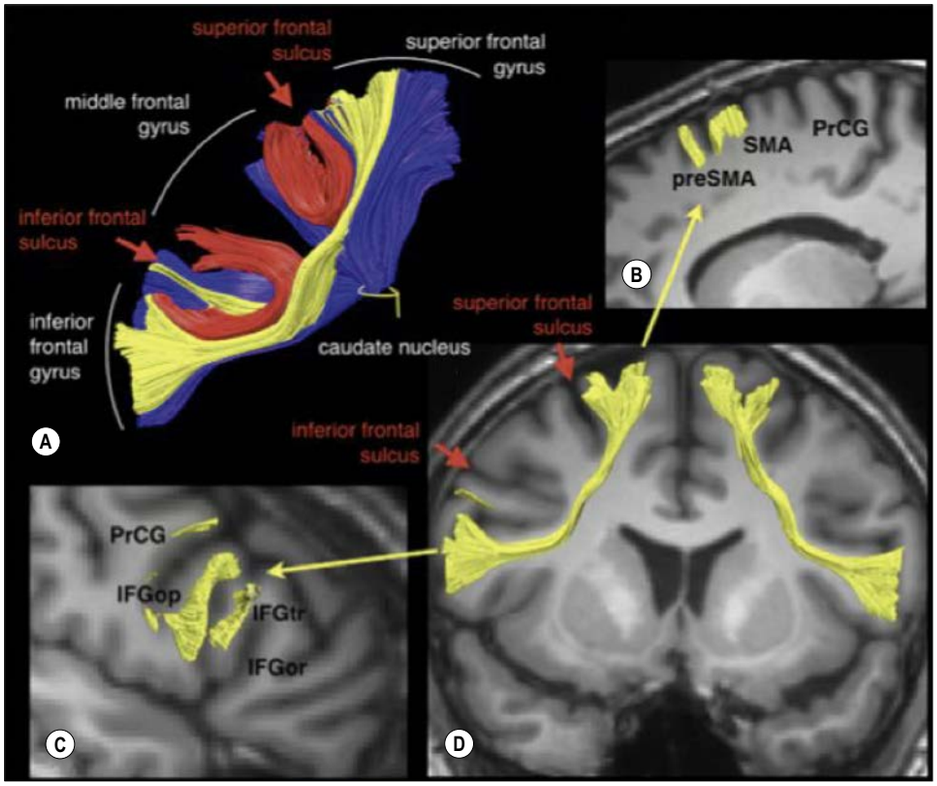

Fig. 32.65 Intralobar associative connections and projection fibres of the prefrontal cortex. **A**, The frontal aslant tract (yellow) connects superior and inferior regions of the posterior frontal lobe. It is medial to the short U-fibres (red) connecting superior, middle and inferior frontal gyri, and crosses fronto-striatal fibres (blue) projecting to the caudate nucleus and putamen. **B**, Medial cortical projections of the frontal aslant tract terminating in the supplementary motor area (SMA) and preSMA. **C**, Lateral cortical projections of the frontal aslant tract terminating in the precentral gyrus (PrCG) and pars opercularis (IFGop) and triangularis (IFGtr) of the inferior frontal gyrus. Other abbreviation: IFGor, inferior frontal gyrus, pars orbitalis. (Adapted with permission from Catani M et al 2012 Short frontal lobe connections of the human brain. Cortex 48: 273–91.)

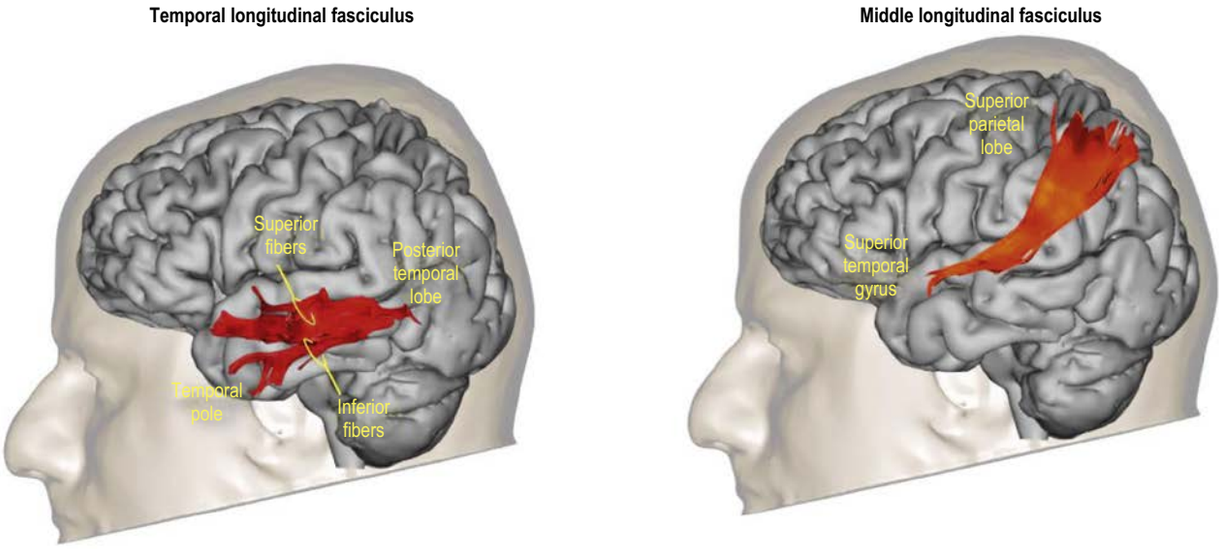

Fig. 32.71 Left: the temporal longitudinal fasciculus (TLF) is a long intralobar tract of the temporal lobe connecting posterior, mid- and anterior areas of the temporal gyri. It can be devided into superior (TLF I) and inferior (TLF II) branches. Right: the middle longitudinal fasciculus is a long interlobar tract connecting the superior temporal area to the posterior parietal lobe running medial to the long segment of the arcuate fasciculus.

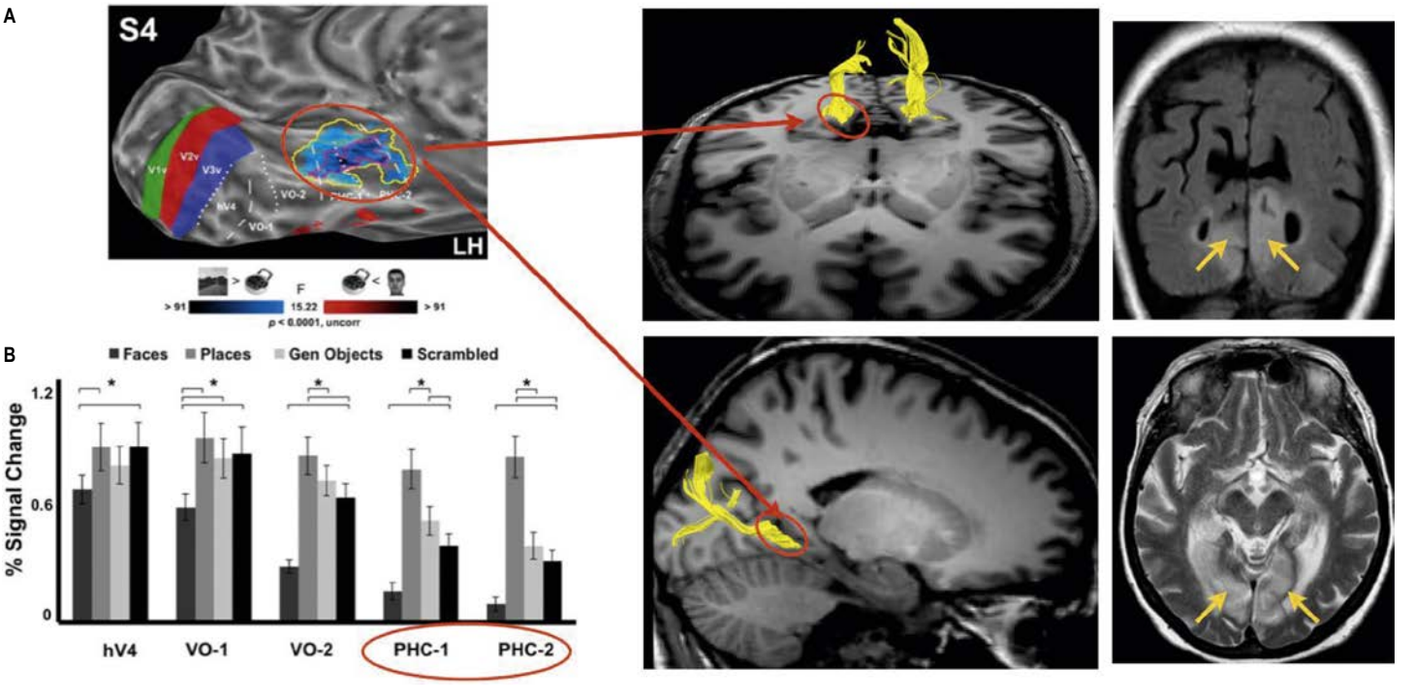

Fig. 32.72 The medial occipital longitudinal tract (MOLT, yellow tract) connects early visual areas (V1, V2, V3) of the cuneus and lingual gyrus with the posterior parahippocampal area (PPA, indicated by orange arrows and orange circles). The PPA includes the posterior (PHC-1) and anterior parahippocampal cortex (PHC-2) and is a region that responds selectively to images of scenes, places and buildings compared to other association areas (hV4, VO-1, VO-2) (Arcaro et al 2009). Damage to the MOLT or its cortical projections (indicated by yellow arrows) manifests with deficits in spatial navigation and memory for configurations (Lazzarino et al 2014).

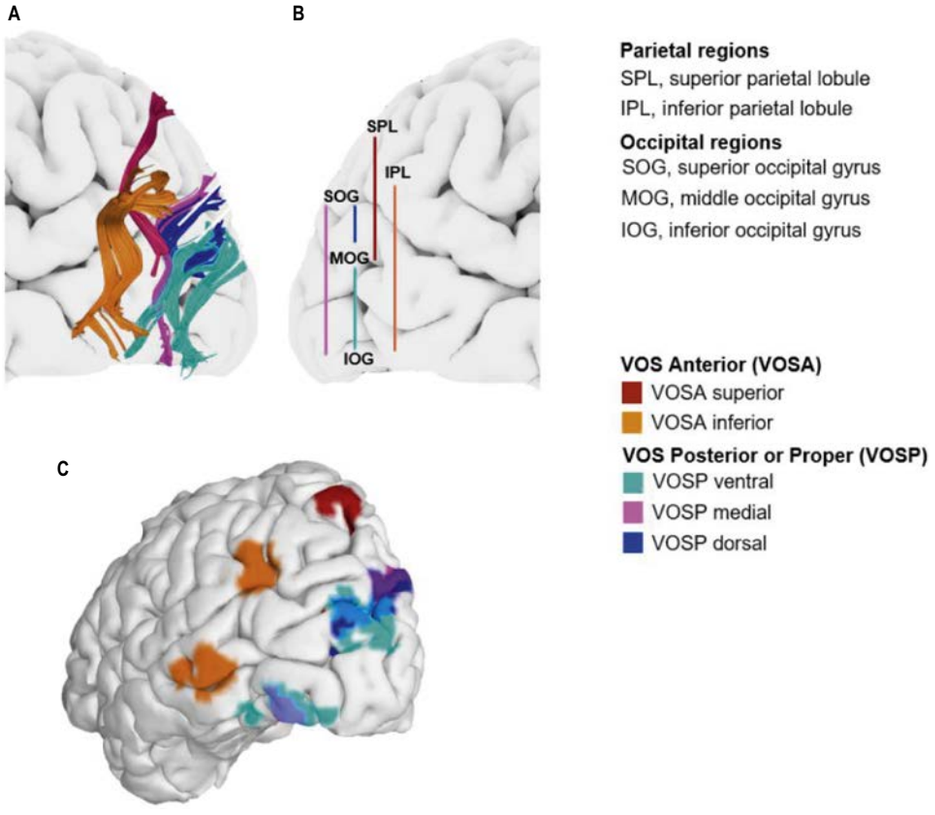

Fig. 32.73 The vertical occipital tract (VOS) of Wernicke is a system of short and long connections between superior, middle and inferior occipital regions. This tract can be divided into an anterior network (VOSA) composed of superior and inferior fibres, and a posterior network (VOSP) composed of ventral, medial and dorsal fibres. VOSA connects to the posterior parietal cortex. (Courtesy of Marco Catani and Ahmad Beyh, Natbrainlab.)

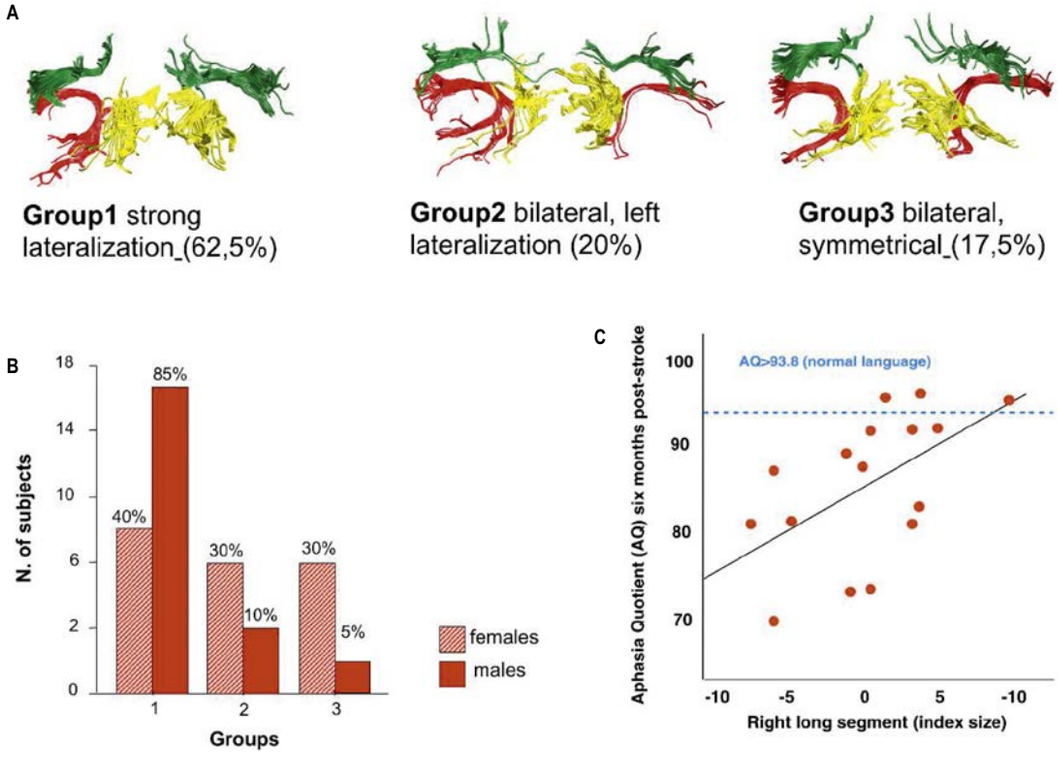

Fig. 32.75 Distribution of the pattern of lateralization of the arcuate long segment (red) in the healthy adult population (**A**) and according to sex (**B**). **C**, Recovery of language after left hemisphere stroke is higher in patients with a larger long segment in the right hemisphere. (With permission from Catani M, Allin MPG, Husain M et al 2007 Symmetries in human brain language pathways correlate with verbal recall. PNAS 104:17163–8; and Forkel SJ, Thiebaut de Schotten M, Dell'Acqua F et al 2014 Anatomical predictors of aphasia recovery: a tractography study of bilateral perisylvian language networks. Brain 137:2027–39.)

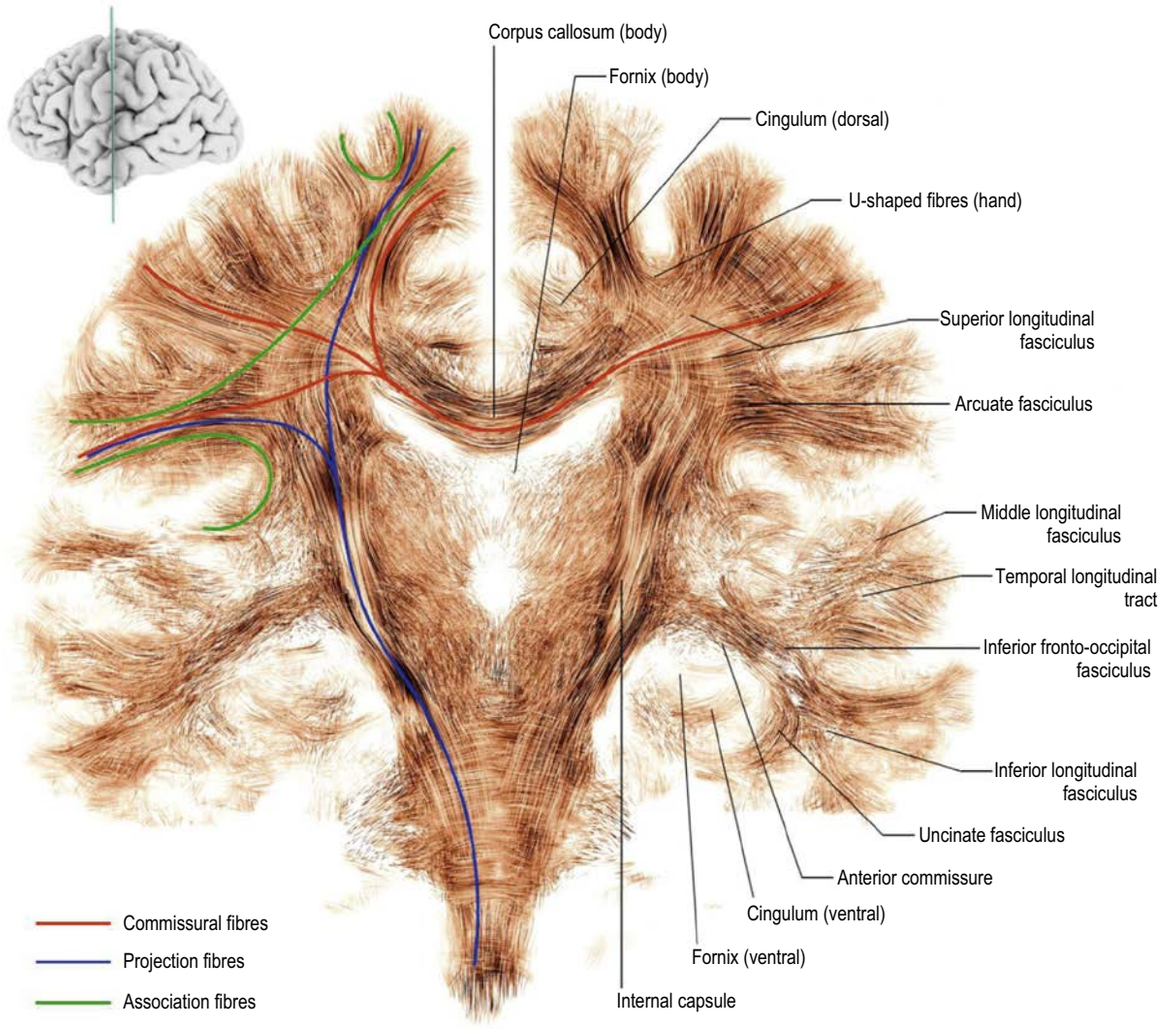

Fig. 32.63 Classification of white matter fibres and location of the major tracts of the cerebral hemispheres passing through a coronal section of the frontoparietal and temporal lobes. The background image was created using diffusion imaging tractography. (Courtesy of Flavio Dell'Acqua and Marco Catani, Natbrainlab.)

(Catani et al 2007) that is more prevalent in the female population and it has been associated with better recovery of language after a left hemisphere stroke (**Fig. 32.75**) (Forkel et al 2014). The arcuate fasciculus is important for language, social communication, working memory and complex limb motor coordination (praxis).

Superior longitudinal fasciculus

The superior longitudinal fasciculus (SLF) has three distinct branches as originally described in the monkey brain using axonal tracing methods (Petrides and Pandya 1984). In humans (see Fig. 32.64) (Thiebaut de Schotten et al 2011), the first branch of the superior longitudinal fasciculus (SLF I) connects the superior parietal lobule and precuneus (BA5 and 7) to the superior frontal (BA8, 9, 32) and perhaps to some anterior cingulate areas (BA24). The SLF I processes the spatial coordinates of trunk and lower limbs and contributes to the preparatory stages of movement planning (e.g. anticipation) (Leiguarda and Marsden 2000), oculomotor coordination (Anderson et al 2012), visual reaching (Johnson et al 1996), and voluntary orientation of attention (Corbetta and Shulman 2002). The SLF I is bilateral and there are lateralization differences between left- and right-handers (rightward lateralized in left-handers) (Howells et al 2018).

The second branch of the superior longitudinal fasciculus (SLF II) projects to the posterior region of the inferior parietal lobule (including the cortex buried in the intraparietal sulcus) and the lateral aspect of the superior (i.e. frontal eye field) and middle frontal gyri (BA6, 8, 9). The SLF II is involved in processing the spatial coordinates of the upper limbs, including the hand for reaching and grasping movements (Leiguarda and Marsden 2000, Goldenberg and Spatt 2009), and contributes to tasks requiring attention, visuospatial and spatial working memory (Levy and Goldman-Rakic 2000, Corbetta and Shulman 2002, Thiebaut de Schotten et al 2005). In humans the SLF II is right lateralized in most, but not all, subjects (about 70%) and the degree of lateralization is correlated with asymmetry in behavioural performances for visuospatial tasks (Thiebaut de Schotten et al 2011). This finding indicates that a right hemispheric specialization for visuospatial attention could be related to an unbalanced speed of signal processing along the SLF II of the two hemispheres.

The most ventral branch of the superior longitudinal fasciculus (SLF III) projects to the inferior parietal lobule (supramarginal and anterior angular gyri) and the posterior region of the inferior frontal gyrus and corresponds to the anterior segment of the arcuate fasciculus. In humans, this branch is almost always right lateralized.

Inferior longitudinal fasciculus

The inferior longitudinal fasciculus (ILF) is an occipito-temporal tract that connects early extrastriate visual cortex with the amygdala, parahippocampal gyrus and temporal pole (see Fig. 32.64). Its fibres run lateral to the optic radiations and inferior to the temporal horn. The inferior longitudinal fasciculus carries visual information from occipital areas to the temporal lobe and plays an important role in visual object and face recognition, language, semantic processing and reading (Epelbaum et al 2008, Fox et al 2008, Ffytche et al 2010).

Inferior fronto-occipital fasciculus

The inferior fronto-occipital fasciculus is a bow-tie-shaped bundle connecting medial occipital regions to the prefrontal regions and orbitofrontal cortex. The fibres of the inferior fronto-occipital fasciculus compact in the anterior floor of the external/extreme capsule where they run parallel to the more inferior fibres of the uncinate fasciculus (see Fig. 32.64) (Forkel et al 2014). Within the temporal lobe, the inferior fronto-occipital fasciculus contributes to the temporal stem and covers the temporal horn of the lateral ventricle and the ventricular atrium superiorly and laterally (Türe et al 2000). The functions of the inferior

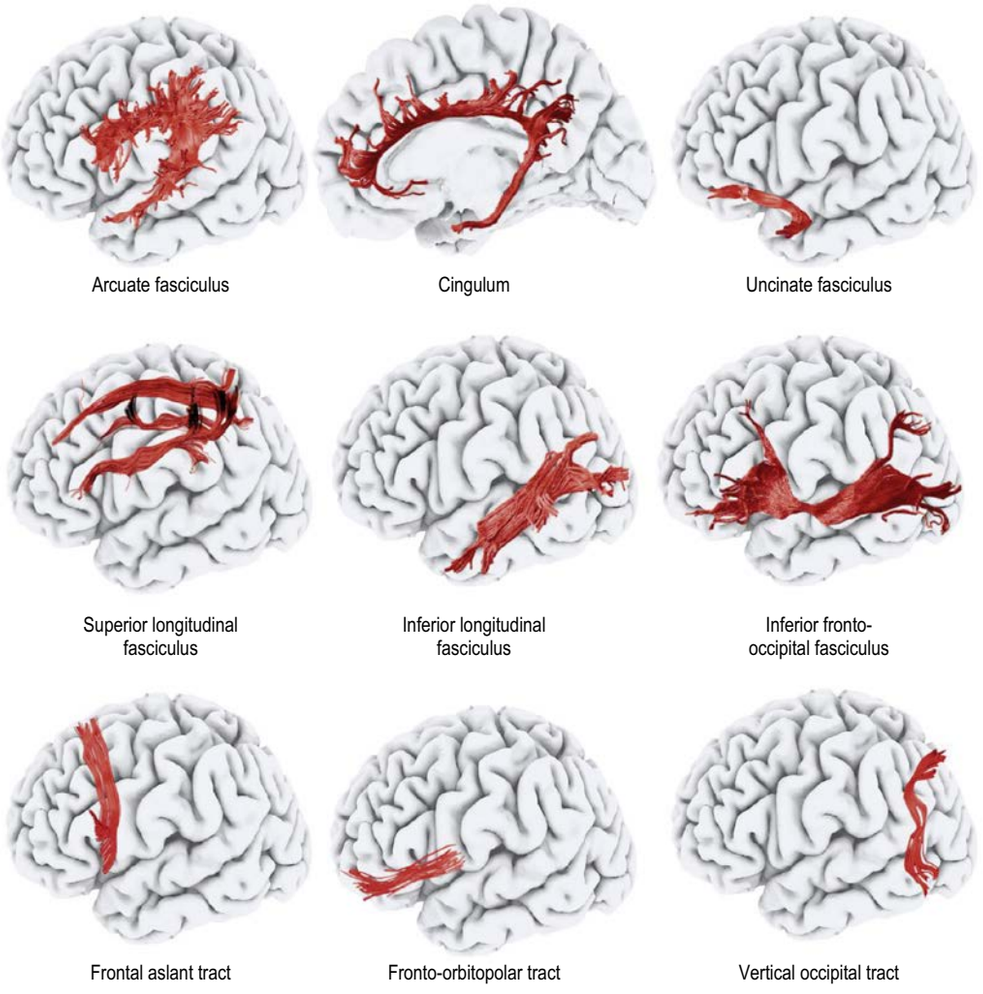

Fig. 32.64 Major interlobar (first and second row) and intralobar association tracts. (Figure kindly provided by Marco Catani, Natbrainlab.)

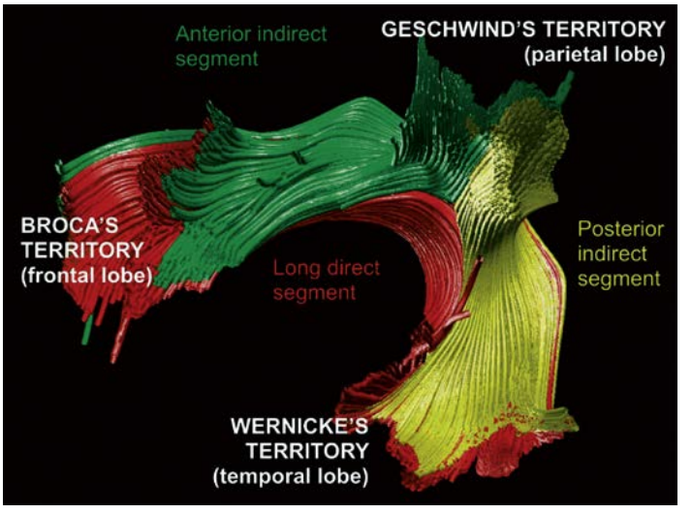

Fig. 32.74 The three segments of the arcuate fasciculus. (Adapted with permission from Catani M, Jones DK, Ffytche DH 2005 Perisylvian language networks of the human brain. Ann Neurol 57:8–16.)

fronto-occipital fasciculus remain largely unknown. The occipital areas connected by the inferior fronto-occipital fasciculus include the lingual gyrus and cuneus, which engage in tasks requiring retrieving information from visual memory, spatial attention and recognition of colours, letters and faces. The anterior projections of the inferior fronto-occipital fasciculus terminate in the medial and lateral orbitofrontal cortex, which activates in tasks requiring top-down modulation (either activation or inhibition) of visual perception and short-term memory. These frontal regions seem especially important in guiding decision-making and social behaviour in relation to the emotional value of external sensory stimuli (Rudrauf et al 2008).

Uncinate fasciculus

The uncinate fasciculus is a hook-shaped bundle that connects the anterior temporal lobe, including the amygdala, with the orbitofrontal region and inferior frontal gyrus (see Fig. 32.64). From the temporal lobe, the uncinate fasciculus enters the anterior floor of the external/extreme capsule between the insula and the putamen. Here, it runs inferiorly to the fronto-occipital fasciculus before splitting into a lateral branch which terminates in the lateral orbito-frontal cortex and inferior frontal gyrus (BA11 and 47), and a medial branch which projects to the medial orbitofrontal cortex, gyrus rectus and subcallosal area (Crosby et al 1962). The uncinate fasciculus plays an important role in lexical retrieval, semantic association, naming and social cognition (Craig et al 2009, Papagno et al 2011, Wilson et al 2011, Catani et al 2013). In addition to language and memory, it is also involved in several aspects of behaviour, including response inhibition, outcome monitoring, object–reward association learning and multimodal sensory integration, especially for olfactory–gustatory–visceral functions (Catani et al 2013). Damage to this tract has been correlated with the severity of antisocial traits in psychopaths (Craig et al 2009) and behavioural symptoms in frontotemporal dementia (D'Anna et al 2016) and traumatic brain injury (Zappalà et al 2012).

Middle longitudinal fasciculus

The middle longitudinal fasciculus runs in the white matter within the superior temporal gyrus, connecting the angular gyrus (area 39) with the superior temporal gyrus (area 22) up to the temporal pole (area 38) (see Fig. 32.71) (Makris and Pandya 2009). It lies medial and ventral to branch II of the superior longitudinal fasciculus and the arcuate fasciculus; lateral and superior to the inferior fronto-occipital fasciculus; and dorsal to the inferior longitudinal fasciculus. Its function is still unknown.

Cingulum

The cingulum lies within the depth of the cingulate and parahippocampal gyri, starting below the rostrum of the corpus callosum within the paraolfactory gyri (see Fig. 32.64). It contains fibres of different length; the longest run from the amygdala, uncus (BA35) and parahippocampal cortex (BA36 and 30) to sub-genual areas of the orbito-frontal lobe (BA25 and 11) (Crosby et al 1962, Nieuwenhuys et al 2008, Catani, Dell'acqua et al 2013). Shorter fibres, that join and leave the cingulum along its length, connect to adjacent areas of the cingulate cortex (BA23 and 24), superior medial frontal gyrus (BA32, 6, 8 and 9), paracentral lobule (BA4), precuneus (BA7), cuneus (BA19), lingual (BA18 and 19), and fusiform gyri (BA19 and 37). The cingulum can be divided into a dorsal and a ventral component (Catani and Thiebaut de Schotten 2012, Jones et al 2013). The dorsal component connects those areas in the anterior cingulate/medial frontal cortex and posterior cingulate/precuneus that form the dorsomedial default-mode network (Raichle et al 2001, Raichle and Snyder 2007, Raichle 2015). The activity of these regions decreases in the transition between a 'resting state' and the execution of goal-directed tasks, irrespective of the nature of the task. The default-mode network has been linked to a number of functions including working memory, focusing attention to sensory-driven activities, understanding other people's intention (mentalizing or theory of mind), prospective thinking (envisioning the future) and memory for personal events (autobiographic memory) (see cingulate cortex). The ventral cingulum connects the amygdala and anterior parahippocampal cortex to retrosplenial regions and posterior parahippocampal areas and forms a network dedicated to spatial orientation and memory for navigation (Aggleton 2008, Vann et al 2009).

Commissural fibres

Commissural fibres originate in one hemisphere, cross the midline and project to the contralateral hemisphere. Homotopic fibres interconnect corresponding cortical areas in the two hemispheres and represent the most prevalent type of commissural connections. Heterotopic commissural fibres connect a cortical area with non-corresponding areas in the contralateral hemisphere. The largest commissural tracts of the human brain are the corpus callosum and the anterior commissure.

Corpus callosum

The corpus callosum contains 150–200 million fibres and is the largest fibre pathway of the human brain. On a midsagittal section, it forms an anteroposterior midline arch approximately 10 cm long that early anatomists subdivided into rostrum, genu, trunk (or body), isthmus and splenium. Each division of the corpus callosum contains fibres that project to specific cortical regions (**Fig. 32.76**).

The rostrum corresponds to the floor of the lateral ventricle and its fibres connect the orbitofrontal cortex. The genu is the most anterior portion of the corpus callosum and forms the anterior wall of the frontal horn of the lateral ventricle. Fibres in the genu curve forwards, as the forceps minor, to connect the areas of the prefrontal cortex. The body forms the roof and lateral wall of the lateral ventricles. Its fibres pass laterally, intersecting with the projection fibres of the corona radiata (see Fig. 32.76B, Video 32.1) to connect premotor and motor areas of the frontal lobe and most areas of the parietal lobe. The isthmus corresponds to a narrow portion of the corpus callosum between the body and the splenium. The fibres of the isthmus connect auditory temporal cortices.

The splenium of the corpus callosum overhangs the posterior ends of the thalami, the fornix, the pineal gland and tectum. A superior and an inferior layer of tela choroidea advance below the splenium through the transverse fissure, forming the velum interpositum cistern within the roof of the third ventricle and between the thalami, just below the bodies of the fornices; it contains the distal branches of the medial posterior choroidal arteries and the internal cerebral veins. The majority of the fibres of the splenium curve back into the occipital lobes as the forceps major. Some fibres of the splenium and isthmus arch forwards along the lateral wall of the inferior horn of the lateral ventricle, and constitute the tapetum. Acquired callosal lesions may manifest with disconnection syndromes characterized by the inability to transfer information or competences from one hemisphere to the other. The technique of severing commissural fibres in epileptic patients (split-brain) was introduced in the 1930s to control the spread of ictal discharge from one hemisphere to the other. Split-brain patients provided an opportunity to understand the functions of the corpus callosum and lateralization of cerebral functions (i.e. left cerebral dominance for language and right dominance for visuospatial functions).

Anterior commissure

The anterior commissure runs within the basal forebrain and fans out laterally within the temporal lobe (**Fig. 32.77**). It is believed to connect areas that include the olfactory bulb and anterior olfactory nucleus; the anterior perforated substance, olfactory tubercle and diagonal band of Broca; the prepiriform cortex; the entorhinal area and adjacent parts of the parahippocampal gyrus; part of the amygdaloid complex (especially the nucleus of the lateral olfactory stria); the bed nucleus of the stria terminalis and the nucleus accumbens; and inferior regions of the temporal and occipital lobes.

The anterior commissure has the shape of a classic bicycle handlebar. It crosses the midline just ventral to the supraoptic recess of the third ventricle, immediately anterior to the major component of the column of the fornix that projects to the mammillary body, and posterior to the smaller components of the fornix that project to the septal nuclei (see Fig. 32.77B). At this point, the anterior commissure bulges inside the third ventricle, just underneath the interventricular foramen. The lamina terminalis is attached superiorly to the midline segment of the anterior commissure and inferiorly to the upper surface of the optic chiasma; the optic recess of the third ventricle is the cleft between the lamina terminalis and the midportion of the superior surface of the chiasma.

Each side of the anterior commissure is composed of a well-defined posterolateral bundle (the hemispheric part) and a smaller, anterior component (the olfactory part) (Déjérine and Déjerine-Klumke 1895). The anterior component curves forwards and vertically through the anterior perforated substance towards each olfactory tubercle. The hemispheric component curves posterolaterally, passing through a deep groove on the anteroinferior aspect of the globus pallidus, and fanning out mostly to the anterior part of the temporal lobe, including the parahippocampal gyrus, but also reaching the occipital lobe posteriorly. This component of the anterior commissure runs parallel to the amygdalofugal peduncles which carry information from the amygdala to the hypothalamic nuclei (Fig. 32.77B).

When passing under the inferior limiting sulcus of the insula, superior to the temporal horn of the lateral ventricle, the fibres of the anterior commissure join the temporal stem, merging with the fibres of the uncinate and inferior fronto-occipital fasciculi. They pass posteriorly as the sagittal stratum, together with the inferior fronto-occipital fasciculus and the fibres of the optic radiation, over the lateral aspect of the temporal horn and ventricular atrium. Within the temporal stem, the fibres of the anterior commissure are mostly medial to the uncinate fasciculus; both are inferior to the inferior fronto-occipital fasciculus. Within the sagittal stratum, they intermingle but run predominantly below the inferior fronto-occipital fasciculus, superior to the fibres of the optic radiation. The line between the anterior and posterior commissures, the AC–PC line, is a very important landmark in stereotactic atlases, used when localizing neuroanatomical targets for stereotactic neurosurgical procedures.

Hippocampal commissure

The hippocampal commissure (commissure of the fornix) is a thin triangular sheet of fibres that lies between the crura of the fornices, connecting the hippocampi (**Fig. 32.78**). It is situated underneath and attached to the splenium, overhanging the pineal region.

Projection fibres

Projection fibres connect the cerebral cortex with the subcortical grey matter of the cerebral hemispheres, brainstem and spinal cord. They include large numbers of both corticofugal (descending) and corticopetal (ascending) fibres. Most of the projection fibres originating in the frontal, parietal and occipital lobes converge in the corona radiata and from here pass through the internal capsule to reach their subcortical targets. The projections forming the internal capsule are termed capsular projections and are separated from the non-capsular projections. The extracapsular fibres include the cortico-striatal projections directed to the most external putamen and projections to the claustrum course through the external capsule. The largest limbic projection tracts (fornix, ansa peduncularis, extracapsular thalamic peduncle, ansa and stria terminalis) also have an extracapsular course and do not contribute to the corona radiata. Except for the fornix and cingulum, most of the temporal projection tracts pass through the temporal stem which can be considered as the posterior extension of the external/extreme capsule. The term temporal stem is derived from its appearance in coronal sections of the temporal lobe, where the region resembles a small cauliflower composed of a single short stem and small florets that correspond to the five longitudinal temporal gyri. The stem originates from the floor

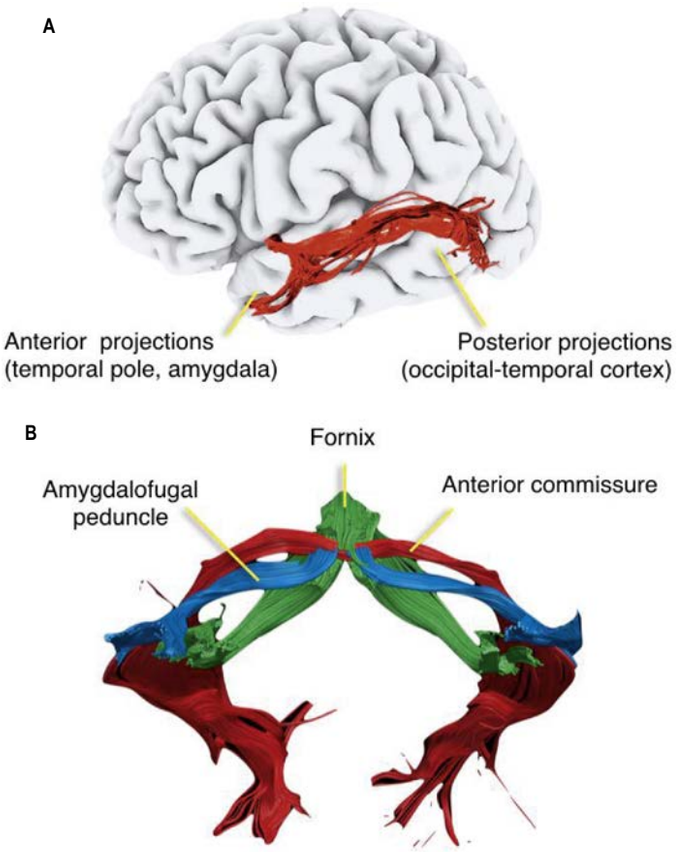

Fig. 32.77 **A**, A lateral view of the anterior commissure showing its anterior and posterior projections. **B**, Relationship between the anterior commissure (red), fornix (green) and amygdalofugal peduncle (blue). (Courtesy of Marco Catani, Natbrainlab.)

of the external/extreme capsule; in its narrowest portion it is contained within a space delimited medially by the lateral ventricle and laterally by the inferior branch of the peri-insular sulcus. Within the posterior temporal stem, these fibres run parallel to the lateral ventricle before spreading outward into the temporal gyri to reach their cortical targets.

Internal capsule

The internal capsule has the shape of a V in horizontal section (axial images), with its vertex (genu) located medially between the head of the caudate nucleus and the thalamus (**Fig. 32.79**). For descriptive purposes, the internal capsule is arbitrarily divided into five parts: anterior limb, located between the putamen and the head of the caudate nucleus; genu, lying laterally and adjacent to the interventricular foramen (of Monro); posterior limb, located between the putamen and the thalamus; retrolenticular or retrolentiform portion, located posterior to the putamen; and sublenticular (or sublentiform) portion, located inferior to the putamen (see Fig. 32.79). The internal capsule contains thalamo-cortical fibres that form the thalamic peduncles, the majority of the cortico-striatal fibres, cortico-nuclear and cortico-spinal tracts that course through the cerebral peduncles, and projections to other nuclei of the brainstem.

Corticospinal and corticonuclear tracts

The corticospinal tract provides direct control by the cerebral cortex over motor centres in the contralateral spinal cord. The corticonuclear tract fulfils a similar function in relation to the motor nuclei of the brainstem that give origin to cranial nerves.

About 20–30% of corticospinal fibres arise from the pyramidal cells in layer V of BA4. The remaining corticospinal fibres originate from the premotor cortex and parietal areas of the postcentral gyrus, superior parietal lobule and operculum. Many axons from BA4 terminate in the ventral horn of the spinal cord: a small percentage establish direct monosynaptic connections with α-motoneurones. Between 40% and 60% of pyramidal tract axons arise from parietal areas, including area 3a, area 5 of the superior part of the parietal lobe and secondary somatosensory areas in the parietal operculum. The majority of parietal fibres to the spinal cord terminate in the deeper layers of the dorsal horn. Motor cortical neurones are active in relation to the force of contraction of agonist muscles; their relation to the amplitude of movement is less clear. Their activity precedes the onset of electromyographic activity by 50–100 milliseconds, suggesting a role for cortical activation in generating rather than monitoring movement.

The corticospinal and corticonuclear fibres that arise within the precentral gyrus are disposed as a fan on a coronal plane throughout the corona radiata. They cross the corpus callosum before entering the genu and posterior limb of the internal capsule (see Fig. 32.76, Video 32.1). To join the internal capsule, the corticospinal and corticonuclear fibres not only converge but also undergo an internal rotation of approximately 90 degrees, because the main axes of the precentral gyrus and of the internal capsule genu and posterior limb are almost perpendicular. Throughout their course the fibres retain their somatotopical motor arrangement, organized according to the homuncular cortical representation, adopting an anterior–cranial to a posterior–caudal disposal along the genu (corticonuclear tract) and the posterior limb (corticospinal tract) of the internal capsule. Within the posterior limb of the internal capsule the fibres concerned with the upper limb are anterior to the fibres representing the trunk and lower limbs. From the internal capsule the fibres converge further into the cerebral peduncles, where the corticospinal and corticonuclear fibres are located in the middle half of the crus between frontopontine fibres (medially) and corticopontine fibres from temporal, parietal and occipital cortices (laterally).

Other descending axons include frontopontine fibres (Arnold's bundle), particularly from areas 4 and 6, and corticorubral fibres, coursing through the anterior limb of the internal capsule. The retrolenticular part of the internal capsule contains parietopontine, occipitopontine and occipitotectal fibres and the sublenticular part contains temporopontine and some parietopontine fibres. All corticopontine fibres that originate from parietal, occipital and temporal lobes collectively form the bundle of Türk.

Thalamic radiations

The thalamic radiations originate from the thalamic nuclei. After a short course through the internal capsule they enter the corona radiata and terminate in the cortex of the ipsilateral hemisphere (**Fig. 32.80**). The thalamic radiations from the anterior and medio-dorsal thalamic nuclei enter the anterior limb of the internal capsule and form the anterior thalamic peduncle that projects to all prefrontal and orbitofrontal cortices. The thalamic nuclei of the ventral group and in part those of the lateral group give origin to the superior thalamic peduncle, which courses through both anterior and posterior limbs of the internal capsule, terminating in the posterior frontal cortex (from ventral anterior and ventral lateral thalamic nuclei) and parietal cortex (from ventral posterior and lateral posterior thalamic nuclei), respectively.

The retrolenticular part of the internal capsule includes the optic radiation and the posterior thalamic radiation originating from the pulvinar and directed to the posterior cortex of the parietal and temporal lobes and the occipital cortex.

The fibres of the optic radiation arise from the lateral geniculate body and the pulvinar, join the retrolenticular and the sublenticular parts of the internal capsule, run within the sagittal stratum over the temporal horn and ventricular atrium, and project posteriorly, passing superiorly and inferiorly to the occipital horn as part of the posterior thalamic peduncle to reach both the superior and inferior lips of the calcarine sulcus. Within the temporal lobe, the fibres of the optic radiation are located along the depths of the superior and middle temporal gyri about 2 cm from the brain surface, medial to the arcuate and inferior fronto-occipital fasciculi and inferior to the auditory radiations. Its fibres are divided into anterior (Flechsig's temporal knee or Meyer's loop), central and posterior bundles. On sagittal sections, the occipital fibres are concentrically distributed around the occipital horn of the lateral ventricle in the following order: callosal fibres (the most internal layer); optic radiations and extrastriate thalamocortical projections (internal sagittal stratum of Sachs); association fibres of the inferior longitudinal fasciculus and inferior fronto-occipital fasciculus (external sagittal stratum of Sachs).

The sublenticular part of the internal capsule contains the auditory radiation from the medial geniculate body and direct fibres from the inferior colliculus, that together project to the superior temporal and transverse temporal gyri (areas 41 and 42). Thalamic fibres from the pulvinar to the temporal cortex and insula are also contained within the sublenticular part of the internal capsule. Fibres of the auditory radiation sweep anterolaterally below and behind the lentiform complex and superiorly to the temporal horn, ventricular atrium and optic radiation. As they enter the temporal stem, the auditory radiations fan out and split into two branches. The superior branch continues laterally towards Heschl's gyrus and the surrounding cortex, where it finally projects to early auditory areas. The inferior branch continues anteriorly along the temporal stem in a space delimited by the inferior border of the putamen, the lateral ventricle and the inferior insula. It is directed towards the anterior temporal lobe and sends many projections to the amygdala and most anterior temporal cortex of the superior, middle and inferior temporal gyri. The acoustic radiations also contain fibres that run in the reverse direction from the temporal cortex and amygdala to the medial geniculate nucleus and inferior colliculus (Pickles 2015). This centrifugal system mediates the top-down modulatory effect by which the temporal cortex and amygdala enhance the response of subcortical nuclei to stimuli of significance.

Fornix

The fornix is the fibre bundle of the hippocampus. It wraps round the thalamus, from which it is separated by the choroidal fissure and the choroid plexus. The fornix consists of the fimbria, crus, body and columns or pillars. The fibres of the alveus converge to form the fimbria fornicis (see Fig. 32.78) along the medial portion of the floor of the inferior horn of the lateral ventricle. At a point beneath the splenium of the corpus callosum, the white matter of the fimbria separates from the hippocampus to become the crus fornicis. The two crura pass upwards and forwards beneath the corpus callosum, joined via fibres that cross in the commissure of the fornix (hippocampal commissure). Beyond this point, the crura merge to become the body of the fornix, which continues anteriorly within the roof of the third ventricle, below the lower border of the septum pellucidum and near the midline. At the level of the interventricular foramen (foramen of Monro) and the anterior commissure, the body splits into two anterior (precommissural) and two posterior (postcommissural) columns: the smaller anterior columns terminate in the hypothalamic nuclei whereas the larger posterior columns project to the mammillary bodies. As they separate from the underlying thalamus, the posterior columns of the fornix form the anterior margins of the interventricular foramen.

A smaller number of fornical fibres project to the anterior thalamic nuclei (anterior medial, anterior ventral and anterior dorsal thalamic nuclei), ventral striatum, medial septum and nucleus reuniens; some are exclusively afferent to the hippocampus, e.g. from the supramammillary and raphe nuclei and the locus coeruleus (Aggleton et al 2010, Jang and Kwon 2013, Jang and Kwon 2014). As a midline white matter tract, the fornix is particularly susceptible to involvement by tumours that favour this route of spread, e.g. glioblastoma multiforme, and to rotational shearing injuries responsible for diffuse axonal injury (Thomas et al 2011).

COMMENTARY

3.1 Comparative anatomy of the corticospinal system

Roger Lemon

The comparative anatomy of the long, corticofugal pathways from cortex to subcortical structures is important because we can interpret the key features of these pathways in humans on the basis of their similarities and differences when compared with other animals. This is particularly true of the corticospinal system. All mammals have a corticospinal tract, which originates from a number of parietal and frontal cortical areas, and which projects to different regions of the spinal cord. However, in functional terms, the different components of the corticospinal projection show large species-specific contrasts. There are also marked variations in other anatomical features, such as range of fibre sizes, spinal trajectory, pattern of termination within the spinal grey matter, and extent of the tract along the length of the spinal cord.

CORTICAL ORIGIN

There is a basic pattern across all mammals for the cortical areas that give rise to the corticospinal tract. There are more areas in primates than in non-primates. In the former they include primary motor (M1) and somatosensory (S1) cortex, parietal area 5, S2, and frontal areas including dorsal and ventral premotor cortex and the supplementary motor area (all area 6) and a family of cingulate motor areas in the cingulate cortex on the medial surface of the hemisphere. In all of these areas, corticospinal fibres arise only from lamina V, which of course is very thick in motor cortex. In humans, all of these areas probably give rise to corticospinal fibres. Classical studies suggested that 60% of these fibres come from the frontal areas and 40% from parietal.

Number and size of axons

The number of fibres in the mammalian corticospinal (pyramidal) tract varies from around 30,000 from each cortical hemisphere in the mouse, up to around 1 million fibres in humans. There is a close relationship between fibre number, overall body weight and brain size. In all mammals the great majority of the fibres are of small diameter (<3 μm). In some large-bodied primates, there are larger fibres (>8 μm) and the largest are in humans (22 μm), but large fibres make up only a few per cent of all fibres in the tract.

Spinal trajectory

The course taken by corticospinal fibres within the spinal cord shows great variation. In rodents, rabbits and opossums most of the fibres are located at the base of the dorsal columns, whereas in elephants and hedgehogs, they are exclusively in the ventral funiculus. In carnivores and primates, most of the fibres are in the dorsolateral funiculus, with a smaller number of uncrossed fibres travelling in the ventral funiculus. A few fibres may also be scattered in the dorsal columns. In humans, fibres making up the lateral corticospinal tract are found throughout the dorsolateral funiculus (**Fig. 3.1.1**), although they are considered to lie slightly medial to the ascending dorsocerebellar tract fibres, which occupy the most lateral part of the dorsolateral funiculus. There is no obvious somatotopic organization within the various corticospinal tracts: fibres from different subdivisions (arm, leg) of M1, for example, are intermingled, as are projections from different cortical areas.

Extent of termination

In primates, including humans, the corticospinal tract extends for the full length of the spinal cord to the most caudal segments of the sacral cord. This is also the case in carnivores and rodents. Thus the tract can influence spinal mechanisms concerned with all four limbs (and tail when present). In some species, such as elephants, and ungulates such as goats, the tract does not extend beyond the upper cervical cord. Indeed, in the elephant the heaviest motor projection is to the facial nucleus, supplying the muscles of its trunk. In rodents, the heaviest motor projection from the cortex is again to the facial nucleus, with direct projections involved in the whisker movements, so important for the rodent's exploration of space.

Pattern of spinal termination

Kuypers (1981) reviewed the pattern of corticospinal termination in the spinal grey matter across different species (see Fig. 3.1.1). He recognized that from rodents to carnivores and New World monkeys and from Old World monkeys to chimpanzees and humans there was a distinctive ventral shift in the pattern of terminations.

Projections to the dorsal horn

Kuypers stressed that in rodents and more primitive mammals, the major termination of the tract was in the dorsal horn, and this has been confirmed repeatedly for mouse and rat (**Fig. 3.1.2**). This suggests that at least one function of the tract, probably shared across all mammals and including humans, is the descending control of afferent input, including nociceptive input. This descending control may be very important for sensorimotor control, and in particular for the rapid recognition of predictable patterns of somatosensory input resulting from planned movements. Descending corticospinal signals can alter pain thresholds. In primates, most of the projections to the dorsal horn probably come from S1 (see Fig. 3.1.2), and there is only a weak projection to the dorsal horn from frontal motor areas.

Intermediate zone

In primates, and some non-primates such as cat, racoon, etc., the motor areas project to the intermediate zone, influencing spinal reflex pathways. In macaques the greatest number of corticospinal boutons are found in lamina VII (**Fig. 3.1.3**), which is the source short propriospinal pathways to motor neurones innervating the distal extremity.

Ventral horn

Direct projections (cortico-motoneuronal (CM) projections) to motor neurones of lamina IX are found only in some primate species, and these are best developed in great apes, such as chimpanzee and in humans (see Fig. 3.1.1). In macaques, quantitative analysis of terminal boutons, labelled after injections of tracer material in the M1 hand/arm region, shows that the number of boutons within lamina IX is second only to those in lamina VII (see Fig. 3.1.3).

Retrograde transneuronal virus labelling from different upper limb muscles in macaques suggests that only two areas give rise to significant numbers of CM projections: the caudal part of M1 ('new' M1) and area 3a.

The functional implications of this conspicuous ventral shift in termination pattern are still being researched, but there are some important clues in terms of the comparative anatomy. The long-standing idea that the presence of direct CM projections contributes to the capacity for skilled control of the hand is supported by the fact that CM projections are only well developed in those primates that are tool users/tool manufacturers. These include the New World capuchin monkey and Old World macaque monkey, baboon and the great apes. There is a well-established correlation between the strength of this projection, the size of postsynaptic excitation in hand and digit motor neurones and the measure of digital dexterity (**Fig. 3.1.4**).

Laterality of projections

It is estimated that in humans around 90% of the fibres in the corticospinal tract decussate to the opposite side and most descend in the lateral corticospinal tract. The remaining 10% descend ipsilaterally, mostly in the ventral corticospinal tract. The functions of these two components of the tract is still being investigated. The classical story is that the crossed fibres are mostly involved in control of the contralateral extremity, via their terminations in lamina VII and the lateral motor neurone pools, while ipsilateral fibres make bilateral terminations in lamina VIII and the medial motor neurone pools, innervating axial and girdle muscles.

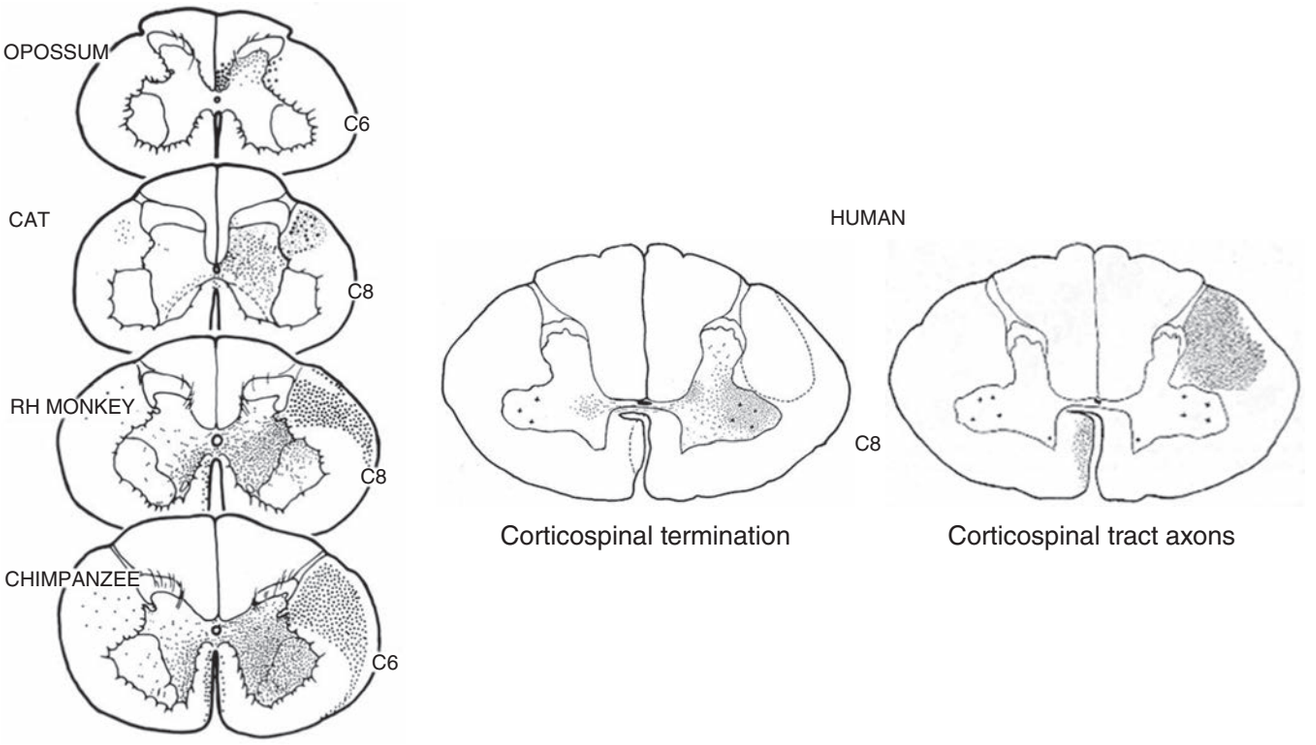

Fig. 3.1.1 Pattern of corticospinal projections from motor cortex in five different species. The black dots in the white matter funiculi indicate the trajectory of crossed corticospinal fibres, which are found in the dorsal columns in the opossum, but mostly in the dorsolateral funiculus in the other species shown. Uncrossed fibres are shown travelling in the ventral funiculus. The black dots in the spinal grey matter indicate the termination of corticospinal fibres, as determined from visualization of degenerating terminals. The diagrams illustrate the ventral shift of terminations from opossum, where most fibres terminate in the contralateral dorsal horn; to cat, where fibres terminate in the contralateral intermediate zone; to the rhesus monkey, chimpanzee and human, which show progressively greater numbers of terminals in the lateral motor neurone pools of the ventral horn. Terminations in ipsilateral lamina VIII are also shown. (Based on Kuypers HGJM 1981 Anatomy of descending pathways. In: Brookhart JM, Mountcastle VB, Brooks VB et al (eds) Handbook of Physiology, vol. 2: Motor Control, pt 1. American Physiological Society, pp. 597–666; and Schoen JHR 1964 Comparative aspects of the descending fibre systems in the spinal cord. Progr Brain Res 11:203-22.)

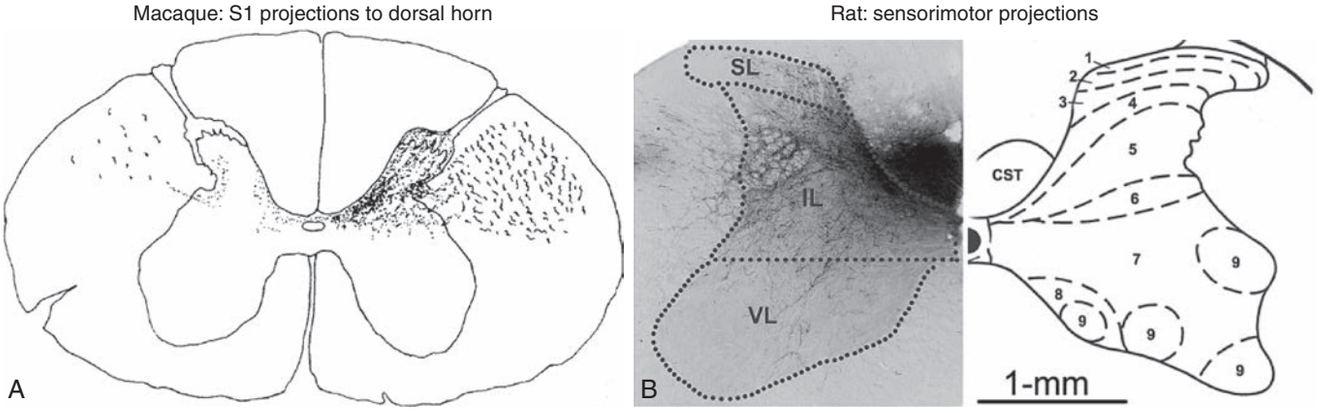

Fig. 3.1.2 Corticospinal projections to the dorsal horn in macaque and rat: **A** shows the labelling of corticospinal terminals in the dorsal horn of the macaque cord after injection of anterograde (H^3 leucine) tracer in the contralateral somatosensory cortex (S1). Most of the terminals are in the dorsal horn, including the most superficial laminae. **B** shows labelling of the corticospinal projection in the rat after injection of anterograde dextran amine tracer in the sensorimotor cortex (S1 + M1). Note that the corticospinal fibres travel mostly at the base of the dorsal columns, and terminate heavily in the dorsal horn, with little or no labelling in the ventral horn (A, With permission from Ralston DD, Ralston HJ 1985 The terminations of corticospinal tract axons in the macaque monkey. J Comp Neurol 242:325–37; B, with permission from Raineteau O, Fouad K, Bareyre FM et al 2002 Reorganization of descending motor tracts in the rat spinal cord. Eur J Neurosci 16:1761–71.)

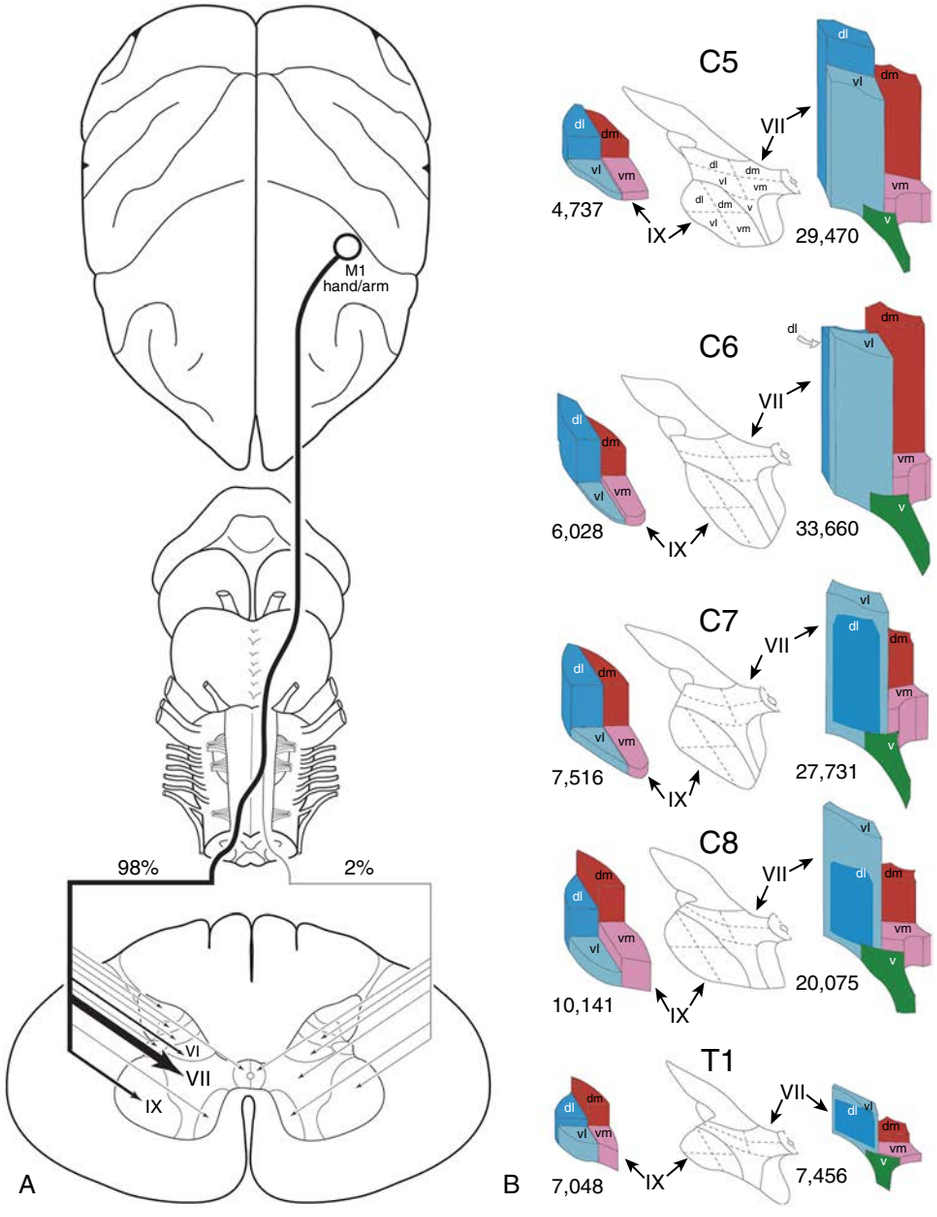

Fig. 3.1.3 Quantification of the M1 corticospinal terminations in the macaque cervical spinal cord. **A**, The overall corticospinal projection from the hand/arm region of the M1. The relative intensity of the projection to spinal cord laminae is indicated by line thickness and arrow head size. The strongest projections are to laminae VI, VII and IX. Note that there is only a weak projection to the dorsal horn. **B**, The relative strength of the contralateral projection to laminae VII and IX at each segmental level illustrated in 3D format. The relative height of each column corresponds to the relative number of estimated boutons labelled after injection of anterograde dextran amine tracers in the arm/hand area of M1, and counted in different quadrants of lamina VII (on the right) and lamina IX (motor nuclei, on the left). The mean number of labelled boutons obtained from three different cases is shown at each cervical level. Note the gradual decrease in the lamina VII projection from rostral to caudal spinal levels and the gradual increase in the lamina IX projection. The lamina IX projection was preferentially distributed to the dorsal quadrants at C5–C7 but was more widely dispersed among the quadrants at C8 and T1 (With permission from Morecraft RJ, Ge J, Stilwell-Morecraft KS et al 2013 Terminal distribution of the corticospinal projection from the hand/arm region of the primary motor cortex to the cervical enlargement in rhesus monkey. J Comp Neurol 521(18):4205–35.)

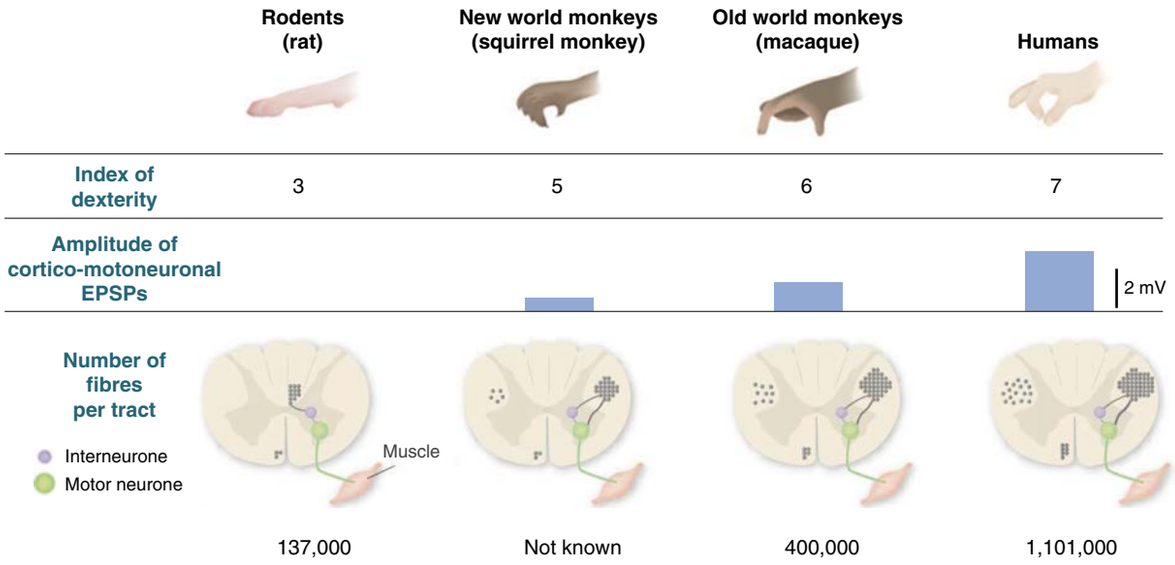

Fig. 3.1.4 Species variation in corticospinal organization and contribution to skilled upper limb movement. Relationship between the organization of corticospinal projections and fine motor skills involving the hand/paw. In rodents, there are no direct cortico-motoneuronal (CM) connections between corticospinal neurones and the cervical motor neurones which innervate forelimb muscles. In these species brainstem pathways and spinal interneurones relay cortical input to motor neurones. In non-human primates and humans, direct CM connections with motor neurones have evolved, together with an increase in the size and number of corticospinal fibres. This is reflected in an increase in the size of the excitatory postsynaptic potential (EPSP) elicited by the corticospinal tract in hand motor neurones. CM EPSP amplitudes were assessed in hand motor neurones either by direct recording (monkeys) or inferred from analysis of hand muscle responses to non-invasive cortical stimulation (humans). These changes in the organization of the corticospinal system correlate with the improvement in the index of dexterity. (With permission from Lemon RN 2008 Descending pathways in motor control. Ann Rev Neurosci 31:195–218.)

This account will need to be revised in the light of research in macaques which points to the fact that the balance between contralateral versus ipsilateral terminations (i.e. where the fibres exert their synaptic actions, as opposed to their trajectory within the cord) may vary substantially between cortical areas and for cervical versus lumbosacral enlargement. Projections from the arm/hand region of macaque M1 terminate almost entirely in the contralateral grey matter of C5–T1 (see Fig. 3.1.3A), suggesting that even those fibres that descend ipsilaterally from the M1 arm/hand area cross at the segmental level and terminate contralaterally. In contrast to the arm/hand region, projections from M1 leg area are bilateral and exert bilateral effects on the lumbosacral cord, and this may reflect the involvement of leg motor cortex in skilled forms of locomotion such as skiing, dancing, etc. Secondary motor areas such as the SMA and the dorsal and ventral premotor areas generally give to a greater degree of bilateral projections to the cervical cord.

CHAPTER
33

Head and neck: overview and surface anatomy

SKIN AND FASCIA

Face and scalp

The superficial fascia of the scalp is firm, dense, fibroadipose, and closely adherent to the skin and to the underlying muscle, epicranius and the epicranial aponeurosis. Posteriorly, the fascia is continuous with the superficial fascia of the back of the neck, and laterally it is prolonged into the temporal region, where it is looser in texture. Three fascial layers (a subcutaneous fibroadipose tissue, a superficial musculo-aponeurotic system (SMAS) and the parotid–masseteric fascia) are recognized on the face superficial to the plane of the facial nerve and its branches. On the lateral side of the head, above the zygomatic arch, the temporoparietal fascia lies in the same plane as, but does not blend with, the superficial musculo-aponeurotic system. It is superficial to the temporal fascia and blends superiorly with the epicranial aponeurosis. The parotid gland is surrounded by a fibrous capsule derived from the deep cervical fascia.

Neck

The superficial cervical fascia is a zone of loose connective tissue between dermis and deep fascia and is joined to both. It contains a variable amount of adipose tissue and platysma but is hardly demonstrable as a separate layer. The deep cervical fascia is conventionally subdivided into three sheets (superficial investing, middle and deep layers) that surround the muscles and viscera of the neck to varying degrees, and the carotid sheath, a condensation of deep fascia around the common and internal carotid arteries, internal jugular vein, vagus and ansa cervicalis. The fascial layers of the neck define a number of potential tissue 'spaces' above and below the hyoid bone (Ch. 37). In health, the tissues within these spaces are either closely applied to each other or are filled with relatively loose connective tissue. However, they offer potential routes by which infection may spread within the head and neck, and between the tissue spaces of the face and the mediastinum. They also offer convenient planes for almost bloodless dissection during surgery.

BONES AND JOINTS

Skull and mandible

The skull is composed of 28 separate bones, most of them paired (Ch. 34). It can be divided into the cranium, consisting of the calvaria (brain box) and basicranium, which together surround and protect the brain; a delicate facial skeleton composed mainly of thin-walled bones, some of which contain air-filled cavities that are known collectively as the paranasal sinuses; and the mandible. The cranial cavity contains the brain and the intracranial portions of the cranial nerves; the blood vessels that supply and drain the brain and the haemopoietic marrow of the overlying bones; the meninges (dura, arachnoid and pia mater); and the cerebrospinal fluid in the subarachnoid space. The cavity is incompletely divided by dural partitions, notably the falx cerebri, lying between the cerebral hemispheres, and the tentorium cerebelli, lying between the cerebellum and occipital lobes. Almost all of the venous blood from the brain and cranial bones drains via sinuses lying between the endosteal and meningeal layers of the dura mater into the internal jugular vein. Internally, the cranial base is divided into anterior, middle and posterior cranial fossae, which contain the frontal and temporal lobes of the cerebral hemispheres and the cerebellum, respectively. Foramina in the bones of the skull base and facial skeleton transmit neurovascular bundles that may be compromised at these sites by pathology or trauma.

The bony orbits contain the eyeballs, oculogyric muscles and lacrimal glands with their associated neurovascular supplies (Chs 44 and 45). The temporal bones contain the inner, middle and external ears (Chs 42 and 43). The maxillae are the largest of the pneumatized bones of the midface; they contain the maxillary air sinuses and bear the upper teeth. The mandible bears the lower teeth and articulates with the temporal bones at the temporomandibular joints. The skull articulates with the first cervical vertebra (atlas); movements of the skull on the cervical vertebrae occur at the atlanto-occipital joints.

The skull provides attachments for many muscles, including all the craniofacial muscles, the oculogyric muscles, the muscles that act on the temporomandibular joint, the superior constrictor of the pharynx, the muscles of the soft palate, all but one of the extrinsic muscles of the tongue, the muscles of the suboccipital region, and the cranial attachments of trapezius and sternocleidomastoid.

Cervical vertebrae

There are seven cervical vertebrae. They are the smallest of the movable vertebrae and are characterized by a disproportionately large vertebral canal. All but the seventh are also characterized by a foramen in each transverse process, the foramen transversarium (these foramina may be absent or sometimes duplicated in the seventh cervical vertebra). The first (atlas), second (axis) and seventh (vertebra prominens) cervical vertebrae are atypical.

Hyoid bone and laryngeal cartilages

The hyoid bone lies in the midline at the front of the neck at the level of the fourth cervical vertebra (Badshah et al 2017). It is suspended from the styloid processes by the stylohyoid ligaments and gives attachment to the suprahyoid and infrahyoid groups of muscles. The skeletal framework of the larynx is formed by a series of cartilages interconnected by ligaments and fibrous membranes and moved by a number of muscles (Ch. 41). The laryngeal cartilages are the single cricoid, thyroid and epiglottic cartilages, and the paired arytenoid, cuneiform, corniculate and tritiate cartilages.

MUSCLES

The striated muscles of the head and neck produce the movements of the facial soft tissues that animate so many aspects of communication; the movements at the temporomandibular joint that happen during mastication and speech (Ch. 38); the conjugate movements of the eyeballs; and the coordinated movements that occur during activities such as swallowing, speaking and turning the head in response to visual and/or auditory stimuli. The 'extrinsic' muscles that run between the axial skeleton and upper limb act on the scapula and humerus (Ch. 49).

The superior tarsal muscle, sphincter and dilator pupillae and the ciliary muscle are composed of smooth muscle (Chs 44 and 45).

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The main arterial supply of the head and neck is derived from branches of the carotid and subclavian arteries (**Figs 33.1–33.2**). Branches of the internal carotid and vertebral arteries anastomose in the circle of Willis within the interpeduncular cistern on the ventral aspect of the brain (Ch. 26).

Carotid system

The cervical portion of the common carotid artery is similar on both sides. Each lies within the carotid sheath of deep cervical fascia, together with the internal jugular vein and vagus nerve. In the lower part of the

neck, the arteries are separated by a narrow gap that contains the trachea, and higher up they are separated by the thyroid gland, larynx and pharynx. At the level of the upper border of the thyroid cartilage (C4), the common carotid artery bifurcates into external and internal carotid arteries: there can be significant variation on one or both sides of the neck. The external carotid artery passes upwards on either side of the neck, inclined at first slightly forwards and then backwards and a little laterally. It usually gives off the ascending pharyngeal, superior thyroid, lingual, facial, occipital and posterior auricular arteries, and then enters the parotid salivary gland where it divides into its terminal branches, the superficial temporal and maxillary arteries. The branches of the external carotid artery supply the face, scalp, tongue, upper and lower teeth and gingivae, palatine tonsil, paranasal sinuses and nasopharyngeal tube, external and middle ears, pharynx, larynx and superior pole of the thyroid gland. They also anastomose with branches of the internal carotid arteries on the scalp, forehead and face, in the orbit, nasopharynx and nasal cavity, and with branches of the subclavian artery in the pharynx, larynx and thyroid glands.

The internal carotid artery supplies most of the ipsilateral cerebral hemisphere, the eye and accessory organs, the forehead and, in part, the external nose, nasal cavity and paranasal sinuses. It passes up the neck anterior to the transverse processes of the upper three cervical vertebrae and enters the cranial cavity via the carotid canal in the petrous part of the temporal bone. The artery has no branches in the neck and so is easily distinguishable from the external carotid artery, should the latter require ligation, e.g. to control haemorrhage from a penetrating injury to the neck (Nowinski et al 2013, 2015).

Subclavian artery

The subclavian arteries give off several branches that supply structures in the head and neck. The vertebral arteries supply the upper spinal cord, brainstem, cerebellum and occipital lobe of the cerebrum. They pass through the foramina transversaria of the first six cervical vertebrae, enter the cranial cavity through the foramen magnum and unite at the lower border of the pons to form the basilar artery (hence this system is often called the vertebrobasilar system). Branches from the thyrocervical trunk supply the inferior poles of the thyroid gland and the parathyroid glands, the larynx and the pharynx, and branches from the costocervical trunks supply deep cervical muscles.

Veins

The veins of the neck lie superficial or deep to the deep investing fascia. Superficial veins ultimately drain into either the external, anterior or posterior external jugular veins; they drain a much smaller volume of tissue than the deep veins. Deep veins tend to drain into either the internal jugular vein or the subclavian vein. The internal jugular vein drains blood from the skull, brain, superficial face and much of the neck. It descends in the neck within the carotid sheath and unites with the subclavian vein behind the sternal end of the clavicle to form the brachiocephalic vein (**Figs 33.3–33.4**). At its junction with the internal jugular vein, the left subclavian vein usually receives the thoracic duct, and the right subclavian vein receives the right lymphatic duct.

Lymphatic drainage

Lymph nodes in the head and neck are arranged in two horizontal rings and two vertical chains on either side of the neck (**Fig. 33.5**). The outer, superficial, ring consists of the occipital, preauricular (parotid), submandibular and submental nodes, and the inner, deep, ring is formed by clumps of mucosa-associated lymphoid tissue (MALT) located primarily in the nasopharynx and oropharynx (Waldeyer's ring). The vertical chain consists of superior and inferior groups of nodes related to the carotid sheath. All lymph vessels of the head and neck drain into the deep cervical nodes, either directly from the tissues or indirectly via nodes in outlying groups (Ch. 17). Lymph is returned to the systemic venous circulation via either the right lymphatic duct or the thoracic duct.

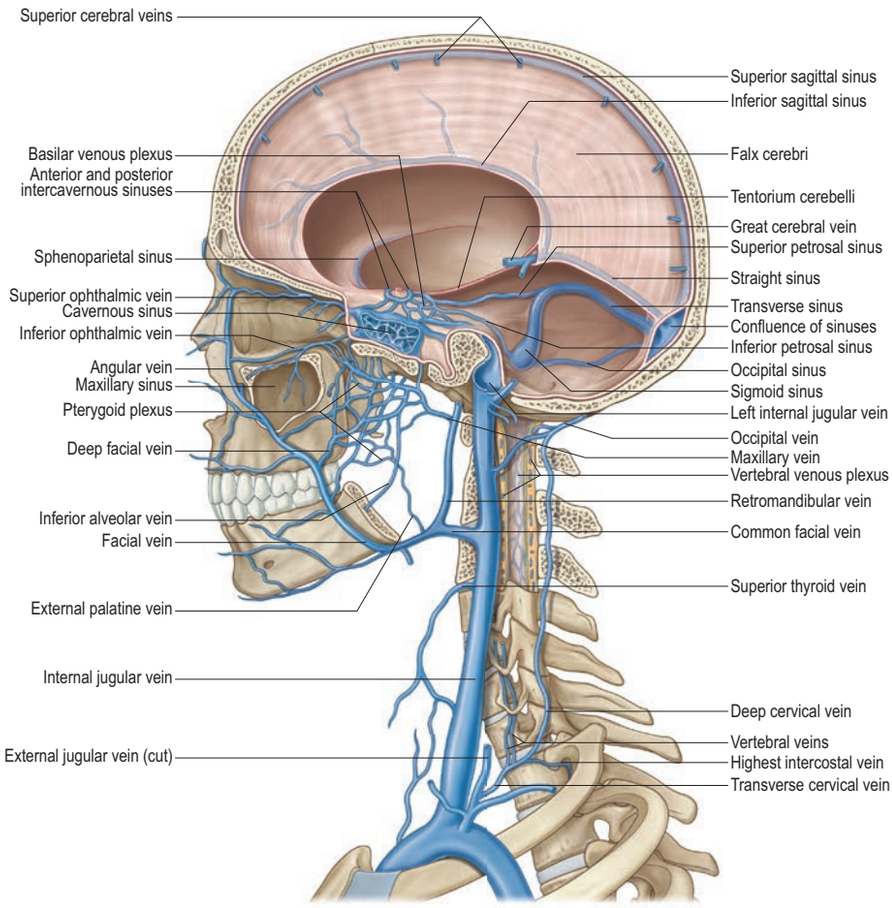

Fig. 33.4 An overview of the deep veins of the head and neck.

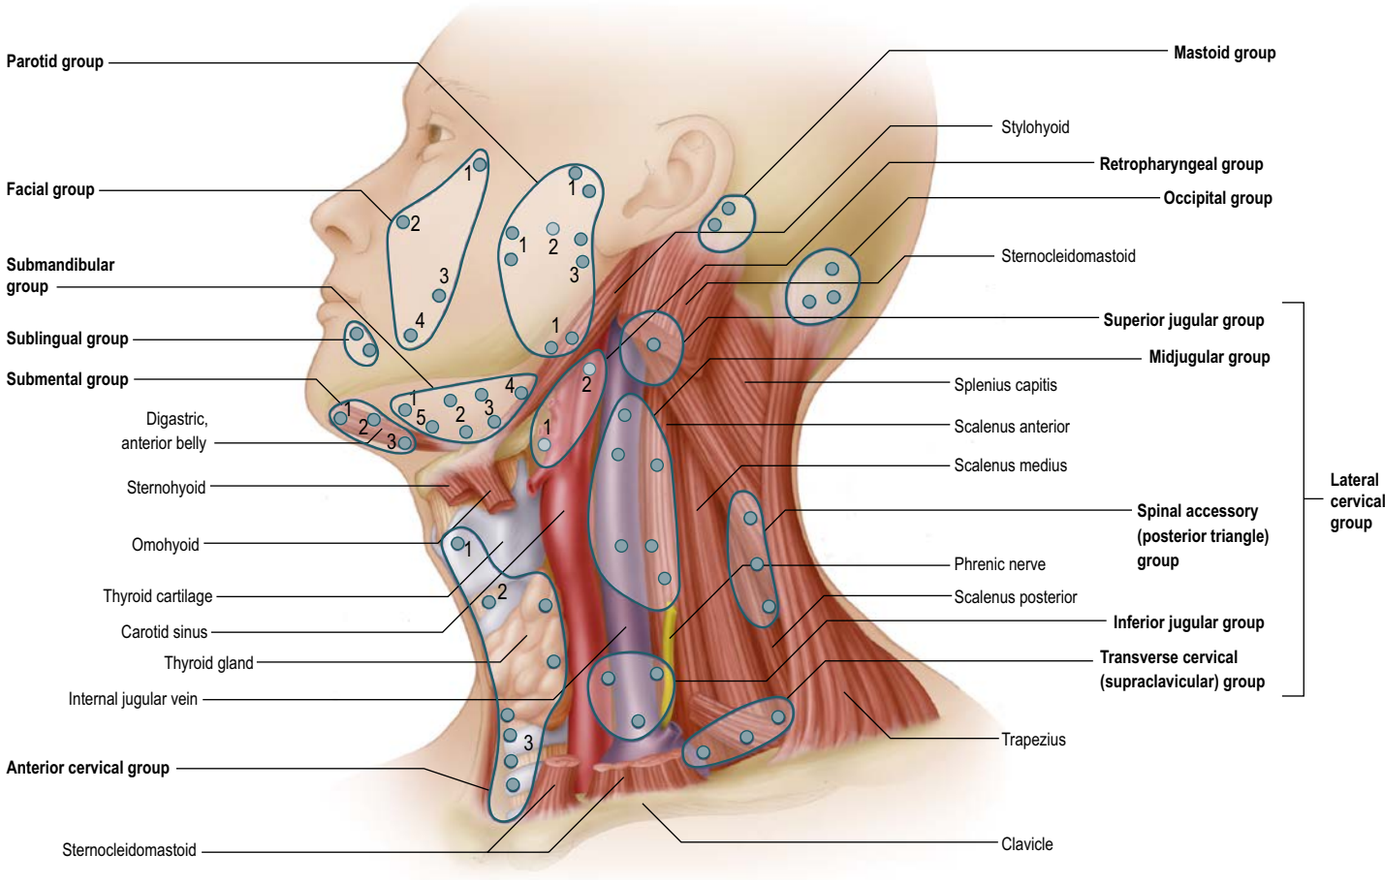
INNERVATION

Cranial nerves

There are 12 pairs of cranial nerves. They are individually named and numbered (using Roman numerals) in a rostrocaudal sequence (see Table 24.1). Some are functionally mixed, others are either purely motor or purely sensory, and some also carry pre- or postganglionic parasympathetic fibres that are secretomotor to the salivary and lacrimal glands or motor to the smooth muscle within the eyeball and orbit. Branches of the oculomotor, trochlear, trigeminal, abducens, facial, glossopharyngeal, vagus, accessory and hypoglossal nerves supply muscle groups within the eyeball, face, neck, pharynx, larynx and tongue. Branches of the trigeminal, glossopharyngeal and vagus nerves transmit general sensory information from the skin of the face and part of the scalp; the epithelium lining the oral and nasal cavities, the paranasal sinuses, middle ear, pharynx and larynx, and the dorsal surface of the tongue and the cornea; the intracranial meninges; and the periosteum and bones of the skull. Branches of the trigeminal nerve innervate the temporomandibular joint. The olfactory, optic, trigeminal, facial, vestibulocochlear and vagus nerves contain axons that transmit the special sensations of olfaction, vision, hearing, balance and taste. The olfactory nerve is the only sensory cranial nerve that projects directly to the cerebral cortex rather than indirectly via the thalamus (Ch. 32). The optic nerve terminates in the thalamus (Ch. 30). The other ten pairs of cranial nerves are attached to the brainstem or, in the case of the (spinal) accessory nerve, to the upper cervical spinal cord; their component fibres arise from or terminate in named cranial nerve nuclei. The cranial nerves pass through named foramina in the skull, often with named vessels.

With one exception, all the cranial nerves are confined to the head and neck. The exception is the vagus, which travels through the neck and thorax, and enters the abdominal cavity by passing through the respiratory diaphragm with the oesophagus.

Reflexes



A number of reflexes involving structures in the head and neck are mediated by sensory and motor branches of the cranial nerves, coordinated via appropriate nuclei in the brainstem. They include swallowing, gagging, retching and vomiting, sneezing and coughing; lacrimation; jaw jerk; visual reflexes (pupillary light reflex and accommodation); and the corneal 'blink' reflex and the cochlear and vestibular reflexes (the stapedial reflex and caloric response of the labyrinth). Reflexes that involve energetic exhalation, e.g. sneezing and coughing, also involve the recruitment of cervical and thoracic spinal neurones to mediate the coordinated contraction of intercostal and abdominal wall muscles that this activity requires.

Spinal nerves

There are eight pairs of cervical spinal nerves (Fig. 33.6). Cutaneous branches of the dorsal rami of the second, third, fourth and fifth cervical nerves innervate the scalp and the skin over the back of the neck, and motor branches of all the cervical dorsal rami supply cervical postvertebral muscles. All the cervical ventral rami supply anterior and lateral groups of prevertebral muscles. The upper four cervical ventral rami form the cervical plexus, whose branches collectively innervate the infrahyoid strap muscles and the respiratory diaphragm, and the skin covering the lateral and anterior parts of the neck, and the angle of the mandible. The lower four cervical ventral rami, together with most of the first thoracic ventral ramus, form the brachial plexus.

Parasympathetic nerves

In the head and neck, the parasympathetic system innervates the salivary and lacrimal glands, the mucous glands of the oral and

Fig. 33.5 An overview of the lymph nodes of the head and neck.

nasal cavities and paranasal sinuses, and the sphincter pupillae and ciliary muscles in the eyeball. Many thousands of preganglionic parasympathetic axons travel in the vagus from cell bodies in the dorsal motor nucleus of the vagus in the medulla oblongata. Although they travel through the neck in the right and left vagi, they are destined for pulmonary, cardiac, oesophageal, gastric and intestinal targets; they synapse in minute ganglia in the walls of the viscera and do not innervate structures in the head and neck.

There are four pairs of parasympathetic ganglia in the head, named ciliary, pterygopalatine, otic and submandibular (Fig. 33.7).

Ciliary ganglion

Preganglionic axons originate in the preganglionic nucleus of the midbrain (Edinger–Westphal nucleus) (Ch. 28). They travel via a branch of the oculomotor nerve (nerve to the inferior oblique) to the ciliary ganglion, where they synapse. Postganglionic fibres travel in the short ciliary nerves, which pierce the scleral coat of the eyeball and run forwards in the perichoroidal space to enter the ciliary muscle and sphincter pupillae. Their activation mediates accommodation of the eye to near objects and pupillary constriction.

Submandibular ganglion

Preganglionic axons originate in the superior salivatory nucleus. They emerge from the brainstem in the nervus intermedius and leave the main facial nerve trunk in the middle ear to join the chorda tympani, which subsequently joins the lingual nerve. In this way, they reach the submandibular ganglion, where they synapse. Postganglionic fibres innervate the submandibular, sublingual and lingual salivary glands; some axons presumably re-enter the lingual nerve to access the lingual glands, while others pass directly along blood vessels to enter the submandibular and sublingual glands.

Some preganglionic fibres may synapse around cells in the hilum of the submandibular gland. Stimulation of the chorda tympani dilates the arterioles in both glands, as well as having a direct secretomotor effect.

Pterygopalatine ganglion

Preganglionic axons travel in the greater petrosal branch of the facial nerve and the nerve of the pterygoid canal, and relay in the pterygopalatine ganglion. Postganglionic secretomotor axons innervate secretory acini and blood vessels in the palatine, pharyngeal and nasal

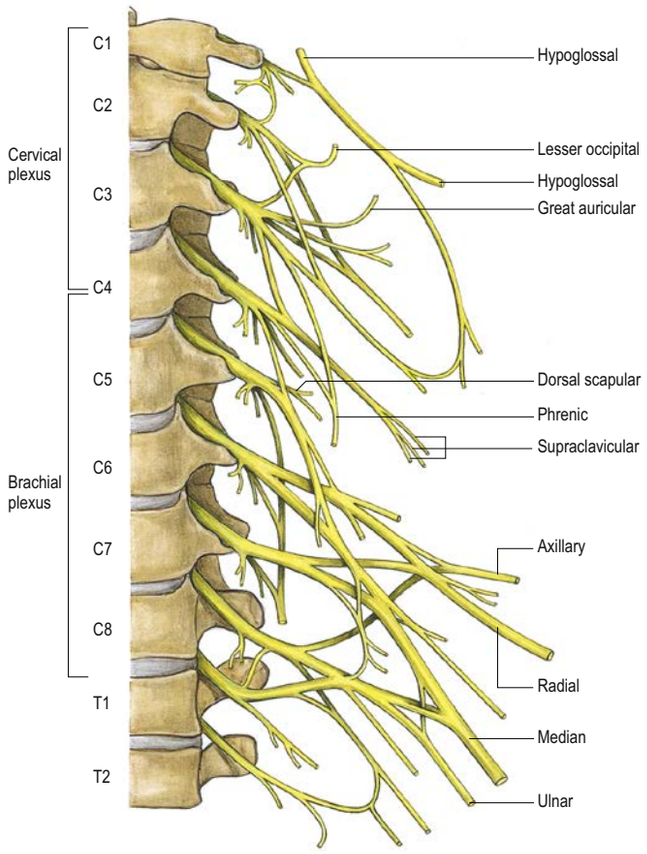

Fig. 33.6 An overview of the nerves forming the cervical and brachial plexuses. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

mucosa via the palatine and nasal nerves: whether they also innervate the lacrimal gland via the zygomatic and zygomaticotemporal branches of the maxillary nerve, as was once thought, is less certain. It is likely that postganglionic orbital branches, carrying a mixture of postganglionic parasympathetic and somatic sensory axons, pass through the inferior orbital fissure and innervate the lacrimal gland and ophthalmic artery directly. Some axons pass into the cranial cavity via the ethmoidal vessels to innervate the choroid; the pterygopalatine ganglion is believed to be the main source of parasympathetic input to the choroid.

Otic ganglion

Preganglionic axons originate in the inferior salivatory nucleus and travel in the glossopharyngeal nerve and its tympanic branch. They traverse the tympanic plexus and lesser petrosal nerve, and pass through the foramen ovale to reach the otic ganglion, where they synapse. Postganglionic fibres pass by communicating branches to the auriculotemporal nerve, which conveys them to the parotid gland. Stimulation of the lesser petrosal nerve produces vasodilator and secretomotor effects.

Sympathetic nerves

In the neck, the sympathetic trunk lies behind and medial to the carotid sheath and anterior to the transverse processes of the cervical vertebrae and the prevertebral muscles. There are usually three cervical ganglia on each side, superior, middle and inferior (cervicothoracic): they may be connected by a solid trunk or by two or three fibrous strands. The ganglia receive preganglionic fibres from neurones whose cell bodies lie in the intermediolateral column of the upper thoracic spinal cord; there is no preganglionic output from the cervical spinal cord. Postganglionic fibres reach their target tissues in the head and neck via the cervical spinal nerves and perivascular nerve plexuses distributed along the carotid and vertebral arteries (see Fig. 33.7).

SURFACE ANATOMY

Surface anatomy of the head

Skeletal landmarks

The palpable bony landmarks of the head can be examined from the back, sides and front (**Figs 33.8–33.9**). The pericraniocervical line, which demarcates the head from the neck, runs from the midpoint of the chin anteriorly to the external occipital protuberance posteriorly.

Calvaria

Most of the superficial aspect of the calvaria is covered by skin, subcutaneous tissue and thin muscles; many bony prominences and surfaces are therefore palpable through the hair and are visible in bald people. Suture lines can be palpated as irregular ridges. The anterior fontanelle, at the junction of the coronal and sagittal sutures, may be palpated up to 24 months after birth. The mastoid process is palpable medial to the lobule of the auricle (pinna). Deep palpation immediately anteroinferior to the mastoid tip reveals the relatively indistinct resistance offered by the styloid process and associated soft tissues. When elongated, the tip of the styloid may be palpated in the tonsillar fossa. Palpation posteroinferiorly to the mastoid tip reveals the firm mass of the transverse process of the atlas (C1). The external occipital protuberance (inion) is a palpable bony protuberance located on the posterior midline of the occipital bone. The point of confluence of the dural venous sinuses is commonly located to the upper right side of the inion (Sheng et al 2012). The superior nuchal lines are palpable passing laterally from the inion. The asterion marks the junction of the occipitomastoid, parietomastoid and occipitoparietal sutures. It may be utilised to define the location of the transverse–sigmoid sinus complex, although it does not always do so (Day and Tschabitscher 1998; Sheng et al 2012). The point at which the transverse sinus becomes the sigmoid sinus and is joined by the superior petrosal sinus may sit deep to the asterion (Sheng et al 2012), although it is often located more anteriorly at a point marked by a palpable shallow depression 1–2 cm posterior to the auricle at a level approximately at the junction of the upper third and lower two-thirds of the auricle.

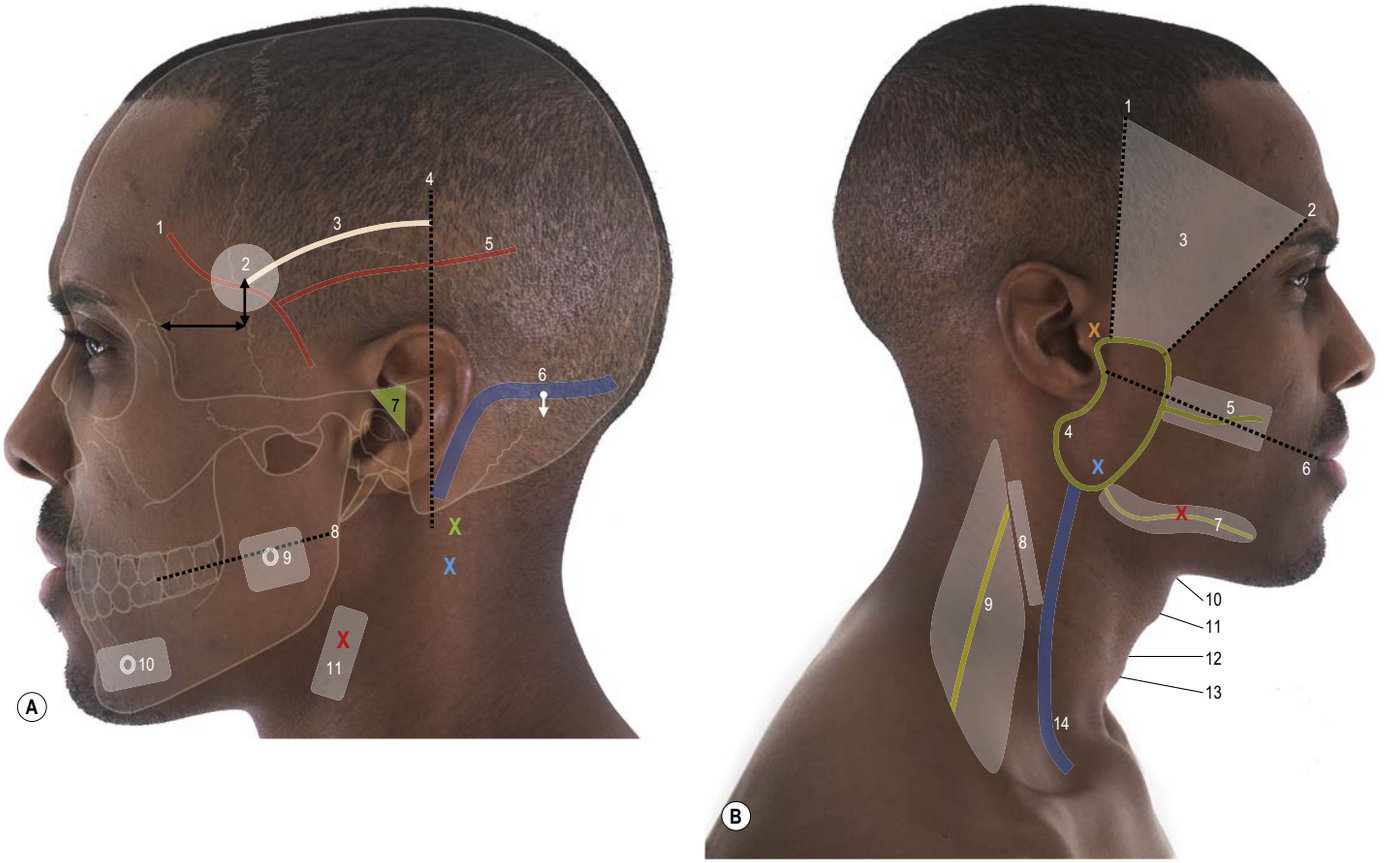

Fig. 33.8 The lateral aspect of the head and neck. **A**, Pterion, meningeal arteries, carotid bifurcation, mental and mandibular foramen. Key: 1, anterior branch of the middle meningeal artery: sits deep to the pterion in over half of subjects; 2, zone of location of the pterion: in a 1 cm diameter circle centred 2.5 cm posterior and 1.5 cm superior (black arrows) to the frontozygomatic suture; 3, lateral (Sylvian) fissure: aligns anteriorly with the anterior part of the squamosal suture in a zone 2.5–4.0 cm anterior to the external acoustic meatus; 4, mastoid line; 5, posterior branch of the middle meningeal artery: runs parallel to the zygomatic arch and sits level with the supraorbital margin on the mastoid line; 6, asterion: commonly sits over or just below (white arrow) the transverse–sigmoid sinus complex; 7, suprameatal triangle; 8, occlusal plane; 9, zone of location (white) of the mandibular foramen: in the majority of cases, the foramen sits level with or below the occlusal plane (8), an average of 2 cm posterior to tooth 8; 10, zone of location (white) of the mental foramen: the foramen commonly sits between the roots of teeth 4 and 5 (range 3–6), usually level with or inferior to the tooth root apex; X (green), transverse process of C1 (atlas); X (blue), transverse process of C2 (axis); 11, zone of location (white) of the bifurcation of the common carotid artery: approximately 0.5–3.0 cm above the level of the thyroid cartilage lamina; X (red), most common level of common carotid bifurcation (vertebral body of C3). **B**, Parotid gland and duct, CN VII and XI, cutaneous branches of cervical plexus and internal jugular vein. Key: 1, porion line; 2, zygomatic sutural line; 3, zone of location of the temporal branches of the facial nerve; 4, parotid gland; 5, zone of location (white) of the parotid duct (green line): sits within 1.5 cm of the middle half of a line passing from the lower tragus to the ipsilateral labial commissure; 6, lower tragus–labial commissure line; 7, zone of location of the marginal mandibular nerve (1.2 cm (range 0.9–1.75 cm) inferior to the mandible when posterior to the facial artery); 8, zone of emergence of the cutaneous branches of the cervical plexus (white), posterior to the middle third of sternocleidomastoid; 9, zone of location of the accessory nerve (white), from 3–10 cm below the tip of the mastoid process to 1–10 cm above the insertion of trapezius into the clavicle; 10, hyoid bone (body); 11, thyroid cartilage (laryngeal prominence); 12, cricothyroid ligament/membrane; 13, cricoid cartilage; 14, external jugular vein; X (blue), angle of the mandible; X (red), facial artery and anterior border of masseter crossing the lower border of the mandible; X (orange), superficial temporal artery. (Adapted with permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008.)

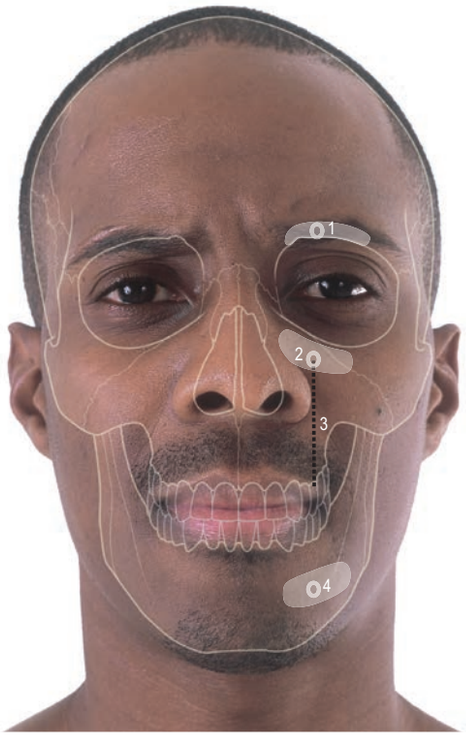

Fig. 33.9 The anterior aspect of the face. Key: 1, zone of location of the supraorbital foramen and neurovascular bundle (white) approximately 3 cm (range 1.8–4.3 cm) from the midline of the face; 2, zone of location of the infraorbital foramen and neurovascular bundle (white), approximately 2.5 cm (range 1.8–3.3 cm) from the midline of the face: aligns with a vertical axis passing through maxillary tooth 5; 3, vertical axis through maxillary tooth 5; 4, zone of location of the mental foramen and neurovascular bundle (white), approximately 2.5 cm from the midline of the face between the root apices of teeth 4 and 5 (range teeth 3–6). (Adapted with permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008.)

Mandible

The mental tubercles are palpable on the anterior chin, and the mandibular body, alveolar processes and teeth are palpable through the cheek. The lower border of the mandible can be traced to the angle, which marks the level of the C2–C3 intervertebral disc (Auerbach et al 2009, Liu, Chen et al 2017). The mental foramen, which transmits the mental nerve and vessels, gradually migrates posteriorly after birth and through childhood (Balcioglu et al 2011). In adults, it lies an average of 2.5 cm (range 2–3 cm) from the midline of the face (Udhaya et al 2013), between the apices of the roots of mandibular teeth 4 and 5 (range teeth 3–6) (Fishel et al 1976, von Arx et al 2013, Udhaya et al 2013). Most foramina usually lie either level with or inferior to the apex of the root of the tooth (Fishel et al 1976). Accessory mental foramina, if present, are mainly situated posterior or inferior to the main mental foramen (Katakami et al 2008). The mandibular foramen lies on the medial surface of the ramus an average of 1.9 cm posterior to the third molar tooth (Nicholson 1985): a 21 mm needle is therefore sufficient to reach the foramen for dental anaesthesia (Menke and Gowgiel 1979). The foramina commonly (Mbajiorgu and Ekanem 2000, Nicholson 1985) lie level with or below the occlusal plane, the remainder sitting above.

The mandibular ramus is largely covered by masseter and the parotid gland. Its posterior border is palpable through the parotid up to the neck of the mandibular condylar process, which lies anterior to the lower tragus or the intertragal notch of the auricle. Movement of the condylar head at the temporomandibular joint is palpable anterior to the tragus during mouth opening/closing. The coronoid process is palpable anterior to the condylar process through the buccal mucosa.

Face

The lateral aspect of the face, from above downwards, consists of the temporal region, cheek and mandible (Ch. 36). The temporal region lies in front of the external ear and above the zygomatic arch. It is demarcated superiorly and posteriorly by the palpable superior temporal line, anteriorly by the frontal process of the zygoma, and inferiorly by the zygomatic arch. The palpable zygomatic arch is formed by the zygomatic process of the temporal bone posteriorly and the temporal process of the zygomatic bone anteriorly, both of which articulate via the palpable temporozygomatic suture. The variable prominence of the 'cheekbone' (zygoma) is largely attributable to the shape of the body of the underlying zygomatic bone. The sharp posterior margin of the frontal process of the zygomatic bone can be palpated superiorly to its articulation with the zygomatic process of the frontal bone at the palpable frontozygomatic suture; the marginal tubercle (Whitnall's tubercle) is palpable just below the suture within the lateral margin of the orbit. From here, the superior temporal line can be palpated passing posteriorly in the line of a gentle curve. The inferior temporal line terminates by curving downwards and forwards to end just above the root of the mastoid process as the supramastoid crest on the squamous part of the temporal bone. The suprameatal triangle overlies the lateral wall of the mastoid (tympanic) antrum and is demarcated superiorly by the palpable supramastoid crest (a palpable ridge of bone posterior to the upper auricle), anteroinferiorly by the posterosuperior margin of the external acoustic meatus, and posteriorly by a vertical line through the posterior border of the external acoustic meatus. The lateral/Sylvian fissure of the brain aligns with the anterior part of squamosal suture in a zone 2.5–4.0 cm anterior to the external acoustic meatus (Rahmah et al 2011). The pterion represents the sutural junction of the frontal, sphenoid, parietal and temporal bones within the temporal fossa. It can be located either within a 1 cm diameter circle centred approximately 2.6 cm posterior and 1.3 cm superior to the posterolateral margin of the frontozygomatic suture (Ma et al 2012), or approximately 4 cm above the midpoint of the zygomatic arch (Ukoha et al 2013). It commonly marks the position of the anterior (frontal) branch of the middle meningeal artery (Ma et al 2012). Knowledge of the surface anatomy of the middle meningeal artery is important for accurate positioning of burr-holes to evacuate extradural haematomas: the posterior (parietal) arterial branch runs backwards and parallel with the upper border of the zygomatic arch and is usually exposed vertically above the mastoid process on a level horizontal with the supraorbital margin. The asterion is a craniometric point at the site of the posterolateral (mastoid) fontanelle. It is found at the junction of the lambdoid, occipitomastoid and parietomastoid sutures, and has been used as a landmark in lateral approaches to the posterior cranial fossa because it defines the superior limit of bone removal for the craniectomy. It should be noted that the asterion commonly sits over, or in the region of, the transverse–sigmoid sinus complex (Sheng et al 2012).

The forehead extends from the hair margin of the scalp to the eyebrows. The rounded frontal tuberosity may be felt approximately 3 cm above the midpoint of each supraorbital margin. The superciliary arch is usually palpable above the orbit and is better marked in the male than the female. The glabella, a small horizontal ridge, is easily palpable between the superciliary arches. Below the glabella, the nasal bones articulate with the frontal bone in a small depression, the nasion, at the root of the nose. With a little finger inserted into the nostril, the bony margins of the anterior nasal aperture can be felt; they are formed by the inferior border of the nasal bone, the sharp margins of the nasal notch of the maxilla, and the co-apted nasal spines of the maxillae (Ch. 39).

The orbital opening is relatively quadrangular and its margins are palpable. The supraorbital margin is formed entirely by the frontal bone. The supraorbital foramen/notch can be palpated along the superomedial orbital margin and lies an average of 2.7 cm (range 1.8–4.3 cm) from the midline of the face, although this position is variable (Chrcanovic et al 2011, Tomaszewska et al 2012). The notch/foramen transmits the supraorbital nerve and vessels, and pressure exerted here with the fingertip can be painful. An additional notch that transmits the supratrochlear neurovascular bundle may be found in the orbital margin more medially, towards the bridge of the nose.

The lateral margin of the orbit consists of the frontal process of the zygomatic bone and the zygomatic process of the frontal bone. The frontozygomatic suture between them may be palpated as a depression. Approximately 1 cm below the suture, the marginal tubercle (Whitnall's) can be palpated on the zygomatic bone, within the lateral orbital margin: the lateral palpebral ligament and the check ligament of lateral rectus are attached to the tubercle. The inferior border of the orbit is formed by the zygomatic bone laterally and the maxilla medially. It blends into the medial margin, which is less obvious, and is formed above by the frontal bone and below by the lacrimal crest of the frontal process of the maxilla. A shallow fossa behind the lower part of the medial wall houses the lacrimal sac. The anterior lacrimal crest is a guide to the location of the anterior ethmoidal artery, which may occasionally require ligation to control severe epistaxis; the artery lies approximately 2.4 cm posterior to the crest. The optic canal lies approximately 4.5 cm posterior to the infraorbital margin (approximately 4.2 cm from the anterior lacrimal crest); these distances are important in orbital floor exploration in order to avoid optic nerve injury. The

inferior orbital fissure lies approximately 2 cm posterolateral to the infraorbital margin; it does not contain any important structures and therefore surgery can be performed safely in this region. The infraorbital foramen, which transmits the infraorbital nerve and vessels, lies below the middle of the infraorbital margin. It is commonly aligned with a vertical axis passing through maxillary tooth 5 (Raschke et al 2013) and lies an average of 2.5 cm (range 1.8–3.3 cm) from the midline of the face and 6.4 mm (range 3.2–12.1 mm) below the inferior orbital margin (Chrcanovic et al 2011, Raschke et al 2013). In neonates, the infraorbital nerve is located approximately half-way along a line drawn from the angle of the mouth to the midpoint of the palpebral fissure (Bosenberg and Kimble 1995).

The anterior surface of the maxilla is extensive and may be palpated between the infraorbital margin and the alveolar processes that bear the upper (maxillary) teeth. The canine eminence overlies the root of the canine tooth and separates the incisive fossa anteriorly from the deeper canine fossa posteriorly. The bone of the canine fossa is thin and may be removed easily to access the maxillary sinus via an intraoral approach as part of a Caldwell–Luc procedure. The palatine process of the maxilla and the horizontal plate of the palatine bone form the roof of the mouth and are palpable. The incisive (nasopalatine) foramen sits in the midline of the palate, immediately posterior to the incisive papilla, approximately 7.4 mm from the labial surface of the alveolar ridge (Mraiwa et al 2004), and transmits the sphenopalatine artery and nasopalatine nerve. The greater palatine foramen transmits the greater palatine artery and nerve and is commonly located in the region medial to maxillary tooth 8 (range from level with tooth 7 to posterior to tooth 8 (Sujatha et al 2005, Jaffar and Hamadah 2003)), approximately 16 mm from the midline (Wang et al 1988).

Soft tissues and viscera

The muscular, fatty and cutaneous features that so clearly differentiate individuals are readily apparent on inspection. The external features of the eyelids and eyebrows are described in Chapters 44 and 36, respectively. The tympanic membrane may be examined under direct vision using an auroscope and is described in Chapter 42. The retinal vascular supply may be examined directly by ophthalmoscopy (Ch. 45).

The temporalis muscle is palpable if the palmar surface of the hand is placed over the temporal region and the jaw is clenched and relaxed. The anterior border of masseter is palpable and prominent when the jaw is clenched. The masseter is thicker in boys than in girls in both the relaxed and contracted state (Charalampidou et al 2008). With the mouth open, it is possible to examine the teeth, gingivae, tongue and the palatine tonsils lying between the anterior and posterior faucial arches (palatoglossal and palatopharyngeal arches) formed by palatoglossus (anterolaterally) and palatopharyngeus (posteromedially), respectively. Peritonsillar abscess (quinsy) can cause ipsilateral tonsillar enlargement with contralateral displacement of the uvula; parapharyngeal tumours displace the ipsilateral tonsil and palate medially. The openings of the ducts of the submandibular glands can be seen on either side of the lingual frenulum at its point of intersection with the sublingual mucosal folds. The lingual nerve often passes close (2–3 mm) to the lingual side of the alveolar process housing the root of mandibular tooth 8; some lingual nerves can contact the mandibular bone directly or pass across the retromolar triangle (Behnia et al 2000).

Parotid gland

The parotid gland is soft and indistinct to palpation. The superior border sits inferior to the zygomatic arch, passing from the mandibular condyle towards masseter. The anterior border passes inferiorly along the posterior border of masseter, often overlying its lateral surface, then over the mandibular angle to meet the anterior border of sternocleidomastoid, approximately 2 cm posteroinferior to the mandibular angle. The inferior border lies at the level of the C3 vertebral body. The posterior border corresponds to a curve traced from the mandibular condyle to the mastoid process. The deep part of the gland lies within the prestyloid part of the parapharyngeal space. Tumours arising in this region present with medial displacement of the soft palate and palatine tonsil. The parotid duct arises from the anterior border of the gland and can be palpated on the anterior border of a clenched masseter. The duct often follows a curved trajectory and passes along, or within 1.5 cm of, the middle half of a line drawn from the lower border of the tragus to the ipsilateral labial commissure (Stringer et al 2012, Toure et al 2015) (**Fig. 33.8B**). The duct runs over masseter as far as the anterior border of the muscle, and then bends sharply, pierces the underlying buccinator and buccal mucosa and opens into the mouth opposite maxillary tooth 7: the orifice of the duct is visible and palpable. Duct cannulation is required for sialography, ductal dilation and basket retrieval of ductal stones (sialoliths).

Pulses

The facial artery can be palpated in two places; as it crosses the lower border of the mandible immediately anterior to masseter and also on the face, approximately 1 cm lateral to labial commissure. The superficial temporal artery is palpable immediately anterior to the tragus of the auricle. The artery divides into frontal and parietal branches approximately 2.5 cm above the zygomatic arch; both branches are palpable.

Facial nerve

The facial nerve may be injured in its extracranial course as a result of facial trauma and laceration, or iatrogenically during surgery involving the parotid or submandibular glands or the temporomandibular joint, or during facelift procedures. Knowledge of the topographical and surgical landmarks is therefore essential if the nerve is to be preserved during surgery.

The nerve exits the skull at the stylomastoid foramen and so is initially deep to the posterior margin of the external acoustic meatus; the nerve trunk lies approximately 9 mm from the tip of the mastoid process and 14 mm from the transverse process of C1 (Greyling et al 2007). It usually divides within the parotid gland into five main branches that radiate across the face (**Fig. 33.10**; see Fig. 36.24). Cadaveric and intraoperative microdissection studies have revealed that the course of its branches is highly variable and therefore surface coordinates only approximate their trajectory or zone of location. The temporal branches emerge from the superior surface of the parotid and cross the zygomatic arch approximately 1 cm anterior to the superficial temporal artery as that vessel also crosses the zygomatic arch, both nerve and vessel travelling towards the pterion and the superolateral brow. The majority lie in the zone between two lines: line 1 (porion line) joins two points each situated 12 mm from the porion on both the supraorbitomeatal line and the infraorbitomeatal line; and line 2 (zygomatic sutural line) is a line joining the temporozygomatic and frontozygomatic sutures (Davies et al 2012). These branches may be injured in facial rhytidectomy, coronal or endoscopic brow lifting, and temporal craniotomy. The buccal branches run both above and below the parotid duct. The marginal mandibular nerve emerges from the anteroinferior parotid gland and passes anteriorly. When posterior to the facial artery, the nerve almost always lies inferior to the lower border of the mandible by approximately 1.2 cm (range 0.9–1.75 cm) (Batra et al 2010), although some branches can lie as much as 3.6 cm inferiorly (Davies et al 2016). The nerve re-enters the face by crossing the lower border of the mandible near the anterior border of masseter, where it passes superficial to the facial artery and vein. Regional incisions should be made at least two fingers' breadth or 4 cm below the lower border of the mandible to avoid injuring the nerve (Chowdhry et al 2010, Davies et al 2016), and the resultant upturned ipsilateral mouth caused by paralysis of depressor anguli oris and depressor labii inferioris. During surgery, lateral flexion and axial rotation of the head away from the side of the incision may help to move the marginal mandibular nerve superiorly.

Dermatomes

The delineation of individual dermatome position is based on clinical evidence. The dermatomes of the face are determined mainly by the distribution of the cutaneous branches of the three major divisions of the trigeminal nerve. The skin covering the anterolateral neck, the angle of the mandible, lateral scalp and posterior aspect of the auricle is innervated by branches of the cervical plexus (C2–C4), and the skin covering the back of the head is innervated by the greater occipital nerve (C2, posterior primary ramus).

Surface anatomy of the neck

Skeletal and cartilaginous landmarks

The neck extends from the pericraniocervical line superiorly to the level of the clavicle, scapula, first rib and superior manubrium inferiorly. Posteriorly, the spinous processes of C2 and C7 are the most prominent and may be palpated in the midline (the former via deep palpation). The remaining cervical spines are indistinct because they are covered by the ligamentum nuchae, on either side of which lie the masses of the postvertebral musculature. On either side, the transverse process of C1 is palpable in the hollow region posteroinferior to the mastoid process tip; deep palpation inferiorly may reveal the transverse process of C2.

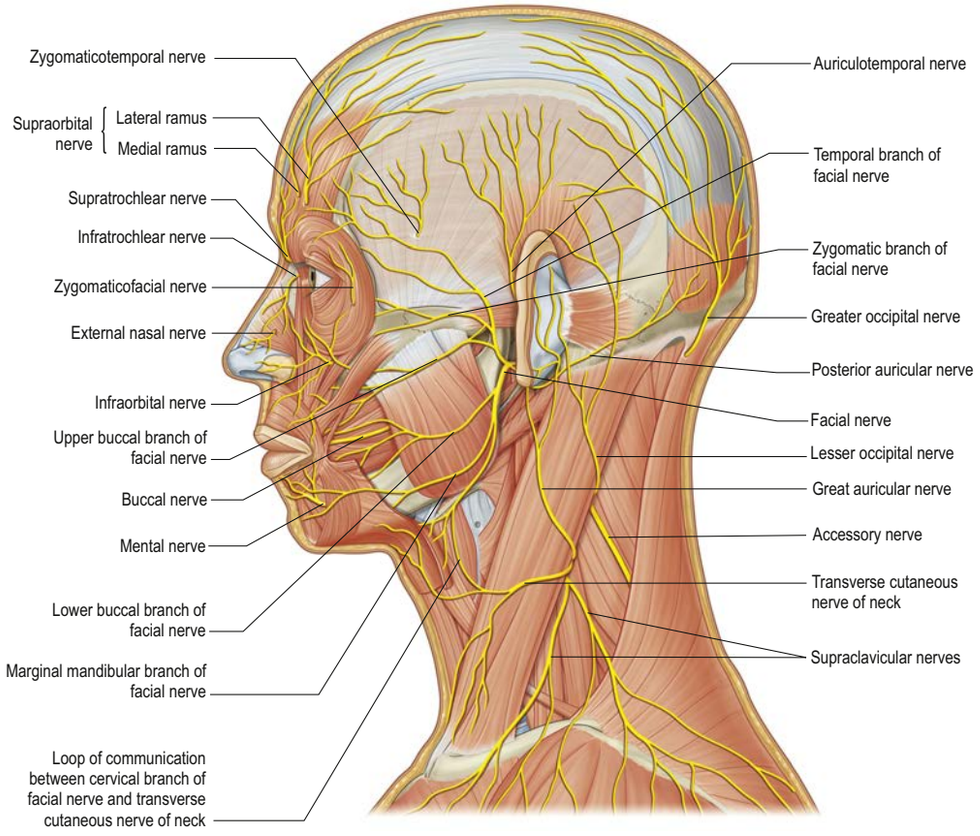

Fig. 33.10 The distribution of the cutaneous branches of the trigeminal nerve and of the cervical plexus, and the motor branches of the facial nerve in the face and neck.

The body of the hyoid bone can be felt in the midline neck a few centimetres below and behind the chin, at the junction of the skin covering the anterior neck and the floor of the mouth. It sits level with the vertebral body of C4 (range vertebral body of C3 to the C5–C6 intervertebral disc) (Mirjalili et al 2012b, Badshah et al 2017, Shen et al 2017), and is higher in neonates and children. The left and right greater horns of the hyoid pass posterosuperiorly from the body, and can be palpated between the finger and thumb of one hand. The laryngeal prominence (Adam's apple) of the thyroid cartilage is palpable in the midline of the neck; the thyroid laminae can be felt passing posterolaterally. The prominence is usually visible in postpubertal males, whereas it is not usually apparent in females. The curved upper border of the thyroid cartilage, the midline superior thyroid notch and the superiorly located depression of the thyrohyoid membrane/ligament are easily palpable. The superior border of the thyroid cartilage lamina commonly sits level with the vertebral body of C4 in females and the vertebral body of C5 in males, but there is considerable variation (range upper half of the vertebral body of C3 to the lower half of the vertebral body of C6) (Mirjalili et al 2012b, Shen et al 2017). The firm, smooth anterior arch of the cricoid cartilage is palpable below the inferior border of the thyroid cartilage. The inferior border of the cricoid cartilage commonly sits level with the vertebral body of C6 in females and the vertebral body of C7 in males (range lower half of the vertebral body of C5 to the lower half of the vertebral body of T1). The indentation between the thyroid and cricoid cartilages is covered by the anterior/median cricothyroid ligament, and is a useful site for emergency access to the airway in cases of obstruction at or above the vocal cords (cricothyroidotomy). In the neonate, the dimensions of the cricothyroid membrane are too small to allow safe passage of an airway (Navsa et al 2005). Confirmation of the surface anatomy of the hyoid bone, thyroid and cricoid cartilages, and jugular (suprasternal) notch is essential prior to performing a tracheostomy (Ellis et al 2004).

The use of palpable anatomical landmarks in the neck to predict vertebral levels is not infallible, especially when the neck is extended for surgery on the cervical spine. There can be a difference of at least one vertebral level: on-table radiographic confirmation of vertebral level is therefore prudent to avoid removal of the wrong intervertebral disc (Liu, Du et al 2017).

The clavicle is a sigmoid-shaped bone that is normally palpable and is easily visible in individuals of lower body mass. Its medial two-thirds are rounded and convex anteriorly and the lateral third is flat and concave anteriorly. For much of its length, the clavicle may be almost encircled by two fingers, but medially its ligamentous attachments make definition more difficult. The jugular notch on the superior surface of the sternal manubrium lies between the expanded medial ends of the clavicles. The posterior end of the first rib may be felt indistinctly within the floor of the posterior triangle of the neck.

Soft tissues and viscera

Triangles and root of the neck

The neck is divided into anterior and posterior triangles by sternocleidomastoid (**Fig. 33.11**). The anterior triangle may be further subdivided into submental, muscular, carotid and digastric triangles, and the posterior triangle may be divided into occipital and supraclavicular triangles. Above the hyoid bone, the musculature runs in a predominantly horizontal or oblique direction, and below the hyoid it runs in a vertical direction. The muscles forming the boundaries of the subtriangles of the neck are not readily palpable or visible, although they may be landmarked according to their attachment points, e.g. the two bellies of digastric lie along a line from the anterior midline of the chin to the lateral aspect of the hyoid body and then towards the medial surface of the mastoid process.

The root of the neck is the transitional zone between the neck, thorax and upper limbs. Communication with the thorax via the superior thoracic aperture (thoracic inlet) is marked anteriorly by the superior surface of the manubrium. The trachea is palpable in the midline superior to the jugular notch, a region that may also contain the left brachiocephalic vein, especially in the very young and elderly adults. The apices of the lungs are located posterior to the medial third of the clavicle (Mirjalili, Hale et al 2012).

Anterior triangle

The base of the anterior triangle is formed by the inferior border of the mandible and a line from its angle to the mastoid process. The sides are formed by the midline anteriorly and by the anterior border of sternocleidomastoid laterally. By using these borders, several major vessels and lymphatic node groups situated deep to the sternocleidomastoid muscle are not currently located within a triangle of the neck. It would be preferable, therefore, for the posterior border of sternocleidomastoid to form the lateral boundary of the anterior triangle (Ch. 35), especially since the

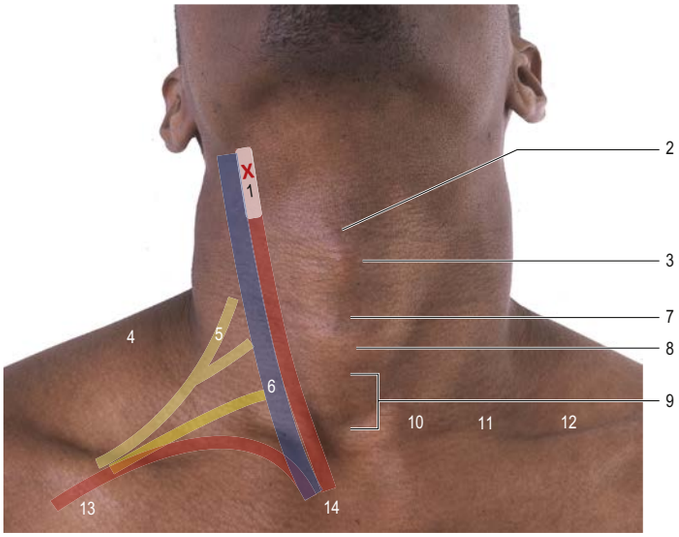

Fig. 33.11 The anterior and posterior triangles of the neck. Key: 1, zone of carotid artery bifurcation (white): usually 0.5–3.0 cm above the level of the thyroid lamina; 2, thyroid notch with thyrohyoid ligament (indented region) above; 3, laryngeal prominence; 4, trapezius; 5, course of brachial plexus (C5 root leading to upper trunk); 6, lesser supraclavicular fossa overlying the internal jugular vein; 7, median cricothyroid ligament; 8, cricoid cartilage; 9, isthmus of thyroid gland; 10, sternal head of sternocleidomastoid; 11, clavicular head of sternocleidomastoid; 12, greater supraclavicular fossa (of posterior triangle); 13, right subclavian artery; 14, right common carotid artery; X (red) carotid bifurcation at the vertebral body of C3. (Adapted with permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008.)

neck triangles are used in the diagnosis and management of regional masses or lumps. The triangle is best palpated bimanually with the examiner standing behind the subject and using both hands to examine the structures within. Inspection reveals the rounded tendinous sternal head of sternocleidomastoid, which arises from the superior part of the anterior surface of the manubrium, and the broader, more vertical clavicular head, which arises from the upper surface of the medial third of the clavicle. The indentation of the lesser supraclavicular fossa sits between the two heads: the fossa contains the internal jugular vein before it joins the subclavian vein posterior to the sternoclavicular joint and therefore represents an access point for central venous cannulation.

The trachea and its cartilaginous 'rings' may be palpated in the midline inferior to the cricoid cartilage and above the jugular notch. It may be deviated laterally by thyroid masses/growth, atelectasis or tension pneumothorax. The thyroid gland consists of two soft, palpable lobes lying on either side of the lower half of the laminae of the thyroid cartilage and upper part of the trachea, their lower borders extending towards the sternal end of the clavicle on each side. Swallowing may assist palpation of the gland. The lobes are joined by the isthmus (approximately 2 cm wide), which usually sits anterior to the second and third tracheal cartilages; these cartilages may therefore be impalpable.

As a rule, most head and neck lymph node groups are only clinically palpable when enlarged. Lymph nodes above the hyoid bone tend to be distributed in a horizontal plane either on or below the pericranio-cervical line, and anterior and posterior to the auricle, whereas the deep cervical nodes run relatively vertically and are related to the internal jugular vein. Enlarged jugulodigastric nodes are palpable in the indented region posterior to the mandibular angle and anterior to sternocleidomastoid. Palpation medial and deep to the inferior border of the mandible can reveal enlarged nodes within the submental and submandibular triangles. Superficial cervical nodes lie adjacent to the external and anterior jugular veins and are landmarked with them.

The submandibular gland is palpable within the submandibular triangle. It extends approximately 2 cm inferior to the inferior border of the posterior part of the body of the mandible and may reach the greater horn of the hyoid bone. Its posterior border is level with the angle of the mandible, from where it extends anteriorly for approximately 4 cm.

Posterior triangle

The posterior triangle is bounded by the posterior border of sternocleidomastoid, the middle third of the superior surface of the clavicle (the base of the triangle), and the anterior margin of trapezius. Its apex is the point where sternocleidomastoid and trapezius approximate at the superior

nuchal line. The lower portion of the posterior triangle forms the greater supraclavicular fossa, an important clinical area that lies just above and behind the clavicle at the confluence of the superior thoracic aperture and the opening (aditus) to the axilla and arm. It is best inspected from in front and palpated from behind. Scalenus anterior and medius are palpable as firm masses in the floor of the triangle, posterior to the lower part of sternocleidomastoid. The near-vertical interscalene groove is palpable between them, at or near the level of the vertebral body of C6; it serves as a landmark for the upper trunk of the brachial plexus.

When the greater supraclavicular fossa is inspected, the pulsation of the great veins may be seen if the central venous pressure is raised. The fossa is also a common site in which to feel pathologically enlarged supraclavicular lymph nodes. In particular, cancers of the lung can spread to left- and right-sided nodes, and cancers of the upper gastrointestinal tract can spread to left-sided nodes. The subclavian artery may be felt pulsating as it crosses the first rib, posterior to the medial end of the clavicle, and the upper and middle trunks of the brachial plexus may be felt superior and posterior to the artery. The posterior end of the first rib may be felt as a fullness in the posterior aspect of the fossa. A point approximately 2.5 cm above the middle of the medial third of the clavicle marks the level of the neck of the first rib and is thus the surface marking for the apex of the dome of the cervical pleura and apex of the lung covered by the suprapleural membrane (Sibson's fascia). Any penetrating injury (iatrogenic or otherwise) in this region will run the risk of creating a pneumothorax.

Course of vessels

Carotid arteries

In the neck, the common carotid artery and the internal carotid artery may be represented by an almost straight line passing from the sternoclavicular joint to a point just posterior to the mandibular condyle. The level at which the common carotid artery bifurcates into internal and external carotid arteries is variable (Lo et al 2006). It occurs most commonly level with the vertebral body of C3, but ranges from the level of the vertebral body of C1 to the vertebral body of C5 (Furukawa et al 2012, Mirjalili et al 2012b, Shen et al 2017). Relative to the thyroid cartilage, the bifurcation most commonly sits above the upper border of the lamina by an average of 1.8 cm (Mirjalili et al 2012b, Shen et al 2017). The common carotid artery may be compressed against the prominent transverse process of C6 (the carotid tubercle or Chassaignac's tubercle), which commonly sits lateral to the cricoid cartilage in females and just above this level in males. Above this level, the artery is superficial and its pulsation may be readily felt beneath the anterior border of sternocleidomastoid.

Subclavian artery

The subclavian artery enters the root of the neck behind the sternoclavicular joint. It passes through the inferior part of the palpable interscalene groove and arches upwards to reach a point approximately 2 cm above the clavicle deep to the posterior border of sternocleidomastoid, before passing across the upper surface of the first rib posterior to the midpoint of the clavicle. The subclavian pulse may be palpated posterior to the clavicle at either the lateral border of sternocleidomastoid or where the artery crosses the first rib.

Subclavian and brachiocephalic veins

The subclavian vein sits anterior to the subclavian artery and follows a similar course by passing over the first rib into the root of the neck (inferior neck). It lies closest to the clavicle at the junction of its middle and medial thirds, approximately 7 cm from the midline (Hale et al 2010). The subclavian vein typically joins the internal jugular vein to form the brachiocephalic vein posterior to the sternoclavicular joint (Mirjalili, Hale et al 2012, Pak et al 2017), but other configurations have been described (Keough et al 2016, Shen et al 2016). Subclavian vein cannulation is described in Chapter 35.

Anterior jugular vein

The anterior jugular vein runs downwards from beneath the chin, approximately a finger's breadth from the midline. It turns laterally approximately 2.5 cm from the sternal end of the clavicle and passes beneath sternocleidomastoid to drain into the external jugular vein. The veins of each side join to form the jugular venous arch just above the jugular notch. The anterior jugular vein may be encountered if the operator drifts laterally while creating a surgical airway.

External jugular vein

The external jugular vein lies superficial to sternocleidomastoid and may be represented by a line that starts just below and behind the angle of the mandible and runs to a point close to the lateral extent of the junction of sternocleidomastoid with the clavicle. It drains into the subclavian vein after penetrating the investing layer of deep cervical fascia and may be kinked at this point. If the proximal part of the vein is damaged, it may be held open by the surrounding fascia, and air may then be sucked in during breathing, resulting in an air embolus. The external jugular vein can be distended if venous pressure is raised, e.g. by performing a Valsalva manoeuvre (forced expiration against a closed glottis and mouth, and blocked nostrils), by supraclavicular digital pressure or if the vessel is kinked.

Internal jugular vein

The internal jugular vein runs in the carotid sheath, lying just lateral or anterolateral to the pulsating carotid arteries. It therefore has similar surface markings to those described for the common and internal carotid arteries and is represented by a broad band passing from just medial to the mastoid process to the sternoclavicular joint, where it joins the subclavian vein (Mirjalili et al 2012a). The inferior bulb of the internal jugular vein lies in the lesser supraclavicular fossa (the depression between the sternal and clavicular heads of sternocleidomastoid), where it may be accessed for central vein cannulation. In children under the age of 5 years, the vein is less than 1 cm deep to skin (Roth et al 2008). The jugular venous pulse reflects the jugular venous pressure (central venous pressure) and may be used as a measure of cardiac function. Pulsation of the great veins may be seen in this region if the central venous pressure is raised (e.g. right-sided heart failure). Internal jugular vein cannulation is described in Chapter 35.

Course of nerves

Accessory nerve

The approximate course of the (spinal) accessory nerve can be mapped by dividing sternocleidomastoid into thirds and drawing a line from the junction of the upper and middle thirds to a point on the anterior border of trapezius about 5 cm above the clavicle: both points vary considerably. The nerve emerges from the posterior border of sternocleidomastoid approximately 6.5 cm (range 3–10 cm) below the tip of the mastoid process. It commonly sits 1.5 cm (range 0–3.8 cm) above the point at which the great auricular nerve passes around the posterior border of the muscle (Salgarelli et al 2009). It crosses the posterior triangle and penetrates the anterior border of trapezius approximately 4.5 cm (range 1–10 cm) above the clavicular insertion of trapezius (Symes and Ellis 2005, Mirjalili et al 2012c). Accessory nerves usually divide into 2–4 branches prior to trapezius.

Cervical plexus

The cutaneous branches of the cervical plexus emerge from behind the posterior border of the middle third of sternocleidomastoid, commonly up to 2 cm inferior to the accessory nerve (Mirjalili et al 2012c) (see Figs 33.8B, 33.10). The greater auricular point (emergence of the greater auricular nerve from the posterior border of sternocleidomastoid) usually sits above the midpoint of sternocleidomastoid, around 6.0 ± 1.4 cm from the mastoid process tip (Raikos et al 2017). The great auricular nerve can be damaged during rhytidectomy. It passes towards the lobule of the auricle and the angle of the mandible, crossing superficial to sternocleidomastoid approximately 6.5 cm below the lower border of the external acoustic meatus; the external jugular vein sits approximately 0.5 cm anteriorly at this position (McKinney and Katrana 1980).

Brachial plexus

The roots and trunks of the brachial plexus can be represented by a line passing between the midpoint of the posterior border of sternocleidomastoid and the midpoint of the clavicle. In thin individuals, the scalene muscles are visible when the head is laterally flexed to the contralateral side; the roots/upper trunk are palpable in the almost vertical interscalene groove, which is located posterior to scalenus anterior. The trunks lie in the lower part of the posterior triangle of the neck, and the divisions lie behind the clavicle near the lateral border of the first rib. Normally the cords enter the axilla above the first part of the subclavian artery, closely surround its second part, and give off branches around the third part.

Cervical sympathetic ganglia

The superior cervical ganglion lies slightly anterior to the (palpable) transverse process of C2 (axis). The middle cervical ganglion, when present, lies just anterior to the transverse process of C6 (the tubercle of this vertebra is palpable in the anterior neck, often lateral to the cricoid cartilage). The inferior cervical ganglion may be fused with the first thoracic cervical ganglion, forming the stellate or cervicothoracic ganglion. Stellate ganglion block is often used to perform a sympathetic nerve block to the head and neck or to the arm (Ellis et al 2004).

The intimate relationship of the lingual nerve to the lower third molar region is a significant factor in the morbidity associated with third molar extractions. This extensive cadaver study reported that in 14% of patients the lingual nerve was located above the lingual crest and that in 22% the nerve was in direct contact with the lingual plate of the alveolar process.

Day JD, Tschabitscher M 1998 Anatomic position of the asterion. Neurosurgery 42:198–9.
The asterion has been used as a landmark in lateral approaches to the posterior fossa. It is not strictly reliable in terms of locating the underlying posterior fossa dura but it does lie directly over the transverse–sigmoid sinus complex. Caution must therefore be taken when placing burr-holes to avoid damage to the venous sinuses with potentially very serious consequences.

CHAPTER
34

The skull

The skull is the bony skeleton of the head. It houses the brain, the organs of special sense, and the upper parts of the respiratory and digestive systems and provides attachments for many of the muscles of the head and neck. Movement is restricted and is found only in relation to the mandible at the temporomandibular joint and at the atlanto-occipital joint for movement of the head in relation to the neck.

The skull consists of the neurocranium, viscerocranium (facial skeleton) and mandible. The neurocranium may be subdivided into the calvaria (sometimes called the cranial vault) and the basicranium (also known as the cranial base). The neurocranium encloses the brain, intracranial portions of the cranial nerves, blood vessels, meninges and cerebrospinal fluid. Its walls are formed by parts of the frontal, ethmoid, parietal, sphenoid, temporal and occipital bones. The viscerocranium hangs down from the front of the neurocranium and houses the organs of sight, smell and taste, as well as the openings to the respiratory and digestive systems via the nose and mouth, respectively.

Internally, the cranial base can be divided into three regions corresponding to the floor of the anterior, middle and posterior cranial fossae. In clinical parlance, the terms skull base and cranial base are frequently used as though they are synonymous. Indeed, inspection of the inferior surface of a skull confirms that the middle and posterior cranial bases are the same as the middle and posterior skull bases. However, the anterior cranial base and the anterior skull base should not be used interchangeably because the anterior skull base includes the inferior surface of the facial skeleton, whereas the internal surface of the anterior cranial base is the floor of the anterior cranial fossa and may be further subdivided into a midline (central) and two lateral parts. During development, the parts of the skull where the bones are derived by endochondral ossification constitute the chondrocranium; the remaining bones are derived by intramembranous ossification.

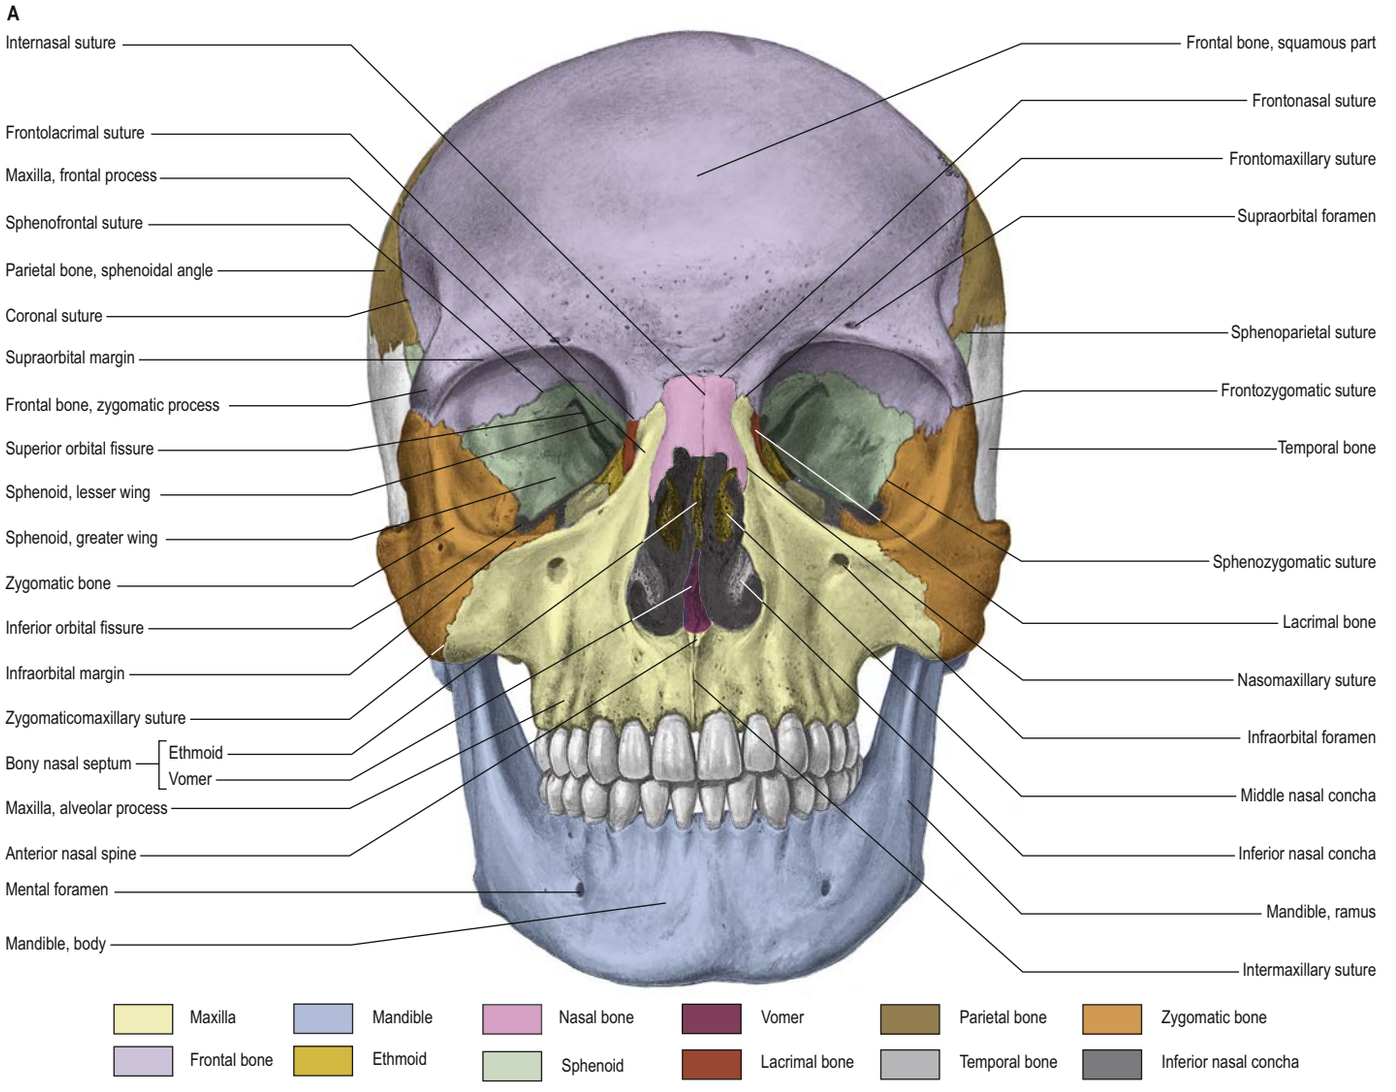
The skull is the most complex bony structure in the body. The young adult skull is composed of an average of 28 separate bones, many of which are paired; some in the median plane are single, though symmetric. Most of the vault bones are flat and consist of two tables or plates of compact bone enclosing a narrow layer of relatively dense cancellous marrow (diploic bone). The marrow within the skull bones is a site of haemopoiesis, at least in the young individual. These bones form by intramembranous ossification of a highly vascular connective tissue membrane and have often been referred to as 'dermal' in deference to their alleged ancient phylogenetic origin. The inner table is thinner and more brittle while the outer tends to be thicker and more resilient; this is important to remember when examining fractures to the skull caused by either blunt or sharp trauma. This bone type is also of considerable value in cranial bone grafting in the young, where the two tables can be split to produce an autograft for use in maxillofacial reconstruction. The skull bones vary in thickness in different regions, with the bones of the viscerocranium being rather delicate and therefore particularly susceptible to fracture.

The majority of bones in the skull articulate via fibrous joints called sutures, which facilitate growth rather than movement in the developing skull. The three main sutural morphologies reflect the magnitude of strain placed on them. Thus, the margins of adjacent bones of a suture may be smooth and meet end to end, giving a simple (butt-end) suture (e.g. median palatine suture); may be bevelled, so that the border of one bone overlaps the other (e.g. parietotemporal suture); or may present numerous projections that interlock, giving a serrated jigsaw appearance (e.g. lambdoid suture). The complexity of serrated sutures increases from the inner to the outer surface. Fusion across sutures (synostosis) can start early in the third decade, although its variability precludes using this information to assess age with any degree of accuracy. The process of fusion starts on the internal surface of the cranium first and proceeds externally; the coronal and sagittal sutures are often the first to display synostosis. By middle age, many of the larger sutures will show evidence of synostosis, although there are some that rarely show fusion, e.g. the zygomaticofacial. Premature fusion of sutures during the early growth phase of the skull (craniosynostosis) results in various abnormalities.

The bones forming the base of the skull also play an important role in the overall growth of the face and the neurocranium. They develop mainly via endochondral ossification and the joints between most of them are primary cartilaginous joints. One of the most important is the spheno-occipital synchondrosis, between the body of the sphenoid anteriorly and the basilar part of the occipital bone posteriorly; fusion between them is generally completed between 13 and 18 years of age. Other joints include the occipital synchondroses and the jugular growth plate (or petro-exoccipital articulation).

The two sites of synovial articulation associated with the exterior of the skull are the temporomandibular joint (between the glenoid fossa of the temporal bone and the condylar process of the mandible) and the atlanto-occipital joint (between the condyles of the occipital bone and the superior articular facets of the atlas). Movement at these joints does not facilitate rotation but participates in flexion and extension in the anteroposterior plane and bilateral flexion in the transverse plane.

Many important neurological and vascular structures enter and exit the skull via foramina. The skull is often fractured following direct trauma. In addition to the main foramina, irregular emissary foramina allow veins situated externally on the face and scalp to communicate with those lying intracranially; spread of infection along these routes may have serious clinical consequences (e.g. cavernous sinus thrombosis).



In the account of the skull that follows, only generalized standard views will be considered. A more detailed account of each individual bone will be found associated with the relevant regional text (Berkovitz and Moxham 1994).

FRONTAL (ANTERIOR) VIEW

Viewed from the front, the skull is generally ovoid in shape and is wider above than below (Fig. 34.1). The upper part is formed by the frontal bone, which underlies the forehead region above the orbits. Superomedial to each orbit is a rounded superciliary arch (more pronounced in males), between which there may be a median elevation, the glabella. The glabella may show the remains of the interfrontal (metopic) suture, which usually closes in the first postnatal year (Weinzweig et al 2003) but persists in a small percentage of adult skulls in various ethnic groups. A retained interfrontal suture is usually present in the inferior portion of the suture, a feature known as metopism. The frontal bone articulates with the two nasal bones at the frontonasal sutures, which is marked by a depression at the root of the nose; the point at which the frontonasal and internasal sutures meet is the anthropometric landmark known as the nasion.

The upper part of the face is occupied by the orbits and the bridge of the nose. Each orbital opening is roughly quadrangular in shape, although this can differ depending on ancestral origin (Ch. 44). The upper, supraorbital, margin is formed entirely by the frontal bone, interrupted at the junction of its sharp lateral two-thirds and rounded medial third by the supraorbital notch or foramen, which transmits the supraorbital vessels and nerve. The lateral margin of the orbit is formed largely by the frontal process of the zygomatic bone and is completed above by the zygomatic process of the frontal bone; the frontozygomatic suture between them lies in a palpable depression. The infraorbital margin is formed by the zygomatic bone laterally and the maxilla medially. Both lateral and infraorbital margins are sharp and palpable. The medial margin of the orbit is formed above by the frontal bone and below by the lacrimal crest of the frontal process of the maxilla.

The central part of the face is occupied mainly by the paired maxillae, separated by the anterior nasal aperture. Each maxilla contributes to the upper jaw, the floor and medial wall of the orbital cavity, the lateral wall of the nose, the floor of the nasal aperture and the bone of the cheek. The anterior nasal spine marks the upper limit of the intermaxillary suture at the lower margin of the anterior nasal aperture and is palpable in the nasal septum. The infraorbital foramen transmits the infraorbital vessels and nerve and lies about 1 cm below the middle of the infraorbital margin. The maxillary alveolar process bears the upper teeth. The short, thick zygomatic process of the maxilla has an oblique upper surface that

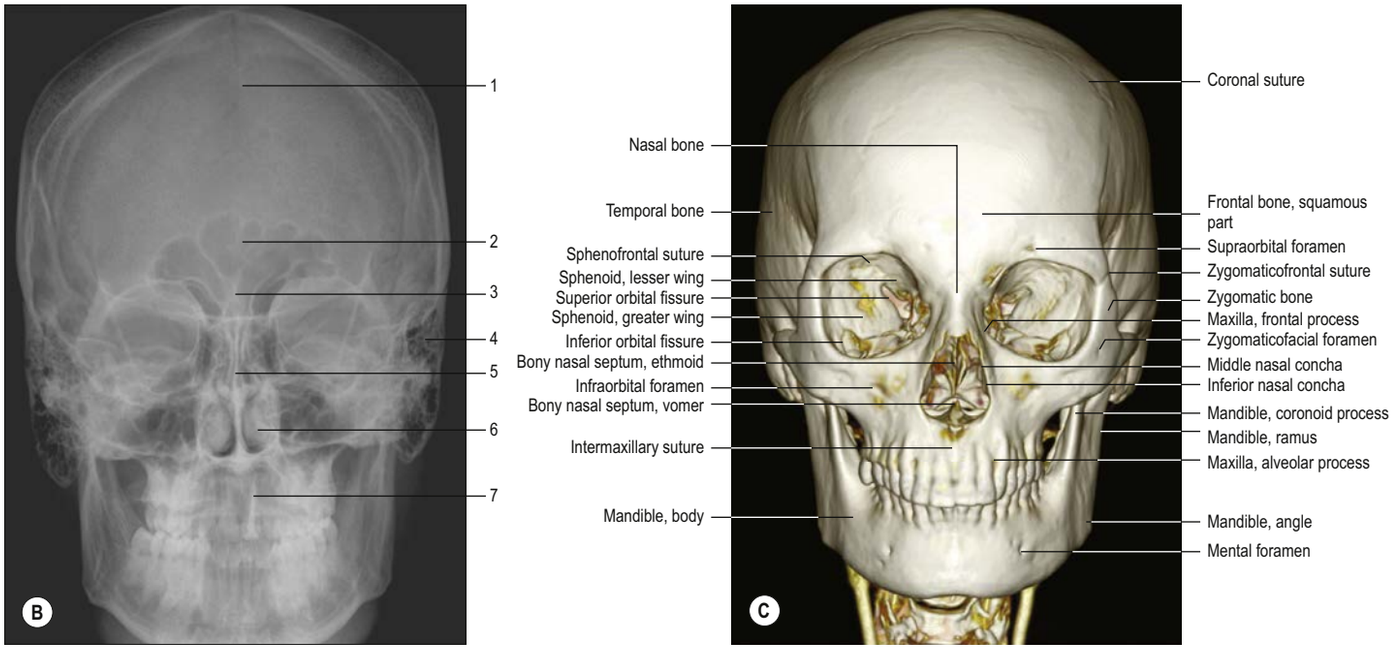


Fig. 34.1 **A**, The bones of the adult skull, frontal aspect. **B**, An anteroposterior radiograph of the skull and upper cervical spine, young adult. Key: 1, sagittal suture; 2, frontal sinus; 3, crista galli; 4, mastoid air cells; 5, nasal septum; 6, inferior concha; 7, dens of axis. **C**, Volume rendered CT of the head with an anteroposterior view of the skull. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

articulates with the zygomatic bone at the zygomaticomaxillary suture. The frontal process of the maxilla ascends posterolateral to the nasal bone to articulate with it medially, the frontal bone superiorly and the lacrimal bone laterally.

The anterior nasal aperture is piriform in shape, wider below than above and bounded by the paired nasal bones and maxillae. The upper boundary of the aperture is formed by the nasal bones while the remainder is formed by the maxillae. In life, several cartilages (septal, lateral nasal, major and minor alar) help to delineate two nasal cavities. The shape of these bones can be used quite successfully to predict the shape of the cartilaginous nose in forensic facial reconstructions (Wilkinson and Rynn 2012).

The lower part of the face, below the external nose, is formed from the alveolar arch of the maxillae and the upper dentition, and the body and alveolar process of the mandible and the lower dentition. In the midline, the mental protuberance produces the characteristic prominence of the chin. The mental foramen, which transmits the mental nerve and accompanying vessels, lies in the same vertical plane as the supraorbital and infraorbital foramina.

Anteroposterior radiographs of the skull clearly show the central location of the paranasal air sinuses in the frontal bone, maxilla and ethmoid. The sinuses exhibit wide anatomical variations which can be useful indicators of identity when postmortem images are compared with antemortem clinical films.

POSTERIOR VIEW

The parietal, temporal and occipital bones form the entirety of the posterior view (Fig. 34.2). The superolateral region is occupied by the parietal bones, the mastoid region of the temporal bones makes up the inferolateral regions, and the central portion is occupied by the squamous portion of the occipital bone, which is the reason why this aspect is also referred to as the occipital view. The parietal bones articulate with the occipital bone at the lambdoid suture, which extends inferiorly into the occipitomastoid and the parietomastoid sutures behind and above the mastoid processes, respectively. The lambda is the anthropometric point where the occipital bone meets the two parietal bones. Accessory sutural bones (or wormian bones) are islands of bone that may be found within a suture. They may arise from separate centres of ossification and they appear to have no clinical significance, being of genetic rather than pathological aetiology; their initial formation is thought to be caused by a degree of dural strain and increased sutural width (Bellary et al 2013). They are most frequent in the lambdoid suture, which is the most tortuous of the sutures. However, they are also often observed within the sagittal and coronal sutures. A large, central interparietal bone is not uncommon and is sometimes referred to as an Inca bone (see Fig. 34.2). Wormian bones are considered to be markers for various congenital diseases, including osteogenesis imperfecta and cleidocranial dysostosis.

The external occipital protuberance is a midline elevation on the occipital bone that can become particularly well developed and palpable in males and is a marker for sex estimation. The location of the protuberance coincides with the anthropometric inion. Superior nuchal lines extend laterally from the protuberance and represent the boundary between the scalp and the neck. Inferior nuchal lines run parallel to, and below, the superior nuchal lines; a set of highest nuchal lines may sometimes develop above the superior lines. The external occipital protuberance, nuchal lines and roughened external surface of the occipital bone between the nuchal lines afford attachment to the muscles of the neck.

SUPERIOR VIEW

Seen from above, the contour of the calvaria varies greatly but is usually ellipsoid, or more strictly, a modified ovoid with its greatest width lying nearer to the occipital pole (Fig. 34.3). Four bones constitute this view and articulate via three well-defined sutures. The squamous part of the frontal bone is anterior, the squamous part of the occipital bone is posterior, and the two parietal bones meet in the midline separating the frontal from the occipital bone. The maximal parietal convexity on each site is palpable at the parietal tuber or eminence; it is most conspicuous in the female (retention of a paedomorphic appearance). The superior and inferior temporal lines run close to the parietal eminence but are best seen in a lateral view.

The coronal suture marks the articulation between the posterior margin of the frontal bone and the anterior margins of the two parietal bones. It descends across the calvaria and projects inferiorly until it meets the junction between the greater wing of the sphenoid and the squamous temporal bone at the pterion. The sagittal suture runs in the midline between the two parietal bones and extends from the bregma anteriorly to the lambda posteriorly. The lambdoid suture delineates the articulation between the posterior borders of the right and left parietal bones and the superior border of the occipital bone.

The bregma represents the position of the anterior fontanelle in the young child. This diamond-shaped, membrane-filled space located between the two frontal and two parietal bones of the developing fetal skull persists until approximately 18 months after birth. A depression can sometimes be found posterior to the bregma (post-bregmatic depression) and is often used as an indicator of sub-Saharan African ancestral origin. The lambda, at the junction of the sagittal and lambdoid sutures, represents the site of the posterior fontanelle, which persists for the first 2–3 months after birth.

A parietal foramen may pierce either or both parietal bones near the sagittal suture about 3.5 cm anterior to the lambda. It transmits a small emissary vein from the superior sagittal sinus. The vertex is the highest point on the skull and it usually occupies a position in the middle third of the sagittal suture.

LATERAL VIEW

The skull, viewed from the side, can be subdivided into three zones: face (anterior), temporal region (middle) and occipital region (posterior)

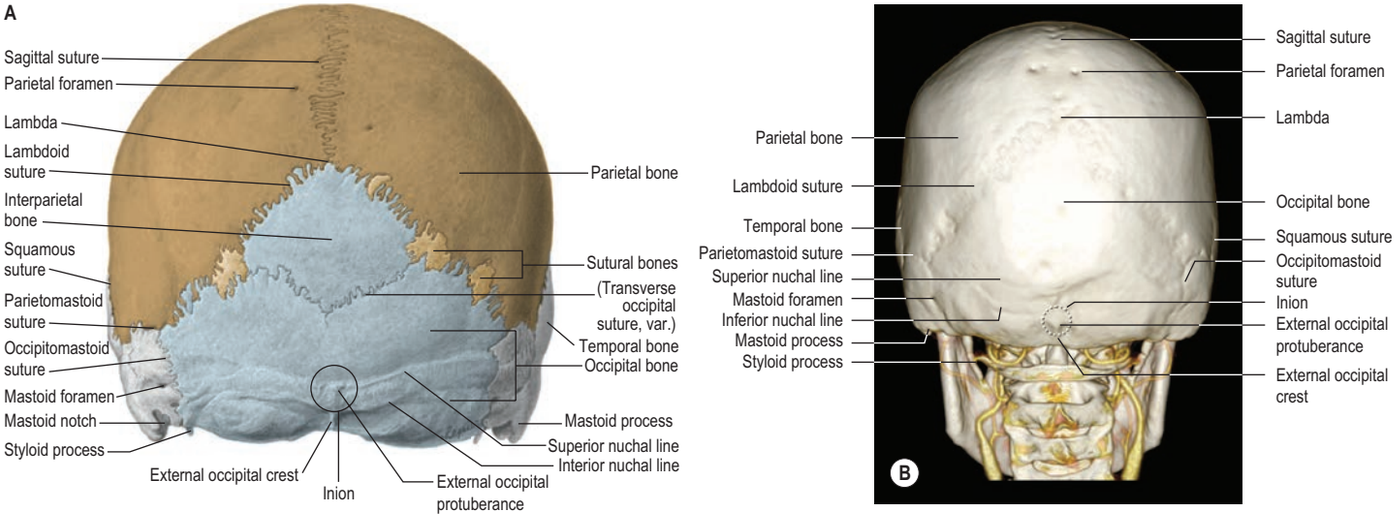

Fig. 34.2 **A**, The bones of the adult skull, posterior aspect. **B**, Volume rendered CT of the head with a posteroanterior view of the skull. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

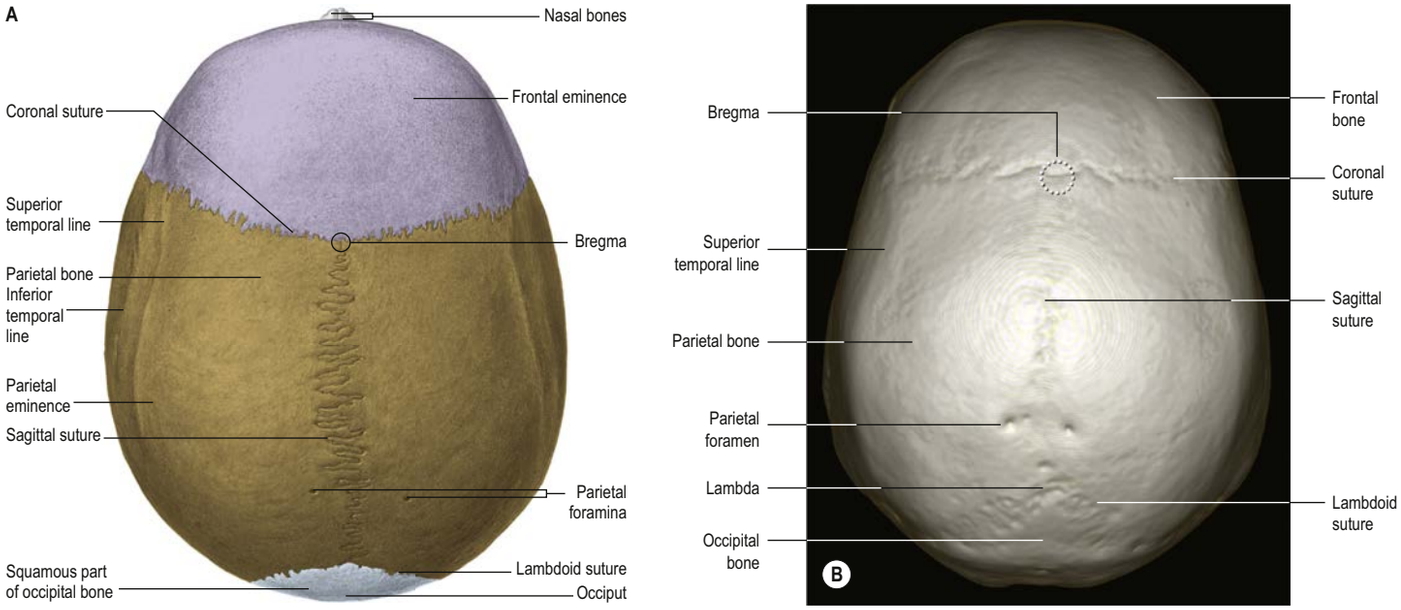

Fig. 34.3 **A**, The bones of the adult skull, superior aspect. **B**, Volume rendered CT of the head with a superior view of the skull. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

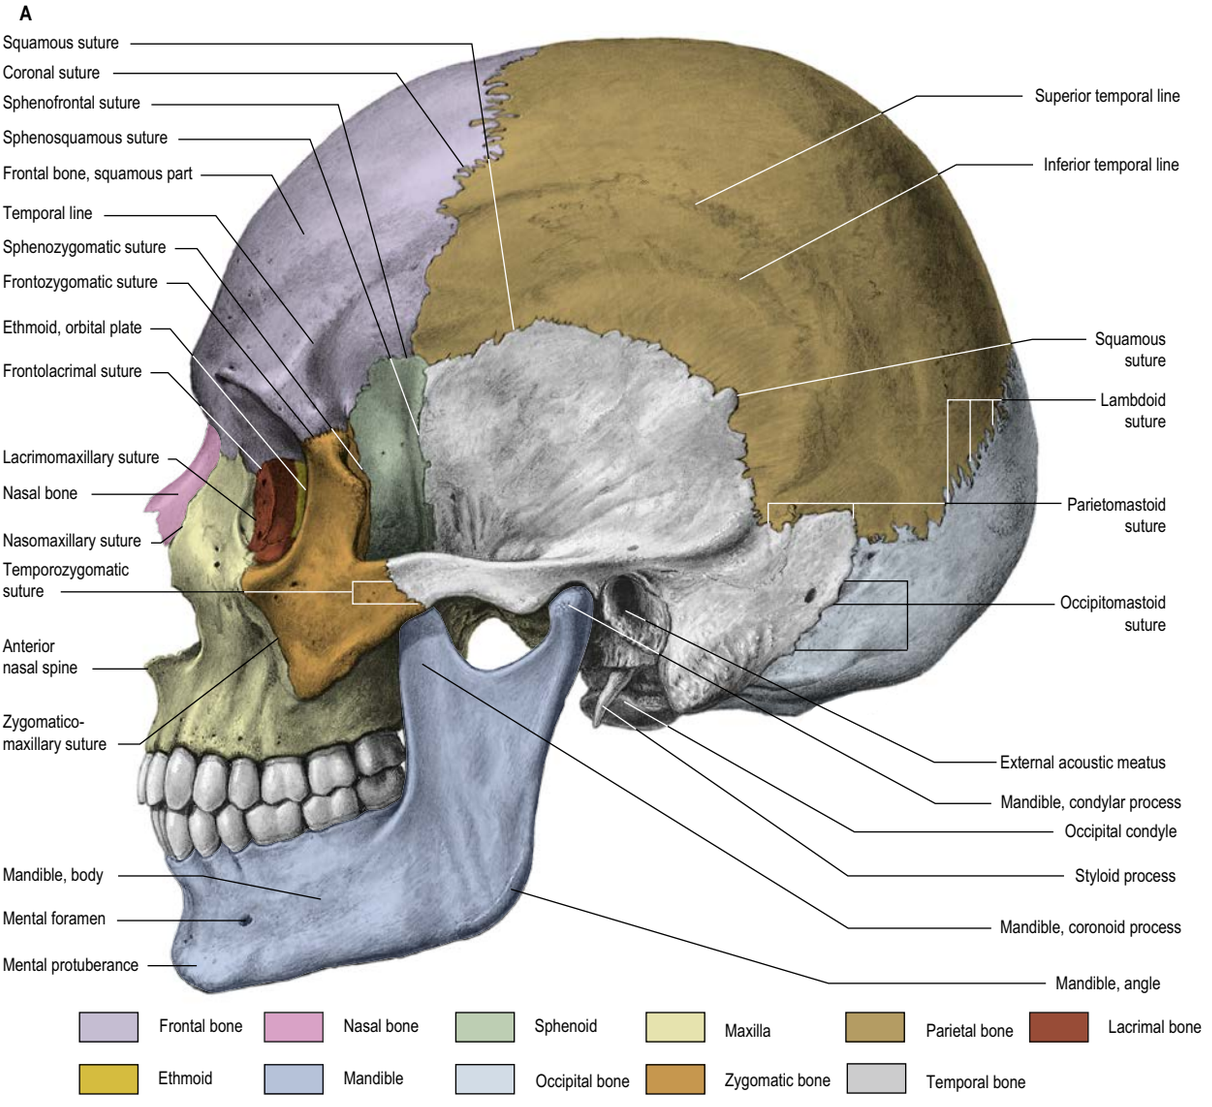
(Fig. 34.4). The face has been considered in the section on the anterior view of the skull.

The temporal region can be divided into an upper temporal fossa and a lower infratemporal fossa, separated by the position of the zygomatic arch. The upper temporal fossa is bounded inferiorly by the zygomatic arch, superiorly and posteriorly by the temporal lines, and anteriorly by the frontal process of the zygomatic bone. It is continuous inferiorly with the infratemporal fossa deep to the zygomatic arch. The temporal lines often present anteriorly as distinct ridges but become much less prominent as they arch posteriorly across the parietal bone. The inferior temporal line becomes more prominent as it curves down the posterior part of the squamous temporal bone, forming a supramastoid crest at the base of the mastoid process. The superior temporal line gives attachment to the temporal fascia while the inferior temporal line provides attachment for temporalis.

The floor of the temporal fossa is formed by the frontal and parietal bones superiorly and the greater wing of the sphenoid and squamous part of the temporal bone inferiorly. All four bones of one side meet at a roughly H-shaped sutural junction called the pterion. This is an important anthropometric landmark because it commonly overlies both the anterior branch of the middle meningeal artery and the lateral fissure of the cerebral hemisphere (Ma et al 2012). The pterion corresponds to the site of the anterolateral (sphenoidal) fontanelle of the neonatal skull, which closes in the third month after birth.

The vertical suture between the sphenoid and temporal bones, the sphenosquamosal suture, is formed by articulation between the posterior border of the greater wing of the sphenoid and the anterior border of the squamous part of the temporal bone.



The lateral surface of the ramus of the mandible will be described briefly here because it lies within the middle region of this view of the skull. The ramus is a plate of bone projecting upwards from the body of the mandible; its lateral surface gives attachment to masseter. The ramus bears two prominent processes superiorly, the coronoid process anteriorly and the condylar process posteriorly, separated by the mandibular notch. The coronoid process is the site of insertion of temporalis; the condylar process articulates with the mandibular (glenoid) fossa of the temporal bone at the temporomandibular joint. The inferior and posterior borders of the mandible meet at the angle; it is more commonly splayed in the male, reflecting the larger site of attachment for medial pterygoid on the internal surface.

The zygomatic arch stands proud of the rest of the skull, and the temporal and infratemporal fossae communicate via the gap thus created. In life, this space is largely filled by temporalis. The zygomatic bone is the principal bone of the cheek together with the zygomatic processes of the maxilla and temporal bones. The term 'zygomatic arch' is generally restricted to the temporal process of the zygomatic bone and the zygomatic process of the temporal bone, which articulate at the zygomaticotemporal suture. The suture between the zygomatic process of the frontal bone and the frontal process of the zygomatic bone is the frontozygomatic suture; the suture between the maxillary margin of the zygomatic bone and the zygomatic process of the maxilla is the zygomaticomaxillary suture; and the suture between the sphenoid and zygomatic bones is the sphenozygomatic suture. As the zygomatic process of the temporal bone passes posteriorly, it widens to form the articular eminence (tubercle) of the mandibular fossa anteriorly.

The temporal bone is a prominent structure on the lateral aspect of the skull. Its squamous part lies in the floor of the upper temporal fossa and its zygomatic process contributes to the structure of the cheek. Additional components visible in the lateral view of the skull are the mandibular fossa and its articular eminence, the tympanic plate, the external acoustic meatus (external auditory meatus), and the mastoid and styloid processes. The mandibular fossa is bounded in front by the articular eminence and behind by the tympanic plate. The articular eminence provides a surface over which the mandibular condyle glides during mandibular movements and acts to prevent dislocation of the temporomandibular joint. The tympanic plate of the temporal bone contributes most of the margin of the external acoustic meatus; the squamous part forms the posterosuperior region. The external margin is roughened to provide an attachment for the cartilaginous part of the meatus. A small depression, the suprameatal triangle, lies above and behind the meatus and is related to the lateral wall of the mastoid antrum. The mastoid process is an inferior projection of the temporal bone. It lies posteroinferior to the external acoustic meatus and is the site of attachment of sternocleidomastoid. It is in contact behind with the posteroinferior angle of the parietal bone at the parietomastoid suture and with the squamous part of the occipital bone at the occipitomastoid suture. These two sutures meet the lateral end of the lambdoid suture at the asterion. This coincides with the site of the posterolateral fontanelle in the neonatal skull, which closes during the second year. A mastoid foramen may be found near, or in, the occipitomastoid suture; it transmits an emissary vein from the sigmoid sinus. Sutural bones may appear in the parietomastoid suture.

The styloid process lies anterior and medial to the mastoid process and gives attachment to several muscles and ligaments. Its base is partly ensheathed by the tympanic plate and it descends anteromedially, its tip usually reaching a point medial to the posterior margin of the mandibular ramus. The styloid process is very variably developed. Its length ranges from a few millimetres to a few centimetres and increases with age (Krmpotić Nemanić et al 2009).

The infratemporal fossa is an irregular, postmaxillary space deep to the ramus of the mandible. It communicates with the upper temporal fossa deep to the zygomatic arch. It is best visualized when the mandible is removed but, for completeness, is considered here. Its roof is the infratemporal surface of the greater wing of the sphenoid, the lateral pterygoid plate lies medially, and the ramus of the mandible and styloid process lie laterally and posteriorly, respectively. The infratemporal fossa

has no anatomical floor. Its anterior and medial walls are separated above by the pterygomaxillary fissure lying between the lateral pterygoid plate and the posterior wall of the maxilla. The infratemporal fossa communicates with the pterygopalatine fossa through the pterygomaxillary fissure.

INFERIOR VIEW

With the mandible removed, the inferior surface of the skull extends from the upper incisor teeth anteriorly to the superior nuchal lines of the occipital bone posteriorly (Fig. 34.5). The region contains many of the foramina through which structures enter and exit the cranial cavity. The inferior surface may be conveniently subdivided into anterior, middle, posterior and lateral parts. The anterior part contains the hard palate and the dentition of the maxillary arch and lies at a lower level than the rest of the cranial base. The middle and posterior parts may be arbitrarily divided by a transverse plane passing through the anterior margin of the foramen magnum. The middle part is occupied mainly by the sphenoid bone, the apices of the petrous processes of the temporal bones, and the basilar part of the occipital bone. The lateral part contains the zygomatic arches, mandibular fossae, tympanic plates, the styloid and mastoid processes. The posterior part lies in the midline and is formed almost exclusively from the occipital bone. Whereas the middle and posterior parts are directly related to the cranial cavity (the middle and posterior cranial fossae), the anterior part is some distance from the anterior cranial fossa, being separated from it by the nasal cavities.

Anterior part of inferior surface

The bony palate within the superior alveolar arch is formed by the palatine processes of the maxillae anteriorly and the horizontal plates of the palatine bones posteriorly, all meeting at a cruciform system of sutures (see Fig. 34.5). The median palatine suture runs anteroposteriorly and divides the palate into right and left halves. This suture is continuous with the intermaxillary suture between the maxillary central incisor teeth. The transverse palatine (palatomaxillary) sutures run transversely across the palate between the maxillae and the palatine bones. The palate is arched sagittally and transversely; its depth and breadth are variable but are always greatest in the molar region. The incisive fossa lies behind the central incisor teeth, and the lateral incisive foramina, through which incisive canals pass to the nasal cavity, lie in its lateral walls. Median incisive foramina are present in some skulls and open on to the anterior and posterior walls of the fossa. The incisive fossa transmits the nasopalatine nerve and the termination of the greater palatine vessels. When

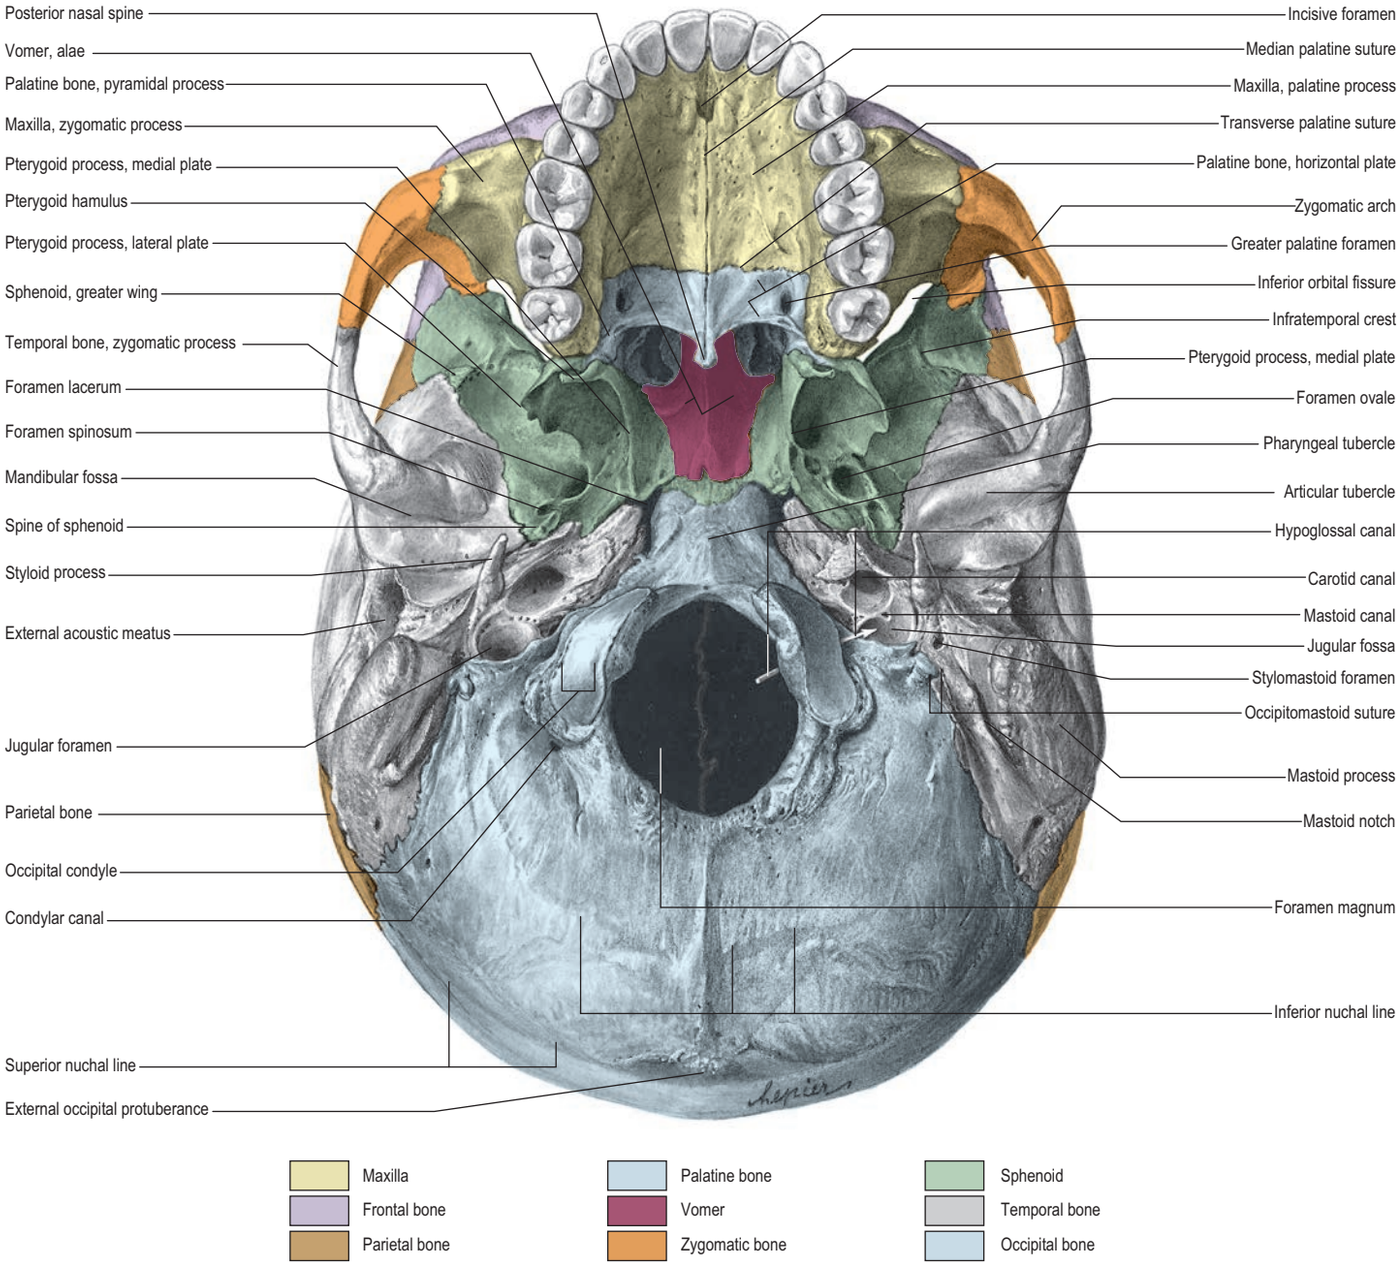

Fig. 34.5 The external surface of the base of the adult skull. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

median incisive foramina are present, the left nasopalatine nerve usually traverses the anterior foramen and the right nerve traverses the posterior foramen. The greater palatine foramen lies near the lateral palatal border of the transverse palatine suture; a vascular groove, deeper behind and shallower in front, leads forwards from the foramen. The lesser palatine foramina, usually two, lie behind the greater palatine foramen and pierce the pyramidal process of the palatine bone, which is wedged between the lower ends of the medial and lateral pterygoid plates. The palate is pierced by many other small foramina and is marked by pits for palatine glands. Variably prominent palatine crests extend medially from behind the greater palatine foramina. The posterior border projects back as the posterior nasal spine. In the adult, the alveolar arch normally bears a maximum of 16 sockets or alveoli for the teeth; the sockets vary in size and depth. Some are single and some are subdivided by septa, according to the morphology of the dental roots.

The nasal fossae lie above the hard palate and are separated by the nasal septum in the midline. The bony nasal septum is formed from the perpendicular plate of the ethmoid superiorly and the vomer inferiorly. The upper border of the vomer approximates to the inferior aspect of the body of the sphenoid, where it expands into an ala on each side. The two posterior nasal apertures (choanae) are located at the end of the nasal fossae; they are separated by the free posterior border of the vomer and bounded below by the posterior border of the horizontal plates of the palatine bones, above by the sphenoid and laterally by the medial pterygoid plates.

Middle part of inferior surface

The middle part of the inferior surface is made up from the sphenoid, petrous parts of the temporal bones and the basiocciput (see Fig. 34.5). It extends from the posterior nares anteriorly to an artificial line drawn transversely through the anterior margin of the foramen magnum posteriorly. In the adult, the body of the sphenoid fuses with the basiocciput, at the spheno-occipital synchondrosis, to form a midline bar of bone that extends posteriorly to the foramen magnum (internally, this is known as the clivus). The basiocciput bears a small midline pharyngeal tubercle, which gives attachment to the pharyngeal raphe, the highest attachment of the superior pharyngeal constrictor.

The petrous processes of the two temporal bones pass from the lateral sides of the base of the skull and fill the triangular space between the greater wing of the sphenoid anteriorly and the lateral margins of the basiocciput posteriorly. Each petrous process meets the basilar part of the occipital bone at a petro-occipital junction, which is deficient posteriorly at the jugular foramen. The petrosphenoidal junction and the groove for the pharyngotympanic tube lie between the petrous process and the infratemporal surface of the greater wing of the sphenoid. The apex of the petrous process does not meet the spheno-occipital synchondrosis; the deficit so produced is the foramen lacerum.

Pterygoid processes descend from the junction between the greater wing and body of the sphenoid, separated by a pterygoid fossa. Anteriorly, the plates are fused, except inferiorly, where they are separated by the pyramidal process of the palatine bone. Sutures are usually discernible at this site in young skulls. Laterally, the pterygoid plates are separated from the posterior maxillary surface by the pterygomaxillary fissure, which leads into the pterygopalatine fossa. The posterior border of the medial pterygoid plate is sharp, and bears a small projection near the midpoint, above which it is curved and attached to the pharyngeal end of the pharyngotympanic tube. Above, the medial pterygoid plate divides to enclose the scaphoid fossa. Below, it projects as a slender pterygoid hamulus, which curves laterally and is grooved anteriorly by the tendon of tensor veli palatini. The pterygoid hamulus gives origin to the pterygomandibular raphe. The lateral pterygoid plate projects posterolaterally and its lateral surface forms the medial wall of the infratemporal fossa. Superiorly and laterally, the pterygoid process is continuous with the infratemporal surface of the greater wing of the sphenoid bone, which forms part of the roof of the infratemporal fossa. This surface forms the posterolateral border of the inferior orbital fissure and bears an infratemporal crest associated with the origin of the upper part of lateral pterygoid. The infraorbital and zygomatic branches of the maxillary nerve and accompanying vessels pass through the inferior orbital fissure. Laterally, the greater wing of the sphenoid articulates with the squamous part of the temporal bone.

The medial aspect of the greater wing of the sphenoid presents a crescent of foramina of which only the most posterior two, foramen ovale and foramen spinosum, can be viewed on the basal aspect. The foramen ovale lies medial to the foramen spinosum and lateral to the foramen lacerum on the infratemporal surface of the greater wing of the sphenoid bone. It transmits the mandibular division of the trigeminal nerve, the lesser petrosal nerve, the accessory meningeal branch of the maxillary artery and an emissary vein that connects the cavernous venous sinus to the pterygoid venous plexus in the infratemporal fossa. Posterolaterally, the smaller and rounder foramen spinosum transmits the middle meningeal artery and a recurrent meningeal branch of the mandibular nerve. The irregular spine of the sphenoid projects posterolateral to the foramen spinosum. The medial surface of the spine is flat and, with the adjoining posterior border of the greater wing of the sphenoid, forms the anterolateral wall of a groove that is completed posteromedially by the petrous part of the temporal bone. This groove, the auditory sulcus, contains the cartilaginous pharyngotympanic tube, which leads posterolaterally into the bony portion of the tube that lies within the petrous part of the temporal bone. Occasionally, the foramen ovale and foramen spinosum are confluent or the posterior edge of the foramen spinosum may be defective. A small foramen, the sphenoidal emissary foramen (of Vesalius), is sometimes found between the foramen ovale and scaphoid fossa. When present, it contains an emissary vein linking the pterygoid venous plexus in the infratemporal fossa with the cavernous sinus in the middle cranial fossa.

The foramen lacerum is bounded in front by the body and adjoining roots of the pterygoid process and greater wing of the sphenoid bone; posterolaterally, by the apex of the petrous part of the temporal bone; and medially, by the basilar part of the occipital bone. Although nearly 1 cm long, it is not traversed by any major structure. The almost circular carotid canal lies behind and posterolateral to the foramen lacerum in the petrous part of the temporal bone. The internal carotid artery enters the skull through this foramen, ascends in the carotid canal, and turns anteromedially to reach the posterior wall of the foramen lacerum. It ascends through the upper end of the foramen lacerum, accompanied by venous and sympathetic nerve plexuses. Meningeal branches of the ascending pharyngeal artery and emissary veins from the cavernous sinus also traverse the foramen lacerum. In life, the lower part of the foramen lacerum is partially occluded by cartilaginous remnants of the embryological chondrocranium. The pterygoid canal can be seen on the base of the skull at the anterior margin of the foramen lacerum, above and between the pterygoid plates of the sphenoid bone. It leads into the pterygopalatine fossa and transmits the nerve of the pterygoid canal and accompanying blood vessels.

Posterior part of inferior surface

The posterior part of the inferior surface of the skull is predominantly formed by the occipital bone (see Fig. 34.5). Prominent features are the foramen magnum and associated occipital condyles, jugular foramen, mastoid notch and the squamous part of the occipital bone up to the external occipital protuberance and the superior nuchal lines, hypoglossal canals (anterior condylar canals) and condylar canals (posterior condylar canals).

The foramen magnum lies in an anteromedian position and leads into the posterior cranial fossa. It is oval and wider behind, with its greatest diameter being anteroposterior. It contains the lower end of the medulla oblongata, meninges, cerebrospinal fluid, vertebral arteries and veins, and the accessory nerves; the apical ligament of the dens and the tectorial membrane pass through it to attach to the internal basiocciput. Anteriorly, the margin of the foramen magnum is slightly overlapped by the occipital condyles, which project down to articulate with the superior articular facets on the lateral masses of the atlas. Each occipital condyle is oval in outline and orientated obliquely so that its anterior end lies nearer the midline than its posterior end. It is markedly convex anteroposteriorly, less so transversely, and its medial aspect is roughened by ligamentous attachments. The hypoglossal canal is directed laterally and slightly forwards, traverses deep to each condyle and transmits the hypoglossal nerve, a meningeal branch of the ascending pharyngeal artery and an emissary vein from the basilar plexus. A depression, the condylar fossa, lies immediately posterior to the condyle and may contain a (posterior) condylar canal for an emissary vein from the sigmoid sinus. This fossa accommodates the posterior margin of the atlas when the head is fully extended. A jugular process articulates with the petrous part of the temporal bone lateral to each condyle and its anterior free border forms the posterior boundary of the jugular foramen.

Laterally, the occipital bone approximates with the petrous part of the temporal bone anteriorly at the petro-occipital junction, and the mastoid process of the temporal bone more posteriorly at the occipitomastoid suture. The jugular foramen, a large, asymmetric and irregular hiatus, lies at the posterior end of the petro-occipital junction between the jugular process of the occipital bone and the jugular fossa of the petrous part of the temporal bone (see Fig. 42.1C) (Vogl and Bisdas 2009). A number of important structures pass through this foramen: inferior petrosal sinus

(anterior); glossopharyngeal, vagus and accessory cranial nerves (middle); and internal jugular vein (posterior). A mastoid canaliculus runs through the lateral wall of the jugular fossa and transmits the auricular branch of the vagus nerve. The canaliculus for the tympanic branch of the glossopharyngeal nerve lies on the ridge between the jugular fossa and the opening of the carotid canal. A small notch, related to the inferior glossopharyngeal ganglion, may be found medially on the upper boundary of the jugular foramen (it is more easily identified internally). The orifice of the cochlear canaliculus may be found at the apex of the notch.

The squamous part of the occipital bone exhibits the external occipital protuberance, supreme, superior and inferior nuchal lines, and the external occipital crest, all of which lie in the midline, posterior to the foramen magnum. The region is roughened for the attachment of muscles whose primary function is extension of the skull at the neck.

Lateral part of inferior surface

The lateral part of the inferior surface consists of the zygomatic arch and infratemporal fossa anteriorly and the mandibular fossa, tympanic plate and styloid and mastoid processes posteriorly (see Fig. 34.5). The anterior structures have been considered earlier in this chapter.

The mandibular fossa is a thin-walled, smooth, concave depression in the temporal bone and is most easily inspected when the mandible is removed. The zygomatic arch extends laterally in front of the fossa and a distinct ridge, the articular eminence, lies anterior to the fossa. Three fissures can be distinguished behind the mandibular fossa. The squamotympanic fissure extends from the spine of the sphenoid, between the mandibular fossa and the tympanic plate of the temporal bone, and curves up the anterior margin of the external acoustic meatus. A thin wedge of bone forming the inferior margin of the tegmen tympani lies within the fissure and divides the squamotympanic fissure into petrotympanic and petrosquamous fissures. The petrotympanic fissure transmits the chorda tympani branch of the facial nerve from the intracranial cavity into the infratemporal fossa. The tympanic plate forms the floor of the external acoustic meatus.

The stylomastoid foramen lies between the mastoid and styloid processes on the lateral aspect of the temporal bone. It transmits the facial nerve and the stylomastoid artery. The distance from the styloid process to the stylomastoid foramen decreases with age (Krmpotić Nemanić et al 2009). A groove, the mastoid notch, lies medial to the mastoid process and gives origin to the posterior belly of digastric. A groove related to the occipital artery often lies medial to the mastoid notch. A mastoid foramen may be present near, or in, the occipitomastoid suture; when present, it transmits an emissary vein from the sigmoid sinus. The external acoustic meatus lies in front of the mastoid process. It is surrounded inferiorly by the tympanic plate, which partly ensheathes the base of the styloid process as the vaginal process.

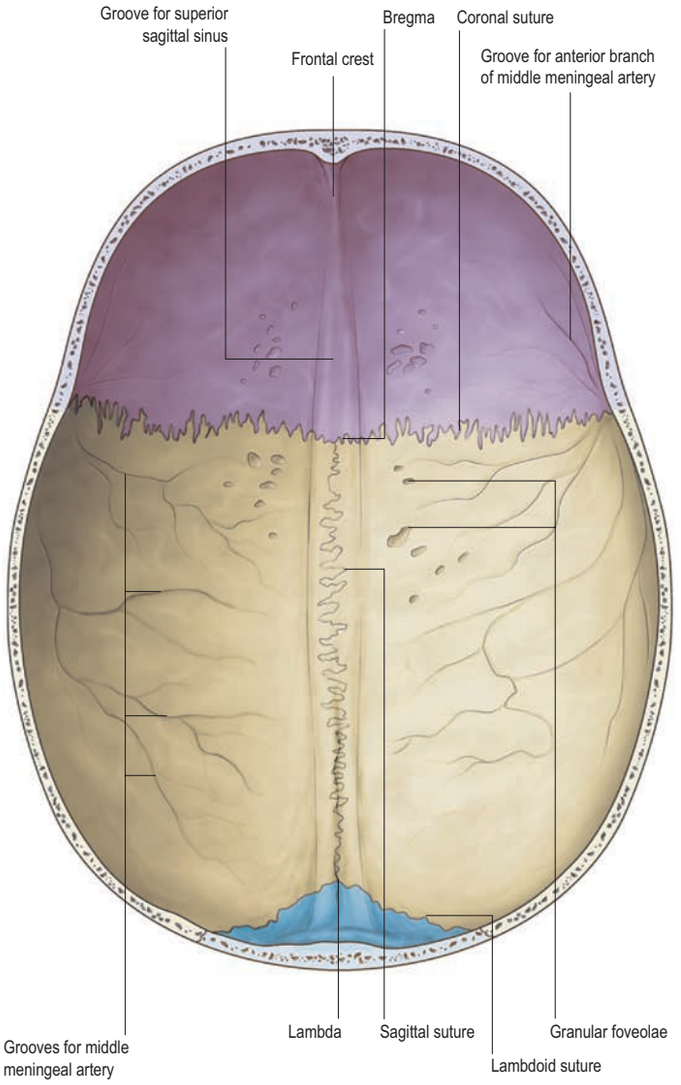

Fig. 34.6 The internal surface of the cranial vault. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

INTERNAL SURFACE OF CALVARIA

The internal surface of the calvaria is deeply concave and includes most of the frontal and parietal bones and the squamous part of the occipital bone, variously united at the coronal, sagittal and lambdoid sutures (Fig. 34.6). Inconstant foramina are seen in the parietal bones near the sagittal sulcus and anterior to the lambdoid suture; they admit emissary veins associated with the superior sagittal sinus. The internal surfaces of the frontal and parietal bones are grooved by furrows that house the frontal and parietal branches of the middle meningeal vessels; the grooves contain the openings of minute channels that admit perforating vessels to the haemopoietic marrow within the diploic bone. Impressions for cerebral gyri are less distinct on the bones of the calvaria than they are on the cranial base.

The falx cerebri, a dural partition that separates the two cerebral hemispheres of the brain, is attached anteriorly to a backward-projecting anteromedian frontal crest. The crest exhibits a groove that widens as it passes back below the sagittal suture and becomes continuous with the sagittal sulcus, which houses the superior sagittal sinus. Irregular depressions, granular foveolae, which become larger and more numerous with age, lie on either side of the sulcus and usually house arachnoid granulations.

CRANIAL FOSSAE (ANTERIOR, MIDDLE, POSTERIOR)

The base of the cranial cavity is divided into three distinct fossae: the anterior, middle and posterior cranial fossae (Fig. 34.7). The floor of the anterior cranial fossa is at the highest level and the floor of the posterior fossa is at the lowest.

Detailed descriptions of the microsurgical anatomy of each region of the cranial base are beyond the scope of this book, and the interested reader is directed in the first instance to Rhoton (2007).

Anterior cranial fossa

The anterior cranial fossa is formed by the frontal, ethmoid and sphenoid bones, and supports the frontal lobes of the cerebral hemispheres. Its floor is composed of the orbital plate of the frontal bone, the cribriform plate and crista galli of the ethmoid bone, and the lesser wings, jugum sphenoidale and prechiasmatic sulcus of the sphenoid.

A perforated plate of bone, the cribriform plate of the ethmoid bone, spreads across the midline between the orbital plates of the frontal bone and is depressed below them, forming part of the roof of the nasal cavity. Olfactory nerves pass from the nasal mucosa to the olfactory bulb of the brain through numerous small foramina in the cribriform plate. Anteriorly, a spur of bone, the crista galli, projects upwards between the cerebral hemispheres and serves as an attachment for the falx cerebri. A depression between the crista galli and the crest of the frontal bone is crossed by the frontoethmoidal suture. It bears the foramen caecum, which is usually a small blind-ended depression formed by the developmental involution of a dural diverticulum that extends through the foramen caecum to the columella; in adults, it occasionally accommodates a vein draining from the nasal mucosa to the superior sagittal sinus. Failure of the foramen caecum to close may cause nasal dermoid cysts and nasoethmoidal encephaloceles in children.

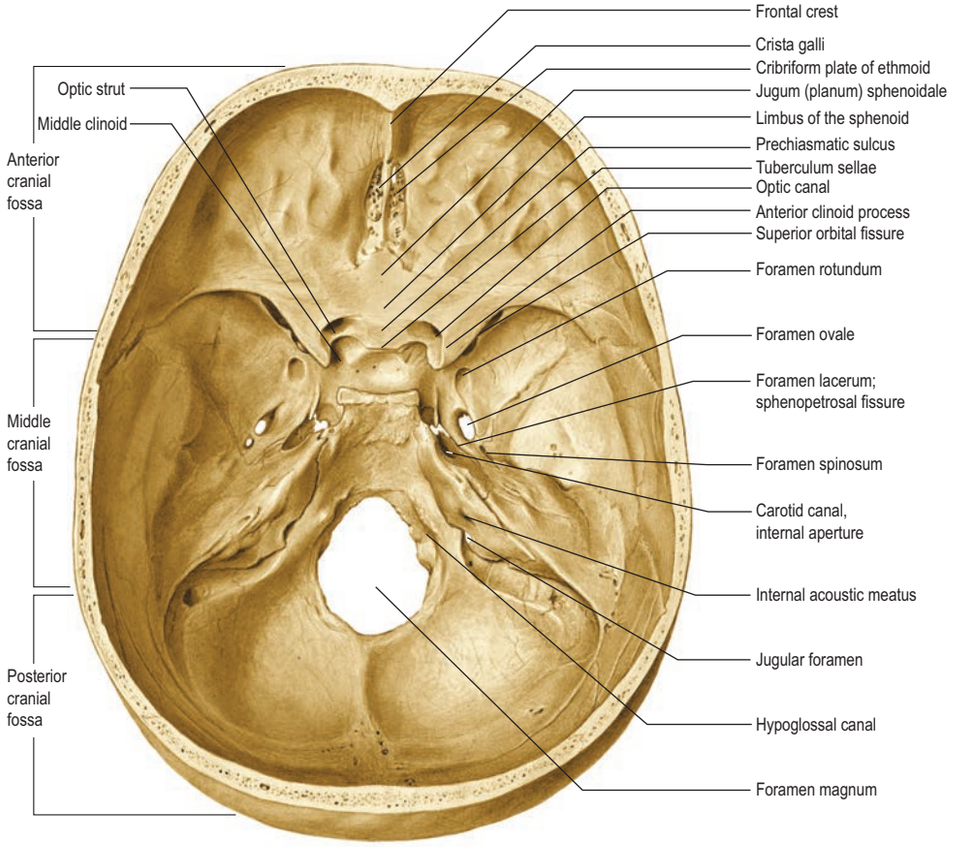

Fig. 34.7 The floor of the cranial cavity showing the cranial fossae. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

The anterior ethmoidal nerve and vessels enter the cranial cavity where the cribriform plate meets the orbital part of the frontal bone. They then pass into the roof of the nasal cavity via a small foramen by the side of the crista galli. The posterior ethmoidal canal, which transmits the posterior ethmoidal nerve and vessels, opens at the junction of the posterolateral corner of the cribriform plate and jugum sphenoidale. The convex orbital plate of the frontal bone separates the brain from the orbit and bears impressions of cerebral gyri and small grooves for meningeal vessels. Posteriorly, it articulates with the anterior border of the lesser wing of the sphenoid laterally and the jugum sphenoidale medially. The jugum sphenoidale is a flat surface on the upper aspect of the sphenoid bone that connects the two lesser wings, also known as the planum sphenoidale. The limbus of the sphenoid bone is a prominent ridge on the body of the sphenoid that forms the posterior border of the jugum sphenoidale and the anterior border of the prechiasmatic sulcus. The latter is an osseous groove that runs transversely between the optic canals. The optic chiasma usually lies above the prechiasmatic sulcus, while the medial orbital surface of the frontal lobes and olfactory tracts lie above the jugum sphenoidale (see Fig. 34.7.)

The posterior boundary of the lesser wing forms the posterior boundary of the anterior cranial fossa; the medial end of the lesser wing constitutes the anterior clinoid process. The lesser wing and the anterior clinoid process join the sphenoid body by two roots that are separated by the optic canal. The anterior root, broad and flat, forms the roof of the optic canal and is continuous with the jugum sphenoidale, while the smaller and thicker posterior root, also known as the optic strut, joins the body of the sphenoid bone at the lateral aspect of the posterior bank of the prechiasmatic sulcus or tuberculum sellae (see Fig. 34.7). The optic strut of the anterior clinoid process separates the optic canal from the superior orbital fissure (Kerr et al 2012). Each optic canal transmits the optic nerve and ophthalmic artery.

Middle cranial fossa

The middle cranial fossa is formed by the sphenoid and temporal bones and supports the temporal lobes of the cerebral hemispheres. It is bounded in front by the posterior aspect of the lesser and greater wings of the sphenoid, behind by the superior border of the petrous part of the temporal bone, laterally by the squamous part of the temporal bone and greater wing of the sphenoid, and medially by the lateral aspect of the sphenoid body, including the carotid sulcus, sella turcica and dorsum sellae.

The middle cranial fossa communicates with the orbits by the superior orbital fissures, each bounded above by a lesser wing, below by a greater wing, and medially by the body of the sphenoid bone and optic strut. The fissures contain the oculomotor, trochlear and abducens nerves, and the lacrimal, frontal and nasociliary branches of the ophthalmic division of the trigeminal nerve, together with filaments from the internal carotid plexus (postganglionic sympathetic), the superior and inferior ophthalmic veins, the orbital branch of the middle meningeal artery, and the recurrent branch of the lacrimal artery.

The central part of the cranial base, located between both middle cranial fossae, is formed by the body of the sphenoid bone, which contains the sphenoidal sinuses. The body of the sphenoid bone is deeply concave and houses the pituitary gland (hypophysis); it is therefore termed the pituitary (hypophysial) fossa, also known as the sella turcica because it resembles the shape of a Turkish saddle (Paluzzi et al 2012). The face and floor of the sella turcica are located within the sphenoidal air sinuses, which is why the most direct surgical route to the pituitary fossa is the trans-sphenoidal approach. The anterior edge of the sella is formed by a bony prominence, the tuberculum sellae, which is continuous anteriorly with the prechiasmatic sulcus; the posterior boundary presents a vertical pillar of bone, the dorsum sellae. The superolateral angles of the dorsum are expanded as the posterior clinoid processes. A fold of dura, the diaphragma sellae, is attached to the anterior and posterior clinoid processes and roofs over the pituitary fossa. The cavernous sinus lies lateral to the pituitary fossa. The lateral wall of the body of the sphenoid contains a shallow carotid sulcus related to the internal carotid artery as it ascends from the carotid canal and runs through the cavernous sinus.

Each anterior clinoid process covers the roof of the cavernous sinus and the paraclinoidal segment of the internal carotid artery as it leaves the cavernous sinus and pierces the dura to enter the intradural space. The anterior clinoid process gives attachment to the anterior petroclinoidal ligament, which forms the free margin of the tentorium cerebelli, and the interclinoidal ligament, which lies between the anterior and posterior clinoids. The middle clinoid process arises from the body of the sphenoid

bone at the anterolateral margin of the sella turcica and may be connected to the anterior clinoid process by a thin osseous bar, formed by ossification of the caroticoclinoid ligament. The resulting caroticoclinoid foramen or ring surrounds the paraclinoidal segment of the internal carotid artery (Fernandez-Miranda et al 2012). While anterior and posterior clinoids are always present, middle clinoids are not constant. A recent study revealed that the middle clinoid process was usually identifiable in fine-cut head computed tomogram–angiogram scans, and sometimes had at least one caroticoclinoid ring.

The greater wing of the sphenoid bone contains three consistent foramina and other small variable foramina. The foramen rotundum, situated just below the medial end of the superior orbital fissure, leads forwards into the medial aspect of the inferior orbital fissure and opens into the pterygopalatine fossa; it contains the maxillary nerve (second division of trigeminal nerve).

Behind the foramen rotundum is the foramen ovale, which transmits the mandibular nerve (third division of trigeminal nerve). The foramen spinosum lies just posterolateral to the foramen ovale and transmits the middle meningeal artery and veins; these vessels groove the floor and lateral wall of the middle cranial fossa. The foramen ovale and foramen spinosum open into the underlying infratemporal fossa. When present, the small sphenoidal emissary foramen lies anteromedial to the foramen ovale and lateral to the foramen rotundum; it transmits an emissary vein through which the cavernous sinus and pterygoid plexus communicate.

The foramen lacerum is a misnomer because it is a gap, not a true foramen, formed by the incomplete confluence of the pterygosphenoidal and petroclival fissures. It may therefore also be called the sphenopetroclival synchondrosis. It lies posteromedial to the foramen ovale at the transition between the carotid sulcus of the sphenoid bone and the petrous carotid canal, bounded laterally by the lingula of the sphenoid and the petrolingual ligament extending to the petrous apex. The lower portion of the foramen lacerum is filled with fibrocartilage extending from the pterygosphenoidal fissure, pharyngotympanic tube and basopharyngeal fascia. The upper portion of the foramen contains the laceral segment of the internal carotid artery and should be considered as the rostral extension of the petrous carotid canal (Tauber et al 1999). The only structures that enter or exit the intracranial cavity through the foramen lacerum are the pterygoid (Vidian) nerve and vessels, terminal branches of the ascending pharyngeal artery and small emissary veins connecting the extracranial pterygoid plexus with the intracranial cavernous sinus.

The superior border of the petrous part of the temporal bone separates the middle and the posterior cranial fossae, and is grooved by the superior petrosal sinus. The trigeminal impression, which accommodates the trigeminal ganglion, is situated on the anterior surface of the petrous part of the temporal bone near its apex. A smooth trigeminal notch leads into the impression and lies on the upper border of the petrous part, anteromedial to the groove for the superior petrosal sinus. At the level of the notch, the trigeminal nerve passes from the posterior to the middle cranial fossa, and separates the superior petrosal sinus from the underlying bone. The petrosphenoidal ligament (of Gruber) lies at the anterior end of the trigeminal notch, attached to a minute bony spicule, the petrous tubercle (Iaconetta et al 2003). The ligament runs in a superior, anterior and medial direction to attach to the posterior and lateral aspect of the posterior clinoid. The abducens nerve bends sharply across the upper petrous border and medially over the lateral edge of the dorsum sellae or petrosal process of the sphenoid, and typically passes under the petrosphenoidal ligament to enter the cavernous sinus (Ozveren et al 2002). This interdural space (between dural layers), limited superiorly by the petrosphenoidal ligament, inferiorly by the petrosal process, laterally by the petrous apex, and medially by the dorsum sellae, is known as Dorello's canal (Ambekar et al 2012). It is also defined as the petroclival venous confluence because it is filled with blood from the adjacent venous sinuses, namely: the inferior and superior petrosal, cavernous and basilar plexus (Barges-Coll et al 2010).

Lateral to the trigeminal impression, a narrow groove passes posterolaterally into the hiatus for the greater petrosal nerve (also known as the facial hiatus); the hiatus and groove for the lesser petrosal nerve lies even further laterally (Kakizawa et al 2007). Posterolateral to the facial hiatus, a rounded arcuate eminence is produced by the underlying superior semicircular canal. A line bisecting the angle subtended by the arcuate eminence and the greater petrosal nerve estimates the location of the roof of the internal acoustic meatus (internal auditory canal) in the middle fossa. The petrous segment of the internal carotid artery runs from the carotid foramen to the foramen lacerum within the carotid canal of the petrous part of the temporal bone. The greater petrosal nerve travels above and parallel to the petrous carotid canal, which may be dehiscent. The osseous portion of the pharyngotympanic tube and tensor tympani run parallel and just lateral to the petrous carotid canal within the floor of the middle fossa. The cochlea is situated within the petrous part of the temporal bone, just medial to the posterior aspect of the petrous carotid canal and anterior to the internal acoustic meatus and arcuate eminence. The portion of petrous bone that is limited anteriorly by the mandibular nerve, laterally by the greater petrosal nerve, medially by the superior petrosal sinus, and posteriorly by the internal acoustic meatus and cochlea is named the posteromedial (or Kawase's) triangle of the middle fossa. The surgical procedure known as anterior petrosectomy consists of removal of this bone in order to access the posterior fossa from the middle fossa approach (Kawase et al 1985) (Ch. 43).

The lateral surface of the petrous part of the temporal bone is formed by the tegmen tympani, a thin osseous lamina that separates the tympanic cavity (middle ear) from the middle fossa. Chronically elevated intracranial pressure may cause erosion of the tegmen tympani and spontaneous cerebrospinal fluid otorrhoea. The posterior part of the tegmen tympani forms the roof of the mastoid antrum, lateral to the arcuate eminence, and is also called the tegmen mastoideum. In young skulls, a petrosquamous suture may be visible at the lateral limit of the tegmen tympani but it is obliterated in adults. The tegmen tympani then turns down as the lateral wall of the osseous portion of the pharyngotympanic tube, and its lower border may appear in the squamotympanic fissure. Lateral to the anterior part of the tegmen tympani, the squamous part of the temporal bone is thinned over a small area that coincides with the deepest part of the mandibular fossa.

Posterior cranial fossa

The posterior cranial fossa is formed by the sphenoid, temporal and occipital bones, and contains the cerebellum, pons and medulla oblongata. It is bounded in front by the dorsum sellae, posterior aspects of the body of the sphenoid bone, and the basilar (or clival) part of the occipital bone; behind by the squamous part of the occipital bone; and laterally by the petrous and mastoid parts of the temporal bones and by the lateral (condylar) parts of the occipital bone.

The most prominent feature in the floor of the posterior cranial fossa is the foramen magnum in the occipital bone. The medulla oblongata exits the cranial cavity through the foramen magnum to continue as the spinal cord (see Fig. 35.11). The cerebellum is fully contained within the posterior fossa. When the lower part of the cerebellum, the tonsils, descend abnormally through the foramen magnum, they may cause compression of the medulla at the level of the foramen magnum, a condition called tonsillar herniation or Chiari malformation.

The clivus is a sloping surface that extends from the sella turcica to the foramen magnum, and is formed successively by the dorsum sellae, the posterior part of the body of the sphenoid and the basilar (clival) part of the occipital bone. The spheno-occipital synchondrosis is evident on the clivus of a growing child but not in adults. The clivus is located at the centre of the posterior skull base and separates the nasopharynx from the posterior cranial fossa. Cranial chordomas are malignant tumours that histologically are reminiscent of embryonic notochordal tissue and typically arise within the clival bone (Fernandez-Miranda et al 2014). The clivus reaches its final length at the age of 11 years in both sexes (Krmpotić-Nemanić et al 2005). On each side, the clivus is separated from the petrous part of the temporal bone by a petro-occipital (or petroclival) fissure, filled by a thin plate of cartilage and extending from the foramen lacerum (extracranially) and cavernous sinus (intracranially) to the jugular foramen. The intracranial margins of the fissure are grooved by the inferior petrosal sinus. Chondrosarcomas are malignant tumours composed of transformed cells that produce cartilage; their most common intracranial location is precisely the petroclival fissure.

The jugular foramen is a large opening located between the temporal and occipital bones at the posterior end of the petro-occipital fissure, above and lateral to the foramen magnum. The lower border of the jugular foramen is smooth and is formed by the lateral part of the occipital bone. The upper border is sharp and irregular, and is formed by the petrous part of the temporal bone. It contains a notch, the intrajugular process, which divides the foramen into a large posterolateral compartment, the sigmoid part, which receives the drainage of the sigmoid sinus; and a small anteromedial compartment, the petrosal part, which receives the drainage of the inferior petrosal sinus. The accessory, vagus and glossopharyngeal nerves course in the medial side of the intrajugular process; they lie between the petrosal part (which contains the inferior petrosal sinus accompanied by a meningeal branch of the ascending pharyngeal artery) and the sigmoid part (which contains the sigmoid sinus accompanied by a meningeal branch of the occipital artery). The cochlear canaliculus or aqueduct, which contains the perilymphatic 'duct', is sited in the deepest part of the intrajugular process. The jugular foramina are

typically asymmetric: the right foramen is usually larger than the left, reflecting the right dominance of the sigmoid sinus and jugular vein.

The jugular tubercle is a rounded prominence located at the junction of the basilar and lateral parts of the occipital bone, just medial to the jugular foramen. The accessory, vagus and glossopharyngeal nerves cross the posterior portion of the tubercle on their way to the jugular foramen. The hypoglossal (anterior condylar) canal lies just inferior to the jugular tubercle, superior to the occipital condyle, and medial to and below the lower border of the jugular foramen (Morera et al 2010). It transmits the hypoglossal nerve and its recurrent branch, together with the meningeal branch of the ascending pharyngeal artery and an emissary vein that links the (intracranial) basilar plexus with the (extracranial) internal jugular vein. The canal may be divided by bony septa for different rootlets of the hypoglossal nerve. The occipital condyles form the lateral (or condylar) part of the occipital bone, and they lie within the anterior and lateral aspect of the foramen magnum. On each side, their medial surface bears a tubercle that gives attachments to the alar ligaments of the odontoid process, and their inferior surface is convex and articulates with the upper surface of the lateral mass of the atlas. The posterior condylar canal, when present, is located in the extracranial surface behind and above each occipital condyle; its internal orifice is posterolateral to that of the hypoglossal canal and contains the supracondylar vein and a meningeal branch of the occipital artery.

The posterior surface of the petrous part of the temporal bone forms much of the anterolateral wall of the posterior cranial fossa. It contains the internal acoustic meatus, which lies anterosuperior to the jugular foramen, and transmits the facial and vestibulocochlear nerves, the nervus intermedius and labyrinthine vessels. A small subarcuate fossa lined with dura mater lies posteriorly between the internal acoustic meatus and the opening of the vestibular aqueduct. It houses the saccus and ductus endolymphaticus and a small artery and vein. The suprameatal tubercle is a bony prominence located superiorly between the internal acoustic meatus and the petrous ridge (Seoane and Rhoton 1999).

The mastoid part of the temporal bone lies behind the petrous part of the temporal bone in the lateral wall of the posterior cranial fossa. Anteriorly, it is grooved by a wide sigmoid sulcus that runs forwards and downwards, then downwards and medially, and finally forwards to the jugular foramen; it contains the sigmoid sinus. Superiorly, where the groove touches the mastoid angle of the parietal bone, it becomes continuous with a groove that transmits the transverse sinus, and then crosses the parietomastoid suture and descends behind the mastoid antrum. A mastoid foramen, which transmits an emissary vein from the sigmoid sinus and a meningeal branch of the occipital artery, may be sited here. The lowest part of the sigmoid sulcus crosses the occipitomastoid suture and grooves the jugular process of the occipital bone. The right sigmoid sulcus is usually larger than the left.

The squamous part of the occipital bone displays a median internal occipital crest. This runs posteriorly from the foramen magnum to an internal occipital protuberance, gives attachment to the falx cerebelli, and may be grooved by the occipital sinus. The internal occipital protuberance is close to the confluence of the sinuses. It is grooved bilaterally by the transverse sinuses, which curve laterally with an upward convexity to the mastoid angles of the parietal bones. The groove for the transverse sinus is usually deeper on the right, where it is generally a continuation of the superior sagittal sinus, while on the left it is frequently a continuation of the straight sinus. On both sides, the transverse sulcus is continuous with the sigmoid sulcus. Below the transverse sulcus, the internal occipital crest separates two shallow fossae that house the cerebellar hemispheres. The posterior clinoid process and the margins of the grooves for the transverse and superior petrosal sinuses all provide anchorage for the attached margin of the tentorium cerebelli.

DISARTICULATED INDIVIDUAL BONES

Individual bones are described in the appropriate chapters. The bones of the facial skeleton and cranial vault are described in the chapters on the face and scalp (Ch. 36), nose, nasal cavity and paranasal sinuses (Ch. 39), external and middle ear (Ch. 42), and orbit (Ch. 44). The sphenoid and mandible are described in the chapter on the infratemporal fossa (Ch. 38) and the occipital bone is described in the chapter on the back (Ch. 46).

JOINTS

The general characteristics of cranial sutures and the detailed anatomy of the temporomandibular joint and the atlanto-occipital joints are described in Chapters 5, 38 and 46, respectively. Sutural bones are described on page 560.

NEONATAL, PAEDIATRIC AND SENESCENT ANATOMY

The skull at birth

At birth, the calvaria is large in proportion to other skeletal parts, reflecting precocious cerebral maturation. The facial region is relatively small and constitutes only about one-eighth of the neonatal skull, whereas it constitutes about half of the adult skull (Fig. 34.8). Smallness of the face at birth is due mainly to the rudimentary stage of development of the mandible and maxillae; the teeth are unerupted and the maxillae are not yet pneumatized (invaded by air cells). The nose lies almost entirely between the orbits, and the lower border of the nasal aperture is only slightly lower in position than the orbital floors. Bones of the calvaria are unilaminar and lack diploë. Frontal and parietal tuberosities are prominent; in the frontal view, the greatest width occurs between the parietal tuberosities. The glabella, superciliary arches and mastoid processes are not developed and the cranial base is relatively short and narrow.

Ossification is incomplete, and many bones are still in several elements that are united by fibrous tissue or cartilage. The 'os incisivum' is continuous with the maxilla; pre- and postsphenoids may have just united. The two halves of the frontal bone and the mandible; the squamous, lateral and basilar parts of the occipital bone; and the petromastoid and squamotympanic parts of the temporal bone are all separate. The fibrous membrane within which the calvaria forms remains unossified at the six angles of the parietal bones, producing six fontanelles: two single midline (anterior and posterior) and two lateral pairs (sphenoidal/anterolateral and mastoid/posterolateral). The anterior fontanelle is the largest, measuring approximately 4 cm in anteroposterior and 2.5 cm in transverse dimensions. It occupies the junction between the sagittal, coronal and frontal sutures and is rhomboid in shape. The posterior fontanelle lies at the junction between the sagittal and lambdoid sutures and is triangular in shape. The sphenoidal (anterolateral) and mastoid (posterolateral) fontanelles are small and irregular in shape and lie at the sphenoidal and mastoid angles of the parietal bones, respectively.

At birth, the orbits appear relatively large. The developing tooth germs are generally contained within the alveolar crypts, although eruption of the upper central incisor teeth can occur prior to, or shortly after, birth. Temporal bones differ greatly from their adult form. The internal ear, tympanic cavity, auditory ossicles and mastoid antrum are all almost adult in size, the tympanic plate is an incomplete ring that has usually started to fuse with the squamous part, and the mastoid process is absent. The external acoustic meatus is short, straight and wholly cartilaginous. The external aspect of the tympanic membrane faces more inferiorly than laterally, in accord with the basal cranial contour. The stylomastoid foramen is exposed on the lateral surface of the skull, the styloid process has not yet commenced ossification, the mandibular fossa is flat and more lateral, and its articular tubercle is undeveloped. The paranasal sinuses are rudimentary or absent and only the maxillary sinuses are usually identifiable.

The skull is moulded by slow compression during vaginal birth. That part of the scalp that is more central in the birth canal is often temporarily oedematous (caput succedaneum) as a result of interference with venous return. Fontanelles and the openness and width of the sutures allow bones of the cranial vault some overlap during the process of birth; the skull is compressed in one plane with compensatory orthogonal elongation. These deformations disappear within the first week after birth.

Postnatal growth

Although postnatal growth of the calvaria (cranial vault) and facial skeleton usually proceeds in a coordinated fashion, these regions exhibit different rates and temporal periods of expression. In general, early growth of the vault is largely influenced by cerebral maturation while growth of the facial skeleton responds to spatial requirement for the development of the teeth and the muscles of mastication. Growth of the cranial base is largely independent of both vault and facial development, and therefore the three regions will be considered separately. (For further reading, see Belden (1998), Sgouros et al (1999), Sperber et al (2001) and Cunningham et al (2016).

Growth of the calvaria

Growth of the calvaria is rapid during the first year and then continues at a slower rate until the seventh year, when it has reached almost adult dimensions. For most of this period, expansion is largely

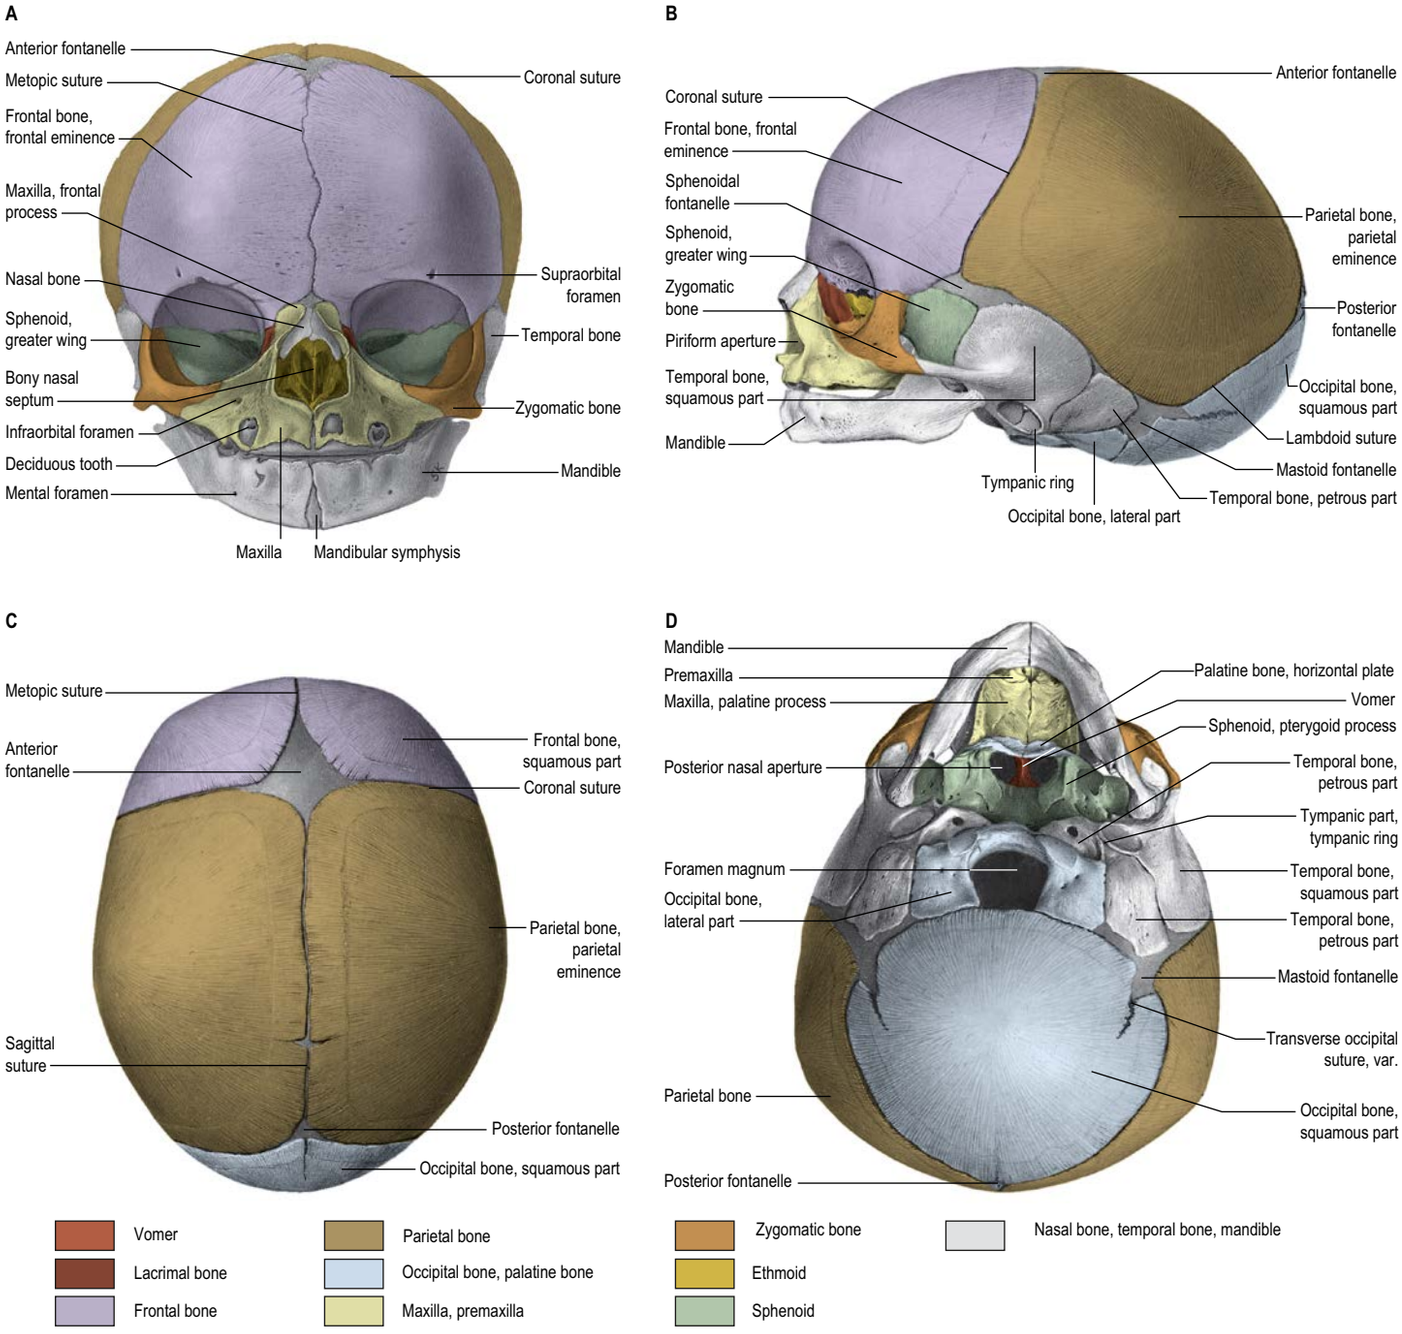

Fig. 34.8 A–D, The neonatal skull: **A**, frontal aspect; **B**, lateral aspect; **C**, superior aspect; D, basal aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

concentric; overall form is determined early in the first year and remains largely unaltered thereafter. However, the shape of the vault is not solely related to cerebral growth, but is also influenced by genetic factors that manifest in an extensive range of shapes and sizes that may be sufficient to allow an evaluation of ethnic origin. During the first and early second years, growth occurs primarily through ossification at apposed margins of bones (which possess an osteogenic layer), accompanied by some accretion and absorption of bone at surfaces in order to adapt to continually altering curvatures. Growth in breadth is said to take place at the sagittal, sphenofrontal, sphenotemporal, occipitomastoid and petro-occipital junctions, while growth in height is said to occur at the frontozygomatic and squamosal sutures, pterion and asterion. During this period, fontanelles are closed by progressive ossification of the bones around them, but separate isolated centres of ossification may develop into sutural bones (Fig. 34.9). The sphenoidal and posterior fontanelles close within 2 or 3 months of birth and the mastoid fontanelles usually close near the end of the first year. Wide variability in both the size and the timing of closure of the anterior fontanelle has been reported, but most will have closed by the middle of the second year and almost all will have closed by 24 months (Pindrik et al 2014).

Early in the first years, the calvarial bones start interlocking at sutural junctions and further expansion is largely achieved by accretion and absorption on external and internal bone surfaces, respectively. At the same time the bones also thicken, although this is not a uniform process. At birth, the vault is unilaminar; the tabular structure with intervening diploë is generally apparent soon thereafter. Thickening of the vault and development of external muscular markings reflect the influences of musculoskeletal maturation. The mastoid processes do not usually develop until the second year and they are pneumatized in the sixth year (Cunningham et al 2016). (For further reading about craniofacial morphology in preterm infants, see Paulsson and Bondemark 2009).

Growth of the cranial base

Growth of the cranial base, which is largely responsible for cranial lengthening, occurs at the cartilaginous joints between the sphenoid and

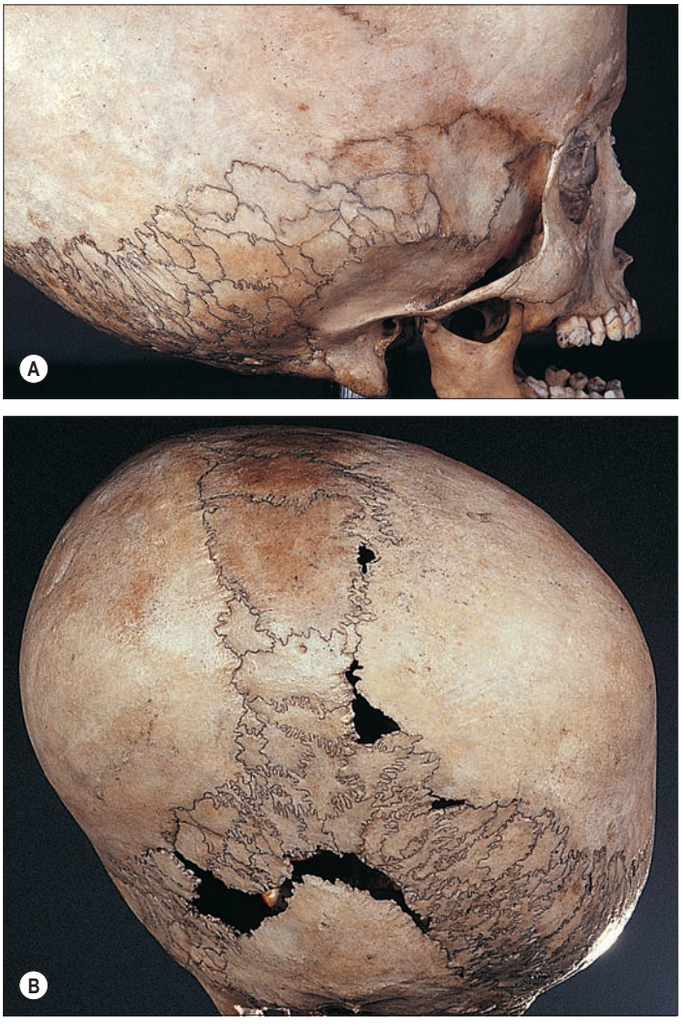

Fig. 34.9 The hydrocephalic skull of a 25-year-old male showing numerous sutural bones. **A**, Lateral view. **B**, Posterior view. (Courtesy of the Museum of the Royal College of Surgeons of England, photograph by Mr J Carr.)

ethmoid anteriorly, and especially between the sphenoid and occipital bones posteriorly (Lieberman et al 2000). Most of the growth occurs during the first five years of life (Sgouros et al 1999), but continues at the spheno-occipital synchondrosis until mid-teenage years. The prolonged period of continued expansion reflects a significant delaying mechanism that allows the continued and relatively late eruption of the permanent dentition. There is some evidence that growth may cease at about 15 years following eruption of the second molars, and this can often lead to insufficient space for growth of the third molars. A pubertal growth spurt has been ascribed to both sexes; it tends to occur some 2 years earlier in females and is likely to continue until the eighteenth year in the male (Ch. 23). The anterior cranial base is significantly shorter in very preterm infants (less than 27 weeks) (Paulsson and Bondemark 2009).

Growth of the facial skeleton

Growth of the facial skeleton occurs over a longer time period than is witnessed for the calvaria. The ethmoid and the orbital and upper nasal cavities have almost completed growth by the seventh year. Orbital and upper nasal growth is achieved by sutural accretion, with deposition of bone preferentially occurring on the facial aspects of the sutural junctions. The maxilla is carried downwards and forwards by expansion of the orbits and nasal septum and by sutural growth, especially at the fontanelles and zygomaticomaxillary and pterygomaxillary sutures. In the first year, growth in width occurs at the symphysis menti and mid-palatal, internasal and frontal sutures; such growth diminishes or even ceases when the symphysis menti and frontal suture close during the first few years, even though the mid-palatal suture persists until mature years. Facial growth continues up to puberty and shows a period of expansion that is linked to the growth spurt and hormonal influences of secondary sexual alteration. After sutural growth, near the end of the second year, expansion of the facial skeleton occurs by surface accretion on the face, alveolar processes and palate, and resorption in the walls of the maxillary sinuses, the upper surface of the hard palate and the labial aspect of the alveolar process. Coordinated growth and divergence of the pterygoid processes reflect deposition and resorption of bone on appropriate surfaces.

Obliteration of the calvarial sutures progresses with age, starting between 20 and 30 years internally and somewhat later on the exterior. Closure times vary greatly. Obliteration usually begins in the coronal or sagittal sutures and then extends into the lambdoid suture. The size of the mandible and maxillae diminish following the loss of teeth and consequent resorption of alveolar bone; this reduces the vertical depth of the face and increases the mandibular angles.

Craniosynostosis

Sutural growth makes an important contribution to growth of the skull, especially during the first few years of life. Premature closure of sutures (craniosynostosis) leads to restriction of growth along the sutures, producing morphological changes that may result in skull deformity (Sharma 2013). Biomechanical forces and genetically determined local expression of growth factors have been implicated in the aetiology of premature fusion but the reasons are not fully understood. Premature fusion may occur in one or more of the cranial sutures; when the sutures around the cranial base are involved, severe limitation of facial bone growth will occur. Metabolic disorders such as rickets and familial hypophosphatasia can also result in synostosis. Raised intracranial pressure with or without hydrocephalus, visual deterioration and mental retardation may result. Scaphocephaly (sagittal craniosynostosis) is the most common and leads to lengthening of the vault in an anteroposterior direction; it can also occur in conjunction with other sutures, e.g. Crouzon's syndrome. Coronal synostosis, either unilateral (plagiocephaly) or bilateral (brachycephaly/oxycephaly), is the next most frequently seen and results in reduced anteroposterior development with marked supraorbital recession. When it is unilateral, the face develops asymmetrically and is rotated away from the side with premature fusion. Metopic craniosynostosis (trigonocephaly) and pansynostosis (turricephaly), where both the coronal and sphenofrontal sutures are involved, are much less common.

Craniofacial dysostosis syndromes, such as Crouzon's, Apert's, Saethre–Chotzen, Pfeiffer's and Carpenter's, show varying degrees of calvarial synostoses that are usually accompanied by a significant lack of growth in the midface. Early release of the calvarial synostoses does not result in normal facial growth, and a midfacial osteotomy at the Le Fort III level is usually required later in life. When significant orbital hypertelorism develops, a transcranial bipartitioning procedure is needed in order to bring the two orbits together.

Altered patterns of skull growth resulting in altered profiles can also be achieved deliberately by affecting sutural growth using binding and other pressure, as has been practised in certain cultures of the world (Fig. 34.10) (Tubbs et al 2006). The earliest known record of the practice is from Iraq and dates back to 45,000 BCE (Gerszten and Gerszten 1995).

Congenital anomalies affecting the skull

A large number of malformations and anomalies affect the bones and associated soft tissue structures of the skull and are the result of a localized error of morphogenesis during embryological development. Many are recognized patterns of malformation that are presumed to share the same aetiology. They do not arise as the result of a single isolated error in morphogenesis and are described as syndromes; specific texts should be consulted for further details.

IDENTIFICATION FROM THE SKULL

There are many ways of identifying an individual; in physical and forensic anthropology, the most important are concerned with determining biological and personal identity (Wilkinson and Rynn 2012). Biological identity pertains to those features that allow an individual to be classified in relation to features present in other individuals, e.g. sex, age, ancestry and stature, whereas personal identity establishes criteria that are characteristic and discriminatory for a particular individual, e.g. DNA, fingerprints, facial appearance and dental information. The skull is a useful source of information for establishing both biological and personal identity and is probably the most studied region of the skeleton.

Sex estimation

The estimation of sex from a juvenile skull is notoriously unreliable. While sexual differences have been detected in measurements of the

Fig. 34.10 Intentional skull modification: characteristic elongation of the cranial vault produced by head-binding of a newborn. (Courtesy of John Langdon.)

mandible, orbits, tooth size and pattern of dental eruption, they do not reach a level of statistical discrimination that will allow accurate and reliable assessment. It is equally difficult to assign sex to the face of a child because the faces of prepubertal boys and girls are comparable; perceivable sexual dimorphism is not generally manifest until secondary sexual development is under way. Growth in the female face ceases in advance of that of the male and therefore female sex-related characteristics are more paedomorphic. The defining characteristics of sex in an adult skull are therefore male in orientation and reflect the effects of the increased mass of the muscles of mastication, which are attached to the mandible, and of the muscles associated with maintaining the erect head. It is reported that using the skull alone, sex can be predicted with over 80% accuracy in the adult, which is encouraging, given that research has shown that the correct sex can usually be predicted from the adult living face with 96% accuracy.

Generally speaking, a male skull is more robust than the more gracile female skull, although there are obvious genetic, and therefore ancestral, variations that must be considered when attempting to assign sex from a skull. A female forehead is generally higher, more vertical and more rounded than a male forehead (where the frontal eminences are retained). A male mandible is generally more robust and larger than a female mandible; it displays a greater height in the region of the symphysis menti, the chin is squarer, the condyles are larger, the sites of muscle attachments are more pronounced and the gonial angle is generally less than 125°. A male skull generally also has thicker and more rounded orbital margins; pronounced supraorbital ridges; a well-defined glabella in the midline above the root of the nose; more pronounced temporal lines; and a supramastoid crest that extends posterior to the external acoustic meatus.

Other sites of muscle attachment on the skull also reflect the biomechanical requirement to keep the more robust male head erect. They include the mastoid process for sternocleidomastoid, and the nuchal lines, especially the external occipital protuberance, for the attachment of the ligamentum nuchae: both are more robust in a male skull. The male cranial base is generally more robust and the bone is thicker than in a female skull, which means that this area of the skull survives burial particularly well and is therefore of value in sex identification from fragmentary remains.

Age estimation

Age is a continuous variable; establishing chronological age from a skull is predicated on the concept that structures change with age at a relatively constant and predictable rate. The relationship between chronological age and skeletal maturity is closest in the juvenile years, and therefore greater accuracy is achieved in the prediction of age from the juvenile than from the adult skull.

The neonatal skull has been described above. Examples of additional features that allow reliable age determination throughout the subadult years are: development of the nasal spine (by year 3), completion of the hypoglossal canal (by year 4), formation of the foramen of Huschke (by year 5), ossification of the dorsum sellae (by year 5), and fusion of the different parts of the occipital bone (by year 7) (Cunningham et al 2016). The fontanelles are usually all closed by the end of the second year; the posterolateral is the first to close in the first 2 months after birth, and the anterior fontanelle is the last to close around the middle to end of the second year. The mastoid process appears in the second year and the metopic suture between the two frontal bones is usually closed by the end of the first year. The sphenoccipital synchondrosis will fuse between 11 and 16 years in the female and 13 and 18 years in the male, while the vomer and the ethmoid will fuse between 20 and 30 years of age. The last part of the skull to show active age-related growth is the jugular synchondrosis (also known as the jugular growth plate), a small triangular area sited posterolateral to the jugular foramen in the occipitotemporal suture. Fusion here has been reported to commence in the second and third decades, depending on population group, and bilateral fusion may not be completed before the middle of the fourth decade; in a small proportion of individuals, the plate may remain unfused into the sixth decade. Closure of the cranial sutures is age-related but the correlation is not strong and displays strong genetic variation. Thus, while it can be said that suture closure may begin in the early part of the third decade, and it is likely that many of the sutures will be obliterated with advancing age, it is not a reliable means of establishing the age of an individual. See Cunningham et al (2016) for further information on age estimation from the juvenile skeleton.

The most accurate means of estimating age from the skull (of both a living and a deceased individual) is by assessment of dental maturation. Tooth development can be studied throughout the entire juvenile age span (from the early embryo to the adolescent), and importantly, dental age and chronological age have been shown to exhibit a stronger correlation than skeletal and chronological age due to being influenced less by environmental factors compared to the skeleton. Further, the teeth tend to survive inhumation successfully and are remarkably resilient to extrinsic factors, ensuring their value in forensic investigations.

The chronological pattern of dental maturation is well documented and is an extremely important tool for age evaluation. Tooth development can be separated into a number of well-defined stages: deciduous mineralization (crown and root), deciduous emergence and maturation, deciduous root resorption, shedding of deciduous teeth, mineralization (crown and root) of permanent dentition, emergence and maturation of deciduous dentition, and attrition of permanent crowns. These stages do not occur in a linear fashion; while some of the deciduous teeth are emerging, permanent teeth are already being formed. For example, mineralization of the deciduous central incisor commences around the fifteenth week post fertilization, and this is the first tooth to emerge within the first 5 months after birth. All deciduous teeth are in occlusion by around 3 years of age. The first deciduous teeth to be shed are generally the central and lateral incisors around 7 years of age, when the permanent incisors emerge. The last deciduous tooth to be shed is generally the second molar in the tenth year. The first permanent tooth to show mineralization is the first molar, which occurs around the time of birth (sometimes earlier and sometimes later); it is also the first permanent tooth to emerge at around 6 years of age, and it will reach occlusion by the end of the seventh year. The last permanent tooth to emerge is the third molar; the variability of this occurrence makes it of restricted value for age prediction.

The time taken for a crown to form can be calculated from ground sections with considerable accuracy by counting the number of daily cross-striations from the neonatal line. These cross-striations are considered to result from the circadian rhythm inherent in the rate of enamel matrix secretion. For permanent teeth, the time taken for the crown to form can be calculated by counting the number of the enamel striae and multiplying by the individual's periodicity. Patterns of mineralization, emergence and shedding may be supplemented by analyses of tooth length and apical width ratios, cementum apposition, secondary dentine formation, incremental enamel lines, attrition rates, root translucency and dentine transparency (Whittaker and MacDonald 1989). Chemical analysis of the stable isotopes of carbon, oxygen and nitrogen from teeth can provide important information concerning the nature of the diet of an individual and is used in paleodiet analysis and in studies of pathophysiology and nutrition in archaeological and living human populations (Reitsema 2013).

Morphological assignment of ancestry

Physical anthropologists working in both archaeological and forensic arenas are frequently asked to assign a race/ancestry to a given skeleton, in order to facilitate an investigation into an unidentified body (Edgar and Hunley 2009). The traditional view of ancestry is as 'one of the major subdivisions of mankind, regarded as having a common origin and exhibiting a relatively constant set of physical traits' (Bamshad and Olson 2003). However, the usefulness of being able to classify ancestry when attempting to identify an individual from decomposed human remains varies depending on the degree of admixture in the local population compared to the level of admixture in the individual. For example, ancestry does not form part of the biological profile in some South American countries, because the majority of the local population is a mix of several ancestry groups; whereas if a body found in the Highlands of Scotland was assessed as being anything other than of Caucasoid ancestry, it might narrow the field of search considerably.

In forensic/biological anthropology there are at least four broad, overlapping ancestry groups. A relatively high proportion of individuals exhibit a degree of admixture such that variation within a group is often as great as the variation between groups. With the occasional exception (e.g. pelvis (Iscan and Cotton 1985) and femur (Gill 2001)), ancestry is almost exclusively evident in the skull.

Forensic facial approximation, reconstruction and depiction

There are four primary methods of legally identifying a body: DNA, fingerprint, dental and radiological matching. These are all matching processes, meaning that both postmortem and antemortem equivalent data are required for comparison to one another. If the body is past a certain point of decomposition, postmortem data might be unobtainable or corrupted: even DNA is damaged in both fire and water. Alternatively or additionally, the antemortem data might not exist if the individual in life was not on any databases, which is more common than one might suppose: a healthy, law-abiding citizen with perfect teeth might not be on any of these databases. When an investigation into an unidentified body runs into this problem, using forensic facial reconstruction to present an image of the face via the media might be the only way to generate leads for the investigation. Eliciting a recognition reaction from a friend or a family member of a missing person might in turn generate a DNA or fingerprint sample, a set of dental records for comparison, or even a missing person photograph upon which Craniofacial Superimposition can be performed, aligning the 3D skull with the photograph for a direct anatomical comparison, without all the estimations and averages involved in the initial facial reconstruction.

Commonly applied techniques to estimate a face from a skull (Fig. 34.11) combine three areas: the soft tissue depth and pattern across the face; facial feature estimation (eyes, nose, lips and ears all based on separate research); anatomical interpretation of the musculature, including attachment sites and muscle shape. The anatomical methodology is underpinned by scientific standards, anthropometry and morphological patterning in order to predict distinctive facial characteristics. The process can be automated or practitioner-led; although a few practitioners still use traditional clay modelling, most contemporary facial reconstructions are produced using non-invasive clinical/surface imaging, 3D digital technology and photo-editing software. Method summaries are described in a number of anthropology texts (Clement and Ransom 1998, Stephan 2009, Wilkinson 2010, Wilkinson and Rynn 2012).

Neck

CHAPTER 35

The neck extends from the base of the cranium and the inferior border of the mandible to the thoracic inlet.

SKIN

The skin in the neck is normally under tension. Lines of greatest tension have been termed 'relaxed skin tension lines'; surgical incisions made along these lines are said to heal better with minimal postoperative scarring.

Cutaneous vascular supply and lymphatic drainage

The blood vessels supplying the skin of the neck are derived principally from the facial, occipital, posterior auricular and subclavian arteries. They form a rich network within platysma and in the subdermal plexus, which accounts for the viability of the various skin flaps raised during neck dissection, irrespective of whether or not platysma is included. Great care must be taken in their design to avoid three-point junctions especially if the area has been irradiated previously or is infected, when its viability can be compromised.

The anterior cervical skin is supplied mainly by the superior thyroid artery and the transverse cervical branch of the subclavian artery. The posterior skin is supplied by branches from the occipital artery and the deep cervical and transverse cervical branches of the subclavian artery. The superior skin is supplied by the occipital artery and its upper sternocleidomastoid branch, and the submandibular and submental branches of the facial artery. Inferiorly, the skin is supplied by the transverse cervical and/or suprascapular branches of the subclavian artery.

The pattern of venous drainage of the skin of the neck mirrors the arterial supply: the veins drain into the jugular and facial veins. The profuse blood supply to the facial and neck skin facilitates the design of random flaps, which can often be made larger in this region than elsewhere.

Many lymphatic vessels draining the superficial cervical tissues skirt the borders of sternocleidomastoid to reach the superior or inferior deep cervical nodes. Some pass over sternocleidomastoid and the posterior triangle to drain into the superficial cervical and occipital nodes (see Fig. 35.15). Lymph from the superior region of the anterior triangle drains to the submandibular and submental nodes. Vessels from the anterior cervical skin inferior to the hyoid bone pass to the anterior cervical lymph nodes near the anterior jugular veins, and their efferents go to the deep cervical nodes of both sides, including the infrahyoid, prelaryngeal and pretracheal groups (**Fig. 35.1A**). An anterior cervical node often occupies the suprasternal space (of Burns).

Cutaneous innervation

The cervical skin is innervated by branches of cervical spinal nerves, via both dorsal and ventral rami (see Fig. 47.8). The dorsal rami supply skin over the back of the neck and scalp, and the ventral rami supply skin covering the lateral and anterior portions of the neck, and the angle of the mandible (**Fig. 35.1B**). The dorsal rami of the first, sixth, seventh and eighth cervical nerves have no cutaneous distribution in the neck. The greater occipital nerve mainly supplies the scalp; it comes from the medial branch of the dorsal ramus of the second cervical nerve. The medial branches of the dorsal rami of the third, fourth and fifth cervical nerves pierce trapezius to supply skin over the back of the neck sequentially. The ventral rami of the second, third and fourth cervical nerves supply named cutaneous branches (the lesser occipital, great auricular, transverse cutaneous and supraclavicular nerves), via the cervical plexus (see Fig. 35.1B) (see p. 595 for details of the motor branches of the cervical plexus).

Lesser occipital nerve

The lesser occipital nerve is derived mainly from the second cervical nerve (although fibres from the third cervical nerve may sometimes contribute). It first passes anterior to the plane of the accessory nerve (spinal accessory nerve) before winding around it and becoming anterior to it. It next ascends along the posterior margin of sternocleidomastoid. Near the cranium it perforates the deep fascia and passes up on to the scalp behind the auricle to supply the skin and connect with the great auricular and greater occipital nerves and the auricular branch of the facial nerve. Its auricular branch supplies the skin on the upper third of the medial aspect of the auricle and connects with the posterior branch of the great auricular nerve. The auricular branch is occasionally derived from the greater occipital nerve. It has been suggested that compression or stretching of the lesser occipital nerve contributes to cervicogenic headache (Lucas et al 1994).

Great auricular nerve

The great auricular nerve is the largest ascending branch of the cervical plexus. It arises from the second and third cervical rami, encircles the posterior border of sternocleidomastoid, perforates the deep fascia and ascends on the muscle beneath platysma with the external jugular vein. On reaching the parotid gland, it divides into anterior and posterior branches. The anterior branch is distributed to the facial skin over the parotid gland and connects in the gland with the facial nerve. This cross-innervation between somatic sensory supply (great auricular) and parasympathetic secretomotor fibres to the parotid is considered to be part of the anatomical basis for the phenomenon of gustatory sweating (Frey's syndrome), seen after parotidectomy with its inherent disruption of the secretomotor nerve supply. The posterior branch supplies the skin over the mastoid process and on the back of the auricle (except its upper part); a filament pierces the auricle to reach the lateral surface, where it is distributed to the lobule and concha. Efforts are made to preserve the posterior branch at parotid surgery in order to avoid a sensory deficit of the pinna. The posterior branch communicates with the lesser occipital nerve, the auricular branch of the vagus and the posterior auricular branch of the facial nerve. Division of the greater auricular nerve during neck surgery results in loss of sensation of a variable amount of the lower half of the auricle, which some patients initially find unpleasant.

Transverse cervical cutaneous nerve

The transverse cervical cutaneous nerve arises from the second and third cervical rami. It curves round the posterior border of sternocleidomastoid near its midpoint and runs obliquely forwards, deep to the external jugular vein, to the anterior border of the muscle. It perforates the deep cervical fascia, and divides under platysma into ascending and descending branches that are distributed to the anterolateral areas of the neck. The ascending branches ascend to the submandibular region, forming a plexus with the cervical branch of the facial nerve beneath platysma. Some branches pierce platysma and are distributed to the skin of the upper anterior areas of the neck. The descending branches pierce platysma and are distributed anterolaterally to the skin of the neck, as low as the sternum.

Supraclavicular nerves

The supraclavicular nerves arise from a common trunk formed from rami from the third and fourth cervical nerves and emerge at the posterior border of sternocleidomastoid. Descending under platysma and the deep cervical fascia, the trunk divides into medial, intermediate and lateral (posterior) branches, which diverge to pierce the deep fascia a little above the clavicle. The medial supraclavicular nerves run inferomedially across the external jugular vein and the clavicular and sternal heads of sternocleidomastoid to supply the skin as far as the midline and as low as the second rib. They also supply the sternoclavicular joint. The intermediate supraclavicular nerves cross the clavicle to supply the skin over pectoralis major and deltoid down to the level of the second rib, next to the area of supply of the second thoracic nerve. Overlap between these nerves is minimal. The lateral supraclavicular nerves descend superficially across trapezius and the acromion, supplying the skin of the upper and posterior parts of the shoulder.

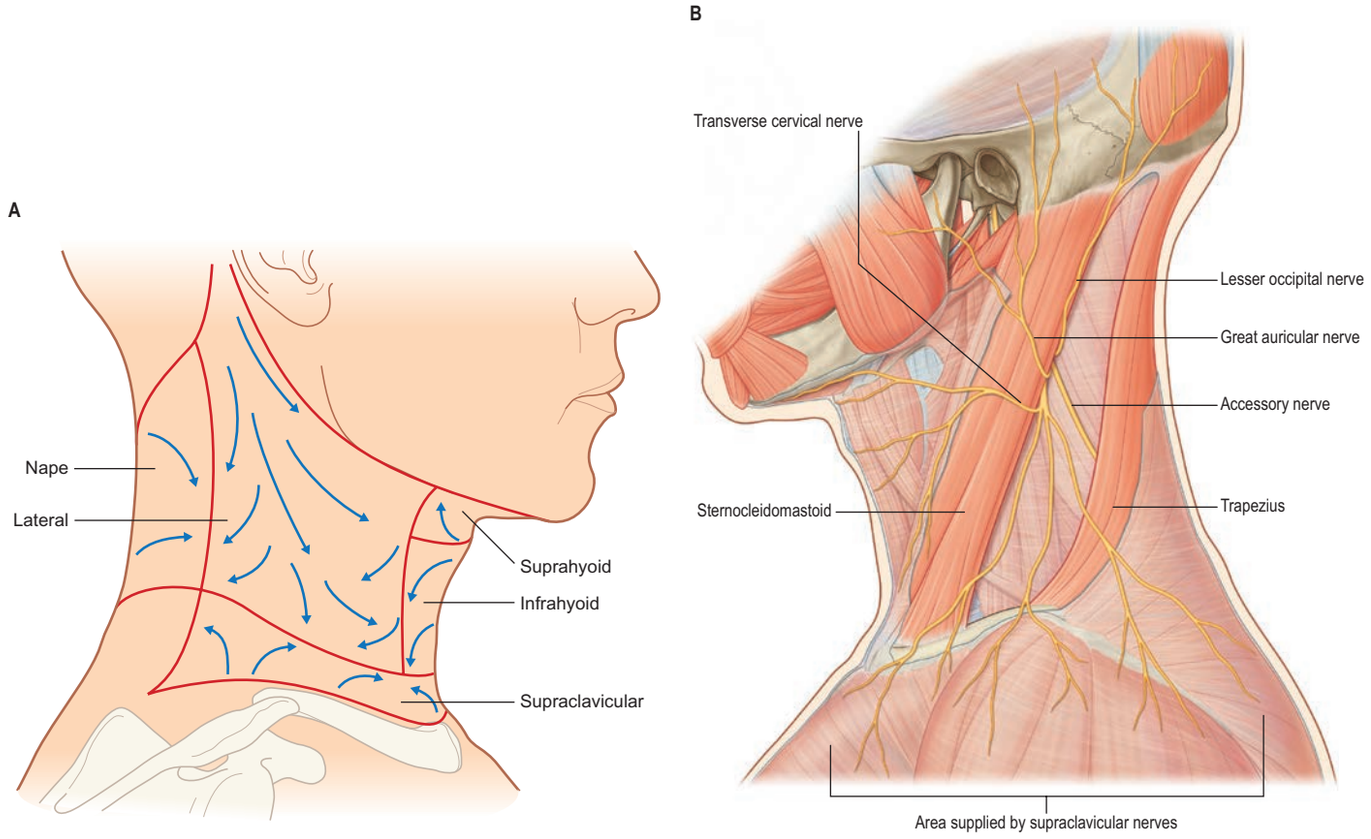

Fig. 35.1 **A**, Direction of lymphatic drainage of the skin of the neck. The lymphatics of the skin in the suprahyoid region drain to level I, the submental and submandibular lymph nodes. The lymphatics of the skin of the rest of the neck drain to levels II, III and IV, apart from the posterior lateral neck skin lymphatics which drain into the spinal accessory nodes in the posterior triangle (refer to Fig. 35.3B for levels). **B**, The cutaneous branches of the cervical plexus. The accessory nerve is also shown as it crosses the posterior triangle to supply trapezius. Note that the interval between the upper attachments of sternocleidomastoid and trapezius is not normally as extensive as shown here (A, Adapted with permission from Warner L, Jennings C, Watkinson JC 2018 Surgical anatomy of the neck. In: Watkinson JC, Clarke RW (eds) Scott-Brown's Otorhinolaryngology: Head and Neck Surgery, Volume 3, 8th ed. Boca Raton: CRC Press. B, Adapted from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

BONES, JOINTS AND CARTILAGES

The bones and cartilages of the neck are the cervical vertebrae and the hyoid bone, and the cartilages of the upper respiratory tract, including the larynx. The cervical vertebrae, the occipital bone and the atlanto-occipital and atlanto-axial joints are described in Chapter 46, and the laryngeal cartilages are described in Chapter 41.

Hyoid bone

The U-shaped hyoid bone (Fig. 35.2) is suspended from the tips of the styloid processes by the stylohyoid ligaments. It has a body and two greater and two lesser horns or cornua.

Body

The body is irregular, elongated and quadrilateral. Its anterior surface is convex, faces anterosuperiorly, and is crossed by a transverse ridge with a slight downward convexity. A vertical median ridge often bisects the upper part of the body but rarely extends to the lower part. The posterior surface is smooth and concave, faces posteroinferiorly, and is separated from the epiglottis by the thyrohyoid membrane and loose areolar tissue. There is a bursa between the hyoid bone and the membrane. Geniohyoid is attached to most of the anterior surface of the body, above and below the transverse ridge; the medial part of hyoglossus invades the lateral geniohyoid area. The lower anterior surface gives attachment to mylohyoid, the line of attachment lying above sternohyoid medially and omohyoid laterally. The lowest fibres of genioglossus, the hyoepiglottic ligament and (most posteriorly) the thyrohyoid membrane are all attached to the rounded superior border. Sternohyoid is attached to the inferior border medially and omohyoid is attached laterally.

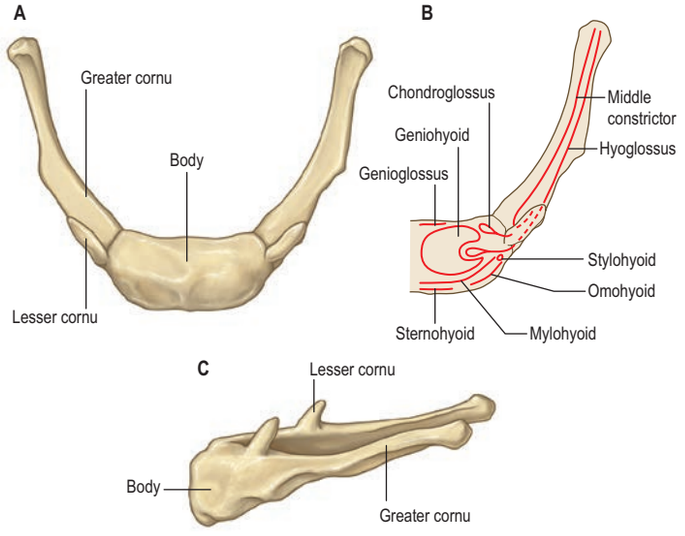

Fig. 35.2 The hyoid bone. **A**, Anterosuperior aspect. **B**, Anterosuperior aspect, showing the positions of muscular attachments. **C**, Lateral aspect.

Occasionally, the medial fibres of thyrohyoid and, when present, levator glandulae thyroideae, are attached along the inferior border.

The body of the hyoid is removed to excise thyroglossal duct cysts together with its tract (Sistrunk's procedure). During descent from its origin within the tongue base, the duct tract passes either posterior or anterior or through the body of the hyoid, which must be excised in continuity.

Greater cornua

In early life, the greater cornua are connected to the body by cartilage, but after middle age they are usually united by bone. They project backwards (curving posterolaterally) from the lateral ends of the body. They are horizontally flattened and taper posteriorly, and each ends in a tubercle. When the throat is gripped between finger and thumb above the thyroid cartilage, the greater cornua can be identified and the bone can be moved from side to side.

The middle pharyngeal constrictor and, more laterally (i.e. superficially), hyoglossus are attached along the whole length of the upper surface of each greater cornu. Stylohyoid is attached near the junction of the cornu with the body. The fibrous loop for the digastric tendon is attached lateral and a little posterior to hyoglossus. The thyrohyoid membrane is attached to the medial border and thyrohyoid is attached to the lateral border. The oblique inferior surface is separated from the thyrohyoid membrane by fibroareolar tissue.

Lesser cornua

The lesser cornua are two small conical projections at the junctions of the body and greater cornua. At its base, each is connected to the body by fibrous tissue and occasionally to the greater cornu by a synovial joint that occasionally becomes ankylosed.

The middle pharyngeal constrictors are attached to the posterior and lateral aspects of the lesser cornua. The stylohyoid ligaments are attached to their apices and are often partly calcified, and the chondroglossi are attached to the medial aspects of their bases.

Ossification

The hyoid bone develops largely from cartilages of the second (Reichert's cartilage) and third pharyngeal arches: the lesser cornua from the second and the greater cornua from the third. The body appears to develop from a midline mesenchymal condensation of the hypobranchial eminence (Rodríguez-Vázquez et al 2011). Chondrification is seen in embryos at stages 18–20 (42–50 postfertilization days). Ossification of the bone is seen after postmenstrual week 30. The body of the hyoid bone is ossified by postnatal month 4 and the greater cornua by postnatal month 6. Ossification proceeds from six centres, i.e. a pair for the body and one for each cornu. Ossification begins in the greater cornua towards the end of intrauterine life, in the body shortly before or after birth, and in the lesser cornua around puberty. The greater cornual apices remain cartilaginous until the third decade and epiphyses may occur here. They fuse with the body. Synovial joints between the greater and lesser cornua may be obliterated by ossification in later decades.

Joints

The atlanto-occipital and atlanto-axial joints are described in Chapter 46.

TRIANGLES OF THE NECK

Anterolaterally, the neck appears as a somewhat quadrilateral area, limited superiorly by the inferior border of the mandible and a line continued from the angle of the mandible to the mastoid process, inferiorly by the upper border of the clavicle, anteriorly by the anterior median line, and posteriorly by the anterior margin of trapezius. This quadrilateral area can be further divided into anterior and posterior triangles by sternocleidomastoid, which passes obliquely from the sternum and clavicle to the mastoid process and occipital bone (**Fig. 35.3**). These triangles and subdivisions are somewhat arbitrary because many major structures – arteries, veins, lymphatics, nerves and some viscera – transgress their boundaries without interruption. The triangles provide invaluable assistance in surface anatomical and clinical examination.

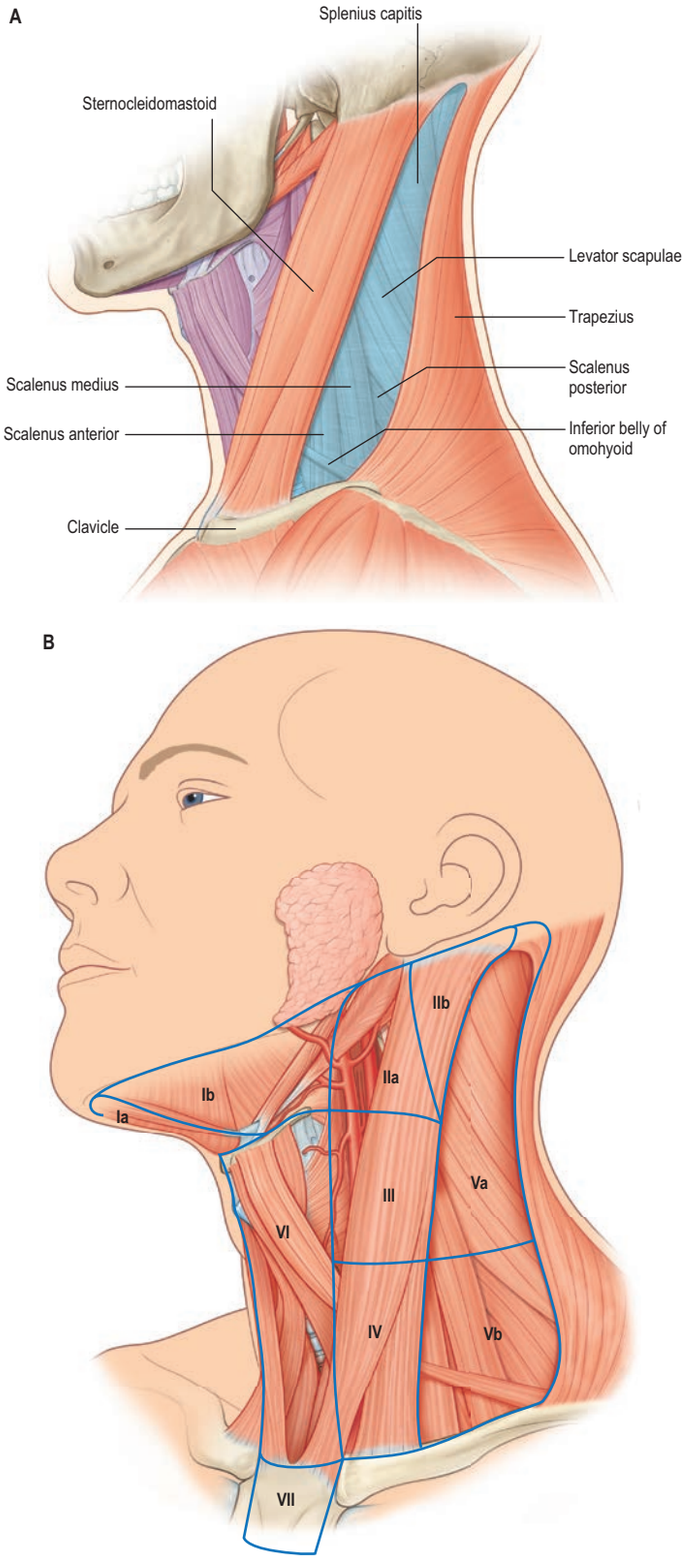

Fig. 35.3 **A**, The anterior and posterior triangles of the neck, left lateral aspect. See the note in the caption to Fig. 35.1B. **B**, Surgical levels of the neck. (A, Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010. B, With permission from Brennan P, Standring S, Wiseman S (eds) Gray's Surgical Anatomy. Elsevier. Copyright 2019.)

Anterior triangle of the neck

By tradition, the anterior triangle of the neck is bounded anteriorly by the median line of the neck and posteriorly by the anterior margin of sternocleidomastoid. It should be noted that the bulk of sternocleidomastoid is not included in the delineation of either the anterior or posterior triangles, even though the most important structures in the neck, the major vessels and lymph nodes of levels II, III and IV, lie deep to the muscle (see Fig. 35.3). The base of the triangle is the inferior border of the mandible and its projection to the mastoid process, and the apex is at the manubrium sterni. The anterior triangle can be subdivided into suprahyoid and infrahyoid areas above and below the hyoid bone, and into digastric, submental, muscular and carotid triangles by the passage of digastric and omohyoid across the anterior triangle (see Fig. 35.3). The lymphatic contents of both the anterior and posterior triangles can also be divided into levels I to V, facilitating radiological reporting as well as neck dissection terminology (Fig. 35.3B).

Digastric triangle

The digastric triangle is bordered above by the lower border of the mandible and its projection to the mastoid process, posteroinferiorly by the posterior belly of digastric and by stylohyoid, and anteroinferiorly by the anterior belly of digastric. It is covered by the skin, superficial fascia, platysma and deep fascia, which contain branches of the facial and transverse cutaneous cervical nerves. Its floor is formed by mylohyoid and hyoglossus. The anterior region of the digastric triangle contains the submandibular gland, which has the facial vein superficial to it and the facial artery deep to it. The submental and mylohyoid arteries and nerves lie on mylohyoid. The submandibular lymph nodes are variably related to the submandibular gland. The posterior region of the digastric triangle contains the lower part of the parotid gland. The external carotid artery, passing deep to stylohyoid, curves above the muscle, and overlaps its superficial surface as it ascends deep to the parotid gland before entering it. The internal carotid artery, internal jugular vein and vagus nerve lie deeper and are separated from the external carotid artery by styloglossus, stylopharyngeus and the glossopharyngeal nerve.

Submental triangle

The single submental triangle is demarcated by the anterior bellies of both digastric muscles. Its apex is at the chin, its base is the body of the hyoid bone and its floor is formed by both mylohyoid muscles. It contains lymph nodes and small veins that unite to form the anterior jugular vein. The structures within the digastric and submental triangles are described in more detail with the floor of the mouth.

Muscular triangle

The muscular triangle is bounded anteriorly by the median line of the neck from the hyoid bone to the sternum, inferoposteriorly by the anterior margin of sternocleidomastoid and posterosuperiorly by the superior belly of omohyoid. The triangle contains omohyoid, sternohyoid, sternothyroid and thyrohyoid.

Carotid triangle

The carotid triangle is limited posteriorly by sternocleidomastoid, anteroinferiorly by the superior belly of omohyoid and superiorly by stylohyoid and the posterior belly of digastric. In the living (except the obese), the triangle is usually a small visible triangular depression, sometimes best seen with the head and cervical vertebral column slightly extended and the head contralaterally rotated. The carotid triangle is covered by the skin, superficial fascia, platysma and deep fascia containing branches of the facial and cutaneous cervical nerves. The hyoid bone forms its anterior angle and adjacent floor; it can be located on simple inspection and verified by palpation. Parts of thyrohyoid, hyoglossus and inferior and middle pharyngeal constrictor muscles form its floor. The carotid triangle contains the upper part of the common carotid artery and its division into external and internal carotid arteries. Overlapped by the anterior margin of sternocleidomastoid, the external carotid artery is first anteromedial, then anterior to the internal carotid artery. Branches of the external carotid artery are encountered in the carotid triangle. The superior thyroid artery runs anteroinferiorly, the lingual artery anteriorly with a characteristic upward loop, the facial artery anterosuperiorly, the occipital artery posterosuperiorly and the ascending pharyngeal artery medial to the internal carotid artery. Arterial pulsation greets the examining finger. The superior thyroid, lingual, facial, ascending pharyngeal and sometimes the occipital veins correspond to the branches of the external carotid artery, and all drain into the internal jugular vein. The hypoglossal nerve crosses the external and internal carotid arteries. It curves round the origin of the lower sternocleidomastoid branch of the occipital artery, and at this point the superior root of the ansa cervicalis leaves it to descend anteriorly in the carotid sheath. The internal laryngeal nerve and, below it, the external laryngeal nerve lie medial to the external carotid artery below the hyoid bone. Many structures in this region, such as all or part of the internal jugular vein, associated deep cervical lymph nodes, and the vagus nerve, may be variably obscured by sternocleidomastoid, and, pedantically, are thus 'outside the triangle'.

Posterior triangle of the neck

The posterior triangle is delimited anteriorly by the posterior edge of sternocleidomastoid, posteriorly by the anterior edge of trapezius, and inferiorly by the middle third of the clavicle (see Fig. 35.3). Its apex is between the attachments of sternocleidomastoid and trapezius to the occiput and is often blunted, so that the 'triangle' becomes quadrilateral. The roof of the posterior triangle is formed by the investing layer of the deep cervical fascia. The floor of the triangle is formed by the prevertebral fascia overlying splenius capitis, levator scapulae and the scalene muscles. It is crossed, approximately 2.5 cm above the clavicle, by the inferior belly of omohyoid, which subdivides it into occipital and supraclavicular triangles. The contents of the posterior triangle include fat, lymph nodes (level V), the accessory nerve (which runs in the roof of the triangle, subdivides level Va above and Vb below), cutaneous branches of the cervical plexus, inferior belly of omohyoid, branches of the thyrocervical trunk (transverse cervical and suprascapular arteries), the third part of the subclavian artery, and the external jugular vein. The superficial position of the accessory nerve as it traverses the posterior triangle makes it vulnerable to iatrogenic damage in neck surgery. The anterior and lateral groups of prevertebral muscles form the floor of the posterior triangle.

Occipital triangle

The occipital triangle constitutes the upper and larger part of the posterior triangle, with which it shares the same borders, except that inferiorly it is limited by the inferior belly of omohyoid. Its floor, from above down, is formed by splenius capitis, levator scapulae, and scaleni medius and posterior; semispinalis capitis occasionally appears at the apex. The triangle is covered by skin, superficial and deep fasciae, and inferiorly by platysma. The accessory nerve pierces sternocleidomastoid and crosses levator scapulae obliquely downwards and backwards to reach the deep surface of trapezius. The surface marking of its course is in a line from the junction of the superior third and inferior two-thirds of sternocleidomastoid, to the junction of the inferior third and superior two-thirds of trapezius. Cutaneous and muscular branches of the cervical plexus emerge at the posterior border of sternocleidomastoid. Inferiorly, supraclavicular nerves, transverse cervical vessels and the uppermost part of the brachial plexus cross the triangle. Lymph nodes lie along the posterior border of sternocleidomastoid from the mastoid process to the root of the neck.

Supraclavicular triangle

The supraclavicular triangle is the lower and smaller division of the posterior triangle, with which it shares the same boundaries, except that superiorly it is limited by omohyoid. It corresponds in the living neck with the lower part of a deep, prominent hollow, namely: the greater supraclavicular fossa. Its floor contains the first rib, scalenus medius and the first slip of serratus anterior. Its size varies with the extent of the clavicular attachments of sternocleidomastoid and trapezius, and also the level of the inferior belly of omohyoid. The triangle is covered by skin, superficial and deep fasciae, and platysma, and crossed by the supraclavicular nerves. Just above the clavicle, the third part of the subclavian artery curves inferolaterally from the lateral margin of scalenus anterior across the first rib to the axilla. The subclavian vein is behind the clavicle and is not usually in the triangle, but it may rise as high as the artery and even accompany it behind scalenus anterior. The brachial plexus is partly superior, and partly posterior, to the artery and is always closely related to it. The trunks of the brachial plexus may be palpated easily here if the neck is contralaterally flexed and the examining finger is drawn across the trunks at right-angles to their length. With the musculature relaxed, pulsation of the subclavian artery may be felt and the arterial flow can be controlled by retroclavicular compression against the first rib. The suprascapular vessels pass transversely behind the clavicle, below the transverse cervical artery and vein. The external jugular vein descends behind the posterior border of sternocleidomastoid to end in the subclavian vein. It receives the transverse cervical and suprascapular veins, which form a plexus in front of the third part of the subclavian artery. It is joined occasionally by a small vein that crosses the clavicle anteriorly from the cephalic vein. Other structures within the triangle include the nerve to subclavius, which crosses the triangle, and lymph nodes.

CERVICAL FASCIA

The organization of the layers of the cervical fascia, and of the tissue 'spaces' they enclose, may determine the spread of disease in the head and neck, and facilitates both the differential diagnosis and the surgical management of that disease, particularly in the suprahyoid neck.

Superficial cervical fascia

Like superficial fascia elsewhere in the body, the superficial cervical fascia is not a separate stratum but a zone of loose connective tissue between dermis and deep fascia and is joined to both. It covers platysma but is hardly demonstrable as a separate layer. It may contain considerable amounts of adipose tissue, especially in females, which presumably explains why it is sometimes referred to simply as subcutaneous fat. In the lower cervical region, aponeurotic fibres of platysma gradually fan out in this layer and either become skin ligaments or continue into the fascia covering pectoralis major and deltoid (Nash et al 2005).

Deep cervical fascia

Three layers – superficial investing, middle and deep – are recognized (Fig. 35.4). Details of their precise attachments and contents vary between authors. For further reading, see Som and Curtin (2011).

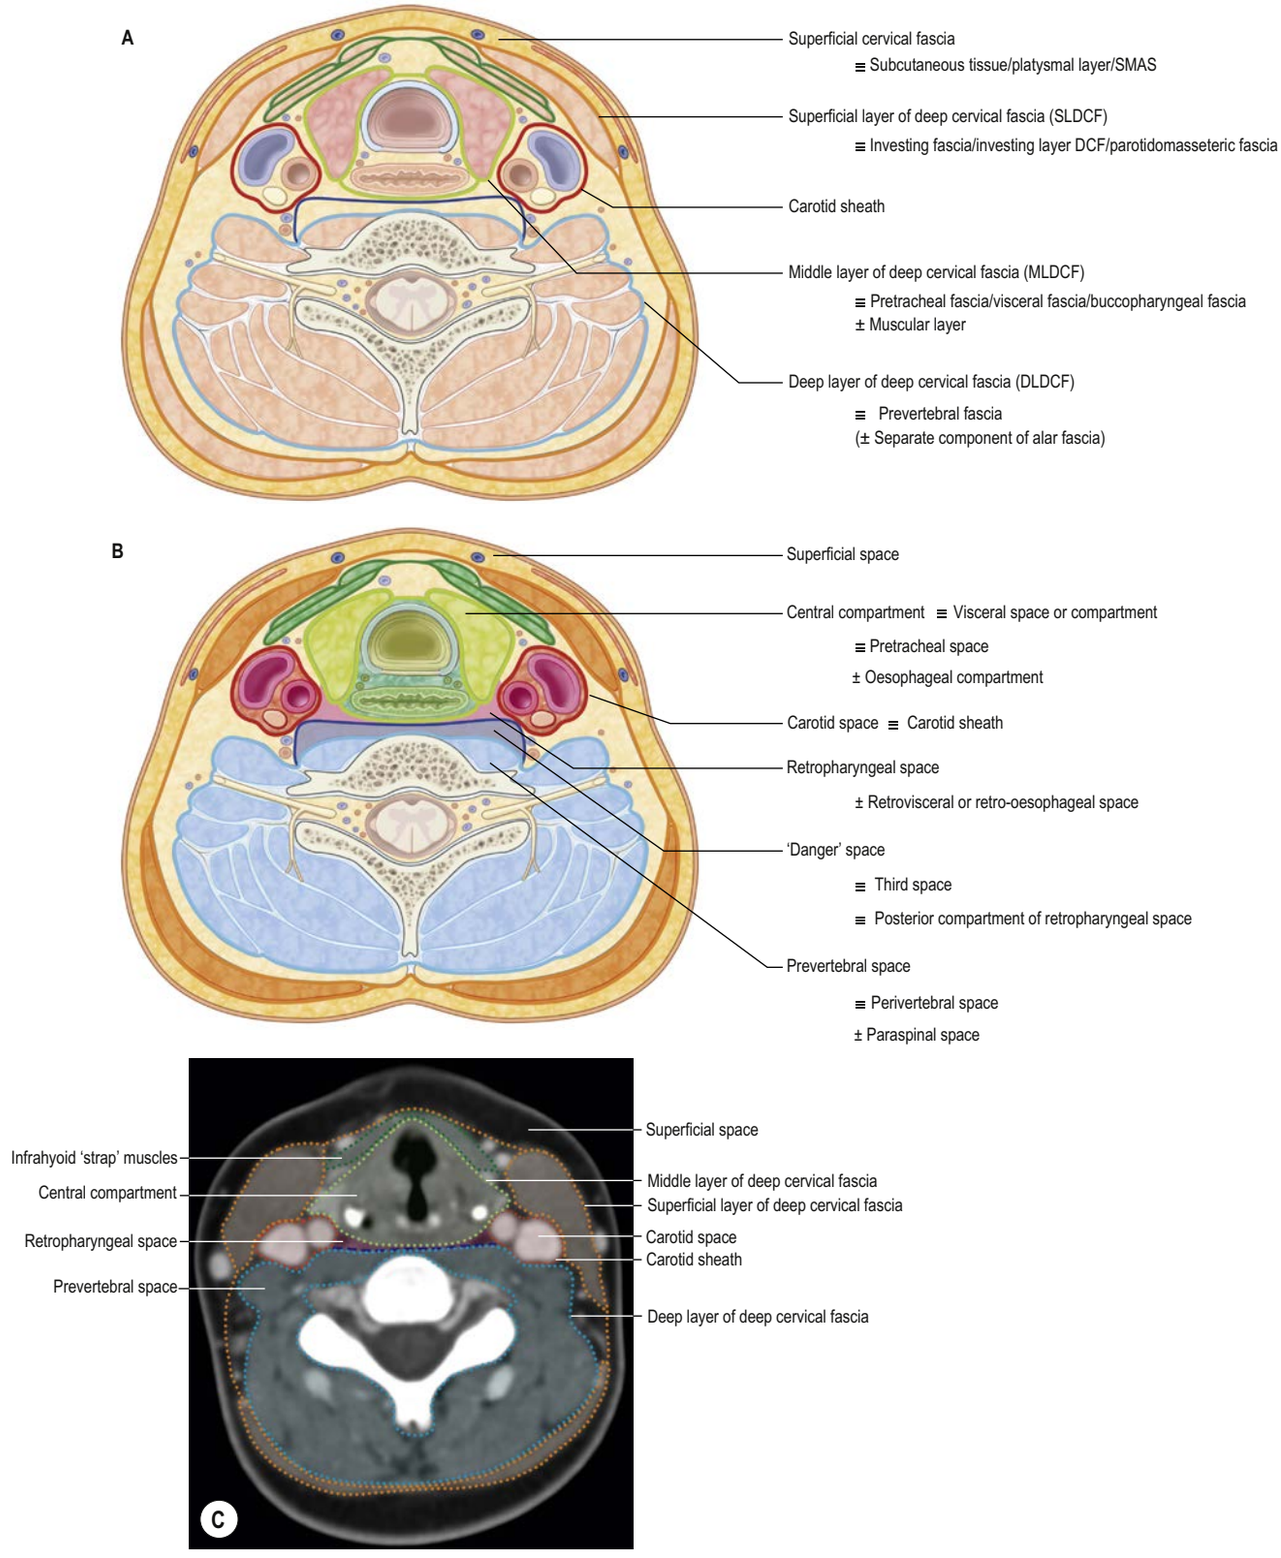

Fig. 35.4 **A**, The layers of cervical fascia. Abbreviation: SMAS, superficial musculo-aponeurotic system. **B**, The deep 'spaces' in the neck. **C**, Axial CT of the neck with intravenous contrast medium at the level of C6 showing the deep cervical fascia and deep 'spaces' of the neck; the 'danger' space is at the dashed dark blue line at the posterior aspect of the retropharyngeal space. (A, B, Infrahyoid transverse section of the neck, adapted from McMinn RMH Last's Anatomy. Redrawn with permission from Guidera AK, Dawes PJD, Stringer MD 2012 Cervical fascia: a terminological pain in the neck. ANZ Surg 82:786–91.)

Investing layer of deep cervical fascia

The investing or superficial layer of the deep cervical fascia encircles the neck, ensheathing trapezius and sternocleidomastoid. The portions between trapezius and sternocleidomastoid, and in the anterior triangle of the neck, are formed of areolar tissue, indistinguishable from that in the superficial cervical fascia and deep potential tissue spaces. Superiorly, the deep fascia fuses with periosteum along the superior nuchal line of the occipital bone, over the mastoid process and along the entire base of the mandible. Between the angle of the mandible and the anterior edge of sternocleidomastoid, it is particularly strong. Between the mandible and the mastoid process, it is related to the parotid gland, extending beneath it to become attached to the zygomatic arch. From this region, the strong stylomandibular ligament ascends to the styloid process. Inferiorly, along trapezius and sternocleidomastoid, the investing layer of the deep cervical fascia is attached to the acromion, clavicle and manubrium sterni, fusing with their periostea. A short distance above the manubrium, the investing layer interweaves with aponeurotic fibres of platysma and the fascia investing the strap muscles. It is organized into superficial and deep layers, which are attached to the anterior border of the manubrium, and to the posterior border and the interclavicular ligament, respectively. Between these two layers, a slit-like interval, the suprasternal space, contains a small amount of areolar tissue, the lower parts of the anterior jugular veins and the jugular venous arch, the sternal heads of the sternocleidomastoid muscles and sometimes a lymph node.

Middle layer of deep cervical fascia

Many of the variations in the descriptions of cervical fascia concern the middle layer. (For a detailed discussion, see Som and Curtin (2011).) It is usually subdivided into a muscular layer that surrounds the infrahyoid strap muscles and a visceral layer that includes both the pretracheal and buccopharyngeal fasciae. The visceral layer extends inferiorly from the base of the skull posteriorly and the hyoid bone and thyroid cartilage anteriorly. Laterally, it provides fascial sheaths of varying thickness for the thyroid gland, larynx, trachea, pharynx and oesophagus, and merges with the investing layer of deep cervical fascia and with the carotid sheath (see Fig. 35.4). Inferiorly, it continues into the superior mediastinum along the great vessels and fuses with the fibrous pericardium.

Deep layer of deep cervical fascia

The deep layer of cervical fascia consists of dorsal and ventral layers: the prevertebral and alar fasciae, respectively. In some descriptions, the prevertebral layer is synonymous with the deep layer.

The prevertebral fascia lies closest to the vertebral bodies, covering the anterior surface of longus capitis and longus colli. It extends inferiorly from the skull base, descending in front of longus colli into the superior mediastinum, where it blends with the anterior longitudinal ligament. It passes laterally and posteriorly as the scalene fascia, which covers the scalene muscles, splenius capitis and levator scapulae. All the ventral rami of the cervical nerves are initially behind the prevertebral fascia. The nerves to the rhomboids and serratus anterior and the proximal portions of the phrenic nerve retain this position throughout their course in the neck, but the accessory nerve lies superficial to the prevertebral fascia. As the subclavian artery and the brachial plexus emerge from behind scalenus anterior, they carry the prevertebral fascia downwards and laterally behind the clavicle as the axillary sheath. The prevertebral fascia is attached to the spinous processes of the vertebrae and forms a fascial floor for the posterior triangle of the neck.

The alar fascia is a coronally orientated sheet, attached to the transverse process of the cervical vertebrae. It lies anterior to the prevertebral fascia, from which it is separated by loose connective tissue that fills the so-called danger space (see below), and posterior to the pharynx/oesophagus and the visceral layer of the middle deep cervical fascia, from which it is separated by loose connective tissue that fills the retropharyngeal space (see Fig. 35.4). It passes anterolaterally to fuse with the prevertebral fascia and extends inferiorly from the skull base to about the level of the seventh cervical vertebra (it varies between C6 and T4), where it fuses with the visceral layer of middle cervical fascia, thereby delimiting the lowest extent of the retropharyngeal and danger spaces.

Carotid sheath

The carotid sheath is a condensation of deep cervical fascia around the common and internal carotid arteries, internal jugular vein, vagus nerve and ansa cervicalis. It is thicker around the arteries than the vein, an arrangement that allows the vein to expand. Peripherally, the sheath is connected to adjacent fascial layers by loose areolar tissue. Debate continues as to whether the carotid sheath is formed by all three layers of the deep cervical fascia, or exclusively by the deep or the superficial layer, or whether there is a demonstrable fascial ensheathment (Guidera et al 2012).

Suprapleural membrane (Sibson's fascia)

The suprapleural membrane (Sibson's fascia) serves as a plane of separation between the lower neck and the thorax. It is attached anteriorly to the inner border of the first rib, and posteriorly to the anterior border of the transverse process of the seventh cervical vertebra and is covered and strengthened by a few spreading muscular fibres derived from the scaleni.

Tissue spaces and the spread of infection

The fascial layers of the neck define a number of potential tissue 'spaces' above and below the hyoid bone. In health, the tissues within these spaces are closely applied to one another or are filled with relatively loose connective tissue.

Visceral space

The visceral space contains the pharynx, cervical oesophagus, larynx, trachea, thyroid and parathyroid glands, recurrent laryngeal nerves, and the cranial sympathetic trunk. It is bounded anteriorly by the fascia that encloses the infrahyoid strap muscles (muscular layer of middle deep cervical fascia), posteriorly by the alar fascia, and laterally by the carotid sheath on either side. It may be subdivided into an anterior visceral (pretracheal) space and a posterior visceral space. These spaces communicate freely between the levels of the mid-thyroid cartilage and the inferior thyroid artery but are separated inferiorly by the fascia associated with the artery.

Anterior visceral space

This space, also known as the pretracheal space, contains the trachea, thyroid and parathyroid glands, larynx, cervical oesophagus, recurrent laryngeal nerves and the cranial sympathetic trunks. It extends superiorly from the hyoid bone and the attachments of the strap muscles and their fasciae to the hyoid bone and thyroid cartilage down into the anterior portion of the superior mediastinum. It communicates with the posterior visceral space around the sides of the larynx, the caudal portion of the pharynx and the upper cervical oesophagus. It becomes separated from the posterior visceral space at lower levels by dense connective tissue associated with the inferior thyroid artery as the latter approaches the thyroid gland. The portion of the anterior visceral space between the strap fascia and the fascia of the thyroid gland is referred to as the anterior cervical space. Its posterolateral border is either the carotid sheath or the fascia covering sternocleidomastoid. It provides a symmetric landmark on transverse imaging (Smoker and Harnsberger 1991). Infections spreading immediately into the anterior visceral space are usually the result of instrumental or foreign body perforation of the oesophagus.

Posterior visceral space

The posterior visceral space (often referred to as the retropharyngeal space) lies posterior to the pharynx and cervical oesophagus, extending from the skull base down to the superior mediastinum, its caudal limit being the level of fusion between the alar and visceral layers of fascia.

Prevertebral space

The prevertebral tissue space lies between the prevertebral fascia and the vertebral column. It extends from the skull base to the coccyx, enclosing the prevertebral muscles. Infections spread into this space from adjacent vertebrae or their intervertebral discs, the spinal cord, associated nerve roots and spinal nerves. Classically, tuberculosis of the spine breaches the space to a Pott's abscess.

Carotid space

The carotid sheath is a layer of loose connective tissue demarcated by adjacent portions of the investing layer of deep cervical fascia, the pretracheal fascia and the prevertebral fascia. The literature about the carotid space is confusing and best summarized by Som and Curtin (2011).

Danger space

The danger space lies between the alar and prevertebral fasciae, and extends from the skull base down to the posterior mediastinum where the alar, visceral and prevertebral layers of deep cervical fascia fuse. This

potential space is closed superiorly, inferiorly and laterally and infections can only enter it by penetrating its walls. Its loose areolar tissue offers a potential route for rapid downward spread of infection, primarily from the retropharyngeal, parapharyngeal or prevertebral spaces, to the posterior mediastinum.

Cellulitis in the neck

Infections arising superiorly, such as molar dental, tonsillar, vertebral or intervertebral disc-related infections can spread through this network of spaces. There are no tissue barriers running horizontally in the neck, which means that delays in treatment can be disastrous as infection with its associated oedema develops and spreads from the infratemporal fossa down to the mediastinum, crosses the midline through the sublingual and submental spaces, and can even track into the axilla. The organisms responsible are often β-haemolytic streptococci or anaerobes: proteolytic enzymes digest the loose connective tissue to open up the spaces.

Apical abscesses of the second and third mandibular molar teeth can perforate the lingual plate of the mandible below and behind the attachment of mylohyoid and its posterior free border. At this point infection spreads directly into the submandibular space and has easy access to the parapharyngeal and pterygoid spaces posteriorly.

Cellulitis of the neck or deep neck space infections are potentially very serious because of the associated swelling. Obstruction of the upper airway and dysphagia can develop in a matter of a few hours: intubation becomes extremely difficult. Urgent drainage of the spaces is necessary, together with establishment of a secure airway usually by tracheostomy. (For further reading see Oliver and Gillespie (2010), Hedge et al (2012), Maroldi et al (2012).)

Understanding the configuration of the cervical fasciae and spaces is also essential for the placement of local cervical plexus anaesthetic blocks to facilitate operations such as thyroidectomy, parathyroidectomy and carotid endarterectomy (Pandit et al 2000).

MUSCLES

The superficial muscles of the neck are platysma, which lies in the subcutaneous tissue of the neck, sternocleidomastoid and trapezius. Sternocleidomastoid is a key landmark because it divides the neck into anterior and posterior triangles; the anterior triangle may be further subdivided into several smaller named triangles (see above). Muscles in the anterior region are organized into supra- and infrahyoid groups. When removing the body of the hyoid in Sistrunk's operation or in revision surgery, these supra- and infrahyoid muscles are detached. They are also detached to mobilize the cervical and intrathoracic trachea by 'dropping the larynx' during upper airway surgery to resect sections of trachea and repair by primary anastomosis. The suprahyoid muscles connect the hyoid bone to the mandible and the base of the skull and include mylohyoid, geniohyoid, stylohyoid and digastric. The infrahyoid (strap) muscles connect the hyoid, sternum, clavicle and scapula and are arranged in a superficial plane (sternohyoid and omohyoid) and a deep plane (sternothyroid and thyrohyoid).

The muscles that form part of the musculoskeletal column in the neck are described in Chapter 46. They can be considered in three groups, anterior, lateral and posterior: very broadly speaking, the muscles in these groups lie anterior, lateral or posterior to the cervical vertebrae. The anterior and lateral groups include longi colli and capitis; recti capitis anterior and lateralis; scaleni anterior, medius, posterior and minimi (the latter are not always present). The posterior muscle group contains the cervical components of the intrinsic muscles of the back, overlaid by some of the extrinsic 'immigrant' muscles of the back that run between the upper limb and the axial skeleton (trapezius, levator scapulae; Ch. 49). The intrinsic muscles are arranged in superficial and deep layers. The superficial layer contains splenius capitis and cervicis. The deeper layers include the transversospinal group (semispinales cervicis and capitis, multifidus and rotatores cervicis), interspinales and intertransversarii, and the suboccipital group (recti capitis posterior major and minor, and obliquus capitis superior and inferior).

The muscles associated with the pharynx and larynx are described in Chapters 40 and 41, respectively.

Platysma

Platysma is a broad sheet of muscle of varying prominence that arises from the fascia covering the upper parts of pectoralis major and deltoid. Its fibres cross the clavicle and ascend medially in the side of the neck. Anterior fibres interlace across the midline with the fibres of the contralateral muscle, below and behind the symphysis menti. Other fibres attach to the lower border of the mandible or to the lower lip or cross the mandible to attach to the skin and subcutaneous tissue of the lower face. Platysma provides an important blood supply to the overlying skin: careful elevation of a myocutaneous flap in the subplatysmal plane, as part of a neck dissection, includes this muscle and its associated blood supply, and minimizes the risk of skin necrosis and wound breakdown.

Vascular supply Platysma is supplied by the submental branch of the facial artery and by the suprascapular artery (from the thyrocervical trunk of the subclavian artery).

Innervation Platysma is innervated by the cervical branch of the facial nerve, which descends on the deep surface of the muscle close to the angle of the mandible.

Actions Contraction diminishes the concavity between the jaw and the side of the neck, and produces tense, oblique ridges in the skin of the neck. Platysma may assist in depressing the mandible, and, via its labial and modiolar attachments, it can draw down the lower lip and corners of the mouth in extreme facial expressions. Surgery that damages the nerve to platysma, the marginal mandibular nerve or the cervical branches of the facial nerve can result in paralysis of the lower lip.

Sternocleidomastoid

Sternocleidomastoid (Fig. 35.5A) descends obliquely across the side of the neck and forms a prominent surface landmark, especially when contracted. It is thick and narrow centrally, and broader and thinner at each end. The muscle is attached inferiorly by two heads. The medial or sternal head is rounded and tendinous, arises from the upper part of the anterior surface of the manubrium sterni, and ascends posterolaterally. The lateral or clavicular head, which is variable in width and contains muscular and fibrous elements, ascends almost vertically from the superior surface of the medial third of the clavicle. The two heads are separated near their attachments by a triangular interval that corresponds to a surface depression, the lesser supraclavicular fossa. As they ascend, the clavicular head spirals behind the sternal head and blends with its deep surface below the middle of the neck, forming a thick, rounded belly. Sternocleidomastoid inserts superiorly by a strong tendon into the lateral surface of the mastoid process from its apex to its superior border, and by a thin aponeurosis into the lateral half of the superior nuchal line. The clavicular fibres are directed mainly to the mastoid process; the sternal fibres are more oblique and superficial, and extend to the occiput. The direction of pull of the two heads is therefore different, and the muscle may be classed as 'cruciate' and slightly 'spiralized'.

Relations The superficial surface of sternocleidomastoid is covered by skin and platysma, between which lie the external jugular vein, the great auricular and transverse cervical nerves, and the superficial lamina of the deep cervical fascia. Near its insertion, the muscle is overlapped by a small part of the parotid gland. The deep surface of the muscle near its origin is related to the sternoclavicular joint and sternohyoid, sternothyroid and omohyoid. The anterior jugular vein crosses deep to it but superficial to the infrahyoid muscles, immediately above the clavicle. The carotid sheath and the subclavian artery are deep to these muscles. Between omohyoid and the posterior belly of digastric, the anterior part of sternocleidomastoid lies superficial to the common, internal and external carotid arteries, the internal jugular, facial and lingual veins, the deep cervical lymph nodes, the vagus nerve and the rami of the ansa cervicalis. The sternocleidomastoid branch of the superior thyroid artery crosses deep to the muscle at the upper border of omohyoid. The posterior part of sternocleidomastoid is related on its internal surface to splenius capitis, levator scapulae and the scalene muscles, the cervical plexus, the upper part of the brachial plexus, the phrenic nerve and the transverse cervical and suprascapular arteries. The occipital artery crosses deep to the muscle at, or under cover of, the lower border of the posterior belly of digastric. At this point, the accessory nerve passes deep to sternocleidomastoid, then pierces and supplies the muscle, before it reappears just above the middle of the posterior border. At its insertion, the muscle lies superficial to the mastoid process, splenius capitis, longissimus capitis and the posterior belly of digastric.

Vascular supply Sternocleidomastoid receives its blood supply from branches of the occipital and posterior auricular arteries (upper part of muscle), the superior thyroid artery (middle part of muscle) and the suprascapular artery (lower part of muscle). A superiorly based flap can be raised on sternocleidomastoid to include a paddle of skin supplied by perforator vessels (Froes et al 1999), and has been used to reconstruct the lips, floor of mouth and inner aspect of the cheeks. It is not

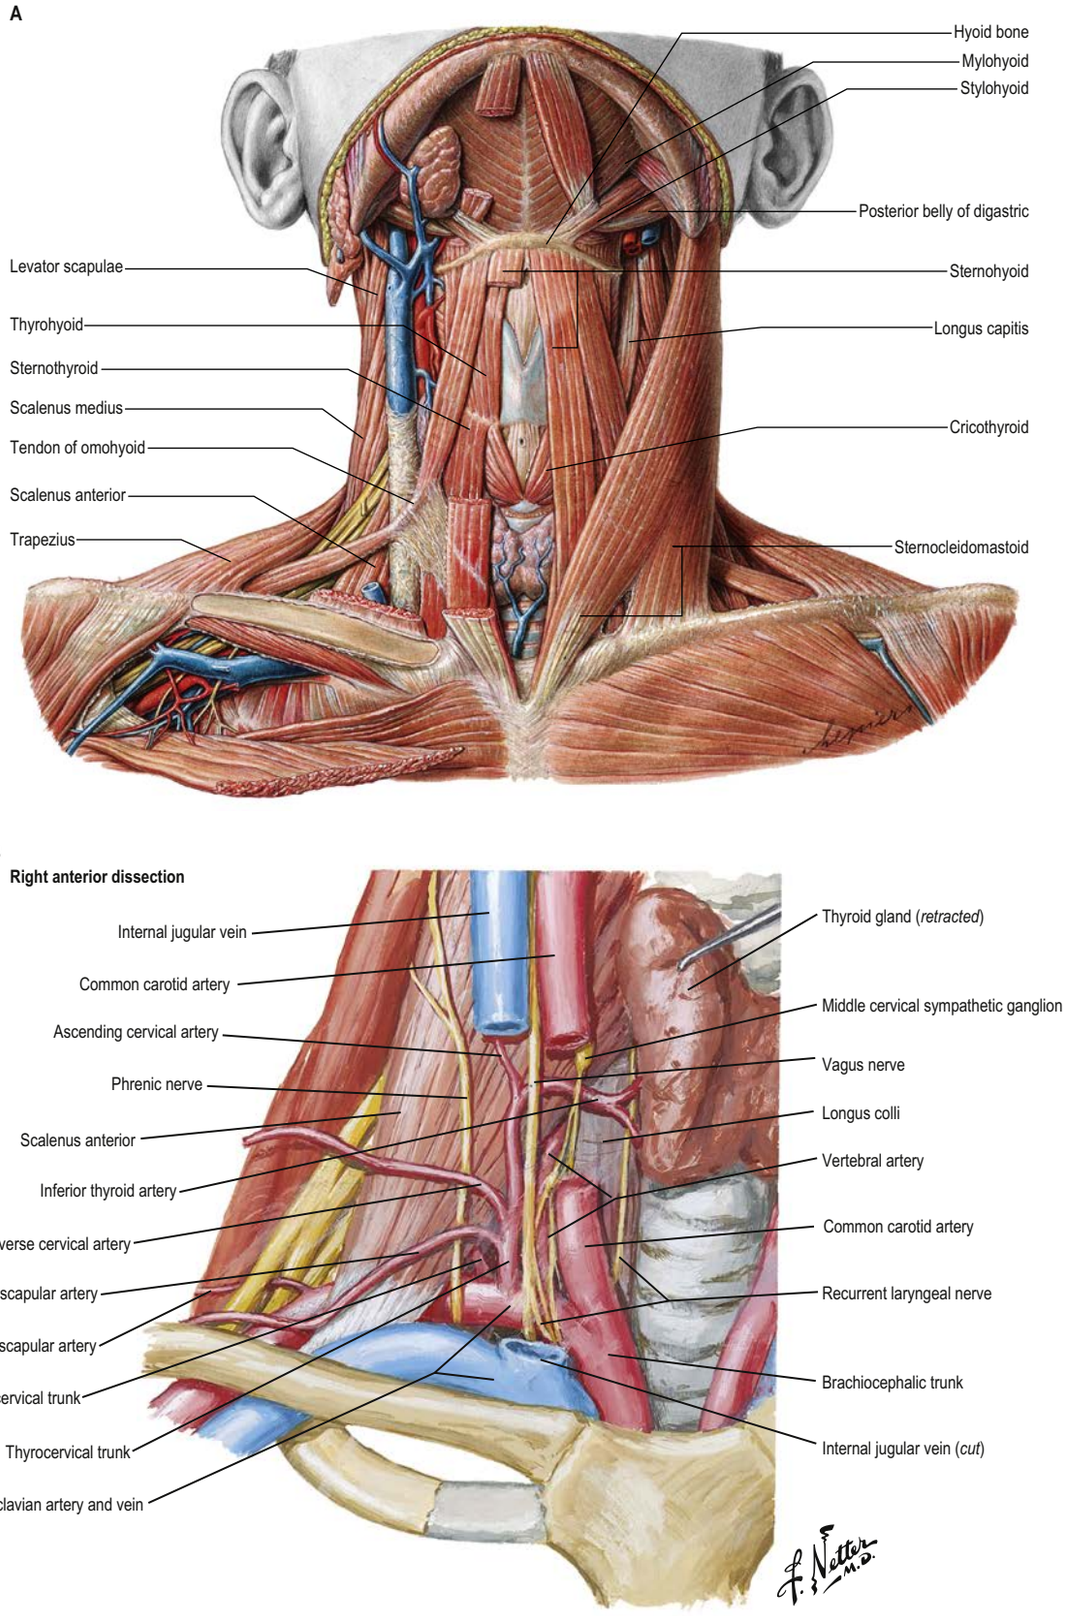

Fig. 35.5 A, Muscles of the neck. Note that the head is slightly extended in order to expose the suprahyoid muscles. **B**, Chassaignac's triangle. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich; B, with permission from Netter FH Atlas of Human Anatomy, 7th ed. Elsevier. Copyright 2019.)

a very reliable flap and its use has been superseded by microvascular free transfer flaps or by conventional myocutaneous flaps such as the pectoralis major flap.

Innervation Sternocleidomastoid is supplied by the accessory nerve. Branches from the ventral rami of the second, third and sometimes fourth cervical spinal nerves also enter the muscle. Although these cervical rami were believed to be solely proprioceptive, clinical evidence suggests that some of their fibres are motor.

Actions Acting alone, each sternocleidomastoid will tilt the head towards the ipsilateral shoulder, simultaneously rotating the head and turning the face towards the opposite side. This movement happens in an upward, sideways glance. A more common visual movement is a level

rotation from side to side, and this probably represents the most frequent use of the sternocleidomastoids. Acting together from below, the muscles draw the head forwards and so help longi colli to flex the cervical part of the vertebral column, which is a common movement in feeding. The two sternocleidomastoids are also used to raise the head when the body is supine; when the head is fixed, they help to elevate the thorax in forced inspiration.

Branchial cysts and fistulae Branchial cysts usually present in the upper neck in early adulthood as fluctuant swellings at the junction of the upper and middle thirds of the anterior border of sternocleidomastoid. The cyst typically passes backwards and upwards through the carotid bifurcation and ends at the pharyngeal constrictor muscles, a course that brings it into intimate association with the hypoglossal, glossopharyngeal and accessory nerves. Great care must be taken to avoid damage to these nerves during surgical removal of a branchial cyst.

Branchial fistulae represent a persistent connection between the second branchial pouch and the cervical sinus. A fistula presents as a small pit adjacent to the anterior border of the lower third of sternocleidomastoid that may weep saliva and become intermittently infected. Excision involves following the tract of the fistula up the neck, often through the carotid bifurcation, and into the distal tonsillar fossa, where it opens into the pharynx.

Branchial cysts, sinuses and fistulae are thought to arise from inclusions of salivary gland tissue in lymph nodes; they may also develop around the parotid gland.

Muscles of the anterior triangle of the neck

Apart from the superficial neck muscles already described, the anterior triangle contains two of the suprahyoid muscles – namely, digastric and stylohyoid – and the four infrahyoid strap muscles (see Fig. 35.5A). The other suprahyoid muscles, namely mylohyoid and geniohyoid, are described with the floor of the mouth in Chapter 37.

Digastric

Digastric has two bellies and lies below the mandible, extending from the mastoid process to the chin (see Fig. 35.5A). The posterior belly, longer than the anterior, is attached in the mastoid notch of the temporal bone and passes downwards and forwards. The anterior belly is attached to the digastric fossa on the base of the mandible near the midline, and slopes downwards and backwards. The two bellies meet in an intermediate tendon that perforates stylohyoid and runs in a fibrous sling attached to the body and greater cornu of the hyoid bone; it is sometimes lined by a synovial sheath. The two bellies of digastric mark out the borders of the submandibular triangle.

Variations Digastric may lack the intermediate tendon and is then attached midway along the body of the mandible. The posterior belly may be augmented by a slip from the styloid process or arise wholly from it. The anterior belly may cross the midline and it is not uncommon for it to fuse with mylohyoid.

Relations Superficial to digastric are platysma, sternocleidomastoid, splenius capitis, longissimus capitis and stylohyoid, the mastoid process, the retromandibular vein, and the parotid and submandibular salivary glands. Mylohyoid is medial to the anterior belly, and hyoglossus, obliquus capitis superior and rectus capitis lateralis, the transverse process of the atlas vertebra, the accessory nerve, internal jugular vein, occipital artery, hypoglossal nerve, internal and external carotid, facial and lingual arteries are all medial to the posterior belly.

Vascular supply The posterior belly is supplied by the posterior auricular and occipital arteries. The anterior belly of digastric receives its blood supply chiefly from the submental branch of the facial artery.

Innervation The anterior belly of digastric is supplied by the mylohyoid branch of the inferior alveolar nerve, and the posterior belly is supplied by the facial nerve. The different innervation of the two parts reflects their separate derivations from the mesenchyme of the first and second branchial arches.

Actions Digastric depresses the mandible and can elevate the hyoid bone. The posterior bellies are especially active during swallowing and chewing.

Stylohyoid

Stylohyoid arises by a small tendon from the posterior surface of the styloid process, near its base. Passing downwards and forwards, it inserts into the body of the hyoid bone at its junction with the greater cornu (and just above the attachment of the superior belly of omohyoid). It is perforated near its insertion by the intermediate tendon of digastric (see Fig. 35.5A). The muscle may be absent or double. It may lie medial to the external carotid artery and may end in the suprahyoid or infrahyoid muscles.

Vascular supply Stylohyoid receives its blood supply from branches of the facial, posterior auricular and occipital arteries.

Innervation Stylohyoid is innervated by the stylohyoid branch of the facial nerve, which frequently arises with the digastric branch, and enters the middle part of the muscle.

Actions Stylohyoid elevates the hyoid bone and draws it backwards, elongating the floor of the mouth.

Stylohyoid ligament

The stylohyoid ligament is a fibrous cord extending from the tip of the styloid process to the lesser cornu of the hyoid bone. It gives attachment to the highest fibres of the middle pharyngeal constrictor and is intimately related to the lateral wall of the oropharynx. Below, it is overlapped by hyoglossus. The ligament is derived from the cartilage of the second branchial arch and may be partially calcified.

Infrahyoid muscles

The infrahyoid muscles are organized so that sternohyoid and omohyoid lie superficially, and sternothyroid and thyrohyoid lie more deeply (see Fig. 35.5A). The muscles are involved in movements of the hyoid bone and thyroid cartilage during vocalization, swallowing and mastication, and are mainly innervated from the ansa cervicalis.

Sternohyoid

Sternohyoid is a thin, narrow strap muscle that arises from the posterior surface of the medial end of the clavicle, the posterior sternoclavicular ligament and the upper posterior aspect of the manubrium (see Fig. 35.5A). It ascends medially and is attached to the inferior border of the body of the hyoid bone. Inferiorly, there is a considerable gap between the muscle and its contralateral fellow, but the two usually come together in the middle of their course and are contiguous above this. Sternohyoid may be absent or double, augmented by a clavicular slip (cleidohyoid), or interrupted by a tendinous intersection.

Vascular supply Sternohyoid is supplied by branches from the superior thyroid artery.

Innervation Sternohyoid is innervated by branches from the ansa cervicalis (C1, 2, 3).

Actions Sternohyoid depresses the hyoid bone after it has been elevated.

Omohyoid

Omohyoid consists of two bellies united at an angle by an intermediate tendon (see Fig. 35.5A). The inferior belly is a flat, narrow band, which inclines forwards and slightly upwards across the lower part of the neck. It arises from the upper border of the scapula, near the scapular notch, and occasionally from the superior transverse scapular ligament. It then passes behind sternocleidomastoid and ends there in the intermediate tendon. The superior belly begins at the intermediate tendon, passes almost vertically upwards near the lateral border of sternohyoid, and is attached to the lower border of the body of the hyoid bone lateral to the insertion of sternohyoid. The length and form of the intermediate tendon vary. It usually lies adjacent to the internal jugular vein at the level of the arch of the cricoid cartilage. The angulated course of the muscle is maintained by a band of deep cervical fascia, attached below to the clavicle and the first rib, that ensheathes the tendon. A variable amount of skeletal muscle may be present in the fascial band; either belly may be absent or double; and the inferior belly may be attached directly to the clavicle and the superior is sometimes fused with sternohyoid.

Vascular supply Omohyoid is supplied by branches from the superior thyroid and lingual arteries.

Innervation The superior belly of omohyoid is innervated by branches from the superior ramus of the ansa cervicalis (C1). The inferior belly is innervated from the ansa cervicalis itself (C1, 2 and 3).

Actions Omohyoid depresses the hyoid bone after it has been elevated. It has been speculated that the muscle tenses the lower part of the deep cervical fascia in prolonged inspiratory efforts, reducing the tendency for soft parts to be sucked inwards.

Sternothyroid

Sternothyroid is shorter and wider than sternohyoid and lies deep and partly medial to it (see Fig. 35.5A). It arises from the posterior surface of the manubrium sterni inferior to the origin of sternohyoid and from the posterior edge of the cartilage of the first rib. It is attached above to the oblique line on the lamina of the thyroid cartilage, where it delineates the upward extent of the thyroid gland. In the lower part of the neck, the muscle is in contact with its contralateral fellow, but the two diverge as they ascend.

Vascular supply Sternothyroid is supplied by branches from the superior thyroid and lingual arteries.

Innervation Sternothyroid is innervated by branches from the ansa cervicalis (C1, 2 and 3).

Actions Sternothyroid draws the larynx downwards after it has been elevated by swallowing or vocal movements. In the singing of low notes, this downward traction would be exerted with the hyoid bone relatively fixed.

Thyrohyoid

Thyrohyoid is a small, quadrilateral muscle that may be regarded as an upward continuation of sternothyroid (see Fig. 35.5A). It arises from the oblique line on the lamina of the thyroid cartilage and passes upwards to attach to the lower border of the greater cornu and adjacent part of the body of the hyoid bone.

Vascular supply Thyrohyoid is supplied by branches from the superior thyroid and lingual arteries.

Innervation Unlike the other infrahyoid muscles, thyrohyoid is not innervated by the ansa cervicalis. In common with geniohyoid, it is supplied by fibres from the first cervical spinal nerve that branch off from the hypoglossal nerve beyond the descendens hypoglossi.

Actions Thyrohyoid depresses the hyoid bone. With the hyoid bone stabilized, it pulls the larynx upwards, e.g. when high notes are sung.

Anterior vertebral muscles

The anterior vertebral group of muscles are longi colli and capitis, and recti capitis anterior and lateralis (**Fig. 35.6**), all of which are flexors of the head and neck to varying degrees. Together with the lateral vertebral muscles, they form the prevertebral muscle group (Sakamoto 2016).

Rectus capitis anterior

Rectus capitis anterior is a short, flat muscle situated behind the upper part of longus capitis. It arises from the anterior surface of the lateral mass of the atlas and the root of its transverse process, and ascends almost vertically to the inferior surface of the basilar part of the occipital bone immediately anterior to the occipital condyle.

Vascular supply Rectus capitis anterior is supplied by branches from the vertebral and ascending pharyngeal arteries.

Innervation Rectus capitis anterior is innervated by branches from the loop between the ventral rami of the first and second cervical spinal nerves.

Actions Rectus capitis anterior flexes the head at the atlanto-occipital joints.

Rectus capitis lateralis

Rectus capitis lateralis is a short, flat muscle that arises from the upper surface of the transverse process of the atlas and inserts into the inferior surface of the jugular process of the occipital bone. In view of its attachments and its relation to the ventral ramus of the first spinal nerve, rectus capitis lateralis is regarded as homologous with the posterior intertransverse muscles.

Vascular supply Rectus capitis lateralis is supplied by branches from the vertebral, occipital and ascending pharyngeal arteries.

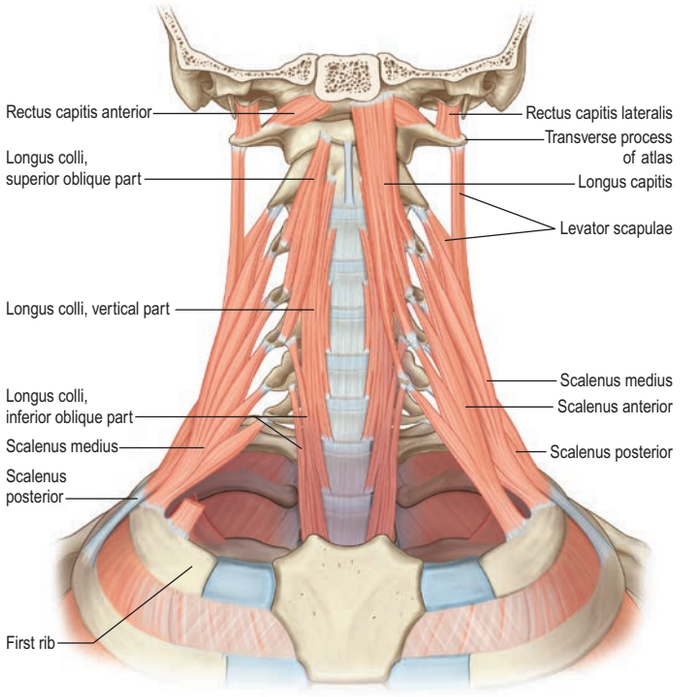

Fig. 35.6 The anterior and lateral vertebral muscles. Scalenus anterior and longus capitis have been removed on the right side.

Innervation Rectus capitis lateralis is innervated by branches from the loop between the ventral rami of the first and second cervical spinal nerves.

Actions Rectus capitis lateralis flexes the head laterally to the same side.

Longus capitis

Longus capitis (see Fig. 35.6) has a narrow origin from tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, fifth and sixth cervical vertebrae, and becomes broad and thick above, where it is inserted into the inferior surface of the basilar part of the occipital bone.

Vascular supply Longus capitis is supplied by the ascending pharyngeal, ascending cervical branch of the inferior thyroid and the vertebral arteries.

Innervation Longus capitis is innervated by branches from the ventral rami of the first, second and third cervical spinal nerves.

Actions Longus capitis flexes the head.

Longus colli

Longus colli (see Fig. 35.6) is applied to the anterior surface of the vertebral column, between the atlas and the third thoracic vertebra. It can be divided into three parts, which all arise by tendinous slips. The inferior oblique part is the smallest, running upwards and laterally from the anterior surfaces of the bodies of the first two or three thoracic vertebrae to the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebrae. The superior oblique part passes upwards and medially from the anterior tubercles of the transverse processes of the third, fourth and fifth cervical vertebrae, to be attached by a narrow tendon to the anterolateral surface of the tubercle on the anterior arch of the atlas. The vertical intermediate part ascends from the anterior surfaces of the bodies of the upper three thoracic and lower three cervical vertebrae to the fronts of the bodies of the second, third and fourth cervical vertebrae.

Vascular supply Longus colli is supplied by branches from the vertebral, inferior thyroid and ascending pharyngeal arteries.

Innervation Longus colli is innervated by branches from the ventral rami of the second, third, fourth, fifth and sixth cervical spinal nerves.

Actions Longus colli flexes the neck forwards. In addition, the oblique parts may flex it laterally, and the inferior oblique part rotates it to the opposite side. Its main antagonist is longissimus cervicis.

Lateral vertebral muscles

Scaleni anterior, medius and posterior extend obliquely between the upper two ribs and the cervical transverse processes. Scalenus minimus (pleuralis) is associated with the suprapleural membrane and cervical pleura, and is described in Chapter 54.

Scalenus anterior

Scalenus anterior lies at the side of the neck deep (posteromedial) to sternocleidomastoid (see Fig. 35.5). Above, it is attached by musculotendinous fascicles to the anterior tubercles of the transverse processes of the third, fourth, fifth and sixth cervical vertebrae. These converge, blend and descend almost vertically, to be attached by a narrow, flat tendon to the scalene tubercle on the inner border of the first rib, and to a ridge on the upper surface of the rib anterior to the groove for the subclavian artery (see Fig. 35.6).

Relations Scalenus anterior forms an important landmark in the root of the neck because the phrenic nerve passes anterior to it and the subclavian artery posterior to it; the brachial plexus lies at its lateral border. The clavicle, subclavius, sternocleidomastoid and omohyoid, lateral part of the carotid sheath, transverse cervical, suprascapular and ascending cervical arteries, subclavian vein, prevertebral fascia and phrenic nerve are all anterior to scalenus anterior. Posteriorly are the suprapleural membrane, pleura, roots of the brachial plexus and the subclavian artery; the latter two separate scalenus anterior from scalenus medius. The proximity of the muscle to the brachial plexus and subclavian artery and vein can give rise to compression syndromes. Below its attachment to the sixth cervical vertebra, the medial border of the muscle is separated from longus colli by an angular interval in which the vertebral artery and vein pass to and from the foramen transversarium of the sixth cervical vertebra. The inferior thyroid artery crosses this interval from the lateral to the medial side near its apex. The sympathetic trunk and its cervicothoracic ganglion are closely related to the posteromedial side of this part of the vertebral artery. On the left side, the thoracic duct crosses the triangular interval at the level of the seventh cervical vertebra and usually comes into contact with the medial edge of scalenus anterior. The musculotendinous attachments of scalenus anterior to anterior tubercles are separated from those of longus capitis by the ascending cervical branch of the inferior thyroid artery.

Chassaignac's triangle is the space between longus colli and scalenus anterior as it attaches to the tubercle of the sixth cervical vertebra (Chassaignac's tubercle); the subclavian vein forms the inferior border (**Fig. 35.5B**). This triangle is important surgically because it forms a posterior relation of the internal jugular vein in level IV: nodes in this area (including the scalene nodes) should be specifically explored in selected neck dissection when the vein is preserved. Lymphadenopathy in this location frequently represents metastatic spread from either the thyroid or from a primary site below the clavicles (the 'rising sun' sign) which may be of breast, lung, stomach or ovary in origin. The thoracic duct is encountered here, either on the left as a main trunk or as a part of a smaller network of lymphatic channels on either side. Care should be taken to avoid injury to these vessels to prevent a chylous fistula or lymph fluid leaks during neck dissection.

Innervation Scalenus anterior is innervated by branches from the ventral rami of the fourth, fifth and sixth cervical spinal nerves.

Actions Acting from below, scalenus anterior bends the cervical portion of the vertebral column forwards and laterally and rotates it towards the opposite side. Acting from above, the muscle helps to elevate the first rib.

Scalenus medius

Scalenus medius, the largest and longest of the scaleni, is attached above to the transverse process of the axis and the anterior surface of the posterior tubercles of the transverse processes of the lower five cervical vertebrae (see Fig. 35.6). It frequently extends upwards to the transverse process of the atlas. Below it is attached to the upper surface of the first rib between the tubercle of the rib and the groove for the subclavian artery.

Relations The anterolateral surface of the muscle is related to sternocleidomastoid (see Fig. 35.5A). It is crossed anteriorly by the clavicle and omohyoid, and it is separated from scalenus anterior by the subclavian artery and ventral rami of the cervical spinal nerves. Levator scapulae and scalenus posterior lie posterolateral to it. The upper two roots of the nerve to serratus anterior and the dorsal scapular nerve (to the rhomboids) pierce the muscle and appear on its lateral surface.

Innervation Scalenus medius is supplied by branches from the ventral rami of the third to eighth cervical spinal nerves.

Actions Acting from below, scalenus medius bends the cervical part of the vertebral column to the same side. Acting from above, it helps to raise the first rib. The scalene muscles, particularly scalenus medius, are active during inspiration, even during quiet breathing in the erect attitude.

Scalenus posterior

Scalenus posterior is the smallest and most deeply situated of the scalene muscles (see Fig. 35.6). It passes from the posterior tubercles of the transverse processes of the fourth, fifth and sixth cervical vertebrae to the outer surface of the second rib, behind the tubercle for serratus anterior, where it is attached by a thin tendon.

Scalenus posterior is occasionally blended with scalenus medius. The scalene muscles vary a little in the number of vertebrae to which they are attached, in their degree of separation and in their segmental innervation.

Vascular supply All the scalene muscles are supplied by the ascending cervical branch of the inferior thyroid artery. Scalenus posterior receives an additional supply from the superficial cervical artery.

Innervation Scalenus posterior is innervated by branches from the ventral rami of the lower three cervical spinal nerves.

Actions When the second rib is fixed, scalenus posterior bends the lower end of the cervical part of the vertebral column to the same side. When its upper attachment is fixed, it helps to elevate the second rib.

Posterior vertebral muscles

Splenius capitis and splenius cervicis are described in Chapter 46.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The common carotid, internal carotid and external carotid arteries provide the major source of blood to the head and neck (**Figs 35.7A, 35.8**). Additional arteries arise from branches of the subclavian artery, particularly the vertebral artery.

The common, internal and external carotid arteries, accompanying veins and nerves all lie in a cleft that is bound posteriorly by the transverse processes of cervical vertebrae and attached muscles, medially by the trachea, oesophagus, thyroid gland, larynx and pharyngeal constrictors, and anterolaterally by sternocleidomastoid and, at different levels, omohyoid, sternohyoid, sternothyroid, digastric and stylohyoid muscles. The common and internal carotid arteries lie within the carotid sheath, accompanied by the internal jugular vein and the vagus nerve.

Common carotid artery

The common carotid arteries differ on the right and left sides with respect to their origins. On the right, the common carotid arises from the brachiocephalic artery as it passes behind the sternoclavicular joint. On the left, the common carotid artery comes directly from the arch of the aorta in the superior mediastinum. The right common carotid, therefore, has only a cervical part whereas the left common carotid has cervical and thoracic parts. Following a similar course on both sides, the common carotid artery ascends, diverging laterally from behind the sternoclavicular joint to the level of the upper border of the thyroid cartilage of the larynx (C3–4 junction), where it divides into external and internal carotid arteries. This bifurcation can sometimes be at a higher or lower level (**Fig. 35.7B**). The angle of bifurcation remains unchanged from infancy to adulthood. However, there is a significant change in the angle of the split between the internal and the external carotid arteries relative to the common carotid artery (Seong et al 2005). The artery may be compressed against the prominent transverse process of the sixth cervical vertebra (Chassaignac's tubercle); above this level it is superficial, and its pulsation can be easily felt.

Relations In the lower part of the neck, the common carotid arteries are separated by a narrow gap that contains the trachea. Above this, the arteries are separated by the thyroid gland, larynx and pharynx. Each artery is contained within the carotid sheath of deep cervical fascia, which also encloses the internal jugular vein and vagus nerve.

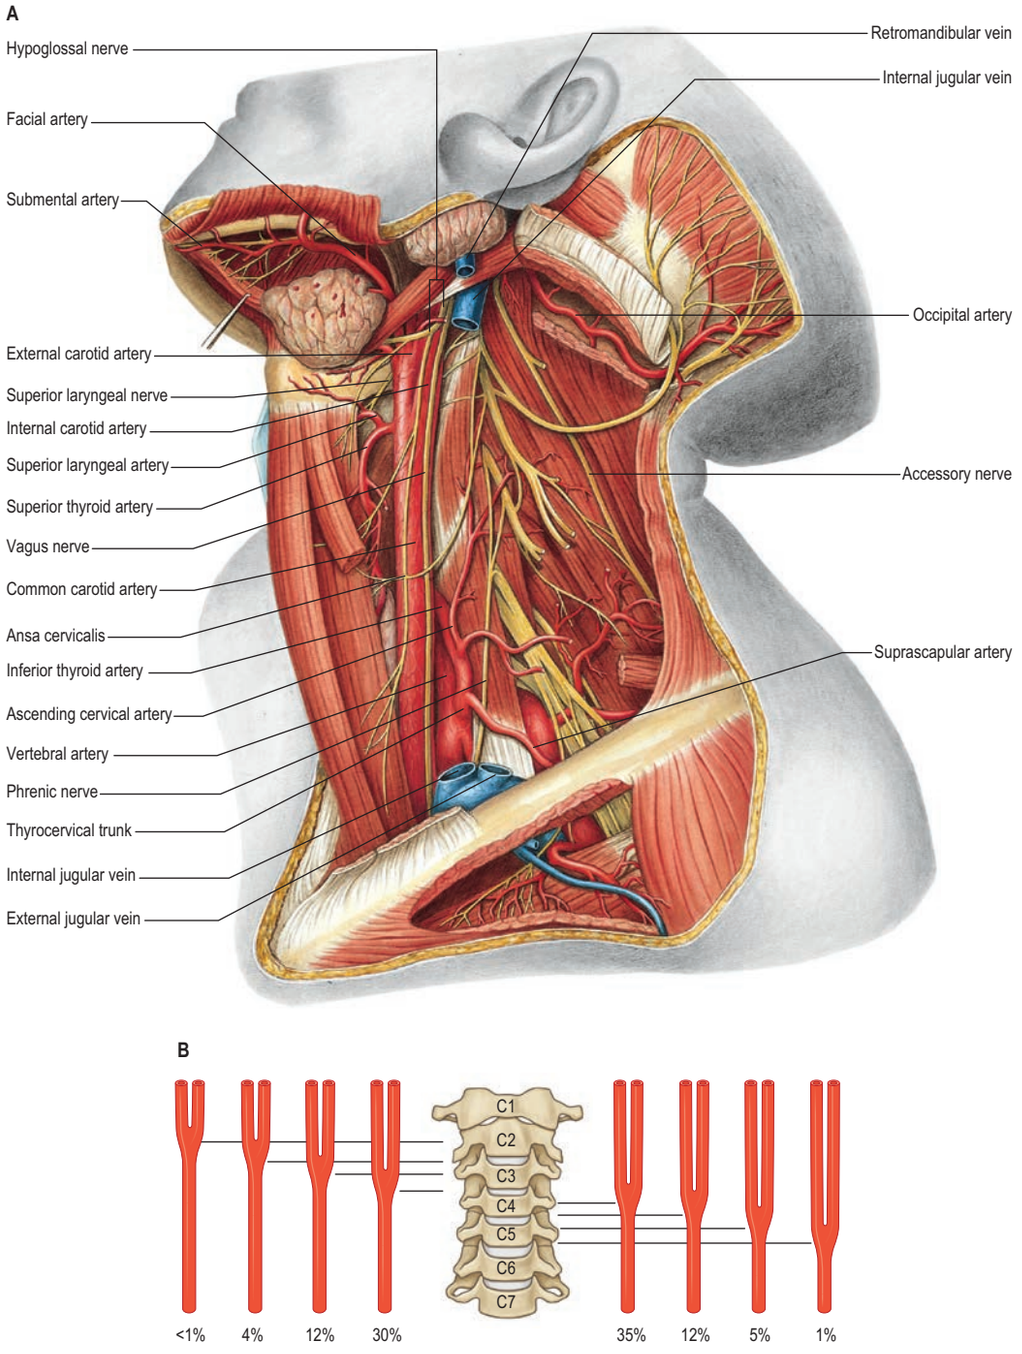

Fig. 35.7 A, Vessels and nerves of the neck, left lateral view. Sternocleidomastoid and the greater part of omohyoid and the internal jugular vein have been removed. Compare with Fig. 35.17, which shows a deeper level of dissection. **B**, The variation in levels of bifurcation of the common carotid artery, related to the cervical vertebrae. (A, B, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

The vein lies lateral to the artery, and the nerve lies between them and posterior to both.

The artery is crossed anterolaterally, at the level of the cricoid cartilage, by the intermediate tendon – sometimes the superior belly – of omohyoid. Below omohyoid, it is sited deeply, and covered by skin, superficial fascia, platysma, deep cervical fascia, and sternocleidomastoid, sternohyoid and sternothyroid. Above omohyoid, it is more superficial, and covered merely by skin, superficial fascia, platysma, deep cervical fascia and the medial margin of sternocleidomastoid; it is crossed obliquely from its medial to lateral side by the sternocleidomastoid branch of the superior thyroid artery. The superior root of the ansa cervicalis, joined by its inferior root from the second and third cervical spinal nerves, lies anterior to, or embedded within, the carotid sheath as it crosses it obliquely. The superior thyroid vein usually crosses near the upper border of the thyroid cartilage, and the middle thyroid vein crosses a little below the level of the cricoid cartilage. The anterior jugular vein crosses the common carotid artery above the clavicle, separated from it by sternohyoid and sternothyroid. Posterior to the carotid sheath are the transverse processes of the fourth to sixth cervical vertebrae, to which are attached longus colli, longus capitis and tendinous slips of scalenus anterior. The sympathetic trunk and ascending cervical branch of the inferior thyroid artery lie between the common carotid artery and the muscles. Below the level of the sixth cervical vertebra, the artery is in an angle between scalenus anterior and longus colli, anterior to the vertebral vessels, inferior thyroid and subclavian arteries, sympathetic trunk and, on the left, the thoracic duct. The oesophagus, trachea, inferior thyroid artery, recurrent laryngeal nerve and, at a higher level, the larynx and pharynx are medial to the sheath and its contents. The thyroid gland overlaps it anteromedially. The internal jugular vein lies lateral and, in the lower neck, also anterior to the artery, while the vagus nerve lies posterolaterally in the angle between artery and vein.

On the right side, low in the neck, the recurrent laryngeal nerve crosses obliquely behind the artery. The right internal jugular vein diverges from it below but the left vein approaches and often overlaps its artery.

The right common carotid artery sometimes arises above the level of the sternoclavicular joint, or it may be a separate branch from the aorta. The left common carotid artery varies in origin more than the right and may arise with the brachiocephalic artery. Division of the

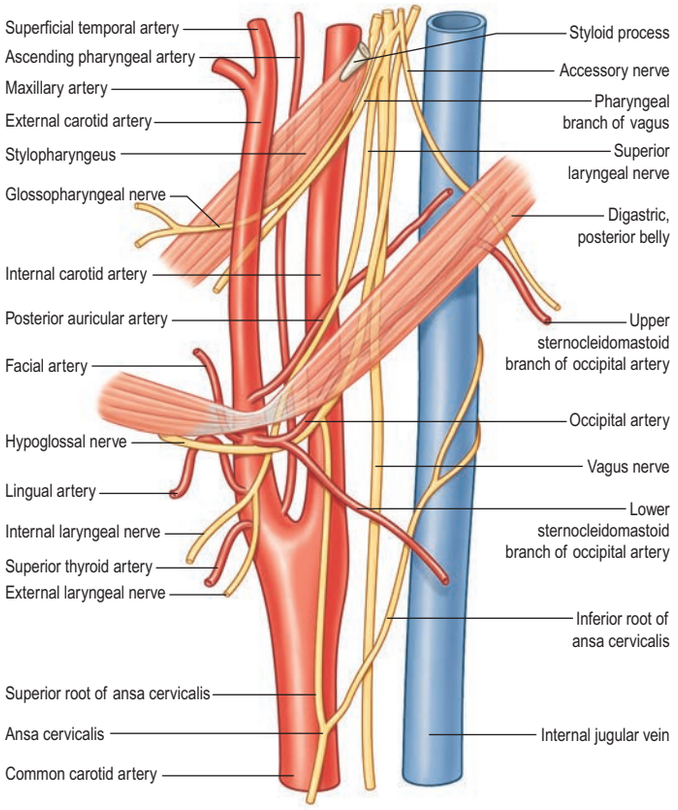

Fig. 35.8 The branches of the external carotid artery. Note the structures that either cross the internal jugular vein and the carotid arteries or intervene between the external and internal carotid arteries.

common carotid may occur higher, near the level of the hyoid bone, or, more rarely, at a lower level alongside the larynx. Very rarely, it ascends without division, so that either the external or internal carotid is absent, or it may be replaced by separate external and internal carotid arteries that arise directly from the aorta, on one side, or bilaterally.

Although the common carotid artery usually has no branches, it may occasionally give rise to the vertebral, superior thyroid, superior laryngeal, ascending pharyngeal, inferior thyroid or occipital arteries.

External carotid artery

The external carotid artery (see Figs 35.7A, 35.8) begins lateral to the upper border of the thyroid cartilage, level with the intervertebral disc between the third and fourth cervical vertebrae. A little curved and with a gentle spiral, it first ascends slightly forwards and then inclines backwards and a little laterally, to pass midway between the tip of the mastoid process and the angle of the mandible. Here, in the substance of the parotid gland behind the neck of the mandible, it divides into its terminal branches, the superficial temporal and maxillary arteries. As it ascends, it gives off several large branches and diminishes rapidly in calibre. In children the external carotid is smaller than the internal carotid, but in adults the two are of almost equal size. At its origin, it is in the carotid triangle and lies anteromedial to the internal carotid artery. It later becomes anterior, then lateral, to the internal carotid as it ascends. At mandibular levels, the styloid process and its attached structures intervene between the vessels; the internal carotid is deep, and the external carotid superficial, to the styloid process. A fingertip placed in the carotid triangle perceives a powerful arterial pulsation, which represents the termination of the common carotid, the origins of external and internal carotids, and the stems of the initial branches of the external carotid.

Relations The skin and superficial fascia, the loop between the cervical branch of the facial nerve and the transverse cutaneous nerve of the neck, the deep cervical fascia and the anterior margin of sternocleidomastoid all lie superficial to the external carotid artery in the carotid triangle. The artery is crossed by the hypoglossal nerve and its vena comitans, and by the lingual, facial and, sometimes, the superior thyroid veins. Leaving the carotid triangle, the external carotid artery is crossed by the posterior belly of digastric and by stylohyoid; it ascends between these muscles and the posteromedial surface of the parotid gland, which it next enters. Within the parotid, the artery lies medial to the facial nerve and the junction of the superficial temporal and maxillary veins. The pharyngeal wall, superior laryngeal nerve and ascending pharyngeal artery are the initial medial relations of the artery. At a higher level, it is separated from the internal carotid artery by the styloid process, styloglossus and stylopharyngeus, glossopharyngeal nerve, pharyngeal branch of vagus nerve and part of the parotid gland. The artery is equally likely to lie medial to the parotid gland, or within it.

The external carotid artery has eight named branches distributed to the head and neck. The superior thyroid, lingual and facial arteries arise from its anterior surface, the occipital and posterior auricular arteries arise from its posterior surface, and the ascending pharyngeal artery arises from its medial surface. The maxillary and superficial temporal arteries are its terminal branches within the parotid gland.

Superior thyroid artery

The superior thyroid artery is the second branch of the external carotid artery. It arises from the anterior surface of the external carotid just below the level of the greater cornu of the hyoid bone (see Figs 35.7A, 35.8). It descends along the lateral border of thyrohyoid to reach the apex of the lobe of the thyroid gland. Lying medially are the inferior constrictor muscle and the external laryngeal nerve; the nerve is often posteromedial, and therefore at risk when the artery is being ligated. Occasionally, it may issue directly from the common carotid.

Branches

The superior thyroid artery supplies the thyroid gland and some adjacent skin. Glandular branches are anterior, which runs along the medial side of the upper pole of the lateral lobe to supply mainly the anterior surface; a branch that crosses above the isthmus to anastomose with its fellow of the opposite side; and posterior, which descends on the posterior border to supply the medial and lateral surfaces and anastomoses with the inferior thyroid artery. A lateral branch sometimes supplies the lateral surface. The superior thyroid artery is often accompanied by the external branch of the superior laryngeal nerve. Care should be taken to preserve this nerve when ligating the superior thyroid artery during surgery because it supplies cricothyroid: iatrogenic damage affects vocal cord function.

The artery has the following named branches: infrahyoid, superior laryngeal, sternocleidomastoid and cricothyroid.

Infrahyoid artery The infrahyoid artery is a small branch that runs along the lower border of the hyoid bone deep to thyrohyoid and anastomoses with its fellow of the opposite side to supply the infrahyoid strap muscles.

Superior laryngeal artery The superior laryngeal artery accompanies the internal laryngeal nerve. Deep to thyrohyoid, it pierces the lower part of the thyrohyoid membrane to supply the tissues of the upper part of the larynx. It anastomoses with its fellow of the opposite side and with the inferior laryngeal branch of the inferior thyroid artery.

Sternocleidomastoid artery The sternocleidomastoid artery descends laterally across the carotid sheath and supplies the middle region of sternocleidomastoid. Like the parent artery itself, it may arise directly from the external carotid artery.

Cricothyroid artery The cricothyroid artery crosses high on the anterior cricothyroid ligament, anastomoses with its fellow of the opposite side and supplies cricothyroid.

Ascending pharyngeal artery

The ascending pharyngeal artery is the first and smallest branch of the external carotid artery. It is a long, slender vessel that arises from the medial (deep) surface of the external carotid artery near the origin of that artery. It is important that it is identified and preserved if the external carotid is being ligated because of its potential to supply to a compromised internal carotid circulation.

The ascending pharyngeal artery ascends between the internal carotid artery and the pharynx to the base of the cranium, crossed by styloglossus and stylopharyngeus; longus capitis is posterior. It gives off numerous small branches to supply longus capitis and longus colli, the sympathetic trunk, the hypoglossal, glossopharyngeal and vagus nerves, and some of the cervical lymph nodes. It anastomoses with the ascending palatine branch of the facial artery and the ascending cervical branch of the inferior thyroid artery. Its named branches are the pharyngeal, inferior tympanic and meningeal arteries.

Pharyngeal artery The pharyngeal artery gives off three or four branches to supply the constrictor muscles of the pharynx and stylopharyngeus. A variable ramus supplies the palate and may replace the ascending palatine branch of the facial artery. The artery descends forwards between the superior border of the superior constrictor and levator veli palatini to the soft palate, and also supplies a branch to the palatine tonsil and the pharyngotympanic tube.

Inferior tympanic artery The inferior tympanic artery is a small branch that traverses the temporal canaliculus with the tympanic branch of the glossopharyngeal nerve and supplies the medial wall of the tympanic cavity.

Meningeal branches The meningeal branches are small vessels that supply the nerves that traverse the foramen lacerum, jugular foramen and hypoglossal canal, and the associated dura mater and adjoining bone. One branch, the posterior meningeal artery, reaches the cerebellar fossa via the jugular foramen, and is usually regarded as the terminal branch of the ascending pharyngeal artery.

Lingual artery

The lingual artery provides the chief blood supply to the tongue and the floor of the mouth (see Figs 35.8, 37.11). It arises anteromedially from the external carotid artery opposite the tip of the greater cornu of the hyoid bone, between the superior thyroid and facial arteries. It often arises with the facial or, less often, with the superior thyroid artery. It may be replaced by a ramus of the maxillary artery. Ascending medially at first, it loops down and forwards, passes medial to the posterior border of hyoglossus and then runs horizontally forwards deep to it. The lingual artery next ascends again almost vertically, and courses sinuously forwards on the inferior surface of the tongue as far as its tip. The further course of the lingual artery is described in Chapter 37.

Relations Its relationship to hyoglossus naturally divides the lingual artery into descriptive 'thirds'. In its first part, the lingual artery is in the carotid triangle. Skin, fascia and platysma are superficial to it, while the middle pharyngeal constrictor muscle is medial. The artery ascends a little medially, then descends to the level of the hyoid bone, and the loop so formed is crossed externally by the hypoglossal nerve. The second part passes along the upper border of the hyoid bone, deep to hyoglossus, the tendons of digastric and stylohyoid, the lower part of the submandibular gland and the posterior part of mylohyoid. Hyoglossus separates it from the hypoglossal nerve and its vena comitans. Here, its medial aspect adjoins the middle constrictor muscle and it crosses the stylohyoid ligament accompanied by lingual veins. The third part is the arteria profunda linguae, which turns upwards near the anterior border of hyoglossus and then passes forwards close to the inferior lingual surface near the frenulum, accompanied by the lingual nerve. Genioglossus is a medial relation, and the inferior longitudinal muscle of the tongue lies lateral to it below the lingual mucous membrane. Near the tip of the tongue, the lingual artery anastomoses with its fellow of the opposite side. Its named branches are the suprahyoid, dorsal lingual and sublingual arteries.

Suprahyoid artery The suprahyoid artery is a small branch that runs along the upper border of the hyoid bone to anastomose with the contralateral artery. It supplies adjacent structures.

Dorsal lingual arteries The dorsal lingual arteries are described in Chapter 37.

Sublingual artery The sublingual artery is described in Chapter 37.

Facial artery

The facial artery (see Figs 35.7, 35.8, 36.25) arises anteriorly from the external carotid in the carotid triangle, above the lingual artery and immediately above the greater cornu of the hyoid bone. In the neck, at its origin, it is covered only by the skin, platysma, fasciae and often by the hypoglossal nerve. It runs up and forwards, deep to digastric and stylohyoid. At first on the middle pharyngeal constrictor, it may reach the lateral surface of styloglossus, separated there from the palatine tonsil only by this muscle and the lingual fibres of the superior constrictor. Medial to the mandibular ramus, it arches upwards and grooves the posterior aspect of the submandibular gland. It then turns down and descends to the lower border of the mandible in a lateral groove on the submandibular gland, between the gland and medial pterygoid. Reaching the surface of the mandible, the facial artery curves round its inferior border, anterior to masseter, to enter the face; its further course is described in Chapter 36. The artery is very sinuous throughout its extent. In the neck, this may be so that the artery is able to adapt to the movements of the pharynx during deglutition, and similarly on the face, so that the artery can adapt to movements of the mandible, lips and cheeks. Facial artery pulsation is most palpable where the artery crosses the mandibular base, and again near the corner of the mouth. There are four branches within the neck and four on the face. The branches in the neck are the ascending palatine, tonsillar, submental and glandular arteries. The branches on the face are described in Chapter 36.

Ascending palatine artery The ascending palatine artery arises close to the origin of the facial artery. It passes up between styloglossus and stylopharyngeus to reach the side of the pharynx, along which it ascends between the superior constrictor of the pharynx and medial pterygoid towards the cranial base. It bifurcates near levator veli palatini. One branch follows this muscle, winding over the upper border of the superior constrictor of the pharynx to supply the soft palate and to anastomose with its fellow of the opposite side and the greater palatine branch of the maxillary artery. The other branch pierces the superior constrictor muscle to supply the tonsil and pharyngotympanic tube, and to anastomose with the tonsillar and ascending pharyngeal arteries (see Fig. 40.7).

Tonsillar artery The tonsillar artery provides the main blood supply to the palatine tonsil. It ascends between medial pterygoid and styloglossus, penetrates the superior constrictor of the pharynx at the upper border of styloglossus, and enters the inferior pole of the tonsil. Its branches ramify in the tonsil and in the musculature of the posterior part of the tongue. The tonsillar artery may sometimes arise from the ascending palatine artery.

Submental artery The submental artery is the largest cervical branch of the facial artery (see Fig. 35.7). It arises as the facial artery separates from the submandibular gland and turns forwards on mylohyoid below the mandible. It supplies the overlying skin and muscles, and anastomoses with a sublingual branch of the lingual and mylohyoid branch of the inferior alveolar artery. At the chin, it ascends over the mandible and divides into superficial and deep branches that anastomose with the inferior labial and mental arteries to supply the chin and lower lip.

Glandular branches Three or four large vessels supply the submandibular salivary gland and associated lymph nodes, adjacent muscles and skin.

Occipital artery

The occipital artery arises posteriorly from the external carotid artery, approximately 2 cm from its origin (see Figs 35.7A, 35.8). At its origin, the artery is crossed superficially by the hypoglossal nerve, which winds round it from behind. The artery next passes backwards, up and deep to the posterior belly of digastric, and crosses the internal carotid artery, internal jugular vein, and hypoglossal, vagus and accessory nerves. Between the transverse process of the atlas and the mastoid process, the occipital artery reaches the lateral border of rectus capitis lateralis. It then runs in the occipital groove of the temporal bone, medial to the mastoid process and attachments of sternocleidomastoid, splenius capitis, longissimus capitis and digastric, and lies successively on rectus capitis lateralis, obliquus capitis superior and semispinalis capitis. Accompanied by the greater occipital nerve, it finally turns upwards to pierce the investing layer of the deep cervical fascia that connects the cranial attachments of trapezius and sternocleidomastoid, and ascends tortuously in the dense superficial fascia of the scalp, where it divides into many branches (see Fig. 46.78).

The occipital artery has two main branches (upper and lower) to the upper part of sternocleidomastoid in the neck. The lower branch arises near the origin of the occipital artery and may sometimes arise directly from the external carotid artery. It descends backwards over the hypoglossal nerve and internal jugular vein, enters sternocleidomastoid and anastomoses with the sternocleidomastoid branch of the superior thyroid artery. The upper branch arises as the occipital artery crosses the accessory nerve and runs down and backwards superficial to the internal jugular vein. It enters the deep surface of sternocleidomastoid with the accessory nerve.

Posterior auricular artery

The posterior auricular artery is a small vessel that branches posteriorly from the external carotid just above digastric and stylohyoid. It ascends between the parotid gland and the styloid process to the groove between the auricular cartilage and mastoid process, and divides into auricular and occipital branches, which are described with the face in

Chapter 36. In the neck, it provides branches that supply digastric, stylohyoid, sternocleidomastoid and the parotid gland. It also gives origin to the stylomastoid artery (described as an indirect branch of the posterior auricular artery in about a third of subjects) that enters the stylomastoid foramen to supply the facial nerve, tympanic cavity, mastoid antrum air cells and semicircular canals. In the young, its posterior tympanic ramus forms a circular anastomosis with the anterior tympanic branch of the maxillary artery.

Internal carotid artery

The internal carotid artery supplies most of the ipsilateral cerebral hemisphere, eye and accessory organs, forehead and, in part, the nose. From its origin at the carotid bifurcation (**Fig. 35.9**; see Fig. 35.8) where there is usually a carotid sinus, it ascends in front of the transverse processes of the upper three cervical vertebrae to the inferior aperture of the carotid canal in the petrous part of the temporal bone. Here, it enters the cranial cavity and turns anteriorly through the cavernous sinus in the carotid groove on the side of the body of the sphenoid bone. It terminates below the anterior perforated substance by division into the anterior and middle cerebral arteries. The internal carotid artery may be divided conveniently into cervical, petrous, cavernous and cerebral parts. Rarely, persistent embryonic branches to the basilar artery from the cervical part of the internal carotid artery may be encountered at the C1–C2 (persistent hypoglossal artery) and C2–C3 (pro-atlantal intersegmental artery) levels.

Relations The internal carotid artery is initially superficial in the carotid triangle, and then passes deeper, medial to the posterior belly of digastric. Except near the skull, the internal jugular vein and vagus nerve are lateral to it within the carotid sheath. The external carotid artery is first anteromedial, but then curves back to lie superficial. Posteriorly, the internal carotid adjoins longus capitis, and the superior cervical sympathetic ganglion lies between them. The superior laryngeal nerve crosses obliquely behind it. The pharyngeal wall lies medial to the artery, which is separated by fat and pharyngeal veins from the ascending pharyngeal artery and superior laryngeal nerve.

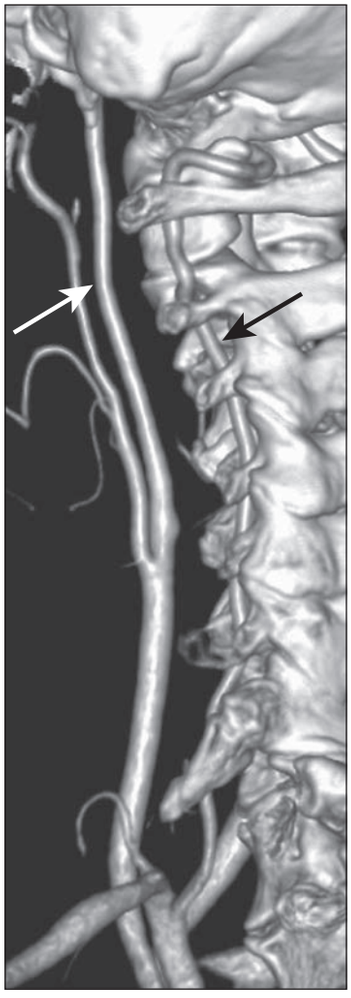

Fig. 35.9 Internal carotid artery anatomy shown on volume rendering of a computed tomographic angiogram. The cervical internal carotid artery (white arrow) is a branchless vessel. Note the course of the vertebral artery (black arrow). (With permission from Kaufman JA, Nesbit GM Carotid and vertebral arteries. In: Kaufman JA, Lee MJ Vascular and Interventional Radiology: The Requisites. Ch. 5. Elsevier, Saunders. Copyright 2014.)

Anterolaterally, the internal carotid artery is covered by sternocleidomastoid. Below the posterior belly of digastric, the hypoglossal nerve and superior root of the ansa cervicalis and the lingual and facial veins are superficial to the artery. At the level of the digastric, the internal carotid is crossed by stylohyoid and the occipital and posterior auricular arteries. Above digastric, it is separated from the external carotid artery by the styloid process, styloglossus and stylopharyngeus, the glossopharyngeal nerve and the pharyngeal branch of the vagus, and the deeper part of the parotid gland. At the base of the skull, the glossopharyngeal, vagus, accessory and hypoglossal nerves lie between the internal carotid artery and the internal jugular vein, which here has become posterior. The length of the artery varies with the length of the neck and the point of the carotid bifurcation. It may arise from the aortic arch, in which case it lies medial to the external carotid as far as the larynx, where it crosses behind it. The cervical portion is normally straight but may be very tortuous, when it lies closer to the pharynx than usual, very near the tonsil. In children, the tonsillocarotid distance increases with growth to a maximum value of 25 mm (Deutsch et al 1995). The internal carotid artery enters the cranium without giving off any branches. It may occasionally be absent.

Occlusive atherosclerotic disease within either the internal carotid or common carotid arteries may cause strokes or transient ischaemic attacks (TIAs) characterized by weakness of the contralateral side. Visual disturbances experienced in the ipsilateral eye and classically described as a 'curtain' falling down over the visual field (amaurosis fugax), may also occur.

Carotid sinus and carotid body

The common carotid artery has two specialized organs near its bifurcation: the carotid sinus and the carotid body. They relay information concerning the pressure and chemical composition of the arterial blood, respectively, and are innervated principally by the carotid branch(es) of the glossopharyngeal nerve, with small contributions from the cervical sympathetic trunk and the vagus nerve.

The carotid sinus usually appears as a dilation of the lower end of the internal carotid in late adolescence (Seong et al 2005) and functions as a baroreceptor.

The carotid body is a reddish-brown, oval structure, 5–7 mm in height and 2.5–4 mm in width. It lies either posterior to the carotid bifurcation or between its branches, and is attached to, or sometimes partly embedded in, their adventitia. Occasionally, it takes the form of a group of separate nodules. Aberrant miniature carotid bodies, microstructurally similar but with diameters of 600 μm or less, may appear in the adventitia and adipose tissue near the carotid sinus.

The carotid body is surrounded by a fibrous capsule, from which septa divide the enclosed tissue into lobules. Each lobule contains glomus (type I) cells, which are separated from an extensive network of fenestrated sinusoids by sustentacular (type II) cells (**Fig. 35.10**). Glomus cells store a number of peptides, particularly enkephalins, bombesin and neurotensin, and amines including dopamine, serotonin (5-hydroxytryptamine, 5-HT), adrenaline (epinephrine) and noradrenaline (norepinephrine), and are therefore regarded as paraneurones. Unmyelinated axons lie in a collagenous matrix between the sustentacular cells and the sinusoidal endothelium, and many synapse on the glomus cells. They are visceral afferents, which travel in the carotid sinus nerve to join the glossopharyngeal nerve. Preganglionic sympathetic axons and fibres from the carotid sinus synapse on parasympathetic and sympathetic ganglion cells, which lie either in isolation or in small groups near the surface of each carotid body. Postganglionic axons travel to local blood vessels; the parasympathetic efferent fibres are probably vasodilatory and the sympathetic ones are vasoconstrictor.

The carotid body receives a rich blood supply from branches of the adjacent external carotid artery, which is consistent with its role as an arterial chemoreceptor. When stimulated by hypoxia, hypercapnia or increased hydrogen ion concentration (low pH) in the blood flowing through it, it elicits reflex increases in the rate and volume of ventilation via connections with brainstem respiratory centres. The bodies are most prominent in children and normally involute in older age, when they are infiltrated by lymphocytes and fibrous tissue. Individuals with chronic hypoxia, or who live at high altitude or suffer from lung disease, may have enlarged carotid bodies as a result of hyperplasia. Disrupted carotid body maturation may play a role in sudden infant death syndrome (Porzionato et al 2013). Benign and malignant paragangliomas develop in association with succinyl dehydrogenase mutations (SDH).

Other small bodies, resembling carotid bodies and also considered to be chemoreceptors, are present near the arteries of the fourth and sixth pharyngeal arches and hence are found near the aortic arch, ligamentum arteriosum and right subclavian artery; they are supplied by the vagus nerve.

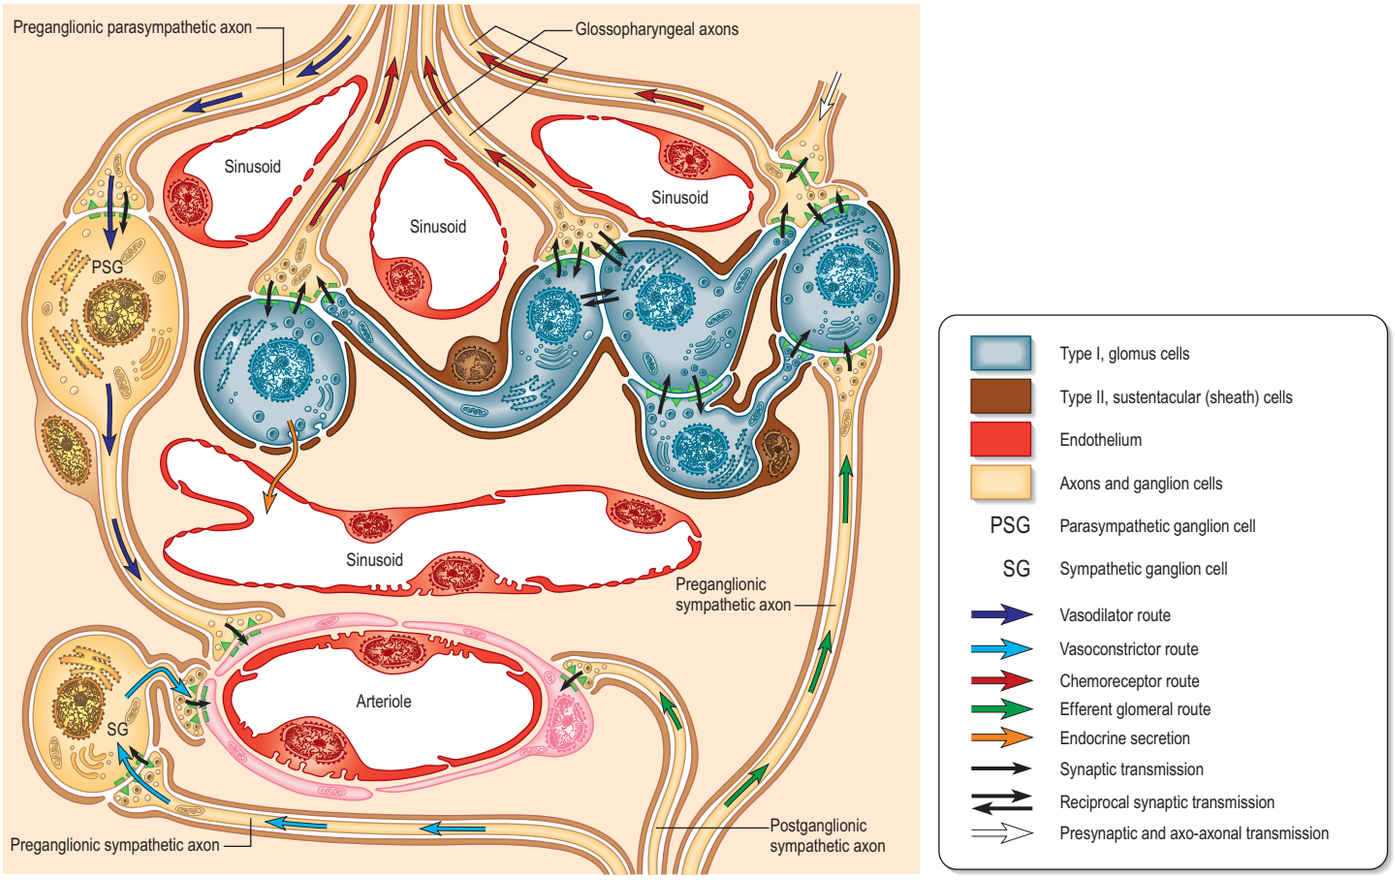

Fig. 35.10 The cellular, neural and vascular architecture of the carotid body. Functional pathways are indicated.

Subclavian artery

The right subclavian artery arises from the brachiocephalic trunk, the left from the aortic arch (see Fig. 35.18). For description, each is divided into a first part, from its origin to the medial border of scalenus anterior; a second part behind this muscle; and a third part from the lateral margin of scalenus anterior to the outer border of the first rib, where the artery becomes the axillary artery. Each subclavian artery arches over the cervical pleura and pulmonary apex. Their first parts differ, whereas the second and third parts are almost identical.

First part of right subclavian artery

The right subclavian artery branches from the brachiocephalic trunk behind the upper border of the right sternoclavicular joint, and passes superolaterally to the medial margin of scalenus anterior. It usually ascends 2 cm above the clavicle but this varies.

Relations The artery is deep to the skin, superficial fascia, platysma, supraclavicular nerves, deep fascia, clavicular attachment of sternocleidomastoid, sternohyoid and sternothyroid. It is at first behind the origin of the right common carotid artery; more laterally, it is crossed by the vagus nerve, the cardiac branches of the vagus and the sympathetic trunk, and by internal jugular and vertebral veins; the subclavian sympathetic loop encircles it. The anterior jugular vein diverges laterally in front of it, separated by sternohyoid and sternothyroid. Below and behind the artery are the pleura and pulmonary apex; they are separated from the artery by the suprapleural membrane, the ansa subclavia, a small accessory vertebral vein and the right recurrent laryngeal nerve, which winds round the lower and posterior part of the vessel (see Fig. 41.11).

First part of left subclavian artery

The first part of the left subclavian artery springs from the aortic arch, behind the left common carotid, level with the disc between the third and fourth thoracic vertebrae. It ascends into the neck, and then arches laterally to the medial border of scalenus anterior.

Relations In the neck, near the medial border of scalenus anterior, the artery is crossed anteriorly by the left phrenic nerve and the termination of the thoracic duct. Otherwise, anterior relations are the same as those of the first part of the right subclavian artery. Posteriorly and inferiorly, the relations of both vessels are identical but the left recurrent laryngeal nerve, medial to the left subclavian artery in the thorax, is not directly related to its cervical part.

Second part of subclavian artery

The second part of the subclavian artery lies behind scalenus anterior; it is short and constitutes the highest part of the vessel (see Fig. 35.18).

Relations The skin, superficial fascia, platysma, deep cervical fascia, sternocleidomastoid and scalenus anterior are anterior. The right phrenic nerve is often described as being separated from the second part of the subclavian artery by scalenus anterior, whereas it crosses the first part of the left subclavian artery. However, both nerves may sometimes lie anterior to the muscle. The suprapleural membrane, pleura and lung, and the lower trunk of the brachial plexus are posteroinferior; the upper and middle trunks of the plexus are superior; and the subclavian vein is anteroinferior, separated by scalenus anterior.

Third part of subclavian artery

The third part of the subclavian artery descends laterally from the lateral margin of scalenus anterior to the outer border of the first rib, where it becomes the axillary artery. It is the most superficial part of the artery and lies partly in the supraclavicular triangle, where its pulsations may be felt and it may be compressed. The third part of the subclavian artery is the most accessible segment of the artery. Since the line of the posterior border of sternocleidomastoid approximates to the (deeper) lateral border of scalenus anterior, the artery can be felt in the anteroinferior angle of the posterior triangle. It can only be effectively compressed against the first rib: with the shoulder depressed, pressure is exerted down, back and medially in the angle between sternocleidomastoid and the clavicle. The palpable trunks of the brachial plexus may be injected with local anaesthetic allowing major surgical procedures to the arm.

Relations The skin, superficial fascia, platysma, supraclavicular nerves and deep cervical fascia are anterior. The external jugular vein crosses its medial end and here receives the suprascapular, transverse cervical and anterior jugular veins, which collectively often form a venous plexus. The nerve to subclavius descends between the veins and the artery; the latter is terminally behind the clavicle and subclavius, where it is crossed by the suprascapular vessels. The subclavian vein is

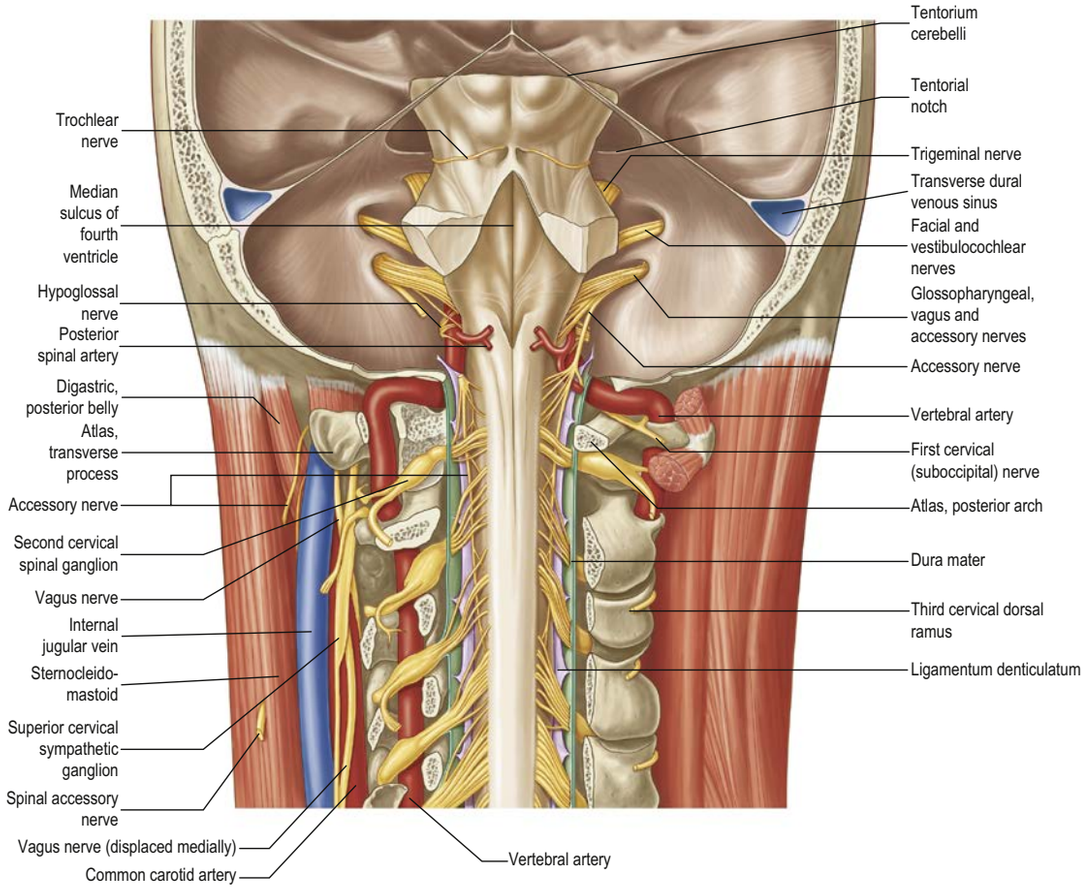

Fig. 35.11 A dissection of the brainstem and the upper part of the spinal cord after removal of large portions of the occipital and parietal bones, the cerebellum and the roof of the fourth ventricle. On the left side, the foramina transversaria of the atlas and the third, fourth and fifth cervical vertebrae have been opened to expose the vertebral artery. On the right side, the posterior arch of the atlas and the laminae of the succeeding cervical vertebrae have been divided and have been removed, together with the vertebral spines and the contralateral laminae. The tentorium cerebelli and the transverse sinuses have been divided and their posterior portions removed.

anteroinferior and the lower trunk of the brachial plexus is posteroinferior, between the subclavian artery and the scalenus medius (and on the first rib). The upper and middle trunks of the brachial plexus (which are palpable here) and the inferior belly of omohyoid are superolateral. The first rib is inferior.

The right subclavian artery may arise above or below sternoclavicular level; it may be a separate aortic branch and be the first or last branch of the arch. When it is the first branch, it is in the position of a brachiocephalic trunk. When it is the last branch, it arises from the left end of the arch, and ascends obliquely to the right behind the trachea, oesophagus and right common carotid to the first rib. When this happens, the right recurrent laryngeal nerve hooks round the common carotid artery. Sometimes, when the right subclavian artery is the last aortic branch, it passes between the trachea and oesophagus and can cause dysphagia, a condition known as dysphagia lusoria. It may perforate scalenus anterior, and very rarely may pass anterior to it. Sometimes, the subclavian vein accompanies the artery behind scalenus anterior. The artery may ascend as high as 4 cm above the clavicle or it may reach only its upper border. The left subclavian artery is occasionally combined at its origin with the left common carotid artery.

Vertebral artery

The vertebral artery arises from the superoposterior aspect of the first part of the subclavian artery. It passes through the foramina in the transverse processes of all of the cervical vertebrae except the seventh, curves medially behind the lateral mass of the atlas and enters the cranium via the foramen magnum (Fig. 35.11). The artery joins its fellow to form the basilar artery at the lower pontine border. Occasionally, it may enter the cervical vertebral column via the fourth, fifth or seventh cervical vertebra (Fig. 35.12).

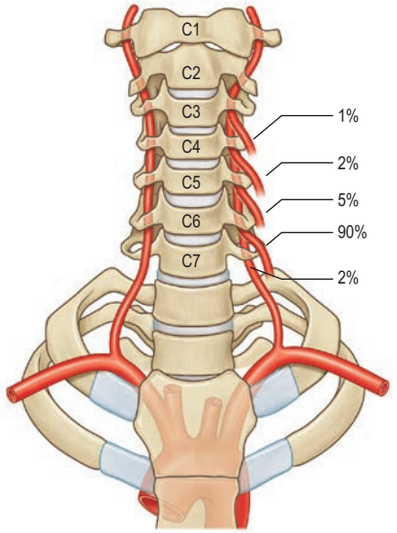

Fig. 35.12 The level of entry of the vertebral artery into the foramina transversaria of the cervical vertebrae. Note that 90% enter at the level of the sixth cervical vertebra. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Relations The first part, V1, passes back and upwards between longus colli and scalenus anterior, behind the common carotid artery and the vertebral vein. It is crossed by the inferior thyroid artery, and by the thoracic duct on the left side and the right lymphatic duct on the right side. The seventh cervical transverse process, the inferior cervical ganglion and ventral rami of the seventh and eighth cervical spinal nerves lie posterior to the artery. The second part, V2, ascends through the transverse foramina of the remaining cervical vertebrae, accompanied by a large branch from the inferior cervical ganglion and a plexus of veins that form the vertebral vein low in the neck. It lies anterior to the ventral rami of the cervical spinal nerves (C2–C6) and ascends almost vertically

to pass through the transverse process of the axis, where it turns laterally to gain access to the transverse foramen of the atlas (see Fig. 35.11). The third part, V3, issues medial to rectus capitis lateralis, and curves backwards and medially behind the lateral mass of the atlas, with the first cervical ventral spinal ramus lying on its medial side. In this position, it lies in a groove on the upper surface of the posterior arch of the atlas, and it enters the vertebral canal below the inferior border of the posterior atlanto-occipital membrane. This part of the artery, covered by semispinalis capitis, lies in the suboccipital triangle. The first cervical dorsal spinal ramus separates the artery from the posterior arch. The fourth part, V4, pierces the dura and arachnoid mater, and ascends anterior to the hypoglossal roots. It inclines anterior to the medulla oblongata and unites with its contralateral fellow to form the midline basilar artery at the lower border of the pons.

Cervical branches of vertebral artery

Spinal branches The spinal branches enter the vertebral canal via the intervertebral foramina and supply the spinal cord and its membranes. They fork into ascending and descending rami, which unite with those above and below, to form two lateral anastomotic chains on the posterior surfaces of the vertebral bodies near the attachment of their pedicles. Branches from these chains supply the periosteum and vertebral bodies, and others communicate with similar branches across the midline; from these connections small rami join similar ones above and below, to form a median anastomotic chain on the posterior surfaces of the vertebral bodies.

Muscular branches Muscular branches arise from the vertebral artery as it curves round the lateral mass of the atlas. They supply the deep muscles of the suboccipital region and anastomose with the occipital, ascending and deep cervical arteries.

Internal thoracic artery

The internal thoracic artery arises inferiorly from the first part of the subclavian artery, 2 cm above the sternal end of the clavicle, opposite the root of the thyrocervical trunk (see Fig. 33.1). It is described further in Chapter 53.

Thyrocervical trunk

The thyrocervical trunk is a short, wide artery that arises from the front of the first part of the subclavian artery near the medial border of scalenus anterior, and divides almost at once into the inferior thyroid, suprascapular and superficial cervical arteries.

Inferior thyroid artery

The inferior thyroid artery loops upwards anterior to the medial border of scalenus anterior, turns medially just below the sixth cervical transverse process, and then descends on longus colli to the lower border of the thyroid gland (see Figs 35.7A, 35.17). It passes anterior to the vertebral vessels and posterior to the carotid sheath and its contents (and usually the sympathetic trunk, whose middle cervical ganglion frequently adjoins the vessel). On the left, near its origin, the artery is crossed anteriorly by the thoracic duct as the latter curves inferolaterally to its termination. Relations between the terminal branches of the artery and recurrent laryngeal nerve are very variable and of considerable surgical importance. The artery usually passes behind the nerve as it nears the gland. However, very close to the gland, the right nerve is equally likely to be anterior, posterior or amongst the branches of the artery, and the left nerve is usually posterior. Together with the inferior thyroid and common carotid arteries, the recurrent laryngeal nerve forms one of the sides of Beahr's triangle (see later). Since the nerve winds around the artery of the sixth branchial arch (aortic arch) on the left side, it is 45° to the midline in its ascent from the chest to the neck. However, on the right side it is slightly more superficial and lateral because it goes around the fourth branchial arch artery (subclavian) in the neck: these variations are important in thyroid surgery and are reversed in dextrocardia. The artery is not accompanied by the inferior thyroid vein.

Muscular branches These supply the infrahyoid muscles, longus colli, scalenus anterior and the inferior pharyngeal constrictor.

Ascending cervical artery The ascending cervical artery is a small branch that arises as the inferior thyroid artery turns medially behind the carotid sheath and ascends on the anterior tubercles of the cervical transverse processes between scalenus anterior and longus capitis. It supplies the adjacent muscles and gives off one or two spinal branches that enter the vertebral canal through the intervertebral foramina to supply the spinal cord and membranes and vertebral bodies, and thereby supplement the spinal branches of the vertebral artery. The ascending cervical artery anastomoses with the vertebral, ascending pharyngeal, occipital and deep cervical arteries.

Inferior laryngeal artery The inferior laryngeal artery ascends on the trachea with the recurrent laryngeal nerve, enters the larynx at the lower border of the inferior constrictor and supplies the laryngeal muscles and mucosa. It anastomoses with its contralateral fellow, and with the superior laryngeal branch of the superior thyroid artery.

Pharyngeal branches These supply the lower part of the pharynx. Tracheal branches supply the trachea and anastomose with the bronchial arteries; oesophageal branches supply the oesophagus and anastomose with the oesophageal branches of the thoracic aorta; inferior and ascending glandular branches supply the posterior and inferior regions of the thyroid gland and anastomose with the contralateral inferior and ipsilateral superior thyroid arteries. The ascending branch also supplies the parathyroid glands.

Suprascapular artery

The suprascapular artery descends laterally across scalenus anterior and the phrenic nerve, posterior to the internal jugular vein and sternocleidomastoid (see Fig. 35.7A). It then crosses anterior to the subclavian artery and brachial plexus, posterior to, and parallel with, the clavicle, subclavius and the inferior belly of omohyoid, to reach the superior scapular border.

Superficial cervical artery

The superficial cervical artery is given off at a higher level than the suprascapular artery. It crosses anterior to the phrenic nerve, scalenus anterior and the brachial plexus, and is covered by the internal jugular vein, sternocleidomastoid and platysma. It crosses the floor of the posterior triangle to reach the anterior margin of levator scapulae and ascends deep to the anterior part of the trapezius, which it supplies, together with the adjoining muscles and the cervical lymph nodes. It anastomoses with the superficial ramus of the descending branch of the occipital artery. About a third of the superficial cervical and dorsal scapular arteries arise in common from the thyrocervical trunk, with a superficial (superficial cervical artery) and a deep (dorsal scapular artery) branch (see Figs 33.1A, 33.2A). The latter passes laterally anterior to the brachial plexus and then posterior to levator scapulae.

Costocervical trunk

On the right, this short vessel arises posteriorly from the second part of the subclavian artery, and, on the left, from its first part. It arches back above the cervical pleura to the neck of the first rib, where it divides into supreme intercostal and deep cervical branches.

Deep cervical artery

The deep cervical artery usually arises from the costocervical trunk (see Fig. 33.1). It is analogous in its first segment to a posterior branch of a posterior intercostal artery, and occasionally is a separate branch of the subclavian artery. It passes back above the eighth cervical spinal nerve between the transverse process of the seventh cervical vertebra and the neck of the first rib (sometimes between the transverse processes of the sixth and seventh cervical vertebrae). It then ascends between semispinales capitis and cervicis to the level of the second cervical vertebra. It supplies adjacent muscles and anastomoses with the deep branch of the descending branch of the occipital artery and branches of the vertebral artery. A spinal branch enters the vertebral canal between the seventh cervical and first thoracic vertebrae.

Dorsal scapular artery

The dorsal scapular artery arises from the third, or less often the second, part of the subclavian artery. It gives off a small branch (which sometimes arises directly from the subclavian artery) to scalenus anterior. It passes laterally through the brachial plexus in front of scalenus medius and then deep to levator scapulae to the superior scapular angle.

Veins

Veins in the neck show considerable variation. They are superficial or deep to the deep fascia but are not entirely separate systems. Superficial veins are tributaries – some with specific names, given below – of the anterior, external and posterior jugular veins (**Figs 35.13–35.14**). They drain a much smaller volume of tissue than the deep veins. The latter drain all but the subcutaneous structures, mostly into the internal jugular vein and also into the subclavian vein.

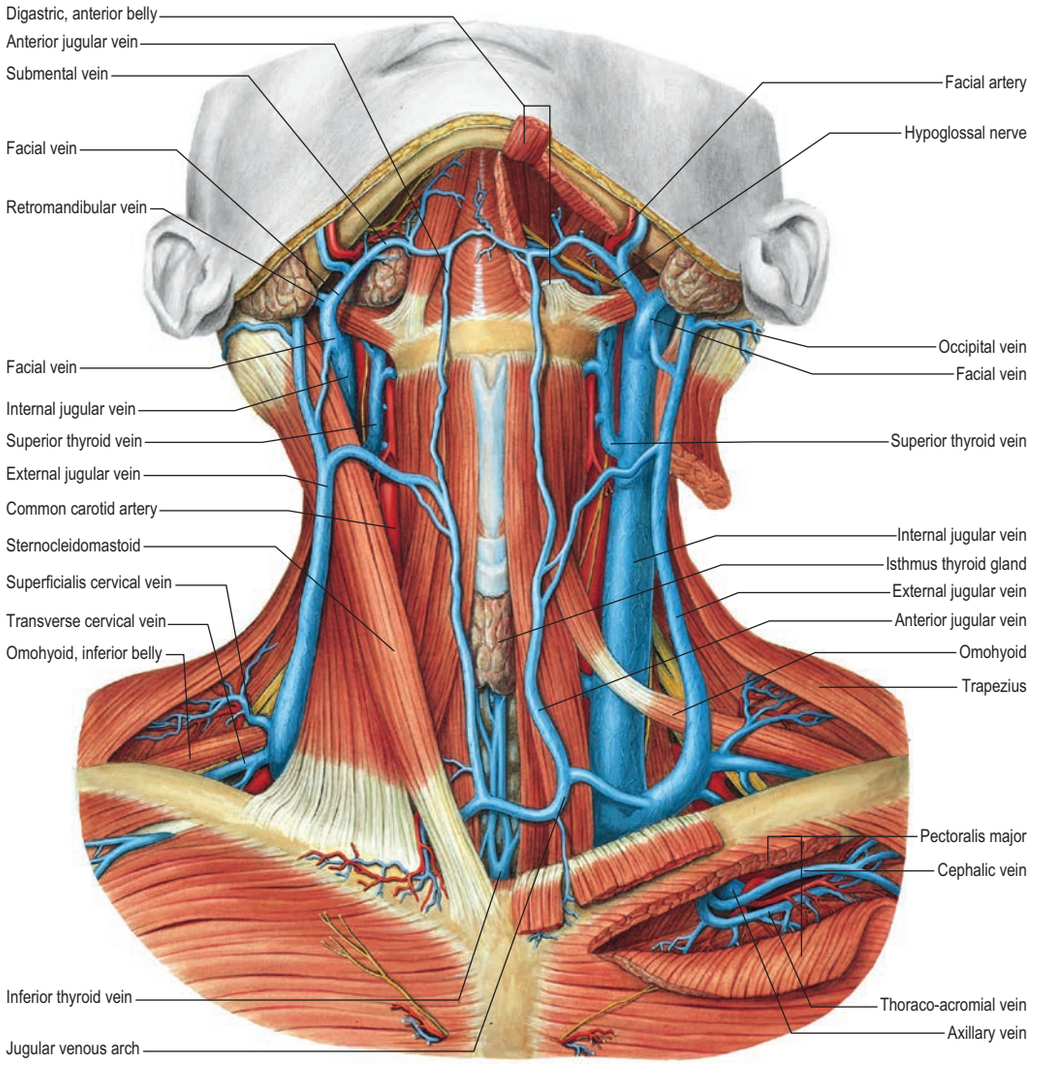

Fig. 35.13 The veins of the neck, seen from the front. The greater part of sternocleidomastoid has been removed on the left side and the cut lower edges have been reflected over the clavicle. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

External jugular vein

The external jugular vein mainly drains the scalp and face, although it also drains some deeper parts. The vein is formed by the union of the posterior division of the retromandibular vein with the posterior auricular vein and begins near the mandibular angle just below or in the parotid gland (see Fig. 33.3A). It descends from the angle to the midclavicle, running obliquely, superficial to sternocleidomastoid, to the root of the neck. Here, it crosses the deep fascia and ends in the subclavian vein, lateral or anterior to scalenus anterior. There are valves at its entrance into the subclavian but they do not prevent regurgitation. Its wall is adherent to the rim of the fascial opening. It is covered by platysma, superficial fascia and skin, and is separated from sternocleidomastoid by deep cervical fascia. The vein crosses the transverse cutaneous nerve and lies parallel with the great auricular nerve, posterior to its upper half. In size, the external jugular vein is inversely proportional to the other veins in the neck and may be double. Between the entrance into the subclavian vein and a point approximately 4 cm above the clavicle, the vein is often dilated, producing a so-called sinus.

Tributaries In addition to formative tributaries, the external jugular receives the posterior external jugular and, near its end, transverse cervical, suprascapular and anterior jugular veins. In the parotid gland, it is often joined by a branch from the internal jugular. The occipital vein occasionally joins it.

Posterior external jugular vein

The posterior external jugular vein begins in the occipital scalp and drains the skin and the superficial muscles that lie posterosuperior in the neck. It usually joins the middle part of the external jugular vein.

Anterior jugular vein

The anterior jugular vein arises near the hyoid bone from the confluence of the superficial submandibular veins. It descends between the midline and the anterior border of sternocleidomastoid. Turning laterally, low in the neck, deep to sternocleidomastoid but superficial to the infrahyoid strap muscles, it either joins the end of the external jugular vein or may enter the subclavian vein directly (see Fig. 33.3A). In size, it is usually inverse to the external jugular vein. It communicates with the internal jugular vein and receives the laryngeal veins and sometimes a small thyroid vein. There are usually two anterior jugular veins, united just above the manubrium by a large transverse jugular arch, receiving the inferior thyroid tributaries. They have no valves and may be replaced by a midline trunk.

Internal jugular vein

The internal jugular vein collects blood from the skull, brain, superficial parts of the face and much of the neck. It begins at the cranial base in the posterior compartment of the jugular foramen, where it is continuous with the sigmoid sinus. At its origin, it is dilated as the superior bulb, which lies below the posterior part of the tympanic floor. The internal jugular vein descends in the carotid sheath, and unites with the subclavian vein, posterior to the sternal end of the clavicle, to form the brachiocephalic vein (see Fig. 35.14). Near its termination, the vein dilates into the inferior bulb, above which is a pair of valves. The jugular bulb is a dynamic structure; it forms after 2 years of age and its size stabilizes in adulthood (Friedmann et al 2011).

Relations From above, rectus capitis lateralis, the transverse process of the atlas, levator scapulae, scalenus medius, scalenus anterior, the cervical

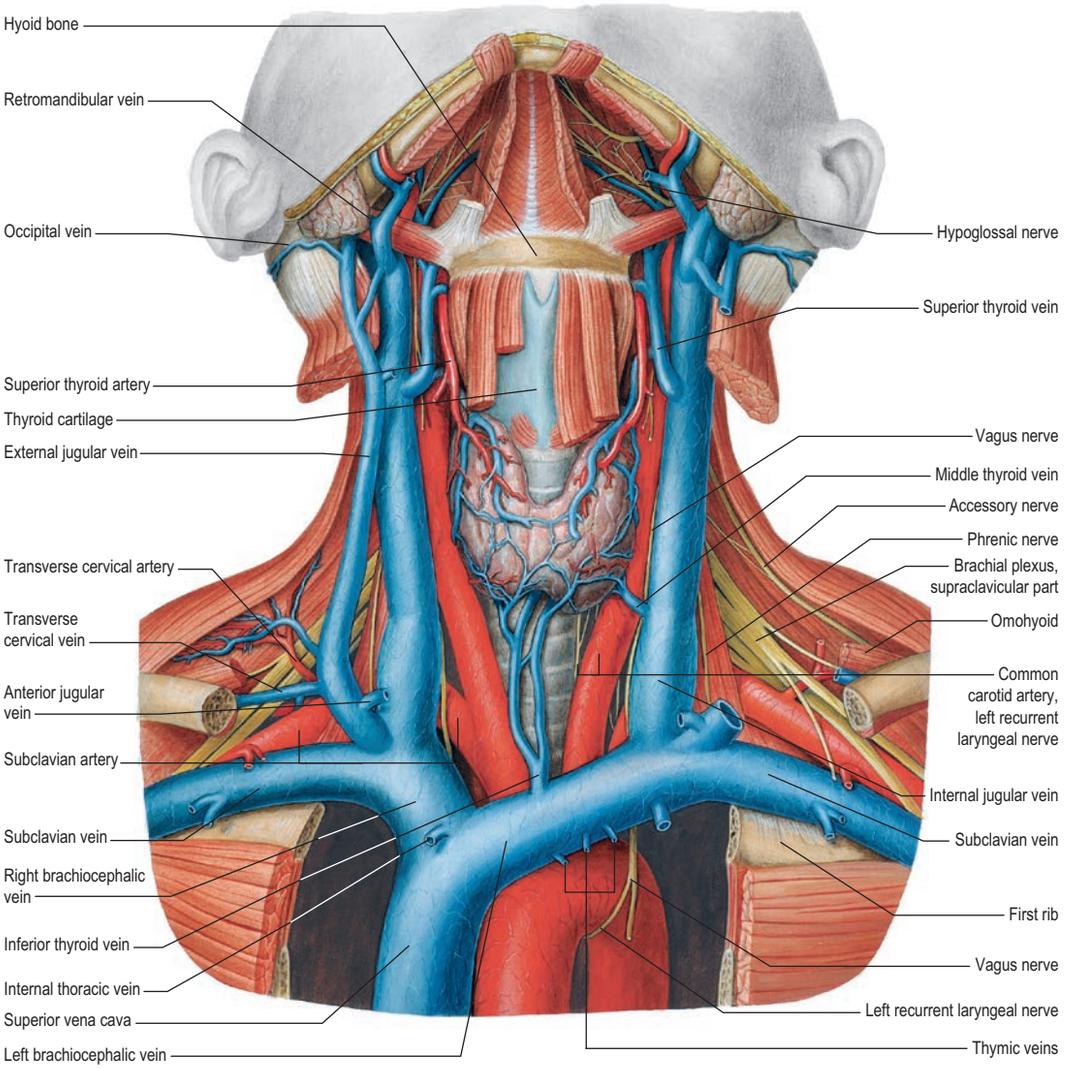

Fig. 35.14 The veins of the neck, seen from the front and at a deeper level than shown in Fig. 35.13. Both sternocleidomastoids have been removed, and additional dissection has exposed the thyroid gland and some of the structures that pass through the upper thoracic aperture. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

plexus, the phrenic nerve, thyrocervical trunk, vertebral vein and the first part of the subclavian artery all lie posterior to the vein. On the left, the internal jugular crosses anterior to the thoracic duct. The internal and common carotid arteries and the vagus nerve are medial to the vein, the vagus lying between and posterior to the vessels. The accessory nerve is sometimes found posterior to the vein. Superficially, the internal jugular vein is overlapped above, then covered below, by sternocleidomastoid, and is crossed by the posterior belly of digastric and the superior belly of omohyoid. The parotid gland, styloid process, accessory nerve (almost always), and the posterior auricular and occipital arteries cross the vein superior to the posterior belly of digastric. Between digastric and omohyoid, the sternocleidomastoid arteries and the inferior root of the ansa cervicalis cross the internal jugular vein, the nerve often passing between the vein and the common carotid artery. Below omohyoid, the vein is covered by the infrahyoid muscles and sternocleidomastoid and is crossed by the anterior jugular vein. Deep cervical lymph nodes lie along the internal jugular, mainly on its superficial aspect. At the root of the neck, the right internal jugular vein is separated from the common carotid artery, but the left usually overlaps its artery. At the base of the skull, the internal carotid artery is anterior to the vein, separated from it by the ninth to twelfth cranial nerves.

Tributaries The inferior petrosal sinus, facial, lingual, pharyngeal, superior and middle thyroid veins, and occasionally the occipital vein, are all tributaries of the internal jugular vein. The internal jugular vein may communicate with the external jugular vein. The thoracic duct opens near the union of the left subclavian and internal jugular veins, and the right lymphatic duct opens at the same site on the right.

Inferior petrosal sinus

The inferior petrosal sinus leaves the skull through the anterior part of the jugular foramen, crosses lateral or medial to the ninth to eleventh cranial nerves, and joins the superior jugular bulb.

Facial vein

The initial part of the facial vein as it lies on the face is described in Chapter 36 (see Fig. 33.3A). From the face, it passes over the surface of masseter, crosses the body of the mandible and enters the neck, where it runs obliquely back under platysma. Here it lies superficial to the submandibular gland, digastric and stylohyoid (see Fig. 35.13). Just anteroinferior to the mandibular angle, it is joined by the anterior division of the retromandibular vein, and then descends superficial to the loop of the lingual artery, the hypoglossal nerve and external and internal carotid arteries, to enter the internal jugular near the greater cornu of the hyoid bone, i.e. in the upper angle of the carotid triangle. Near its end, a large branch often descends along the anterior border of sternocleidomastoid to the anterior jugular vein. Its uppermost segment, above its junction with the superior labial vein, is often termed the angular vein.

Tributaries Submental, tonsillar, external palatine (paratonsillar) and submandibular veins, vena comitans of the hypoglossal nerve (sometimes), and pharyngeal and superior thyroid veins are all tributaries of the portion of the facial vein that lies below the mandible.

Lingual vein

The lingual veins follow two routes. The dorsal lingual veins drain the dorsum and sides of the tongue, join the lingual veins accompanying the

lingual artery between hyoglossus and genioglossus, and enter the internal jugular near the greater cornu of the hyoid bone. The deep lingual vein begins near the tip of the tongue and runs back, lying near the mucous membrane on the inferior surface of the tongue. Near the anterior border of hyoglossus, it joins a sublingual vein from the sublingual salivary gland to form the vena comitans nervi hypoglossi, which runs back between mylohyoid and hyoglossus with the hypoglossal nerve to join the facial, internal jugular or lingual vein (see Fig. 33.3A).

Pharyngeal veins

The pharyngeal veins begin in a pharyngeal plexus external to the pharynx. They receive meningeal veins and a vein from the pterygoid canal, and usually end in the internal jugular vein, but may sometimes end in the facial, lingual or superior thyroid vein.

Superior thyroid vein

The superior thyroid vein is formed by deep and superficial tributaries corresponding to the arterial branches in the upper part of the thyroid gland (see Figs 35.13–35.14). It accompanies the superior thyroid artery, receives the superior laryngeal and cricothyroid veins, and ends in the internal jugular or facial vein.

Middle thyroid vein

The middle thyroid vein drains the lower part of the thyroid gland and receives veins from the larynx and trachea. It crosses anterior to the common carotid artery to join the internal jugular vein behind the superior belly of omohyoid. The middle thyroid vein is encountered early in thyroid, parathyroid and pharyngeal pouch surgery and usually ligated. It is one of only two structures that lie within the paracarotid tunnel, the other being a non-recurrent laryngeal nerve.

Tympanic body

The tympanic body (glomus jugulare) is ovoid, 0.5 mm long and 0.25 mm broad, and lies in the adventitia of the upper part of the superior bulb of the internal jugular vein. It is similar in structure to the carotid body and is presumed to have a similar function. The predominant cell type has morphological similarities to adrenal chromaffin cells, being derived from the neural crest. Cells obtained from glomus jugulare paragangliomas show spontaneous neurite outgrowth in culture and have vasoactive intestinal peptide (VIP)-like activity. The tympanic body may be present as two or more parts near the tympanic branch of the glossopharyngeal nerve or the auricular branch of the vagus as they lie within their canals in the petrous part of the temporal bone. Tumours of tympanic bodies often involve the adjacent cranial nerves and present with pulsatile tinnitus and a husky voice. These tumours grow into the hypotympanum of the middle ear; intraluminal growth, both proximally and distally, is well recognized.

Subclavian vein

The subclavian vein is a continuation of the axillary vein and extends from the outer border of the first rib to the medial border of scalenus anterior, where it joins the internal jugular vein to form the brachiocephalic vein (see Fig. 35.14). The clavicle and subclavius lie anterior to it; the subclavian artery is posterosuperior, separated by scalenus anterior and the phrenic nerve; and the first rib and pleura are inferior. The vein usually has a pair of valves 2 cm from its end. Its tributaries are the external jugular, dorsal scapular and sometimes the anterior jugular vein. At its junction with the internal jugular, the left subclavian vein receives the thoracic duct, and the right subclavian vein receives the right lymphatic duct.

Vertebral vein

Numerous small tributaries from internal vertebral plexuses leave the vertebral canal above the posterior arch of the atlas and join small veins from local deep muscles in the suboccipital triangle. Their union produces a vessel that enters the foramen in the transverse process of the atlas, forms a plexus around the vertebral artery, and descends through successive transverse foramina to end as the vertebral vein. The vein emerges from the sixth cervical transverse foramen, and descends, at first anterior, then anterolateral, to the vertebral artery. It may join the deep cervical vein before it opens superoposteriorly into the brachiocephalic vein; the opening has a paired valve. As it descends, it passes behind the internal jugular vein and anterior to the first part of the subclavian artery. A small accessory vertebral vein usually descends from the vertebral plexus, traverses the seventh cervical transverse foramen and turns forwards between the subclavian artery and the cervical pleura to join the brachiocephalic vein. The vertebral artery or vein can be encountered deep in Chassaignac's triangle and care should be taken when dissecting this area.

Tributaries The vertebral vein connects with the sigmoid sinus by a vessel in the posterior condylar canal, when the latter exists. It also receives branches from the occipital vein, veins draining the prevertebral muscles, and the internal and external vertebral plexuses. It is joined by the anterior vertebral and deep cervical veins (see below), and sometimes, near its end, by the first intercostal vein.

Anterior vertebral vein

The anterior vertebral vein starts in a plexus around the upper cervical transverse processes, descends near the ascending cervical artery between the attachments of scalenus anterior and longus capitis, and opens into the end of the vertebral vein.

Deep cervical vein

The deep cervical vein accompanies its artery between semispinales capitis and cervicis. It is formed in the suboccipital region by the union of communicating branches of the occipital vein, veins draining the suboccipital muscles, and veins from plexuses around the cervical spines. It passes forwards between the seventh cervical transverse process and the neck of the first rib to end in the lower part of the vertebral vein.

Central venous access

Central venous cannulation permits monitoring of the central venous pressure and the administration of drugs directly into the central circulation.

Internal jugular vein cannulation

Lymphatic drainage

Lymph nodes in the head and neck are distributed in terminal and outlying groups (**Fig. 35.15**; see Fig. 33.5). The terminal group is related to the carotid sheath and the nodes it contains are the deep cervical lymph nodes. All lymph vessels of the head and neck drain into this group, either directly from tissues or indirectly through nodes in the outlying groups. Efferents of the deep cervical nodes form the jugular trunk. The right jugular trunk collects lymph from the right arm, right half of the thorax and the right head and neck and terminates in the jugulosubclavian junction or the right lymphatic duct. The left jugular trunk usually enters the thoracic duct, but it may join the internal jugular or subclavian vein. For further reading, see Shah and Patel (2012).

Many vessels draining the superficial cervical tissues skirt the borders of sternocleidomastoid to reach the superior or inferior deep cervical nodes. Others pass to the superficial cervical and occipital nodes. Lymph from the superior region of the anterior triangle drains to the submandibular and submental nodes. Vessels from the anterior cervical skin inferior to the hyoid bone pass to the anterior cervical lymph nodes near the anterior jugular veins. Their efferents go to the deep cervical nodes of both sides, including the infrahyoid, prelaryngeal and pretracheal groups. An anterior cervical node often occupies the suprasternal space. Lymph from tissues of the head and neck internal to the deep fascia drains to the deep cervical nodes directly or through outlying groups that include the retropharyngeal, paratracheal, lingual, infrahyoid, prelaryngeal and pretracheal groups. The lymphatic drainage associated with the nasal region, larynx and oral cavity is described in the appropriate regions. The deep cervical lymphatic nodes lie alongside the carotid sheath, and form superior and inferior groups.

Superior deep cervical nodes The superior deep cervical nodes (level II and III nodes) adjoin the upper part of the internal jugular vein. Most are deep to sternocleidomastoid but a few extend beyond it. One subgroup, consisting of one large and several small nodes, is in a triangular region bounded by the posterior belly of digastric and the facial and internal jugular veins, and is known as the jugulodigastric group. It is concerned especially with drainage of the tongue. Efferents from the upper deep cervical nodes drain to either the lower group or direct to the jugular trunk.

Inferior deep cervical nodes The inferior deep cervical nodes (level IV nodes) are partly deep to sternocleidomastoid and are particularly

The patient is placed in the supine position with the head turned slightly towards the contralateral side. The key anatomical landmarks are the two inferior heads of sternocleidomastoid, which form two sides of a triangle with the clavicle as its base. The internal jugular vein lies between the two heads of the muscle, slightly lateral and anterior to the common carotid artery. In infants and children, cannulation of the vein carries a high incidence of carotid artery puncture; the vein overlaps the artery in the neutral position and head rotation alters the anatomical relation of the two vessels (Hong et al 2010). After the skin has been prepared, local anaesthetic is injected around the apex of the triangle. With one hand palpating the carotid artery, the physician inserts a needle at the apex of the triangle and the tip is directed lateral to the midpoint of the triangle, with a downward angulation of 30°. From a high internal jugular approach, the needle is inserted at the midpoint of the medial border of sternocleidomastoid and directed towards the ipsilateral nipple with a downward angulation of 30–45°. When the left internal jugular vein is cannulated, additional care must be taken to avoid the thoracic duct and the cupula of the pleura, which is higher than on the right side, an arrangement that increases the risk of accidental pneumothorax. The left internal jugular vein is often smaller in diameter than the right (Matthers et al 1992).

Subclavian vein cannulation is performed with the patient supine, the head turned slightly to the contralateral side, and the arms placed by the side. The bed is tilted down by 10° and a small bedroll may be placed between the shoulder blades in order to ensure that the infraclavicular area is more prominent. The skin is cleaned and local anaesthetic injected into the skin 3 cm lateral to the midpoint of the clavicle. The central venous needle is then inserted from the inferior edge of the clavicle towards the suprasternal notch. The needle is directed so that it passes just below the posterior border of the clavicle; care must be taken to avoid downward direction of the needle, which can cause a pneumothorax. Gentle aspiration of the syringe is performed while the needle is being advanced until the subclavian vein is punctured. In children under the age of 3 years, the supraclavicular approach to the subclavian vein is associated with a shorter puncture time and a reduced incidence of guidewire misplacement compared with the infraclavicular approach (Byon et al 2013).

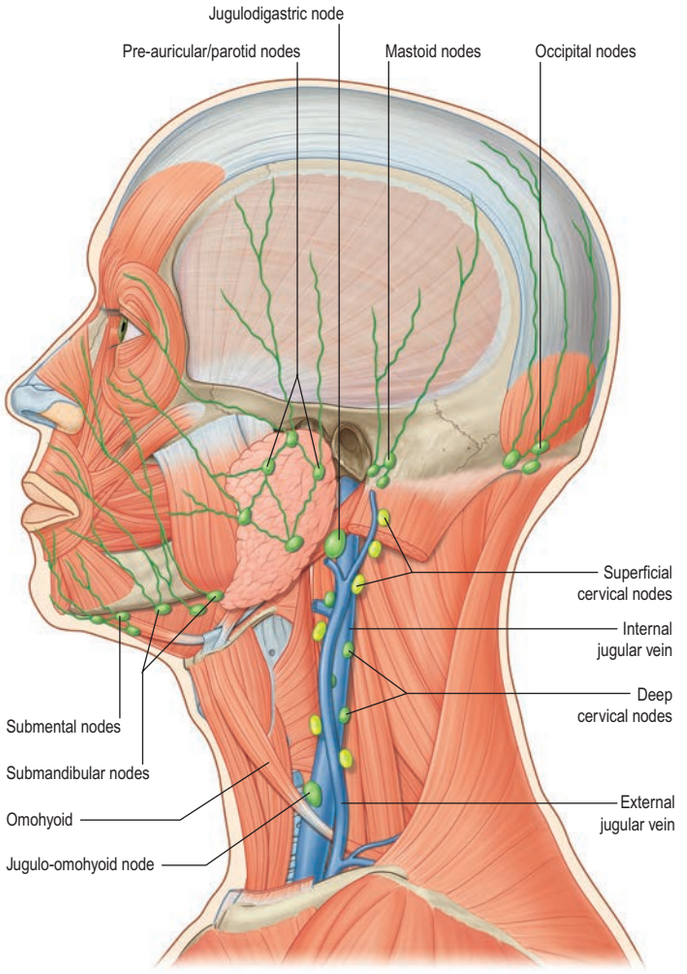

Fig. 35.15 The superficial lymphatic system in the head and neck. The nodes are organized into a superficial group around the head, superficial cervical nodes along the external jugular vein, and deep cervical nodes along the internal jugular vein. (From Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

related to the lower part of the internal jugular vein. Some are closely related to the brachial plexus and subclavian vessels. The jugulo-omohyoid node lies on, or just above, the intermediate tendon of omohyoid, and is concerned especially with lymphatic drainage from the tongue. Efferents from this lower group join the jugular lymph trunk.

Retropharyngeal nodes Retropharyngeal nodes lie between the pharyngeal and prevertebral fasciae and form a median and two lateral groups, the latter anterior to the lateral masses of the atlas along the lateral borders of longus capitis. The nodes receive afferents from the nasopharynx, pharyngotympanic tube and atlanto-occipital and atlanto-axial joints, and drain to the upper deep cervical nodes.

Paratracheal nodes The paratracheal nodes flank both trachea and oesophagus along the recurrent laryngeal nerves. Efferents pass to the corresponding deep cervical nodes.

Infrahyoid prelaryngeal and pretracheal nodes The infrahyoid, prelaryngeal and pretracheal nodes lie beneath the deep cervical fascia. They drain afferents from the anterior cervical nodes, and their efferents join the deep cervical nodes. Infrahyoid nodes are anterior to the thyrohyoid membrane, prelaryngeal nodes lie on the cricovocal membrane, and pretracheal nodes lie anterior to the trachea near the inferior thyroid veins. The paratracheal, infrahyoid, prelaryngeal and pretracheal nodes are important when considering the lymphatic spread of thyroid cancer.

Lingual nodes Lingual nodes are small and inconstant. When present, they are situated on the external surface of hyoglossus and also between the genioglossi. They drain to the upper deep cervical nodes.

Spread of malignant disease in the neck

Cancers arising in the head and neck from regions such as the thyroid gland, larynx, oral cavity and oropharynx, nasopharynx and paranasal sinuses have predictable patterns of spread through the chains of lymph nodes in the neck. It is vitally important to understand these patterns of spread so that the appropriate operation is undertaken for each patient. Clinical experience has shown that the lymph nodes in the neck fall into five distinct groups (see Fig. 33.5, Fig. 35.15). Level I nodes lie in the submandibular triangle bounded by the anterior and posterior bellies of digastric and the lower border of the mandible above. Level I is further divided into level IA (submental triangle) and level IB (submandibular triangle). Level II (upper jugular) nodes lie around the upper portion of the internal jugular vein and the upper part of the accessory nerve. They extend from the skull base to the bifurcation of the common carotid artery or the hyoid bone. Level III (middle jugular) nodes lie around the middle third of the internal jugular vein from the inferior border of level II to the superior belly of omohyoid or the cricothyroid membrane. Level IV (lower jugular) nodes lie around the lower third of the internal jugular vein from the inferior border of level III to the clavicle. The anterior and posterior borders for levels II, III and IV are the lateral border of sternohyoid and the posterior border of sternocleidomastoid, respectively. In other words, deep to sternocleidomastoid in between the anterior and posterior triangles of the neck. Level V (posterior triangle) nodes lie mostly around the lower part of the accessory nerve and the transverse cervical vessels. The accessory nerve divides level V into V_a above and V_b below.

Knowing which levels of nodes are likely to be involved in metastatic spread of a cancer arising in the head and neck helps select the appropriate nodal clearance at surgery. The classic radical neck dissection first described by Crile in 1906 involved a thorough clearance of levels I–V, including the sacrifice of sternocleidomastoid, the internal jugular vein and the accessory nerve. Modified radical neck dissections (functional neck dissections) remove level I–V nodes but spare either or all of sternocleidomastoid, the internal jugular vein and the accessory nerve. Selective neck dissections remove selected groups of nodes, e.g. the supra-omohyoid neck dissection removes level I–III nodes, the lateral neck dissection removes level II–IV nodes, and the posterolateral neck dissection removes level II–V nodes.

Cervical lymphovenous portals

Lymph is returned to the systemic venous circulation via right and left lymphovenous portals that are sited at, or near, the junctions of the internal jugular and subclavian veins (**Fig. 35.16**). The arrangement of these terminations is variable. Usually, three small lymph trunks converge towards their venous junctions on either side of the body: they are joined on the left side by the larger thoracic duct.

On the right side, the three lymph trunks are the right jugular, right subclavian and right bronchomediastinal trunk. The right jugular trunk extends from the terminal lower deep cervical nodes along the ventrolateral aspect of the internal jugular vein and conveys all the lymph from the right half of the head and neck. The right subclavian trunk drains from the terminal apical axillary group. It extends along the axillary and subclavian veins and conveys lymph from the right upper limb and superficial tissues of the right half of the thoraco-abdominal wall, down to the umbilicus anteriorly and iliac crest posteriorly (and includes much of the breast). The right bronchomediastinal trunk ascends over the trachea towards the lymphovenous portal and conveys lymph from the thoracic walls, the right cupula of the diaphragm and subjacent liver, the right lung, bronchi and trachea, the greater part of the 'right heart' (of clinical parlance, not the geometric right half) and a proportionately small drainage from the thoracic oesophagus.

The three right lymphatic trunks usually open independently (**Fig. 35.16B**). Their orifices are clustered either on the ventral aspect of the jugulo/subclavian junction, or in the nearby wall of either of the great veins. Sometimes, one or more of the trunks may bifurcate (or even trifurcate) preterminally and then terminate via multiple orifices. Rarely, the three trunks fuse to form a short, single, right lymphatic duct (about 1 cm long) that inclines across the medial border of scalenus anterior at the root of the neck to reach the ventral aspect of the venous junction, where its orifice is guarded by a bicuspid semilunar valve. An incomplete right lymphatic duct may be present if the subclavian and jugular trunks, or any combination of their terminals, are fused. When this occurs, the bronchomediastinal trunk almost invariably opens separately.

On the left, the four trunks that converge on the left lymphovenous portal are the left jugular and left subclavian trunks, which have a disposition corresponding to that of their counterparts on the right; the left bronchomediastinal trunk, which has a drainage similar to that of the right trunk but which drains more of the heart (the 'left' and part of the

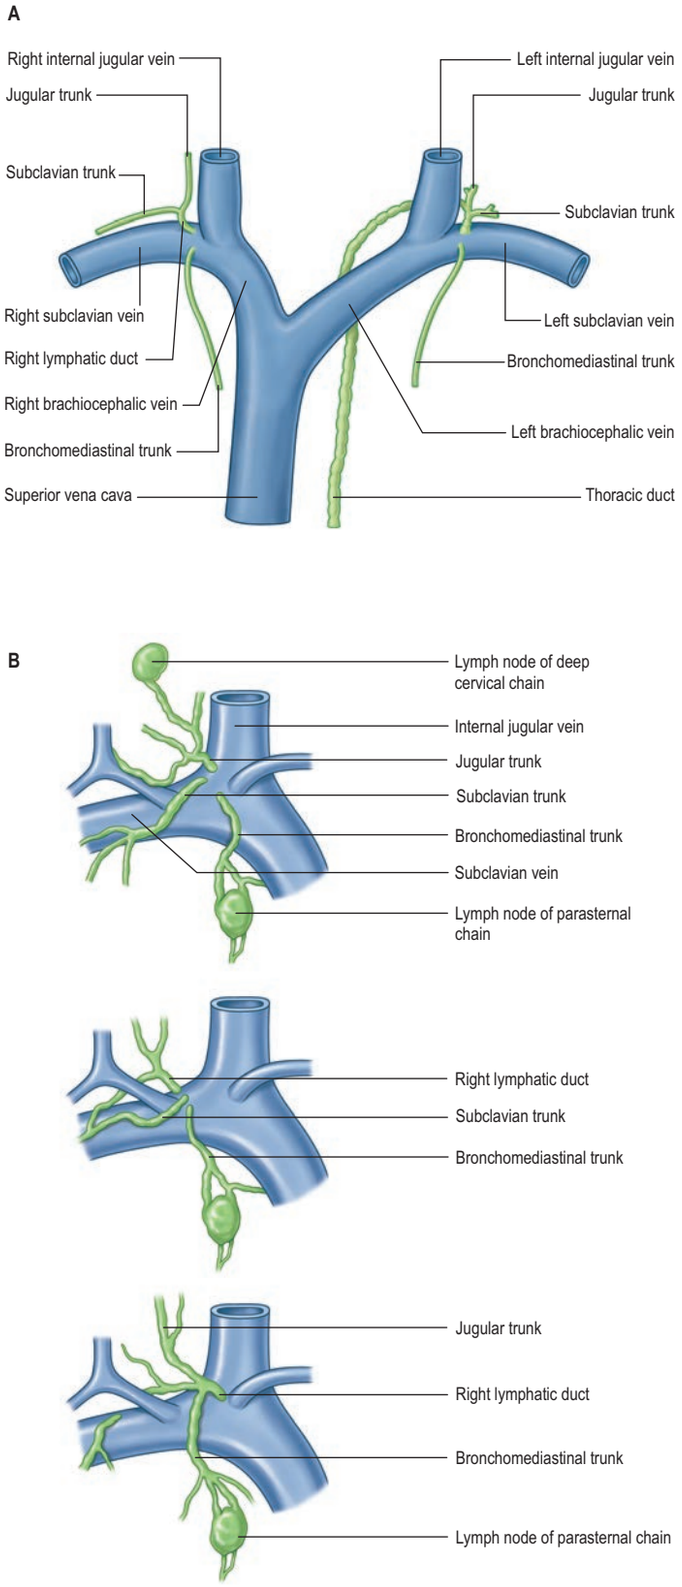

Fig. 35.16 **A**, The termination of the right lymphatic trunk and the thoracic duct. **B**, Variations in the terminal lymphatic trunk nodes of the right side. 'right' hearts of clinical parlance) and more of the oesophagus; and the thoracic duct, which drains all of the rest of the body (Fig. 35.16A).

INNERVATION

The skin, joints, viscera and muscles of the neck are innervated by branches of the glossopharyngeal, vagus and accessory nerves, the cervical spinal nerves and the cervical sympathetic trunk.

The first and second cervical dorsal root ganglia lie on the vertebral arches of the atlas and axis respectively. The first cervical ganglion may be absent. Smaller aberrant ganglia sometimes occur on the upper cervical dorsal roots between the ganglia and cord. The upper four cervical roots are small, and the lower four are large. In general, cervical dorsal roots have a thickness ratio to the ventral roots of 3 : 1, which is greater than is seen in other regions. The first dorsal root is an exception, being smaller than the ventral; occasionally, it is absent. The first and second cervical roots are short and run almost horizontally to their exit from the vertebral canal. From the third to the eighth cervical, they slope obliquely down. Obliquity and length increase successively; however, the distance between spinal attachment and vertebral exit never exceeds the height of one vertebra. For details of the neural anastomoses between the upper cervical nerves and branches of the facial, vagus, hypoglossal and accessory nerves, see Shoja et al (2014).

Cervical ventral rami

Cervical ventral rami, except the first, appear between the anterior and posterior intertransverse muscles. The upper four form the cervical plexus, and the lower four, together with most of the first thoracic ventral ramus, form the brachial plexus. Each receives at least one grey ramus communicans, the upper four from the superior cervical sympathetic ganglion, the fifth and sixth from the middle ganglion, and the seventh and eighth from the cervicothoracic ganglion.

The first cervical ventral ramus, the suboccipital nerve, emerges above the posterior arch of the atlas, and passes forwards lateral to its lateral mass and medial to the vertebral artery. It supplies rectus capitis lateralis, emerges medial to it, descends anterior to the transverse process of the atlas and posterior to the internal jugular vein, and joins the ascending branch of the second cervical ventral ramus.

The second cervical ventral ramus issues between the vertebral arches of the atlas and axis. It ascends between their transverse processes, passes anterior to the first posterior intertransverse muscle and emerges lateral to the vertebral artery, generally between longus capitis and levator scapulae. The ramus divides into an ascending branch, which joins the first cervical nerve, and a descending branch, which joins the ascending branch of the third cervical ventral ramus.

The third cervical ventral ramus appears between longus capitis and scalenus medius. The remaining ventral rami emerge between scalenus anterior and the scalenus medius.

Cervical plexus

The cervical plexus is formed by the ventral rami of the upper four cervical nerves, and supplies some neck muscles and the diaphragm, and areas of skin on the head, neck and chest (see Figs 26.6, 35.1). It is situated in the neck opposite a line drawn down the side of the neck from the root of the auricle to the level of the upper border of the thyroid cartilage. It lies deep to the internal jugular vein, the deep fascia and sternocleidomastoid, and anterior to scalenus medius and levator scapulae. Each ramus, except the first, divides into ascending and descending parts, which unite in communicating loops. From the first loop (C2 and 3), superficial branches supply the head and neck; cutaneous nerves of the shoulder and chest arise from the second loop (C3 and 4). Muscular and communicating branches arise from the same nerves. The branches are superficial or deep. The superficial branches perforate the cervical fascia to supply the skin, while the deep branches in general supply muscles. The superficial branches either ascend (the lesser occipital, great auricular and the transverse cutaneous nerves) or descend (supraclavicular nerves). These nerves are described in detail in this chapter on p. 573. The deep branches form medial and lateral series.

Deep branches – medial series

Communicating branches Communicating branches pass from the loop between the first and second cervical rami to the vagus and hypoglossal nerves and to the sympathetic trunk. The hypoglossal branch later leaves the hypoglossal nerve as a series of branches, namely: the meningeal, superior root of ansa cervicalis, nerves to thyrohyoid and to geniohyoid. A branch also connects the fourth and fifth cervical rami. The first four cervical ventral rami each receive a grey ramus communicans from the superior cervical sympathetic ganglion.

The superior root of the ansa cervicalis (descendens hypoglossi) (see Figs 35.7A, 35.8) leaves the hypoglossal nerve where it curves round the occipital artery and then descends anterior to or in the carotid sheath. It contains only fibres from the first cervical spinal nerve. After giving a branch to the superior belly of omohyoid, it is joined by the inferior root of the ansa from the

second and third cervical spinal nerves. The two roots form the ansa cervicalis (ansa hypoglossi), from which branches supply sternohyoid, sternothyroid and the inferior belly of omohyoid. Another branch is said to descend anterior to the vessels into the thorax to join the cardiac and phrenic nerves.

Muscular branches Muscular branches supply rectus capitis lateralis (C1), rectus capitis anterior (C1, 2), longus capitis (C1–3) and longus colli (C2–4). The inferior root of the ansa cervicalis and the phrenic nerve are additional muscular branches.

The inferior root of the ansa cervicalis (nervus descendens cervicalis) (see Figs 35.7A, 35.8) is formed by the union of a branch from the second with another from the third cervical ramus. It descends on the lateral side of the internal jugular vein, crosses it a little below the middle of the neck, and continues forwards to join the superior root anterior to the common carotid artery, forming the ansa cervicalis (ansa hypoglossi), from which all infrahyoid muscles except thyrohyoid are supplied. The inferior root almost always comes from the second and third cervical ventral rami, but sometimes from the second to fourth, and occasionally from the third alone. Occasionally, too, it may be derived either from the second alone or from the first to third.

Phrenic nerve The phrenic nerve arises chiefly from the fourth cervical ventral ramus but also has contributions from the third and fifth. It is formed at the upper part of the lateral border of scalenus anterior and descends almost vertically across its anterior surface behind the prevertebral fascia (see Fig 35.7A; **Figs 35.17–35.18**). It descends posterior to sternocleidomastoid, the inferior belly of omohyoid (near its intermediate tendon), the internal jugular vein, transverse cervical and suprascapular arteries and, on the left, the thoracic duct. At the root of the neck, it runs anterior to the second part of the subclavian artery, from which it is separated by scalenus anterior (some accounts state that on the left side the nerve passes anterior to the first part of the subclavian artery), and posterior to the subclavian vein. The phrenic nerve crosses serratus anterior from lateral to medial (lying under the prevertebral fascia) and enters the thorax by crossing medially anterior to the internal thoracic artery.

In the neck, each nerve receives variable filaments from the cervical sympathetic ganglia or their branches and may also connect with internal thoracic sympathetic plexuses.

Accessory phrenic nerve The accessory phrenic nerve is composed of fibres from the fifth cervical ventral ramus that run in a branch of the nerve to subclavius. This lies lateral to the phrenic nerve and descends posterior (occasionally anterior) to the subclavian vein. The accessory phrenic nerve usually joins the phrenic nerve near the first rib but may not do so until near the pulmonary hilum or beyond. The accessory phrenic nerve may be derived from the fourth or sixth cervical ventral rami or from the ansa cervicalis.

Deep branches – lateral series

Communicating branches Lateral deep branches of the cervical plexus (C2, 3, 4) may connect with the accessory nerve within sternocleidomastoid, the posterior triangle or beneath trapezius.

Muscular branches Muscular branches are distributed to sternocleidomastoid (C2, 3, 4), trapezius (C2 and possibly C3), levator scapulae (C3, 4) and scalenus medius (C3, 4). Branches to trapezius cross the posterior triangle obliquely below the accessory nerve.

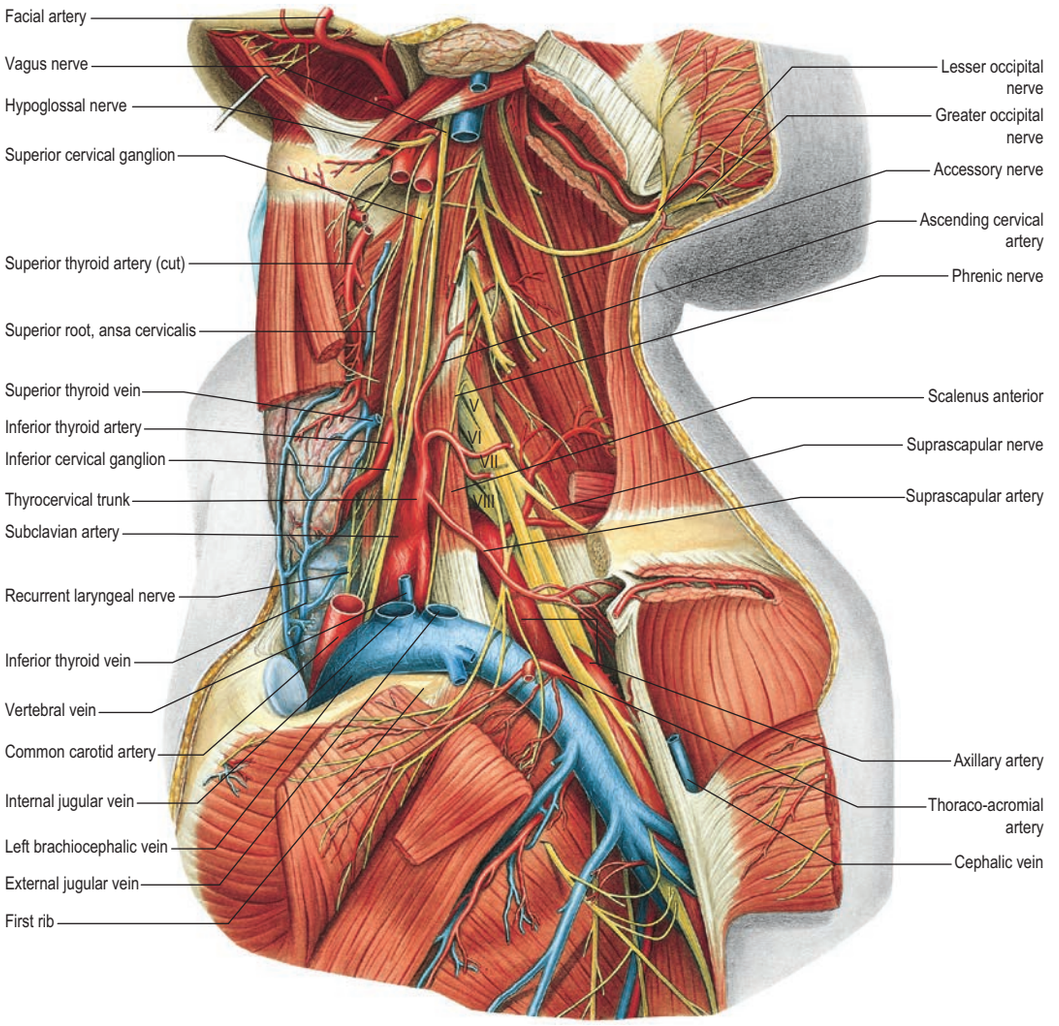

Fig. 35.17 Vessels and nerves of the neck, left lateral view. The left sternocleidomastoid, the greater part of the infrahyoid group of muscles and numerous vessels have been removed in order to expose deeper structures. Compare with Fig. 35.7A, which shows a more superficial level of dissection. The letters V, VI, VII, VIII refer to the anterior primary rami of C5, C6, C7 and C8, respectively. CHAPTER 35

Brachial plexus

The brachial plexus is formed by the union of the ventral rami of the lower four cervical nerves and the greater part of the ventral ramus of the first thoracic spinal nerve. It may also receive contributions from the fourth cervical and second thoracic spinal nerves. As its name suggests, its branches supply the muscles, joints and skin of the upper limb. The relations and distribution of the nerves derived from the brachial plexus are described in detail in the appropriate chapters in Section 6. However, it is also mentioned here because, at its origin, the brachial plexus lies in the posterior triangle of the neck, in the angle between the clavicle and the lower posterior border of sternocleidomastoid. It emerges between the scaleni anterior and medius, superior to the third part of the subclavian artery, and is covered by platysma, deep fascia and skin, through which it is palpable (see Fig. 35.17). It is crossed by the supraclavicular nerves, the nerve to subclavius, the inferior belly of omohyoid, the external jugular vein and the superficial ramus of the transverse cervical artery. The plexus passes posterior to the medial two-thirds of the clavicle, subclavius and the suprascapular vessels, and lies on the first digitation of serratus anterior and on subscapularis.

Cervical dorsal rami

Each cervical spinal dorsal ramus except the first divides into medial and lateral branches, and all innervate muscles. In general, only medial branches of the second to fourth, and usually the fifth, supply skin. Except for the first (sometimes called the suboccipital nerve) and second, each dorsal ramus passes back medial to a posterior intertransverse muscle, curving round the articular process into the interval between semispinalis capitis and semispinalis cervicis. The cervical dorsal rami are described in detail in Chapter 47.

Cranial nerves

Glossopharyngeal nerve

The glossopharyngeal nerve (see Figs 35.8, 35.11; **Fig. 35.19**) supplies motor fibres to stylopharyngeus, parasympathetic secretomotor fibres to the parotid gland (derived from the inferior salivatory nucleus), sensory fibres to the tympanic cavity, pharyngotympanic tube, fauces, tonsils, nasopharynx, uvula and posterior (postsulcal) third of the tongue, and gustatory fibres from the circumvallate papillae.

The nerve leaves the skull through the anteromedial part of the jugular foramen, anterior to the vagus and accessory nerves, and in a separate dural sheath. In the foramen, it is lodged in a deep groove leading from the cochlear aqueductal depression and is separated by the inferior

(Adapted with permission from Shoja M, Oyesiku NM, Shokouhi G et al 2014 Anastomoses between lower cranial and upper cervical nerves: a comprehensive review with potential significance during skull base and neck operations, part II: glossopharyngeal, vagus, accessory, and hypoglossal nerves and cervical spinal nerves 1–4. Clin Anat 27:118–30.)

petrosal sinus from the vagus and accessory nerves. The groove is bridged by fibrous tissue, which is sometimes calcified. After leaving the foramen, the nerve passes forwards between the internal jugular vein and internal carotid artery, and then descends anterior to the latter, deep to the styloid process and its attached muscles, to reach the posterior border of stylopharyngeus. It curves forwards on stylopharyngeus and either pierces the lower fibres of the superior pharyngeal constrictor or passes between it and the middle constrictor to be distributed to the tonsil, the mucosae of the pharynx and postsulcal part of the tongue, the vallate papillae and oral mucous glands.

Two ganglia, superior and inferior, are situated on the glossopharyngeal nerve as it traverses the jugular foramen. The superior ganglion is in the upper part of the groove occupied by the nerve in the jugular foramen. It is small, has no branches and is usually regarded as a detached part of the inferior ganglion. The inferior ganglion is larger and lies in a notch in the lower border of the petrous part of the temporal bone. Its cells are typical unipolar neurones, whose peripheral branches convey gustatory and tactile signals from the mucosa of the tongue (posterior third, including the sulcus terminalis and vallate papillae) and general sensation from the oropharynx, where it is responsible for initiating the gag reflex.

Communicating branches

The glossopharyngeal nerve communicates with the sympathetic trunk and vagus and facial nerves. Its inferior ganglion is connected with the superior cervical sympathetic ganglion. Two filaments from the inferior ganglion pass to the vagus, one to its auricular branch and the other to its superior ganglion. A branch to the facial nerve arises from the glossopharyngeal nerve below the inferior ganglion and perforates the posterior belly of digastric to join the facial nerve near the stylomastoid foramen.

Branches of distribution

The glossopharyngeal nerve has tympanic, carotid, pharyngeal, muscular, tonsillar and lingual branches.

Tympanic nerve The tympanic nerve leaves the inferior ganglion, ascends to the tympanic cavity through the tympanic canaliculus and divides into branches that contribute to the tympanic plexus on the promontory. The lesser petrosal nerve is derived from the tympanic plexus.

Carotid branch The carotid branch is often double. It arises just below the jugular foramen and descends on the internal carotid artery to the wall of the carotid sinus and to the carotid body. The nerve contains primary afferent fibres from chemoreceptors in the carotid body and from the baroreceptors lying in the carotid sinus wall. It may communicate with the inferior ganglion of the vagus, or with one of its branches, and with a sympathetic branch from the superior cervical ganglion (Fig. 35.20).

Pharyngeal branches The pharyngeal branches are three or four filaments that unite with the pharyngeal branch of the vagus and the laryngopharyngeal branches of the sympathetic trunk to form the pharyngeal plexus near the middle pharyngeal constrictor. They constitute the route by which the glossopharyngeal nerve supplies sensory fibres to the mucosa of the pharynx.

Muscular branch The muscular branch supplies stylopharyngeus.

Tonsillar, lingual and lesser petrosal branches The tonsillar, lingual and lesser petrosal branches are described on pages 708–709, 644 and 749, respectively. There are anastomoses between the glossopharyngeal, vagus, greater auricular and other branches of the cervical plexus that may be significant when treating patients with skull base pathology (Shoja et al 2014.)

Lesions of the glossopharyngeal nerve

Damage to the glossopharyngeal nerve is rarely seen without associated involvement of other lower cranial nerves. Transient or sustained hypertension may follow surgical section of the nerve and indicates involvement of the carotid branch. Isolated lesions of the glossopharyngeal nerve lead to loss of sensation over the ipsilateral soft palate, fauces, pharynx and posterior third of the tongue, although this is difficult to assess clinically, and confirmation requires galvanic stimulation. The palatal and pharyngeal (gag) reflexes are reduced or absent and salivary secretion from the parotid gland may also be reduced. Weakness of stylopharyngeus cannot be tested individually. Glossopharyngeal neuralgia consists of episodic brief but severe pain, often precipitated by swallowing and experienced in the throat, behind the angle of the jaw and within the ear. Superior jugular bulb thromboses (e.g. in otitis media) and jugular foramen syndrome (associated with nasopharyngeal carcinoma or a jugular paraganglioma) may cause lesions of the adjacent glossopharyngeal, vagus and accessory nerves, with associated weakness in the muscles supplied in the pharynx and larynx.

Vagus nerve

The vagus is a large mixed nerve. It has a more extensive course and distribution than any other cranial nerve and runs through the neck, thorax and abdomen. Its central connections are described in Chapter 28.

The vagus exits the skull through the jugular foramen, accompanied by the accessory nerve, with which it shares an arachnoid and a dural sheath. Both nerves lie anterior to a fibrous septum that separates them from the glossopharyngeal nerve. The vagus descends vertically in the neck in the carotid sheath, between the internal jugular vein and the internal carotid artery, to the upper border of the thyroid cartilage, and then passes between the vein and the common carotid artery to the root of the neck. Its relationships in this part of its course are therefore similar to those described for these structures (see Figs 35.7A, 35.8, 35.17). Its further course differs on the two sides. The right vagus descends posterior to the internal jugular vein to cross the first part of the subclavian artery and enter the thorax. The left vagus enters the thorax between the left common carotid and subclavian arteries, and behind the left brachiocephalic vein.

After emerging from the jugular foramen, the vagus bears two marked enlargements: a small, round, superior (jugular) ganglion and a larger inferior (nodose) ganglion.

Superior (jugular) ganglion

The superior ganglion is greyish, spherical and approximately 4 mm in diameter. It is connected to the inferior glossopharyngeal ganglion and the sympathetic trunk, the latter by a filament from the superior cervical ganglion.

Inferior (nodose) ganglion

The inferior or nodose ganglion is larger than the superior ganglion, and is elongated and cylindrical in shape with a length of 25 mm and a maximum breadth of 5 mm. It is connected with the hypoglossal nerve, the loop between the first and second cervical spinal nerves, and with the superior cervical sympathetic ganglion. Most visceral afferent fibres have their cell bodies in the nodose ganglion.

Both vagal ganglia are exclusively sensory and contain somatic, special visceral and general visceral afferent neurones. The superior ganglion is chiefly somatic and most of its neurones enter the auricular nerve, whilst neurones in the inferior ganglion are concerned with visceral sensation from the heart, larynx, lungs and the alimentary tract from the pharynx to the transverse colon. Some fibres transmit impulses from taste endings in the vallecula and epiglottis. Large afferent fibres are derived from muscle spindles in the laryngeal muscles. Vagal sensory neurones in the nodose ganglion may show some somatotopic organization. Both ganglia are traversed by parasympathetic and perhaps some sympathetic fibres, but there is no evidence that vagal parasympathetic components relay in the inferior ganglion. Preganglionic motor fibres from the dorsal vagal nucleus and the special visceral efferents from the nucleus ambiguus, which descend to the inferior vagal ganglion, commonly form a visible band, skirting the ganglion in some mammals. These larger fibres probably provide motor innervation to the larynx in the recurrent laryngeal nerve, together with some contribution to the superior laryngeal nerve supplying cricothyroid.

Branches in the neck

The branches of the vagus in the neck are the meningeal, auricular, pharyngeal, carotid body, superior and recurrent laryngeal nerves and cardiac branches.

Meningeal branches Meningeal branches appear to start from the superior vagal ganglion and pass through the jugular foramen to be distributed to the dura mater in the posterior cranial fossa (see Fig. 25.2B).

Auricular branch The auricular branch (Arnold's nerve) arises from the superior vagal ganglion and is joined by a branch from the inferior ganglion of the glossopharyngeal nerve. It passes behind the internal jugular vein and enters the mastoid canaliculus on the lateral wall of the jugular fossa. Traversing the temporal bone, it crosses the facial canal approximately 4 mm above the stylomastoid foramen and here supplies an ascending branch to the facial nerve. Fibres of the nervus intermedius may pass to the auricular branch at this point, which may explain the cutaneous vesiculation in the auricle that sometimes accompanies

geniculate herpes. The auricular branch then traverses the tympanomastoid fissure and divides into two rami. One ramus joins the posterior auricular nerve and the other is distributed to the skin of part of the ear and to the external acoustic meatus.

Pharyngeal branch

The pharyngeal branch of the vagus is the main motor nerve of the pharynx (Ch. 40, Pharyngeal plexus). It emerges from the upper part of the inferior vagal ganglion, passes between the external and internal carotid arteries to the upper border of the middle pharyngeal constrictor, and divides into numerous filaments that join rami of the sympathetic trunk and glossopharyngeal nerve to form a pharyngeal plexus. A minute filament, the ramus lingualis vagi, joins the hypoglossal nerve as it curves round the occipital artery.

Branches to the carotid body Branches to the carotid body are variable in number. They may arise from the inferior ganglion or travel in the pharyngeal branch, and sometimes in the superior laryngeal nerve. They form a plexus with the glossopharyngeal rami and branches of the cervical sympathetic trunk.

Superior laryngeal nerve The superior laryngeal nerve is larger than the pharyngeal branch and issues from the middle of the inferior vagal ganglion. It receives a branch from the superior cervical sympathetic ganglion and descends alongside the pharynx, at first posterior, then medial, to the internal carotid artery, and divides into the internal and external laryngeal nerves (see Figs 35.8, 41.12).

The internal laryngeal nerve is sensory to the laryngeal mucosa down to the level of the vocal folds. It also carries afferent fibres from the laryngeal neuromuscular spindles and other stretch receptors. It descends to the thyrohyoid membrane, pierces it above the superior laryngeal artery and divides into an upper and lower branch. The upper branch is horizontal and supplies the mucosa of the pharynx, the epiglottis, vallecula and laryngeal vestibule. The lower branch descends in the medial wall of the piriform recess, supplies the aryepiglottic fold, the mucosa on the back of the arytenoid cartilage and one or two branches to transverse arytenoid (the latter unite with twigs from the recurrent laryngeal to supply the same muscle). The internal laryngeal nerve ends by piercing the inferior pharyngeal constrictor to unite with an ascending branch from the recurrent laryngeal nerve. As it ascends in the neck, it supplies branches, more numerous on the left, to the mucosa and tunica muscularis of the oesophagus and trachea, and to the inferior constrictor.

The external laryngeal nerve, smaller than the internal, descends behind sternohyoid with the superior thyroid artery, but on a deeper plane. It lies first on the inferior pharyngeal constrictor, and then pierces it to curve round the inferior thyroid tubercle and reach cricothyroid, which it supplies: this branch can be damaged when ligating the superior thyroid artery in thyroid surgery. The nerve also gives branches to the pharyngeal plexus and the inferior constrictor. Behind the common carotid artery, the external laryngeal nerve communicates with the superior cardiac nerve and superior cervical sympathetic ganglion.

Recurrent laryngeal nerve The recurrent laryngeal nerve differs, in origin and course, on the two sides. On the right, it arises from the vagus anterior to the first part of the subclavian artery, and curves backwards below and then behind it to ascend obliquely to the side of the trachea behind the common carotid artery. Near the lower pole of the lateral lobe of the thyroid gland, it is closely related to the inferior thyroid artery and crosses either in front of, behind or between its branches. On the left, the nerve arises from the vagus on the left of the aortic arch, curves below it immediately behind the attachment of the ligamentum arteriosum to the concavity of the aortic arch and ascends to the side of the trachea (see Fig. 35.14). As the recurrent laryngeal nerve curves round the subclavian artery, or the aortic arch, it gives cardiac filaments to the deep cardiac plexus. On both sides, the recurrent laryngeal nerve ascends in or near a groove between the trachea and oesophagus. It is closely related to the medial surface of the thyroid gland before it passes under the lower border of the inferior constrictor, and it enters the larynx behind the articulation of the inferior thyroid cornu with the cricoid cartilage. The recurrent laryngeal nerve supplies all laryngeal muscles, except the cricothyroid, and it communicates with the internal laryngeal nerve, supplying sensory filaments to the laryngeal mucosa below the vocal folds. It also carries afferent fibres from laryngeal stretch receptors. The recurrent laryngeal nerve is described further in Chapter 41 (see Figs 41.11, 41.12). Knowledge of the above anatomy is crucial to understanding of both Beahr's triangle (see later) and the principles of thyroid surgery.

Accessory nerve

The accessory nerve (see Figs 35.7A, 35.11, 35.17) arises from an elongated nucleus of motor neurones in the lateral aspect of the ventral horn. Some rootlets emerge directly, while others turn cranially before exiting; their line of exit is irregular rather than linear. They join to form a trunk, the accessory nerve, which ascends intradurally within the vertebral canal between the ligamentum denticulatum and the dorsal roots of the spinal nerves. The nerve enters the skull via the foramen magnum, behind the vertebral artery. It then turns upwards and passes laterally to reach the jugular foramen, which it traverses in a common dural sheath with the vagus, but separated from that nerve by a fold of arachnoid mater.

As the accessory nerve exits the jugular foramen, it runs posterolaterally and passes either medial or lateral to the internal jugular vein; occasionally, it may pass through the vein. The extradural part of the nerve then crosses the transverse process of the atlas and is crossed by the occipital artery before descending obliquely, medial to the styloid process, stylohyoid and the posterior belly of digastric. Running with the superior sternocleidomastoid branch of the occipital artery, it reaches the upper part of sternocleidomastoid and enters its deep surface, to form an anastomosis with fibres from C2 alone, C3 alone, or C2 and C3 (the ansa of Maubrac). It may also communicate with the anterior root of the first cervical nerve (McKenzie branch).

The accessory nerve occasionally terminates in sternocleidomastoid. More commonly, it emerges a little above the midpoint of the posterior border of sternocleidomastoid, generally above the emergence of the great auricular nerve (usually within 2 cm of it) and between 4 and 6 cm from the tip of the mastoid process. However, the point of emergence is very variable. The nerve then crosses the posterior triangle on levator scapulae (see Fig. 35.7A), separated from it by the prevertebral layer of deep cervical fascia and adipose tissue. Here the nerve is relatively superficial within the roof of the posterior triangle and is related to superficial cervical lymph nodes in levels Va and Vb. Some 3–5 cm above the clavicle, it passes behind the anterior border of trapezius, often dividing to form a plexus on its deep surface, which receives contributions from C2–4 (see below), and then enters the deep surface of the muscle.

The cervical course of the accessory nerve follows a line from the lower anterior part of the tragus to the tip of the transverse process of the atlas, and then across sternocleidomastoid and the posterior triangle to a point on the anterior border of trapezius 3–5 cm above the clavicle.

The accessory nerve is thought to provide the sole motor supply to sternocleidomastoid; the second and third cervical nerves are believed to carry proprioceptive fibres from it. The supranuclear pathway of fibres destined for sternocleidomastoid is not simple; current evidence favours bilateral hemispheric innervation, although opinion varies as to the extent of the ipsilateral input. The motor supply to the descending (upper) and transverse (middle) portions of trapezius is primarily from the accessory nerve under predominantly contralateral supranuclear control. Usually, trapezius receives an innervation from the cervical plexus, in most cases from C3 and C4 (Tubbs et al 2011). A study using intraoperative electroneurography and histochemical analyses found that, when present, the cervical fibres did not consistently innervate all three parts of the muscle (descending, transverse and ascending), and that fibres from C2 usually travelled via the accessory nerve, while fibres from C3 and C4 innervated trapezius independently (Pu et al 2008). In addition to their motor contribution, C3 and C4 also carry proprioceptive fibres from trapezius.

On the basis of the incomplete denervation of the muscle that sometimes happens following sacrifice of both the accessory nerve and the cervical plexus, it has been suggested that trapezius receives a partial motor supply from other sources, possibly via thoracic roots. (For a detailed review of the applied surgical anatomy of the accessory nerve plexus, see Brown (2002).)

Sensory ganglia have been described along the course of the intradural portion of the nerve.

Lesions of the accessory nerve

Lesions of the accessory nerve may be sustained centrally, at its exit from the skull or in the neck. The supranuclear fibres that influence motor neurones innervating sternocleidomastoid decussate twice; a lesion of the corticospinal system above the pons therefore produces weakness of the ipsilateral sternocleidomastoid and contralateral trapezius. Episodic contraction of sternocleidomastoid and trapezius, often accompanied by contraction of other muscle groups, e.g. splenius capitis, occurs in spasmodic torticollis, a focal dystonia. In jugular foramen syndrome, caused by pathologies including nasopharyngeal carcinoma or a jugular paraganglioma, lesions of the glossopharyngeal, vagus and accessory nerves coexist. The accessory nerve can be injured more distally in the neck by trauma or by surgical exploration in the posterior triangle. If

the accessory nerve is sacrificed as part of a radical or modified neck dissection and if the innervation of trapezius is lost, the patient can develop intractable shoulder pain and dysfunction.

Hypoglossal nerve

The hypoglossal nerve is motor to all the muscles of the tongue except palatoglossus. The hypoglossal rootlets run laterally behind the vertebral artery, collected into two bundles that perforate the dura mater separately opposite the hypoglossal canal in the occipital bone, and unite after traversing it. The canal is sometimes divided by a spicule of bone. The nerve emerges from the canal in a plane medial to the internal jugular vein, internal carotid artery and ninth, tenth and eleventh cranial nerves, and passes inferolaterally behind the internal carotid artery and glossopharyngeal and vagus nerves to the interval between the artery and the internal jugular vein (see Fig. 35.8). Here, it makes a half-spiral turn round the inferior vagal ganglion and is united with it by connective tissue. It then descends almost vertically between the vessels and anterior to the vagus to a point level with the angle of the mandible, becoming superficial below the posterior belly of digastric and emerging between the internal jugular vein and internal carotid artery. Often associated with a plexus of veins around the junction of the common facial and internal jugular veins (vena comitans nervi hypoglossi), excessive bleeding here during neck dissection can lead to nerve damage. The nerve loops round the inferior sternocleidomastoid branch of the occipital artery, crosses lateral to both internal and external carotid arteries and the loop of the lingual artery a little above the tip of the greater cornu of the hyoid, and is itself crossed by the facial vein (see Figs 35.7A, 35.8, 35.17). Its course is described further in Chapter 37.

Communicating branches

The hypoglossal nerve communicates with the sympathetic trunk, the lingual, glossopharyngeal and vagus nerves and the pharyngeal plexus. Near the atlas, it is joined by branches from the superior cervical sympathetic ganglion and a filament from the loop between the first cervical ventral ramus and the ascending branch of the second cervical ventral ramus that leaves the hypoglossal nerve as the upper root of the ansa cervicalis. The vagal connections are close to the skull, and numerous filaments pass between the hypoglossal nerve and the inferior vagal ganglion in the connective tissue that unites them. As the hypoglossal nerve curves round the occipital artery, it receives the ramus lingualis vagi from the pharyngeal plexus. Near the anterior border of hyoglossus, it is connected with the lingual nerve by many filaments that ascend on the muscle.

Branches of distribution

The branches of distribution of the hypoglossal nerve are meningeal, descending, thyrohyoid and muscular nerves.

Meningeal branches Meningeal branches leave the nerve in the hypoglossal canal and return through it to supply the diploë of the occipital bone, the dural walls of the occipital and inferior petrosal sinuses, and much of the floor of the anterior wall of the posterior cranial fossa, probably through pathways other than that of the hypoglossal nerve, e.g. upper cervical spinal nerves (see Fig. 25.3).

Descending branch The descending branch (descendens hypoglossi) contains fibres from the first cervical spinal nerve. It leaves the hypoglossal nerve when it curves around the occipital artery, and runs down on the carotid sheath. It provides a branch to the superior belly of omohyoid before joining the descendens cervicalis to form the ansa cervicalis (see Figs 35.7A, 35.8).

Nerves to thyrohyoid and geniohyoid The nerves to thyrohyoid and geniohyoid arise near the posterior border of hyoglossus and are derived from the first cervical ventral ramus.

Lesions of the hypoglossal nerve

The hypoglossal nerve may be damaged during neck dissection. Complete hypoglossal division causes unilateral lingual paralysis and eventual hemiatrophy; the protruded tongue deviates to the paralysed side, and, on retraction, the wasted and paralysed side rises higher than the unaffected side. The larynx may deviate towards the active side in swallowing, as a consequence of the unilateral paralysis of the hyoid depressors associated with loss of the first cervical ventral ramus, which runs with the hypoglossal nerve. If paralysis is bilateral, the tongue is motionless. Taste and tactile sensibility are unaffected but articulation is slow and swallowing very difficult.

The hypoglossal nerve is often used to reanimate the face in patients, particularly the elderly, when their facial nerves have been transected. Direct end-to-end, end-to-side or split-nerve grafts are reliable and offer a robust, effective and quick alternative to more complex reanimation procedures.

Cervical sympathetic trunk

The cervical sympathetic trunk lies on the prevertebral fascia behind the carotid sheath and contains three interconnected ganglia: the superior, middle and inferior (stellate or cervicothoracic) (see Figs 35.17, 35.18). There may occasionally, however, be two or four ganglia. The cervical sympathetic ganglia send grey rami communicantes to all the cervical spinal nerves but receive no white rami communicantes from them. Their spinal preganglionic fibres emerge in the white rami communicantes of the upper five thoracic spinal nerves (mainly the upper three), and ascend in the sympathetic trunk to synapse in the cervical ganglia. In their course, the grey rami communicantes may pierce longus capitis or scalenus anterior.

Superior cervical ganglion

The superior cervical ganglion is the largest of the three ganglia (see Fig. 35.17). It lies on the transverse processes of the second and third cervical vertebrae and is probably formed from four fused ganglia, judging by its grey rami to C1–4. The internal carotid artery within the carotid sheath is anterior, and longus capitis is posterior. The lower end of the ganglion is united by a connecting trunk to the middle cervical ganglion. Postganglionic branches are distributed in the internal carotid nerve, which ascends with the internal carotid artery into the carotid canal to enter the cranial cavity, and in lateral, medial and anterior branches. They supply vasoconstrictor and sudomotor nerves to the face and neck, dilator pupillae and smooth muscle in the eyelids and orbitalis.

Lateral branches The lateral branches are grey rami communicantes to the upper four cervical spinal nerves and to some of the cranial nerves. Branches pass to the inferior vagal ganglion, the hypoglossal nerve, the superior jugular bulb and associated jugular glomus or glomera, and to the meninges in the posterior cranial fossa. Another branch, the jugular nerve, ascends to the cranial base and divides into two; one part joins the inferior glossopharyngeal ganglion and the other joins the superior vagal ganglion.

Medial branches The medial branches of the superior cervical ganglion are the laryngopharyngeal and cardiac. The laryngopharyngeal branches supply the carotid body and pass to the side of the pharynx, joining glossopharyngeal and vagal rami to form the pharyngeal plexus. A cardiac branch arises by two or more filaments from the lower part of the superior cervical ganglion and occasionally receives a twig from the trunk between the superior and middle cervical ganglia. It is thought to contain only efferent fibres, the preganglionic outflow being from the upper thoracic segments of the spinal cord, and to be devoid of pain fibres from the heart. It descends behind the common carotid artery, in front of longus colli, and crosses anterior to the inferior thyroid artery and recurrent laryngeal nerve. The courses on the two sides then differ. The right cardiac branch usually passes behind, but sometimes in front of, the subclavian artery and runs posterolateral to the brachiocephalic trunk to join the deep (dorsal) part of the cardiac plexus behind the aortic arch. It has other sympathetic connections. About mid-neck, it receives filaments from the external laryngeal nerve. Inferiorly, one or two vagal cardiac branches join it. As it enters the thorax, it is joined by a filament from the recurrent laryngeal nerve. Filaments from the nerve also communicate with the thyroid branches of the middle cervical ganglion. The left cardiac branch, in the thorax, is anterior to the left common carotid artery and crosses in front of the left side of the aortic arch to reach the superficial (ventral) part of the cardiac plexus. Sometimes, it descends on the right of the aorta to end in the deep (dorsal) part of the cardiac plexus. It communicates with the cardiac branches of the middle and inferior cervical sympathetic ganglia and sometimes with the inferior cervical cardiac branches of the left vagus, and branches from these mixed nerves form a plexus on the ascending aorta.

Anterior branches The anterior branches of the superior cervical ganglion ramify on the common and external carotid arteries and the branches of the external carotid, and form a delicate plexus around each, in which small ganglia are occasionally found. The plexus around the facial artery supplies a filament to the submandibular ganglion; the plexus on the middle meningeal artery sends one ramus to the otic

ganglion and another, the external petrosal nerve, to the facial ganglion. Many of the fibres coursing along the external carotid and its branches ultimately leave them to travel to facial sweat glands via branches of the trigeminal nerve.

Middle cervical ganglion

The middle cervical ganglion is the smallest of the three and is occasionally absent, in which case it may be replaced by minute ganglia in the sympathetic trunk or may be fused with the superior ganglion. It is usually found at the level of the sixth cervical vertebra, anterior or just superior to the inferior thyroid artery, or it may adjoin the inferior cervical ganglion. It probably represents a coalescence of the ganglia of the fifth and sixth cervical segments, judging by its postganglionic rami, which join the fifth and sixth cervical spinal nerves (but sometimes also the fourth and seventh). It is connected to the inferior cervical ganglion by two or more very variable cords. The posterior cord usually splits to enclose the vertebral artery, while the anterior cord loops down anterior to, and then below, the first part of the subclavian artery, medial to the origin of its internal thoracic branch, and supplies rami to it. This loop is the ansa subclavia and is frequently multiple, lies in close contact with the cervical pleura, and typically connects with the phrenic nerve, and sometimes with the vagus nerve (see Fig. 35.18).

The middle cervical ganglion gives off thyroid and cardiac branches. The thyroid branches accompany the inferior thyroid artery to the thyroid gland. They communicate with the superior cardiac, external laryngeal and recurrent laryngeal nerves, and send branches to the parathyroid glands. Fibres to both glands are largely vasomotor but some reach the secretory cells. The cardiac branch, the largest sympathetic cardiac nerve, arises either from the ganglion itself or more often from the sympathetic trunk cranial or caudal to it. On the right side, it descends behind the common carotid artery and anterior or posterior to the subclavian artery, to the trachea, where it receives a few filaments from the recurrent laryngeal nerve before joining the right half of the deep (dorsal) part of the cardiac plexus. In the neck, it connects with the superior cardiac and recurrent laryngeal nerves. On the left side, the cardiac nerve enters the thorax between the left common carotid and subclavian arteries to join the left half of the deep (dorsal) part of the cardiac plexus. Fine branches from the middle cervical ganglion also pass to the trachea and oesophagus.

Inferior (or cervicothoracic/stellate) ganglion

The inferior cervical ganglion (cervicothoracic/stellate) is irregular in shape and much larger than the middle cervical ganglion (see Fig. 35.18). It is probably formed by a fusion of the lower two cervical and first thoracic segmental ganglia, sometimes including the second and even third and fourth thoracic ganglia. The first thoracic ganglion may be separate, leaving an inferior cervical ganglion above it. The sympathetic trunk turns backwards at the junction of the neck and thorax, and so the long axis of the cervicothoracic ganglion becomes almost anteroposterior. The ganglion lies on or just lateral to the lateral border of longus colli between the base of the transverse process of the seventh cervical vertebra and the neck of the first rib (which are both posterior to it). The vertebral vessels are anterior, and the ganglion is separated from the posterior aspect of the cervical pleura inferiorly by the suprapleural membrane. The costocervical trunk of the subclavian artery branches near the lower pole of the ganglion, and the supreme intercostal artery is lateral.

A small vertebral ganglion may be present on the sympathetic trunk anterior or anteromedial to the origin of the vertebral artery and directly superior to the subclavian artery. When present, it may provide the ansa subclavia. It is also joined to the inferior cervical ganglion by fibres enclosing the vertebral artery and is usually regarded as a detached part of the middle cervical or inferior cervical ganglion. Like the middle cervical ganglion, it may supply grey rami communicantes to the fourth and fifth cervical spinal nerves. The inferior cervical ganglion sends grey rami communicantes to the seventh and eighth cervical and first thoracic spinal nerves, and gives off a cardiac branch, branches to nearby vessels and sometimes a branch to the vagus nerve.

The grey rami communicantes to the seventh cervical spinal nerve vary from one to five (two being the usual number). A third often ascends medial to the vertebral artery in front of the transverse process of the seventh cervical vertebra. It connects with the seventh cervical nerve, and sends a filament upwards through the transverse foramen of the sixth cervical vertebra in company with the vertebral vessels to join the sixth cervical spinal nerve as it emerges from the intervertebral foramen. An inconstant ramus may traverse the transverse foramen of the seventh cervical vertebra. Grey rami to the eighth cervical spinal nerve vary from three to six in number.

The cardiac branch descends behind the subclavian artery and along the anterior aspect of the trachea to the deep cardiac plexus. Behind the artery, it connects with the recurrent laryngeal nerve and the cardiac branch of the middle cervical ganglion (the latter is often replaced by fine branches of the inferior cervical ganglion and ansa subclavia).

The branches to blood vessels form plexuses on the subclavian artery and its branches. The subclavian supply is derived from the inferior cervical ganglion and ansa subclavia, and typically extends to the first part of the axillary artery, although a few fibres may extend further. An extension of the subclavian plexus to the internal thoracic artery may be joined by a branch of the phrenic nerve.

Within the foramina transversaria and intertransverse spaces, the cervical grey rami communicantes form intersegmental arcades as they communicate with one another and the ventral rami of the upper five or six cervical spinal nerves. These arcades accompany the second part of the vertebral artery and create the appearance of a long nerve known as the vertebral nerve. Fine filaments from this nerve and the grey rami communicantes form the vertebral plexus on the surface of the vertebral artery. This plexus contains not only sympathetic efferent fibres but also somatic sensory fibres from the adventitia of the artery with cell bodies in the cervical dorsal root ganglia. The vertebral nerve sends filaments to the posterolateral corners of the cervical intervertebral discs (Bogduk et al 1988), and gives rise to the meningeal branches (sinuvertebral nerves) at each cervical segment. The vertebral plexus, which contains some neuronal cell bodies, continues into the skull along the vertebral and basilar arteries and their branches as far as the posterior cerebral artery, where it meets a plexus from the internal carotid artery. The plexus on the inferior thyroid artery reaches the thyroid gland and connects with the recurrent and external laryngeal nerves, the cardiac branch of the superior cervical ganglion, and the common carotid plexus.

Horner's syndrome

Any condition or injury that destroys the sympathetic trunk ascending from the thorax through the neck into the face results in Horner's syndrome (Bernard–Horner syndrome, oculosympathetic palsy), characterized by a drooping eyelid (ptosis), sunken globe (enophthalmos), narrow palpebral fissure, contracted pupil (meiosis), and vasodilation and lack of thermal sweating (anhydrosis) of the face on the affected side. Classically, this is seen in patients with bronchial carcinomas that have invaded the sympathetic trunk and it is a recognized complication of cervical sympathectomy or a radical neck dissection. Avulsion of the first thoracic nerve from the spinal cord may be diagnosed by development of the syndrome after closed traction lesion of the supraclavicular brachial plexus. Congenital Horner's syndrome has been reported in association with ipsilateral internal carotid artery agenesis (Fons et al 2009). Special features of congenital Horner's syndrome are unilateral straight hair and abnormalities of iris pigmentation in one or both eyes (heterochromia iridis or heterochromia iridum), usually inherited as an autosomal dominant trait and attributed to disruption of the postganglionic sympathetic pathway producing a neurotropic dysgenesis of iris melanocytes (Rennie 2011). Connections between the recurrent laryngeal nerve, the vagus and cervical sympathetic have been linked with Horner's syndrome complicating thyroidectomy.

VISCERA

The main cervical viscera are the submandibular salivary glands, the thyroid and parathyroid glands, and the cervical portions of the trachea and oesophagus.

Submandibular salivary gland

Each submandibular salivary gland is situated behind and below the ramus of the mandible, in the region of the submandibular triangle, between the anterior and posterior bellies of digastric (see Fig. 37.40A). The gland is described in detail in Chapter 37.

Thyroid gland

The thyroid gland, brownish-red and highly vascular, is placed anteriorly in the lower neck, level with the fifth cervical to the first thoracic vertebrae. It is ensheathed by the pretracheal layer of deep cervical fascia and consists of right and left lobes connected by a narrow, median isthmus. It usually weighs 25 g but this varies. The gland is slightly heavier in females and enlarges during menstruation and pregnancy. Estimation of the size of the thyroid gland is clinically important in the evaluation and

management of thyroid disorders and can be achieved non-invasively by means of diagnostic ultrasound. Mean thyroid volume increases with age (Chanoine et al 1991). No significant difference in thyroid gland volume has been observed between males and females from 8 months to 15 years. An enlargement of the thyroid for whatever reason is called a goiter: most swellings are benign, some caused by overactivity (thyrotoxicosis, Graves' disease) and rarely malignant.

The lobes of the thyroid gland are approximately conical. Their ascending apices diverge laterally to the level of the oblique lines on the laminae of the thyroid cartilage, and their bases are level with the fourth or fifth tracheal cartilages. Each lobe is usually 5 cm long, its greatest transverse and anteroposterior extents being 3 cm and 2 cm, respectively. The posteromedial aspects of the lobes are attached to the side of the cricoid cartilage by a lateral thyroid ligament (Berry's ligament). The isthmus connects the lower parts of the two lobes, although occasionally it may be absent. It measures 1.25 cm transversely and vertically, and is usually anterior to the second and third tracheal cartilages, although it can be higher or even sometimes lower because its site and size vary greatly. A conical pyramidal lobe often ascends towards the hyoid bone from the isthmus or the adjacent part of either lobe (more often the left). It is occasionally detached or in two or more parts. A fibrous or fibromuscular band, the levator of the thyroid gland (musculus levator glandulae thyroideae), sometimes descends from the body of the hyoid to the isthmus or pyramidal lobe. (For further reading, see Mohebati and Shaha (2012)).

Ectopic thyroid tissue is rare but may be found around the course of the thyroglossal duct or laterally in the neck, as well as in distant places such as the tongue (lingual thyroid), mediastinum and the subdiaphragmatic organs (Noussios et al 2011). The most frequent location of ectopic thyroid tissue is at the base of the tongue, in particular at the region of the foramen caecum, where it can represent the only thyroid tissue. Small, detached masses of thyroid tissue may be found above the lobes or isthmus as accessory thyroid glands. Vestiges of the thyroglossal duct may persist between the isthmus and the foramen caecum of the tongue, sometimes as accessory nodules or cysts of thyroid tissue near the midline or even in the tongue, where they are called thyroglossal duct cysts.

Surfaces and relations

The convex lateral (superficial) surface of the thyroid gland is covered by sternothyroid: the attachment of this muscle to the oblique thyroid line prevents the upper pole of the gland from extending on to thyrohyoid. Sternohyoid and the superior belly of omohyoid lie more anteriorly, overlapped inferiorly by the anterior border of sternocleidomastoid. The medial surface of the gland is adapted to the larynx and trachea; its superior pole contacts the inferior pharyngeal constrictor and the posterior part of cricothyroid, which separate it from the posterior part of the thyroid lamina and the side of the cricoid cartilage. The external branch of the superior laryngeal nerve is medial to this part of the gland as it passes to supply cricothyroid. Inferiorly, the trachea and, more posteriorly, the recurrent laryngeal nerve and oesophagus (which is closer on the left) are medial relations. The posterolateral surface of the thyroid gland is close to the carotid sheath and overlaps the common carotid artery.

The anterior border of the gland is thin and slants down medially near the anterior branch of the superior thyroid artery. The posterior border is rounded and related inferiorly to the inferior thyroid artery and its anastomosis with the posterior branch of the superior thyroid artery. On the left side, the lower end of the posterior border lies near the thoracic duct. The parathyroid glands are usually related to the posterior border.

The isthmus is covered by sternothyroid, from which it is separated by pretracheal fascia. More superficially it is covered by sternohyoid, the anterior jugular veins, fascia and skin (see Fig. 33.11). The superior thyroid arteries anastomose along its upper border and the inferior thyroid veins leave the gland at its lower border.

Vascular supply and lymphatic drainage

Arteries

The thyroid gland is supplied by the superior and inferior thyroid arteries and sometimes by an arteria thyroidea ima from the brachiocephalic trunk or aortic arch (see Figs 35.14, 35.17). The arteries are large and their branches anastomose frequently both on and in the gland, ipsilaterally and contralaterally. The superior thyroid artery, which is closely related to the external branch of the superior laryngeal nerve, pierces the thyroid fascia and then divides into anterior and posterior branches. The anterior branch supplies the anterior surface of the gland, and the posterior branch supplies the lateral and medial surfaces. The inferior thyroid artery approaches the base of the thyroid gland and divides into superior (ascending) and inferior thyroid branches to supply the inferior and posterior surfaces of the gland. The superior branch also supplies the parathyroid glands. The relationship between the inferior thyroid artery and the recurrent laryngeal nerve is highly variable and of considerable clinical importance; iatrogenic injury to the nerves that supply the larynx represents a major complication of thyroid surgery (Yalçin 2006). The recurrent laryngeal nerve is usually related to the posterior branch of the inferior thyroid artery, which may be replaced by a vascular network (Moreau et al 1998). The most reliable place to identify the recurrent laryngeal nerve is in Beahr's triangle, where the nerve is the third side of this triangle, the other two sides being the inferior thyroid and common carotid arteries. Identification of the recurrent laryngeal nerve can be confirmed by electrical stimulation using a nerve monitor.

Veins

The venous drainage of the thyroid gland is usually via superior, middle and inferior thyroid veins (see Figs 35.13, 35.14, 35.17). The superior thyroid vein emerges from the upper part of the gland, runs with the superior thyroid artery towards the carotid sheath and drains into the internal jugular vein. The middle thyroid vein collects blood from the lower part of the gland; it emerges from the lateral surface of the gland and drains into the internal jugular vein. The inferior thyroid veins arise in a glandular venous plexus that connects with the middle and superior thyroid veins. These veins form a pretracheal plexus, from which the left inferior vein descends to join the left brachiocephalic vein, and the right descends obliquely across the brachiocephalic artery to join the right brachiocephalic vein at its junction with the superior vena cava. The inferior thyroid veins often open via a common trunk into the superior vena cava or left brachiocephalic vein. They drain the oesophageal, tracheal and inferior laryngeal veins and have valves at their terminations.

Lymphatics

Thyroid lymphatic vessels communicate within the gland and the tracheal plexus, passing onwards to prelaryngeal nodes just above the thyroid isthmus and then to pretracheal and paratracheal nodes (level VI). Some may also drain into the brachiocephalic nodes related to the thymus in the superior mediastinum (level VII). Laterally, the gland is drained to the deep cervical nodes (level IV) by vessels lying along the superior thyroid veins. Thyroid lymphatics may drain directly, with no intervening node, to the thoracic duct. In summary, the major lymphatic drainage of the thyroid is to the middle and lower jugular lymph nodes in levels III and IV and to the posterior triangle nodes in level V_b, supplemented by minor drainage to the pretracheal and paratracheal nodes in level VI and to the superior mediastinal nodes in level VII.

Innervation

The thyroid gland receives its innervation from the superior, middle and inferior cervical sympathetic ganglia. Postganglionic fibres from the inferior cervical ganglion form a plexus on the inferior thyroid artery that accompanies the artery to the thyroid gland, and communicates with the recurrent laryngeal nerve and the external branch of the superior laryngeal nerves, the superior cardiac nerve, and the plexus on the common carotid artery.

Imaging

The follicular nature of the thyroid gland is not resolved by current imaging techniques and thus presents a homogeneous texture on cross-sectional imaging (ultrasound, computed tomography, magnetic resonance imaging). Its superficial location makes the thyroid an ideal organ for sonographic examination, facilitating fine needle sampling (FNAC) of any abnormalities (**Fig. 35.21**). The thyroid gland is highly vascular and demonstrates intense contrast enhancement and increased signal on T2-weighted MRI (**Fig. 35.22**). Radionuclide imaging of the thyroid may be performed with technetium (^{99m}Tc) pertechnetate. This readily available radionuclide is trapped by the thyroid in the same way as iodine but is not organified. It yields morphological information and will reveal the presence of ectopic thyroid tissue. Functional data can be obtained with the use of ^{123}iodine or ^{131}iodine, which is trapped and organified. For further reading, see Intenzo et al (2012).

Microstructure

The thyroid gland has a thin capsule of connective tissue that extends into the glandular parenchyma and divides each lobe into irregularly shaped and sized lobules. The functional units of the thyroid are spherical and cyst-like follicles, between 0.02 and 0.9 mm in diameter. Follicles

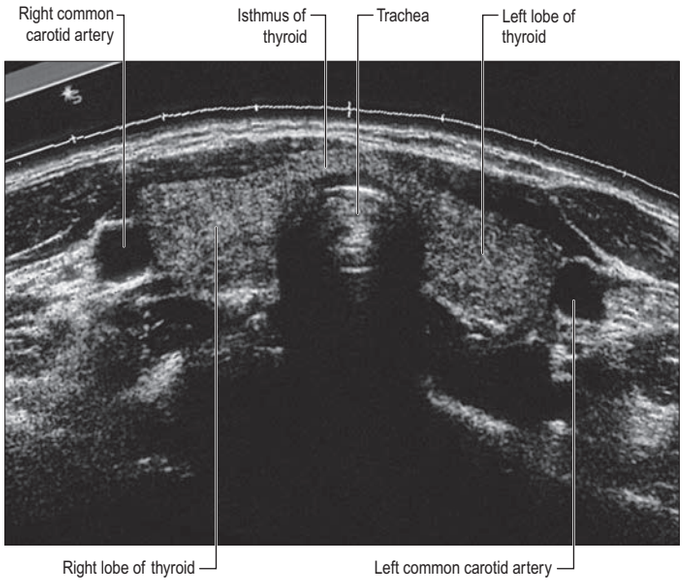

Fig. 35.21 A thyroid sonogram.

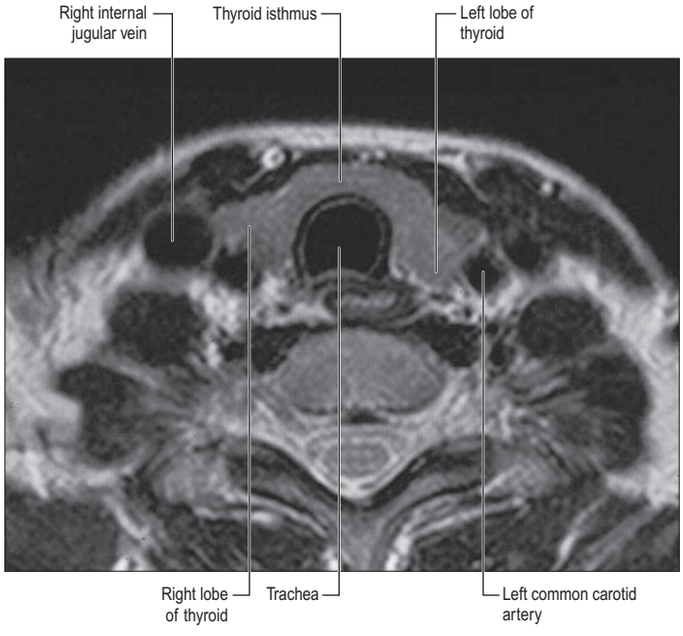

Fig. 35.22 A T2-weighted magnetic resonance image at the level of the thyroid isthmus. Vessels show flow void; compare with Fig. 35.21.

consist of a central colloid core surrounded by a single-layered epithelium resting on a basal lamina (Fig. 35.23). Colloid consists almost entirely of an iodinated glycoprotein, iodothyroglobulin, which is the inactive, stored form of the active thyroid hormones, tri-iodothyronine (T_3) and tetra-iodothyronine or thyroxine (T_4), produced by the follicular epithelial cells. Sufficient iodothyroglobulin is stored extracellularly within follicles to regulate the metabolic activity of the body for up to 3 months. Follicles are surrounded by a delicate connective tissue stroma that contains dense plexuses of fenestrated capillaries, extensive lymphatic networks and sympathetic nerve fibres that supply the arterioles and capillaries. Some nerve fibres end close to the follicular epithelial cells.

Follicular cells Follicular cells vary from squamous or low cuboidal to columnar, depending on their level of activity, which is controlled mainly by circulating hypophysial thyroid-stimulating hormone (TSH, thyrotropin). Resting follicles are large and lined by squamous or low cuboidal epithelium with abundant luminal colloid. Apical microvilli are short in resting cells, but elongate and often branch on stimulation by TSH. Follicles showing differing levels of activity may coexist.

Active follicular cells are highly polarized functionally. The secretion of TSH leads to endocytosis of colloidal droplets at the luminal epithelium (see Fig. 35.23). The hormone stimulates the cells to extend

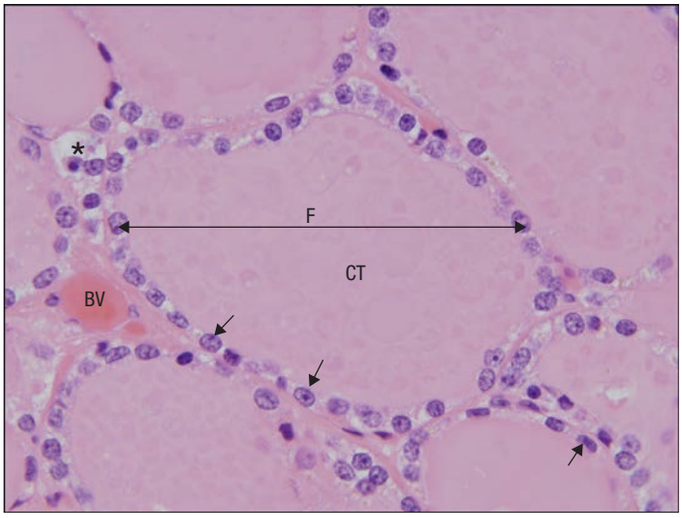

Fig. 35.23 A section through parts of several human thyroid follicles, one of which is labelled (F), showing the follicular epithelium (arrows) enclosing a lumen filled with colloidal thyroglobulin (CT). Calcitonin-secreting C cells are not readily identifiable in routine preparations of human tissue, where they appear as poorly staining (clear) cells within follicles; an example is indicated by the asterisk. A network of blood vessels (BV) within connective tissue septa surrounds the follicles. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

cytoplasmic processes into the luminal colloid and sequester droplets of colloid. The iodinated thyroglobulin in the intracellular colloid droplets is then degraded by follicular cell lysosomes, liberating T_3 and T_4, which pass to the base of the cell, where they are released: they are exported from the thyroid mainly via the blood capillaries and lymphatics. Prolonged high levels of circulating TSH induce follicular cell hypertrophy, progressive resorption of colloid and increased stromal vascularity, and this can result in thyroid enlargement.

Thyroid cancer is usually differentiated and arises from the follicular cells. Following excision any remaining tissue/tumour can be treated with radioactive iodine because the cells retain the ability to both trap and incorporate iodine into tyrosine residues of thyroglobulin. Most differentiated thyroid cancers arise *de novo*. Irradiation of the thyroid in childhood, as might be necessary for the treatment of Hodgkin's lymphoma or as happened in 1986 following the power plant accident in Chernobyl (Ron 2007), is a recognized cause. Routine follow-up is facilitated by serum thyroglobulin measurements: in the athyroid state none should be detectable.

C cells Thyroid parenchyma also contains C (clear) cells, so called because they have pale-staining cytoplasm that is more pronounced in some species than in the human thyroid. C cells are members of the amine precursor uptake and decarboxylation (APUD) system of dispersed neuroendocrine cells. They produce the peptide hormone calcitonin (thyrocalcitonin), which lowers blood calcium by inhibiting bone resorption and calcium recovery from renal tubule ultrafiltrate. C cells populate the middle third of each lateral lobe of the thyroid and are typically found scattered within thyroid follicles, lying inside the basal lamina but not reaching the lumen of the follicle. Occasionally, they occur in clusters in the interfollicular stroma, hence their alternative name of parafollicular cells. C cells give rise to medullary thyroid cancer (MTC) a rare type of malignancy that can be familial and associated with multiple endocrine neoplasia syndromes, i.e. MEN2A when associated with a phaeochromocytoma (benign adrenal tumour) and primary hyperparathyroidism. After excision, patients are followed up both clinically and with serial serum monitoring of plasma calcitonin levels.

Thyroidectomy

Available with the *Gray's Anatomy* e-book

Parathyroid glands

The parathyroid glands are small, yellowish-brown, ovoid or lentiform structures, usually lying between the posterior lobar borders of the thyroid

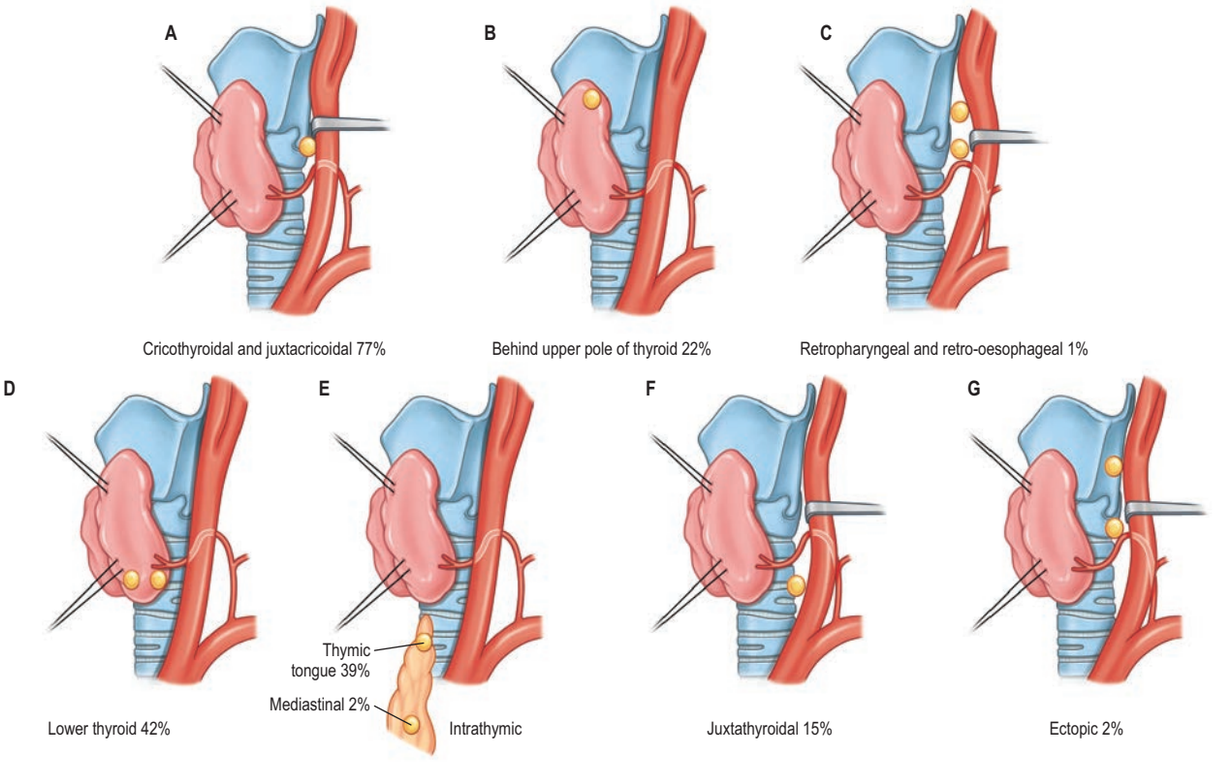

Fig. 35.24 The distribution of superior (**A**–**C**) and inferior (**D**–**G**) parathyroid glands. **A**, Cricothyroidal and juxtathyroidal. **B**, Behind the upper pole of the thyroid. **C**, Retropharyngeal and retro-oesophageal. **D**, Lower thyroid. **E**, Intrathymic. **F**, Juxtathyroidal. **G**, Ectopic. (H–L, *continued online*)

gland and its capsule (Fig. 35.24). They are commonly 6 mm long, 3–4 mm across and 1–2 mm from posterior to anterior, each weighing about 50 mg. There are usually two on each side, superior and inferior, but there may be more, or only three, or many minute ectopic parathyroid islands scattered in connective tissue in the retro-oesophageal/para-oesophageal space, thyroid, carotid sheath, thyrothymic ligament or the thymus (Taterra et al 2019). Very occasionally, an occult gland may follow a blood vessel into a groove on the surface of the thyroid. Normally, the inferior parathyroids migrate to the inferior thyroid poles, but they may descend with the thymus into the thorax or they may be sessile and remain above their normal level near the carotid bifurcation. The anastomotic connection between the superior and inferior thyroid arteries that occurs along the posterior border of the thyroid gland usually passes very close to the parathyroids, and is a useful aid to their identification.

The superior parathyroid glands are more constant in location than the inferior and are usually to be found midway along the posterior borders of the thyroid gland, although they may be higher. The inferior pair are more variably situated (related to their embryological development) and may be either within the fascial thyroid sheath, below the inferior thyroid arteries and near the inferior lobar poles; or outside the sheath, immediately above an inferior thyroid artery; or in the thyroid gland near its inferior pole. These variations are surgically important (Fig. 35.25). A tumour of the inferior parathyroid situated within the fascial thyroid sheath may descend along the inferior thyroid veins anterior to the trachea into the superior mediastinum, whereas if it is outside the sheath, it may extend postero-inferiorly behind the oesophagus into the posterior mediastinum. The superior parathyroids are usually dorsal, and the inferior parathyroids ventral, to the recurrent laryngeal nerves.

The parathyroid glands are very flattened in cross-section and are not normally visible by current imaging methods, including scintigraphy, unless they are enlarged (see Fig. 35.24).

Vascular supply and lymphatic drainage

Both superior and inferior parathyroid glands are usually supplied by the inferior thyroid arteries; the superior parathyroid may be supplied by the superior thyroid artery or from anastomoses between the superior and inferior thyroid arteries. The glands drain into the plexus of veins on the anterior surface of the thyroid. Lymph vessels are numerous and associated with those of the thyroid and thymus glands.

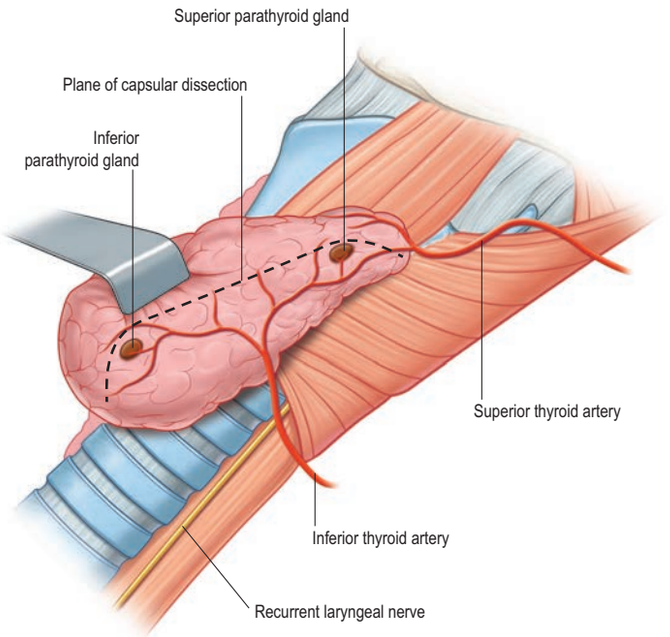

Fig. 35.25 Extracapsular dissection of the thyroid gland preserving the parathyroid glands with their blood supply. The plane of capsular dissection, indicated by the dotted line, allows for mobilization of the parathyroid glands from the thyroid capsule with preservation of their blood supply, and facilitates identification of the recurrent laryngeal nerve. (With permission from Brennan P, Standring S, Wiseman S (eds) Gray's Surgical Anatomy. Elsevier. Copyright 2020.)

Innervation

The nerve supply is sympathetic, either direct from the superior or middle cervical ganglia, or via a plexus in the fascia on the posterior aspect of the thyroid lobe. Parathyroid activity is controlled by variations in blood

Apart from variable enlargement during menstruation and pregnancy, any thyroid swelling is a goitre that may press on related structures. Symptoms most commonly reflect the consequence of pressure on the trachea or on the recurrent laryngeal nerves, and there may also be venous engorgement. During thyroidectomy, care must be taken when ligating the superior and inferior thyroid arteries to avoid iatrogenic injury to adjacent nerves. The external laryngeal nerve runs close to the superior thyroid artery in Joll's triangle, and the recurrent laryngeal nerve runs close to the inferior thyroid artery in Beahr's triangle. Total thyroidectomy may be necessary in the treatment of hyperthyroidism, benign thyroid enlargement in the euthyroid state, and for cancer (which is often combined with a selective neck dissection of the primary major lymph node echelon levels, i.e. III, IV and VI). The parathyroid glands and the recurrent laryngeal nerves are preserved.

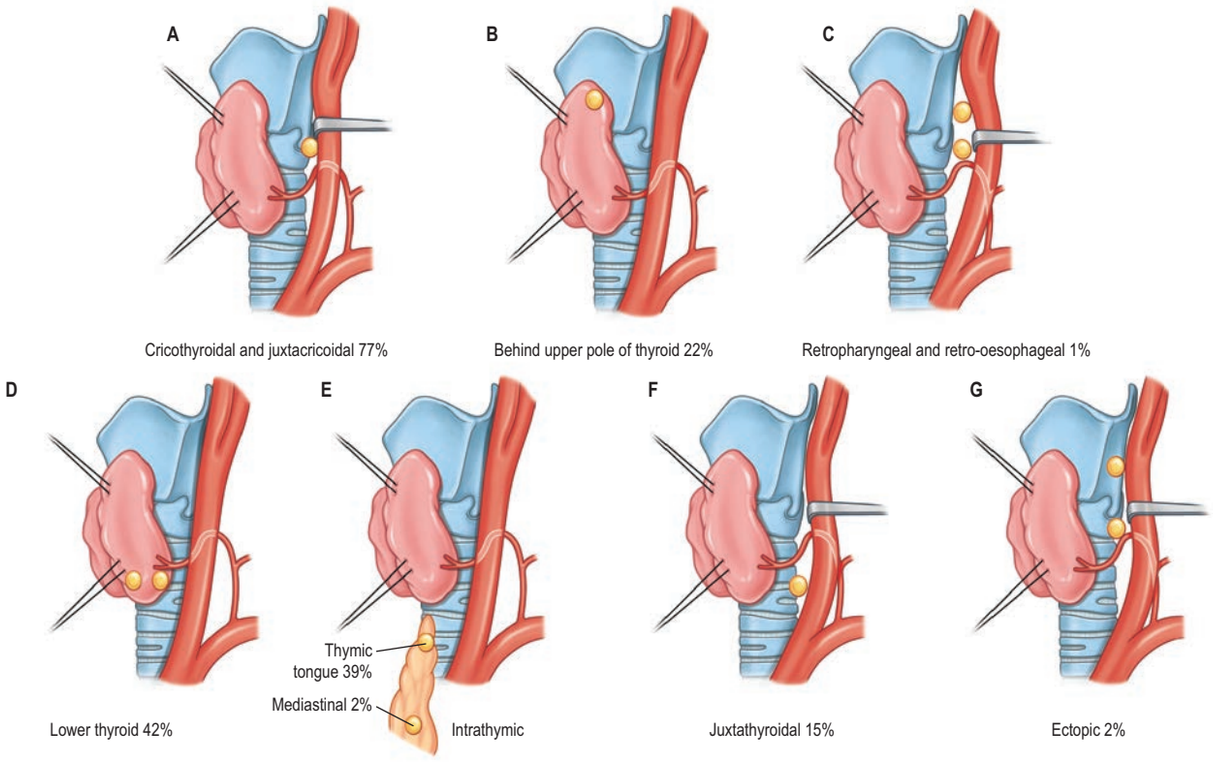

Fig. 35.24 The distribution of superior (**A–C**) and inferior (**D–G**) parathyroid glands. **A**, Cricothyroidal and juxtathyroidal. **B**, Behind the upper pole of the thyroid. **C**, Retropharyngeal and retro-oesophageal. **D**, Lower thyroid. **E**, Intrathymic. **F**, Juxtathyroidal. **G**, Ectopic.

Continued

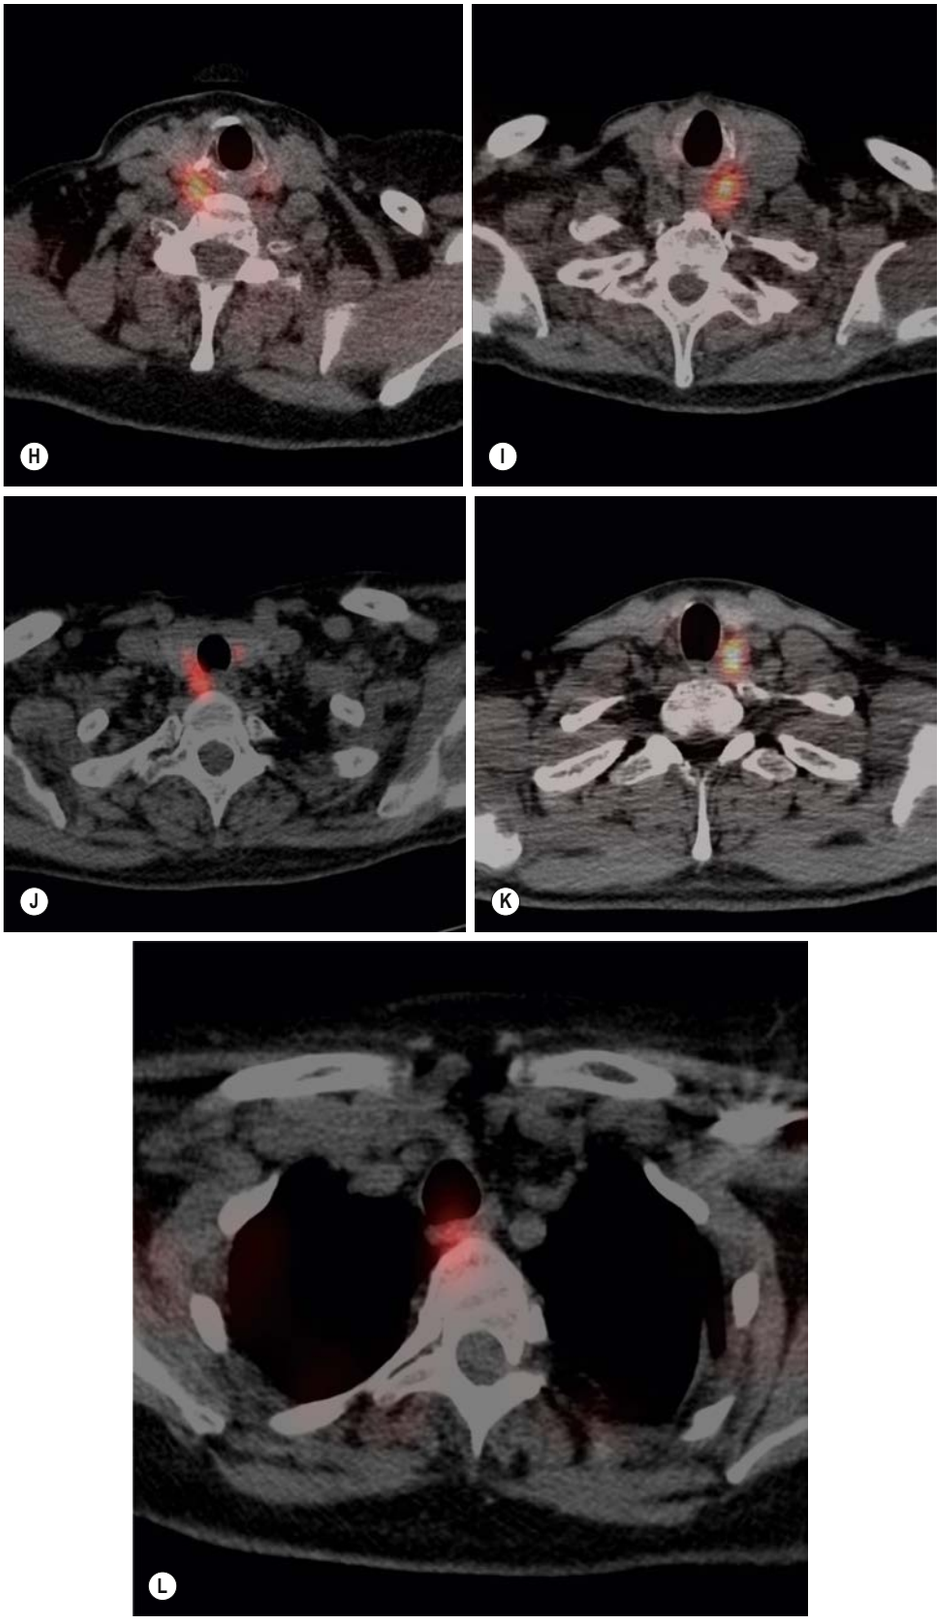

Fig. 35.24, cont'd H–K, Sestamibi SPECT-CT scans showing different positions of the parathyroid glands as adenomas with abnormally increased uptake: **H**, right superior, cricothyroidal and juxtacricoidal; **I**, left superior, cricothyroidal and juxtacricoidal; **J**, right inferior juxtathyroidal; **K**, left inferior paratracheal juxtathyroidal. **L**, Sestamibi SPECT-CT scan showing an ectopic parathyroid gland in a patient with persistent primary hyperparathyroidism after a total thyroidectomy. The increased abnormal uptake is seen in the ectopic gland in a retrotracheal, para-oesophageal position.

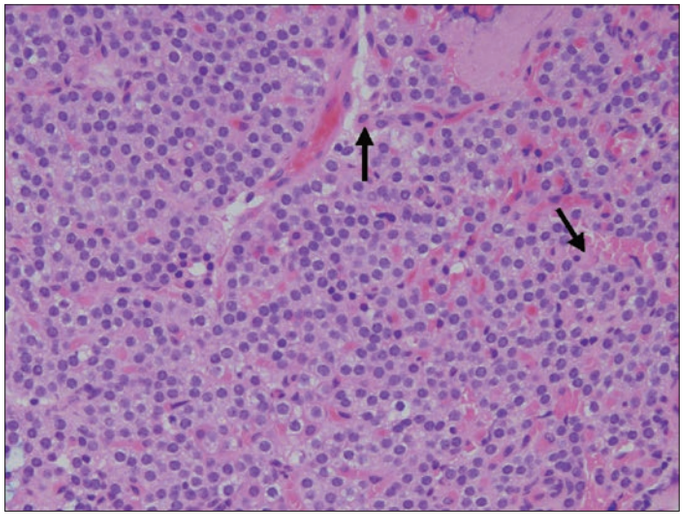

Fig. 35.26 A section of the parathyroid gland, showing clusters and cords of small, tightly packed chief cells surrounded by vascular sinusoids. Scattered oxyphil cells (arrows) are generally larger and more eosinophilic. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

calcium level, and is inhibited by a rise and stimulated by a fall. The nerves are believed to be vasomotor but not secretomotor.

Microstructure

Each parathyroid gland has a thin connective tissue capsule with intraglandular septa but lacks distinct lobules. The glands synthesize and secrete parathyroid hormone (PTH, parathormone), a single-chain polypeptide of 84 amino-acid residues concerned with the control of the level and distribution of calcium and phosphorus. In childhood, the gland consists of wide, irregular, interconnecting columns of chief or principal cells separated by a dense plexus of fenestrated sinusoidal capillaries. After puberty, adipose tissue accumulates in the stroma and typically accounts for about one-third of the adult tissue mass, increasing further with age.

Chief cells differ ultrastructurally according to their level of activity. Active chief cells have large Golgi complexes with numerous vesicles and small membrane-bound granules, whereas glycogen granules are most abundant in inactive cells, which have few of the cytoplasmic features of synthetic or secretory activity, and appear histologically as 'clear' cells. In normal human parathyroid glands, inactive chief cells outnumber active cells in a ratio of 3–5:1 (**Fig. 35.26**). In contrast to the thyroid, where the activities of adjacent follicular cells are coordinated, individual chief cells of the parathyroid glands go through cycles of secretory activity and rest independently, according to serum calcium levels.

A second cell type, the oxyphil (eosinophil) cell, appears just before puberty and increases in number with age. Oxyphil cells are larger than chief cells and contain more cytoplasm which stains deeply with eosin. Their nuclei are smaller and more darkly staining than those of chief cells, and their cytoplasm is unusually rich in mitochondria. The functional significance of oxyphil cells and their relationship to chief cells are uncertain.

Most parathyroid surgery is undertaken for primary hyperparathyroidism, which is the second commonest cause of hypercalcaemia and usually caused by a solitary parathyroid adenoma. The serum parathormone (PTH) is raised. Such tumours can be localized preoperatively using a combination of radionucleide, ultrasound and CT scanning.

ROOT OF THE NECK

The root of the neck is a zone of transition between four discrete anatomical spaces: the neck, the thorax and both upper limbs (see Fig. 35.18) It contains the subclavian vessels; common carotid artery; trunks of the brachial plexus; sympathetic trunk; phrenic, vagus and recurrent laryngeal nerves (all bilaterally); the terminal portion of the thoracic duct (on the left side only); the terminal portion of the right lymphatic duct (on the right side only); and the oesophagus and trachea (in the midline). The brachiocephalic veins are formed by the union of the internal jugular and subclavian veins at the junction of the neck and thorax, behind the head of the clavicle.

The essential anatomical landmark in orientating and understanding the root of the neck is scalenus anterior, covered by the prevertebral layer of deep cervical fascia. It is important to understand its immediate relations. Anteriorly lie sternocleidomastoid and subclavius, the intermediate tendon of omohyoid, the subclavian vein, branches from the thyrocervical trunk of the first part of the subclavian artery (transverse cervical, suprascapular and ascending cervical arteries), and the phrenic nerve. The nerve lies on the surface of scalenus anterior in the root of the neck, before passing between it and the subclavian vein to enter the superior mediastinum and it is the anatomical key to identifying the muscle intraoperatively. Posteriorly, the roots of the brachial plexus and the second part of the subclavian artery separate scalenus anterior from scalenus medius. Pathologies that cause impingement on either the brachial plexus or the subclavian artery may present clinically as an upper limb compression syndrome. The suprapleural membrane and pleura are intimate posterior relations of scalenus anterior. On each side, the apical (cervical) pleura and the apex of the lung bulge up into the root of the neck. The height to which the apical pleura rises, with reference to the first pair of ribs and costal cartilages, varies in different individuals according to the obliquity of their thoracic inlet. Posteriorly, the apical pleura typically reaches the level of the neck of the first rib, forming a domed roof over each side of the thoracic cavity that is strengthened by the suprapleural membrane. Scalenus anterior covers the anterolateral part of the dome of the pleura, separating it from the subclavian vein. The subclavian artery crosses the dome below its summit, immediately above the vein. The costocervical trunk arches backwards from the subclavian artery and crosses the summit of the dome; its supreme intercostal branch descends behind the dome, between the first intercostal nerve laterally and the first thoracic sympathetic ganglion medially.

Medial relations of scalenus anterior are longus colli and the inferior thyroid artery. The two muscles are separated by an angular interval through which the vertebral artery and vein pass to gain access to the foramen transversarium of the sixth cervical vertebra, and more anteriorly the inferior thyroid artery arches from lateral to medial on its way to the thyroid gland. The area also contains some level IV and scalene nodes within Chassaignac's triangle (see Fig. 35.5B). The cervical sympathetic trunk and the inferior cervical ganglion lie close to the posteromedial aspect of the vertebral artery here. The internal thoracic artery descends from the first part of the subclavian artery, passes behind the brachiocephalic vein and, on the right side, is crossed by the phrenic nerve. The vagus nerve descends anterior to the first part of the subclavian artery, and on the right side only, gives off its recurrent laryngeal branch which usually turns around the lower border of the artery. The terminal portions of the thoracic duct and the right lymphatic duct, on the left and right sides, respectively, cross the triangular interval at the level of the seventh cervical vertebra and come into contact with the medial edge of scalenus anterior.

The axillary sheath, an extension of the prevertebral fascia that accompanies the axillary artery and trunks of the brachial plexus, lies lateral to scalenus anterior.

Cervical rib

A small additional rib (cervical rib) may develop in the root of the neck in association with the seventh cervical vertebra. It is often fibrous in nature, although in some cases it may have undergone ossification. A cervical rib may cause compression of the subclavian artery and the lower roots of the brachial plexus, in which case affected individuals will complain of pain, paraesthesia and even pallor of the affected upper limb, a condition known as thoracic outlet syndrome. The occasional co-occurrence of rudimentary or absent twelfth ribs with cervical ribs indicates that a homeotic shift had occurred over a larger part of the vertebral column in affected fetuses (Bots et al 2011). For further reading on homeotic transformations of vertebrae, see Ten Broek et al (2012).

Oesophagus – cervical portion

The oesophagus is a muscular tube approximately 25 cm long, connecting the pharynx to the stomach. It begins in the neck, level with the lower border of the cricoid cartilage and the sixth cervical vertebra. It descends, largely anterior to the vertebral column, into the superior mediastinum. Generally vertical and median, it inclines to the left as

far as the root of the neck, and also bends in an anteroposterior plane to follow the cervical curvature of the vertebral column.

Relations The trachea lies anterior to the oesophagus, attached to it by loose connective tissue. The vertebral column, longus colli and prevertebral layer of deep cervical fascia are posterior, and the common carotid artery and posterior part of the thyroid gland are lateral on each side. In the lower neck, where the oesophagus deviates to the left, it becomes closer to the left carotid sheath and thyroid gland. The thoracic duct ascends for a short distance along its left side. The recurrent laryngeal nerves ascend on each side in or near the tracheo-oesophageal groove.

Vascular supply and lymphatic drainage The cervical part of the oesophagus is mainly supplied by branches from the inferior thyroid arteries. The oesophageal veins drain into the brachiocephalic veins, and lymphatic vessels pass to retropharyngeal, paratracheal or deep cervical lymph nodes in levels III and IV.

Innervation The cervical part of the oesophagus is innervated by the recurrent laryngeal nerves and by the sympathetic plexus around the inferior thyroid artery.

Trachea – cervical portion

The trachea is a tube 10–11 cm long, formed of cartilage and fibromuscular tissue. It descends from the larynx, and extends from the level of the sixth cervical vertebra to the upper border of the fifth thoracic vertebra (see Figs 35.14, 35.22). It lies approximately in the sagittal plane but its point of bifurcation is usually a little to the right. The trachea is flexible and can rapidly alter in length. It is flattened posteriorly, so that in transverse section it is shaped, with some individual variation, like a letter D. Its external transverse diameter is 2 cm in adult males, and 1.5 cm in adult females. The lumen in live adults is 1.2 cm in transverse diameter. In children, the trachea is smaller, more deeply placed and more mobile. Tracheal diameter does not exceed 3 mm in the first postnatal year; during later childhood its diameter in millimetres is about equal to age in years.

Relations The relationships of the trachea to other cervical structures is of clinical significance: tracheostomy is not an uncommon clinical procedure. Anteriorly, the cervical part of the trachea is crossed by skin and by the superficial and deep fasciae. It is also crossed by the jugular arch and overlapped by sternohyoid and sternothyroid. The second to fourth tracheal cartilages are crossed by the isthmus of the thyroid gland, above which an anastomotic artery connects the bilateral superior thyroid arteries. Below and in front are the pretracheal fascia, inferior thyroid veins, thymic remnants and the arteria thyroidea ima (when it exists). In children, the brachiocephalic artery crosses obliquely in front of the trachea at or a little above the upper border of the manubrium. The left brachiocephalic vein may also rise a little above this level. The oesophagus lies posterior to the trachea and separates it from the vertebral column. The paired lobes of the thyroid gland, which descend to the fifth or sixth tracheal cartilage, and the common carotid and inferior thyroid arteries all lie lateral to the trachea. The recurrent laryngeal nerves ascend on each side, in or near the grooves between the sides of the trachea and oesophagus.

Vascular supply and lymphatic drainage The cervical part of the trachea is mainly supplied by branches from the inferior thyroid arteries. The tracheal veins drain into the brachiocephalic veins via the inferior thyroid plexus, and lymphatic vessels drain into the pretracheal and paratracheal nodes.

Innervation The trachea is innervated by branches from the vagi, recurrent laryngeal nerves and sympathetic trunks.

Surgical airway The trachea may be accessed directly in the neck via cricothyroidotomy or tracheostomy. There are numerous indications for performing an elective tracheostomy, including the need to provide prolonged intubation and pulmonary toilet, and management of acute airway obstruction from causes that include laryngeal pathology, trauma (e.g. midface, mandibular or laryngeal fractures), as well as bilateral recurrent laryngeal palsies consequent on thyroid surgery. For detailed descriptions of the operative procedures, appropriate surgical texts should be consulted as well as texts that detail developmental anomalies and anatomical variations (Jarvis 1966, Ger and Evans 1993, Racic et al 2005).

Cricothyroidotomy endangers the cricothyroid artery (a branch of the superior thyroid artery), which is usually found close to the midline, and which reaches the median cricothyroid ligament close to the thyroid cartilage.

CHAPTER 36

Face and scalp

SKIN

The scalp and buccolabial tissues are described here. The structure of the eyelids is discussed in Chapter 44.

Scalp

The scalp extends from the top of the forehead anteriorly to the superior nuchal line posteriorly. Laterally, it projects down to the zygomatic arch and external acoustic meatus. It consists of five layers: skin, subcutaneous tissue, occipitofrontalis (epicranius) and its aponeurosis, subaponeurotic loose areolar tissue and the periosteum of the skull (pericranium).

The skin of the scalp is hairy and rich in sebaceous glands, and is the most common site for sebaceous cysts. The dense subcutaneous connective tissue has the richest cutaneous blood supply in the body. The anterior and posterior muscular bellies of occipitofrontalis are connected by a tough, fibrous, epicranial aponeurosis, and this layer is therefore often called the aponeurotic layer (galea aponeurotica). These three upper layers of the scalp can easily slide on the underlying layer of loose connective tissue. A scalp flap can be raised within the plane between the galea and the pericranium without compromising either the blood or the nerve supply of the scalp because all of these structures lie in the subcutaneous layer (superficial fascia). Anteriorly based subgaleal scalp flaps (bicoronal) provide excellent access to the craniofacial skeleton for the correction of congenital deformity such as craniosynostoses; treatment of craniofacial fractures involving the frontal bone, nasoethmoidal complex, orbit or zygomatic arch; skull-base surgery; or craniotomies. Pericranial flaps can be used to separate the frontal sinus floor from the nasal cavity in the management of fractures of the posterior wall of the frontal sinus (frontal sinus cranialization). Traumatic scalp avulsion may happen if hair becomes trapped in moving machinery or a shearing force is applied in the subgaleal plane during a road traffic accident or fall injury.

The arterial blood supply to the scalp is particularly rich; there are free anastomoses between branches of the occipital and superficial temporal vessels. Scalp lacerations continue to bleed profusely because the elastic fibres of the underlying galea aponeurotica prevent initial vessel retraction. Their repair requires a two-layer closure technique to approximate the galea aponeurotica and skin layers, whereas the pericranial layer, if involved, cannot usually be closed because it retracts.

Eyebrows

The eyebrows are two arched eminences of skin that surmount the orbits. Numerous short, thick hairs are set obliquely in them. Fibres of orbicularis oculi, corrugator and the frontal part of occipitofrontalis are inserted into the dermis of the eyebrows.

Buccolabial tissue

Cheeks

The cheeks are continuous anteriorly with the lips. The external junction is indicated by the nasolabial groove (sulcus) and further laterally by the nasolabial fold, which descends from the side of the nose to the angle of the mouth. The cheek is covered on the outer surface by skin and on the inner surface by mucosa. Each cheek contains the buccinator muscle, and a variable, but usually considerable, amount of adipose tissue, often encapsulated to form a biconcave mass, the buccal fat pad (of Bichat), that is particularly evident in infants. The walls of the cheek contain fibrous connective tissue, vessels, nerves and numerous small buccal mucous (salivary) glands. The buccal fat pad can be used for surgical reconstruction of small intraoral defects of the palate and buccal and retromolar regions.

Lips

The lips are two fleshy folds surrounding the oral orifice. The centre of each lip contains a thick fibrous strand of parallel bundles of skeletal muscle fibres (orbicularis oris, together with incisivus superior and inferior and the direct labial tractors), and their attachments to skin, mucosa or other muscle fibres. The free external surface of each lip is covered by a thin keratinized epidermis and is continuous with the mucosa at the vermilion (red) zone of the lip. The dermis is well vascularized and contains numerous hair follicles, sebaceous glands (Fordyce spots) and sweat glands. Subcutaneous adipose tissue is scanty. The internal mucous surfaces are lined with a thick, non-keratinizing, stratified squamous epithelium. The submucosa is well vascularized and contains numerous minor salivary glands, which may be harvested for histological confirmation of Sjögren's connective tissue disease.

Between the skin and mucosa, the vermilion zone is covered with a specialized keratinized stratified squamous epithelium that is thin near the skin, increases in thickness slightly as the mucosa is approached, and thickens abruptly when true mucosa is reached. The epithelium is covered with transparent, dead squames and its deep surface is highly convoluted, interdigitating with abundant long dermal papillae. The latter carry a rich capillary plexus that imparts a dusky red colour. These surfaces are hairless, their dermis lacks sebaceous, sweat or mucous glands, and they are moistened with saliva by the tip of the tongue. The dense innervation of the lips is reflected in their acute sensitivity to light touch, attributable mainly to the increased density of Meissner's corpuscles (see Fig. 3.29) in the dermal papillae.

The size and curvature of the exposed red-lip surfaces is subject to considerable variation. The attainment of adult dimensions is faster in the upper than in the lower lip; the cutaneous upper lip height normally reaches its adult size at the age of 3 years in females and 6 years in males (Farkas et al 1992). In children, all lip dimensions (distances, areas, volumes) are larger in boys than in girls (Ferrario et al 2000). Upper lip length is significantly shorter in females than in males and follows the growth pattern of the upper airway. Growth plateaus between the ages of 6 and 9 years, increases again from 9 to 16 years, and plateaus between 16 and 18 years (Gonçalves et al 2011).

The line of contact between the lips, the oral fissure, lies just above the incisal edges of the anterior maxillary teeth. On each side, a labial commissure forms the angle (corner) of the mouth, usually near the first premolar tooth. The labial epithelia and internal tissues radiate over the boundaries of the commissure to become continuous with those of the cheek. With age, buccolabial (labiomarginal) grooves appear at the angles of the mouth. On each side, the upper lip is separated from the cheek laterally by the nasolabial groove and is continuous above the nasal ala with the circumalar groove (sulcus). The lower lip is separated from the chin by the mentolabial groove (sulcus).

Externally, the central region of the upper lip presents a shallow vertical groove, the philtrum, limited above by its attachment to the columella of the nose and ending below in a slight tubercle limited by lateral ridges. The lower lip shows a small depression in the midline that corresponds to the tubercle. The junction between the external, hair-bearing skin and the red, hairless surface of the upper lip almost invariably takes the form of a double-curved Cupid's bow. From the centre, it rises rapidly on each side to an apex that corresponds to the lower end of each ridge of the philtrum, and then slopes gently downwards towards the angle of the mouth. The line of contact between the red-lip surfaces is typically almost horizontal. The Cupid's bow is interrupted in cleft lip anomalies.

In the upper lip, a narrow band of smooth tissue related to the subnasal maxillae marks the point at which labial mucosa becomes continuous with gingival mucosa. The corresponding point in the lower lip coincides approximately with the mentolabial sulcus, where the labial mucosa is continuous with mental tissues. The upper and lower lips differ in cross-sectional profile in that neither is a simple fold of uniform thickness. The upper lip has a bulbous asymmetric profile where the skin and red-lip have a slight external convexity, and the adjoining red-lip and mucosa a pronounced internal convexity, creating a mucosal ridge or shelf that can be wrapped around the incisal edges of the parted

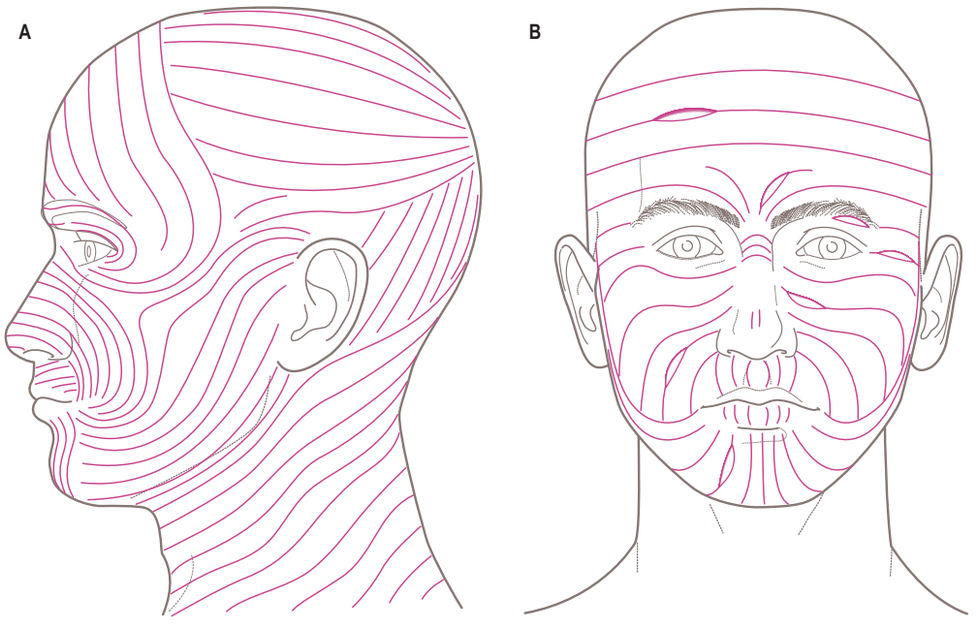

Fig. 36.1 The distribution of relaxed skin tension lines (Kraissl's lines). **A**, Lateral view. **B**, Anterior view.

teeth. The lower lip is on a more posterior plane than the upper lip. In the position of neutral lip contact, the external surface of the lower lip is concave and there is little or no elevation of the internal mucosal surface. The profile of the lips can be modified by muscular activity.

Relaxed skin tension lines and skin flaps on the face

The direction in which facial skin tension is greatest varies regionally. Skin tension lines follow the furrows formed when the skin is relaxed, and are known as 'relaxed skin tension lines' (Borges and Alexander 1962). In the living face, these lines frequently (but not always) coincide with wrinkle lines (**Fig. 36.1**) and can therefore act as a guide in planning elective incisions.

When lesions on the face, such as scars, pigmented lesions and skin cancers, are excised, the dimensions of these lesions often require excision as an ellipse, so that the resulting defect can be closed as a straight line. If the resulting scar is to be aesthetically acceptable, it is important to make the long axis of the ellipse parallel to the natural relaxed skin tension lines, so that the scar will look like a natural skin crease. If the excision line runs contrary to the skin tension lines, the scar may be more conspicuous and will tend to stretch transversely as a result of natural expressive facial movements. When larger lesions are excised, it may be necessary to advance or rotate adjacent soft tissue to fill the defect. The ability to raise these skin flaps is entirely dependent on the regional blood supply; both random pattern and axial pattern skin flaps are used surgically. The richness of the subdermal plexus in the face means that random pattern flaps can be raised with a greater length:breadth ratio than in any other part of the body.

SOFT TISSUE

Fascial layers

Fascia of scalp

The superficial fascia of the scalp is firm, dense and fibroadipose, and adheres closely to both skin and the underlying epicranius and its aponeurosis. Posteriorly, it is continuous with the superficial fascia of the posterior neck, and laterally it is prolonged into the temporal region, where it is looser in texture.

Fascial layers and tissue planes in the face

On the basis of gross dissection and complementary histological studies, four distinct tissue planes are recognized on the face superficial to the plane of the facial nerve and its branches. From superficial to deep, these layers are the skin, a subcutaneous layer of fibroadipose tissue, the superficial musculo-aponeurotic system (SMAS), and the parotid–masseteric fascia.

Subcutaneous fibroadipose tissue

The subcutaneous fibroadipose tissue is a homogeneous layer that is present throughout the face, although the degree of adiposity varies in different parts of the face and with age. Anteriorly, it crosses the nasolabial fold onto the lip. Superiorly, it crosses the zygomatic arch. In both locations, the layer is more fascial than fatty. The fat content of the subcutaneous tissue in the cheek accounts for the cheek mass, and is composed partly by the malar fat pad, a more or less discrete aggregation of fatty tissue inferolateral to the orbital margin.

Superficial musculo-aponeurotic system (SMAS)

The superficial musculo-aponeurotic system (SMAS) is described as a single tissue plane in the face. In some areas it is composed of muscle fibres and elsewhere it is composed of fibrous or fibroaponeurotic tissue; it is not directly attached to bone. When traced below the level of the inferior border of the mandible, it becomes continuous with platysma in the neck. Microdissection has revealed that the SMAS becomes indistinct on the lateral aspect of the face approximately 1 cm below the level of the zygomatic arch. Anteromedially, the SMAS layer blends with the epimysium over some of the mimetic muscles, including zygomaticus major, frontalis and the periorbital fibres of orbicularis oculi (Yousif and Mendelson 1995). In most areas of the face, a distinct sub-SMAS plane can be defined deep to the SMAS that is continuous with the plane between platysma and the underlying investing layer of deep cervical fascia in the neck. However, where the SMAS overlies the parotid gland, it is firmly blended with the superficial layer of the parotid fascia, making it difficult, if not impossible, to define a clear sub-SMAS plane in the region of the parotid.

Parotid–masseteric fascia

The parotid-masseteric fascia is thin, translucent and tough. It covers the parotid duct, the buccal branch of the facial nerve and interconnecting branches from the mandibular nerve where these structures lie on the surface of masseter. Further anteriorly, the parotid–masseteric fascia overlies the buccal fat pad that lies superficial to buccinator and blends with the epimysium on the surface of buccinator. It becomes continuous with the investing layer of deep cervical fascia below the inferior border of the mandible.

Parotid fascia (capsule)

The parotid fascia (parotid capsule) surrounds the parotid gland. Traditionally it was described as an upward continuation of the investing layer of deep cervical fascia in the neck that split to enclose the gland within superficial and deep layers. The superficial layer was thought to be attached superiorly to the zygomatic process of the temporal bone, the cartilaginous part of the external acoustic meatus and the mastoid process, and the deep layer was attached to the mandible, the tympanic plate, and the styloid and mastoid processes of the temporal bone. The current view is that the deep layer of the parotid capsule is derived from the deep cervical fascia but that the superficial layer of the parotid capsule is continuous with the fascia associated with platysma and is a

The following are examples of axial pattern flaps that can be used to reconstruct defects on the face and scalp. The supratrochlear/supraorbital arteries support forehead flaps that are used for nasal reconstruction; there is usually enough skin laxity to allow the majority of the donor site to be closed directly. The frontal branches of the superficial temporal arteries anastomose in the midline, which means that the entire forehead skin can be raised on a narrow pedicle based on just one of the superficial temporal arteries. These flaps can be used to repair many facial defects and also intraoral defects, but the donor site defect cannot be closed directly and must be covered by a skin graft. The parietal branch of the superficial temporal artery and the occipital artery can support hair-bearing flaps from the scalp and are useful for reconstructing defects involving the scalp. The nasolabial flap utilizes the lax skin just lateral to the nasolabial groove. It is not supplied by a named axial artery but rather its blood supply is provided by many small branches from the underlying facial artery that run perpendicular to the skin surface. Nasolabial flaps can be either superiorly or inferiorly based.

component of the SMAS (Mitz and Peyronie 1976, Wassef 1987, Gosain et al 1993). It varies in thickness from a thick fibrous layer anteriorly to a thin translucent membrane posteriorly. It may be traced forwards as a separate layer that passes over the masseteric fascia (also derived from the deep cervical fascia), separated from it by a cellular layer that contains branches of the facial nerve and the parotid duct. Histologically, the parotid fascia is atypical in that it contains muscle fibres in parallel with the fibres of platysma, especially in the lower part of the parotid capsule. Although thin fibrous septa may be seen in the subcutaneous layer histologically, macroscopically there is little evidence of a distinct layer of superficial fascia.

The deep fascia covering the muscles that form the parotid bed (digastric and the styloid group of muscles) contains the stylomandibular and mandibulostylohyoid ligaments. The stylomandibular ligament passes from the styloid process to the angle of the mandible. The more extensive mandibulostylohyoid ligament (angular tract) passes between the angle of the mandible and the stylohyoid ligament for varying distances, generally reaching the hyoid bone. It is thick posteriorly but thins anteriorly in the region of the angle of the mandible. There is some dispute as to whether the mandibulostylohyoid ligament is part of the deep cervical fascia (Ziarah and Atkinson 1981) or lies deep to it (Shimada and Gasser 1988). The stylomandibular and mandibulostylohyoid ligaments separate the parotid gland from the superficial part of the submandibular gland, and so are landmarks of surgical interest.

Temporoparietal and temporal fasciae

Above the level of the zygomatic arch, on the lateral side of the head, the temporoparietal fascia (superficial temporal fascia) constitutes a fascial layer that lies in the same plane as, but is not continuous with, the SMAS. It is quite separate from, and superficial to, the temporal fascia (deep temporal fascia). More superiorly, it blends with the galea aponeurotica. The plane between the temporoparietal fascia and the underlying deep temporal fascia contains loose areolar tissue and a small amount of fat. This tissue plane, the temporoparietal fat pad, is continuous superiorly with the subgaleal plane of loose areolar tissue in the scalp. Running superiorly in the temporoparietal fascia, or just deep to it, are the superficial temporal vessels, the auriculotemporal nerve and its branches, and the temporal branches of the facial nerve. When raising a bicoronal flap, identification of the temporoparietal fat pad helps to separate these two fascial layers, and subsequent dissection in a plane deep to the temporoparietal fascia protects the temporal branch of the facial nerve. The temporal fascia is a dense aponeurotic layer that lies deep to the temporoparietal fat pad and covers temporalis; the superficial fibres of temporalis are attached to the deep surface of the fascia. Superiorly, it is a single layer attached along the length of the superior temporal line, blending with the periosteum. Inferiorly, at approximately the level of the superior orbital rim, the temporal fascia splits into superficial and deep laminae that run downwards and are attached to the lateral and medial margins of the upper surface of the zygomatic arch, respectively. These fascial attachments have a clinical application in the reduction of fractures of the zygomatic complex via a Gillies approach: an instrument is inserted deep to the deep lamina of temporal fascia through a scalp incision and used to elevate depressed zygomatic complex fractures. The fat enclosed between these two layers, the superficial temporal fat pad, contains the zygomatico-orbital branch of the superficial temporal artery and a cutaneous nerve, the zygomaticotemporal branch of the maxillary nerve. The temporal fascia is overlapped by auriculares anterior and superior, the epicranial aponeurosis and part of orbicularis oculi; the superficial temporal vessels and the auriculotemporal nerve ascend over it.

Buccopharyngeal fascia

The buccopharyngeal fascia is a thin layer of fascia that covers buccinator and the superior constrictor of the pharynx (Ch. 40).

Retaining ligaments of the face

The retaining ligaments of the face are fascial bands at specific sites, e.g. the zygomatic ligament (McGregor's patch) and the mandibular ligament. They serve to anchor the skin to the underlying bone. The general cutaneous laxity associated with the ageing process renders facial skin subject to gravitational pull that is resisted by the retaining ligaments. When performing facelift procedures, these ligaments must be surgically divided in order to facilitate redraping of facial skin.

Fascial spaces

The buccal tissue space, lying between the skin and the surface of buccinator, and the infraorbital tissue space, lying between the bony attachments of levator labii superioris and levator anguli oris, can be involved in the spread of odontogenic infection.

BONES OF THE FACIAL SKELETON AND CRANIAL VAULT

The facial skeleton is the anterior part of the skull and includes the mandible. The bones of the nasoethmoidal and zygomaticomaxillary complexes are described here. The mandible is described in Chapter 38.

Parietal bone

The two parietal bones form most of the cranial roof and sides of the skull. Each is irregularly quadrilateral and has two surfaces, four borders and four angles (Fig. 36.2).

The external surface is convex and smooth, with a central parietal tuber (tuberosity). Curved superior and inferior temporal lines cross it and form posterosuperior arches. The temporal fascia is attached to the superior line or arch, and temporalis is attached to the inferior line or arch. The epicranial aponeurosis lies above these lines, and part of the temporal fossa lies below. Posteriorly, close to the sagittal (superior) border, an inconstant parietal foramen transmits a vein from the superior sagittal sinus and sometimes a branch of the occipital artery.

The internal surface is concave and marked by impressions of cerebral gyri and by grooves for the middle meningeal vessels. The latter ascend, inclining backwards, from the sphenoidal (anteroinferior) angle and posterior half (or more) of its inferior border. A groove for the superior sagittal sinus lies along the sagittal border and is completed by the groove on the contralateral parietal bone. The falx cerebri is attached to the edges of the groove. Granular foveolae for arachnoid granulations flank the sagittal sulcus and are most pronounced in old age.

The dentated sagittal border, longest and thickest, articulates with the contralateral parietal bone at the sagittal suture. The anterior part of the squamosal (inferior) border is short, thin and truncated, bevelled externally and overlapped by the greater wing of the sphenoid. The middle part of the inferior border is arched, bevelled externally and overlapped by the squamous part of the temporal bone. The posterior part of the inferior border is short, thick and serrated and articulates with the mastoid part of the temporal bone. The frontal border is deeply serrated, bevelled externally above and internally below, and articulates with the frontal bone to form one half of the coronal suture. The occipital border, deeply dentated, articulates with the occipital bone, forming one half of the lambdoid suture.

The frontal (anterosuperior) angle, approximately 90°, is at the bregma, where the sagittal and coronal sutures meet, marking the site of the anterior fontanelle in the neonatal skull. The sphenoidal (anteroinferior) angle lies between the frontal bone and the greater wing of the sphenoid. Its internal surface is marked by a deep groove or canal for the frontal branches of the middle meningeal vessels. The frontal, parietal, sphenoid and temporal bones usually articulate at the pterion, which marks the site of the sphenoidal fontanelle in the embryonic skull. The frontal bone sometimes articulates with the squamous part of the temporal bone, in which case the parietal bone fails to reach the greater wing of the sphenoid bone. The rounded occipital (posterosuperior) angle is at the lambda, the meeting of the sagittal and lambdoid sutures, which marks the site of the posterior fontanelle in the neonatal skull. The blunt mastoid (posteroinferior) angle articulates with the occipital bone and the mastoid portion of the temporal bones at the asterion. Internally, it bears a broad, shallow groove for the junction of the transverse and sigmoid sinuses.

Ossification

Each parietal bone is ossified from two centres that appear in dense mesenchyme near the tuberosity, one above the other at about postfertilization week 8. These two centres unite early and ossification subsequently radiates from them towards the margins. The angles are therefore the last parts to be ossified, and fontanelles are present at these sites. At birth, the temporal lines are low down; they only reach their final position after the eruption of the molar teeth. Occasionally, the parietal bone is divided by an anteroposterior suture.

Frontal bone

The frontal bone is like half of a shallow, irregular cap and forms the forehead or frons (Fig. 36.3). It has three parts and contains two cavities, the frontal sinuses.

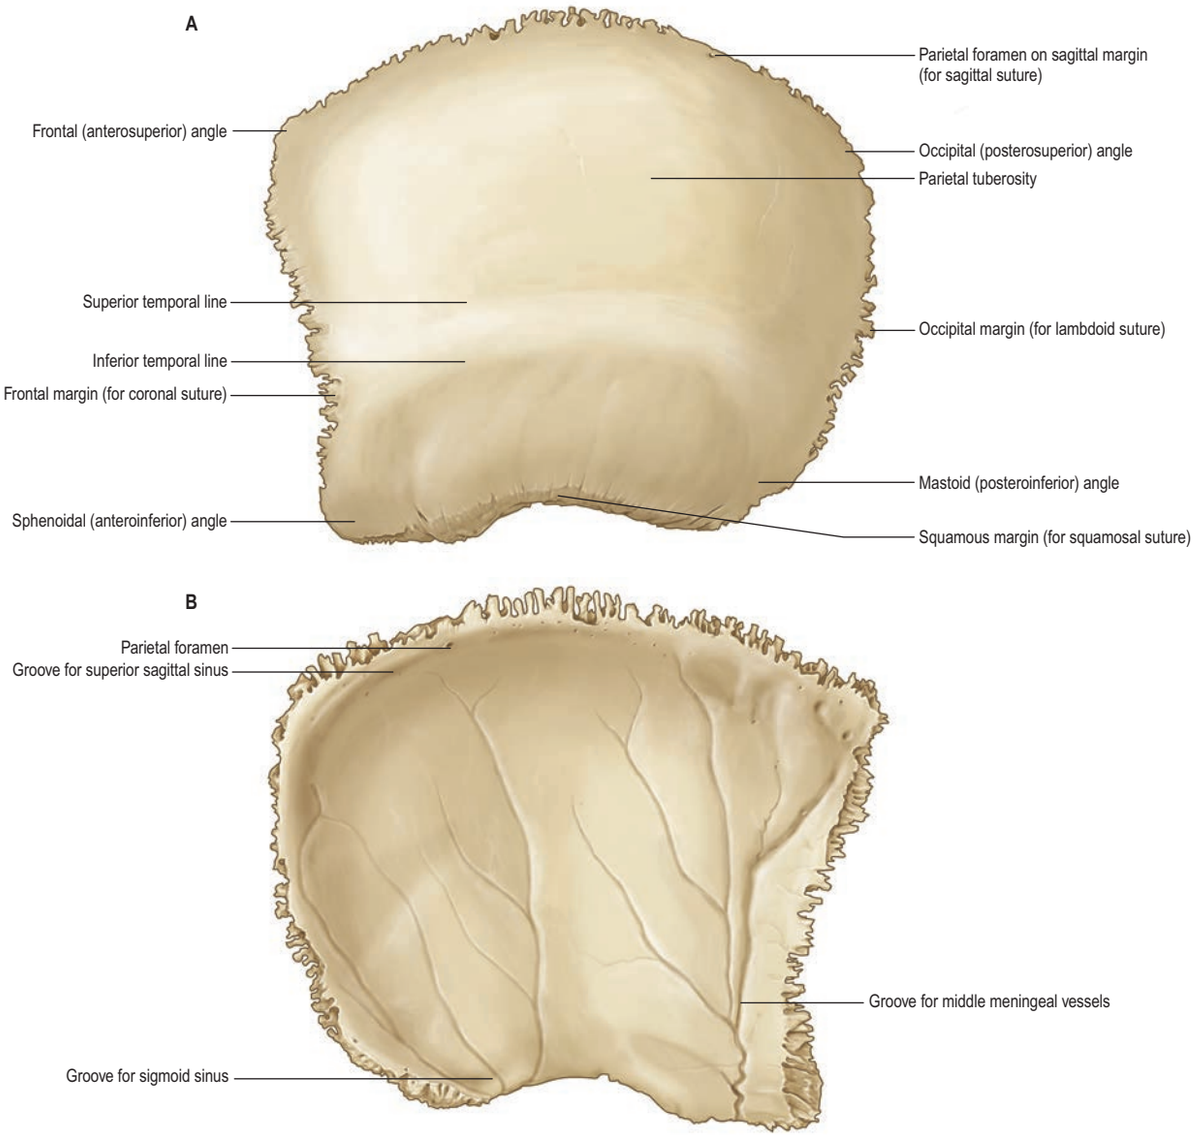

Fig. 36.2 The left parietal bone. **A**, External view. **B**, Internal view.

Squamous part

The squamous part forms the major portion of the frontal bone. Its external surface has a rounded frontal tuber (tuberosity) approximately 3 cm above the midpoint of each supraorbital margin. These tubera vary but are especially prominent in young skulls and more so in adult females than males. Below them, and separated by a shallow groove, are two curved superciliary arches, medially prominent and joined by a smooth median elevated glabella. The arches are more prominent in males: prominence depends partly on the size of the frontal sinuses but is occasionally associated with small sinuses. The curved supraorbital margins of the orbital openings lie inferior to the superciliary arches. The lateral two-thirds of each margin are sharp, the medial one-third is rounded. A supraorbital notch or foramen that transmits the supraorbital vessels and nerve lies at the junction between them and a small frontal notch or foramen may lie medial to the supraorbital notch. The supraorbital margin ends laterally in a strong, prominent zygomatic process that articulates with the zygomatic bone. A line curves posterosuperiorly from the process and divides into superior and inferior temporal lines that continue on the squamous part of the temporal bone. The area of the frontal bone posteroinferior to the temporal lines is the temporal surface and forms the anterior part of the temporal fossa. The parietal (posterior) margin is thick, deeply serrated, and bevelled internally above and externally below. Inferiorly, it becomes a rough, triangular surface that articulates with the greater wing of the sphenoid.

The internal surface of the frontal bone is concave. Its upper, median, part displays a vertical sulcus with edges that unite inferiorly as the frontal crest. The sulcus contains the anterior part of the superior sagittal sinus. The crest ends in a small notch that is completed by the ethmoid bone to form a foramen caecum. The anterior portion of the falx cerebri is attached to the margins of the sulcus and to the frontal crest. The internal surface shows impressions of cerebral gyri, small furrows for meningeal vessels, and granular foveolae near the sagittal sulcus that house arachnoid granulations.

Nasal part

The nasal part of the frontal bone lies between the supraorbital margins. A serrated nasal notch articulates with the nasal bones inferiorly and with the frontal processes of the maxillae and the lacrimal bones laterally. From the centre of the notch posteriorly, the bone projects anteroinferiorly behind the nasal bones and the frontal processes of the maxillae and supports the nasal bridge. The region ends in a sharp nasal spine, on each side of which a small grooved surface partly roofs the ipsilateral nasal cavity. The nasal spine articulates anteriorly with the crest of the nasal bones and posteriorly with the perpendicular plate of the ethmoid bone: it makes a very small contribution to the nasal septum.

Orbital parts

Most of the frontal bone is thick and consists of trabecular tissue lying between two compact laminae. The orbital plates consist entirely of compact bone and are thin and often translucent posteriorly (they can be partly absorbed in old age).

The two orbital plates are curved, triangular laminae separated by a wide ethmoidal notch. They form the largest part of the orbital roofs.

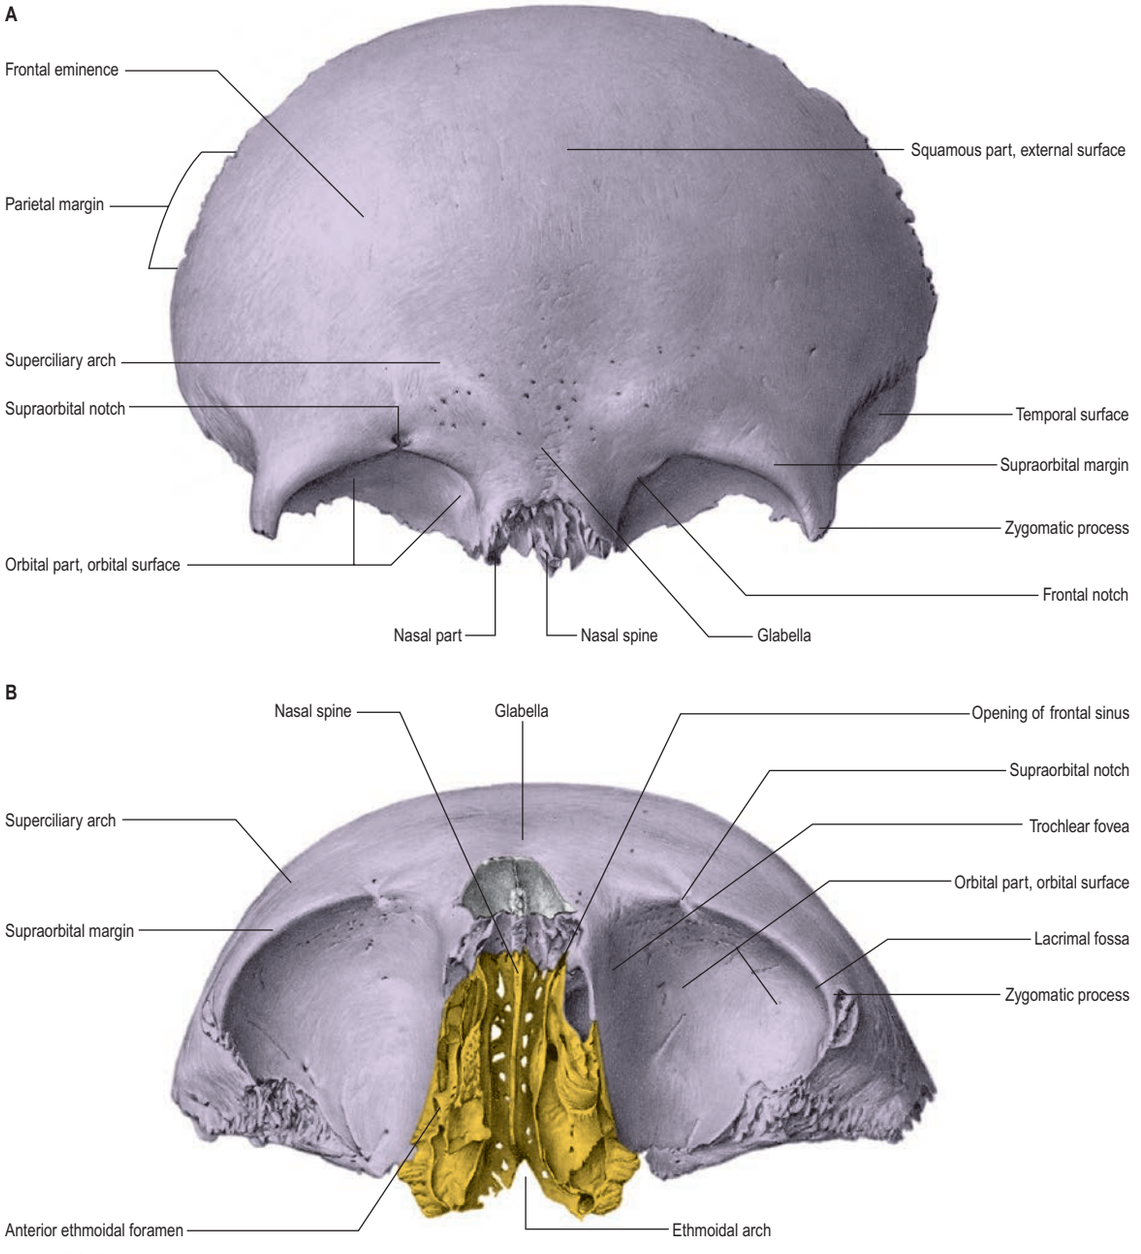

Fig. 36.3 The frontal bone. **A**, Anterior view. **B**, Inferior view, including the articulations between the frontal, ethmoid and nasal bones. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Their orbital surfaces are smooth and concave and each bears a shallow anterolateral fossa for the lacrimal gland. Their convex cerebral surfaces are marked by frontal gyri and faint grooves for meningeal vessels. On each side, the trochlear fovea (or spine) for attachment of a fibrocartilaginous trochlea through which the tendon of superior oblique plays, lies below and behind the medial end of the supraorbital margin, midway between the supraorbital notch and frontolacrimal suture.

The quadrilateral ethmoidal notch is occupied by the cribriform plate of the ethmoid bone. Inferior to its lateral margins, the bone articulates with the labyrinths of the ethmoid bone, and impressions of the ethmoidal air cells can be seen on this surface. Two transverse grooves across each margin are converted into anterior and posterior ethmoidal canals by articulation with the ethmoid bone; these canals open on the medial orbital wall and transmit the anterior and posterior ethmoidal nerves and vessels. The posterior borders of the orbital plates are thin and serrated, and articulate with the lesser wings of the sphenoid; their lateral parts usually appear in the middle cranial fossa between the greater and lesser wings of the sphenoid.

The frontal sinuses are two irregular cavities that ascend posterolaterally for a variable distance between the frontal laminae. They are separated by a thin septum and usually deflected from the median plane, so that they are rarely symmetric. The sinuses are variable in size and usually larger in males. Their openings lie anterior to the ethmoidal notch and lateral to the nasal spine, and each communicates with the middle meatus in the ipsilateral nasal cavity by a frontonasal canal.

The frontal sinuses are rudimentary at birth and can barely be distinguished. They show a primary expansion with eruption of the first deciduous molars at about 18 months, and again when the permanent molars begin to appear in the sixth year. Growth is slow in the early years but it can be detected radiographically by 6 years. They reach full size after puberty, although, with advancing age, osseous absorption may lead to further enlargement. Their degree of development appears to be linked to the prominence of the superciliary arches, which is thought to be a response to masticatory stresses. The frontal sinuses are described in Chapter 39.

Ossification

The frontal bone is ossified in fibrous mesenchyme from two primary centres that appear in about postfertilization week 8, one near each frontal tuber. Ossification extends superiorly, to form half of the main part of the bone; posteriorly, to form the orbital part; and inferiorly, to form nasal parts. Two secondary centres for the nasal spine appear about the tenth year. At birth, the bone consists of two halves. The median suture usually closes in the first postnatal year but may persist as the metopic suture in a small percentage of individuals (see Fig. 34.8A).

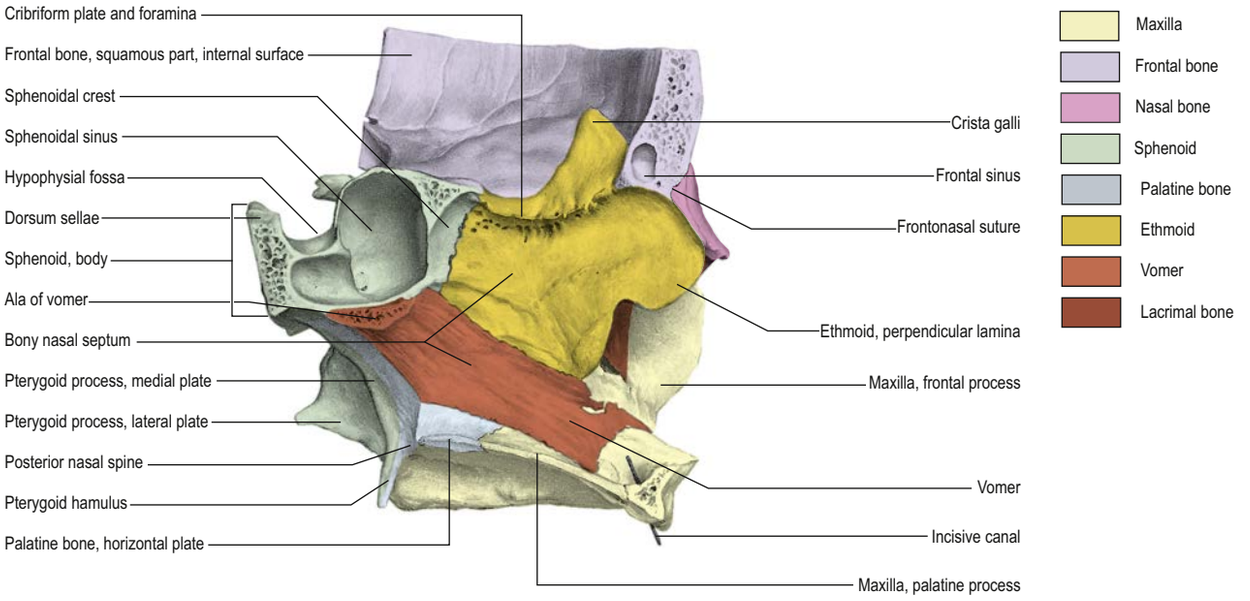

Fig. 36.4 Sagittal view of the facial skeleton, viewed from the right side of the nasal septum, looking towards the left. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

SECTION 4

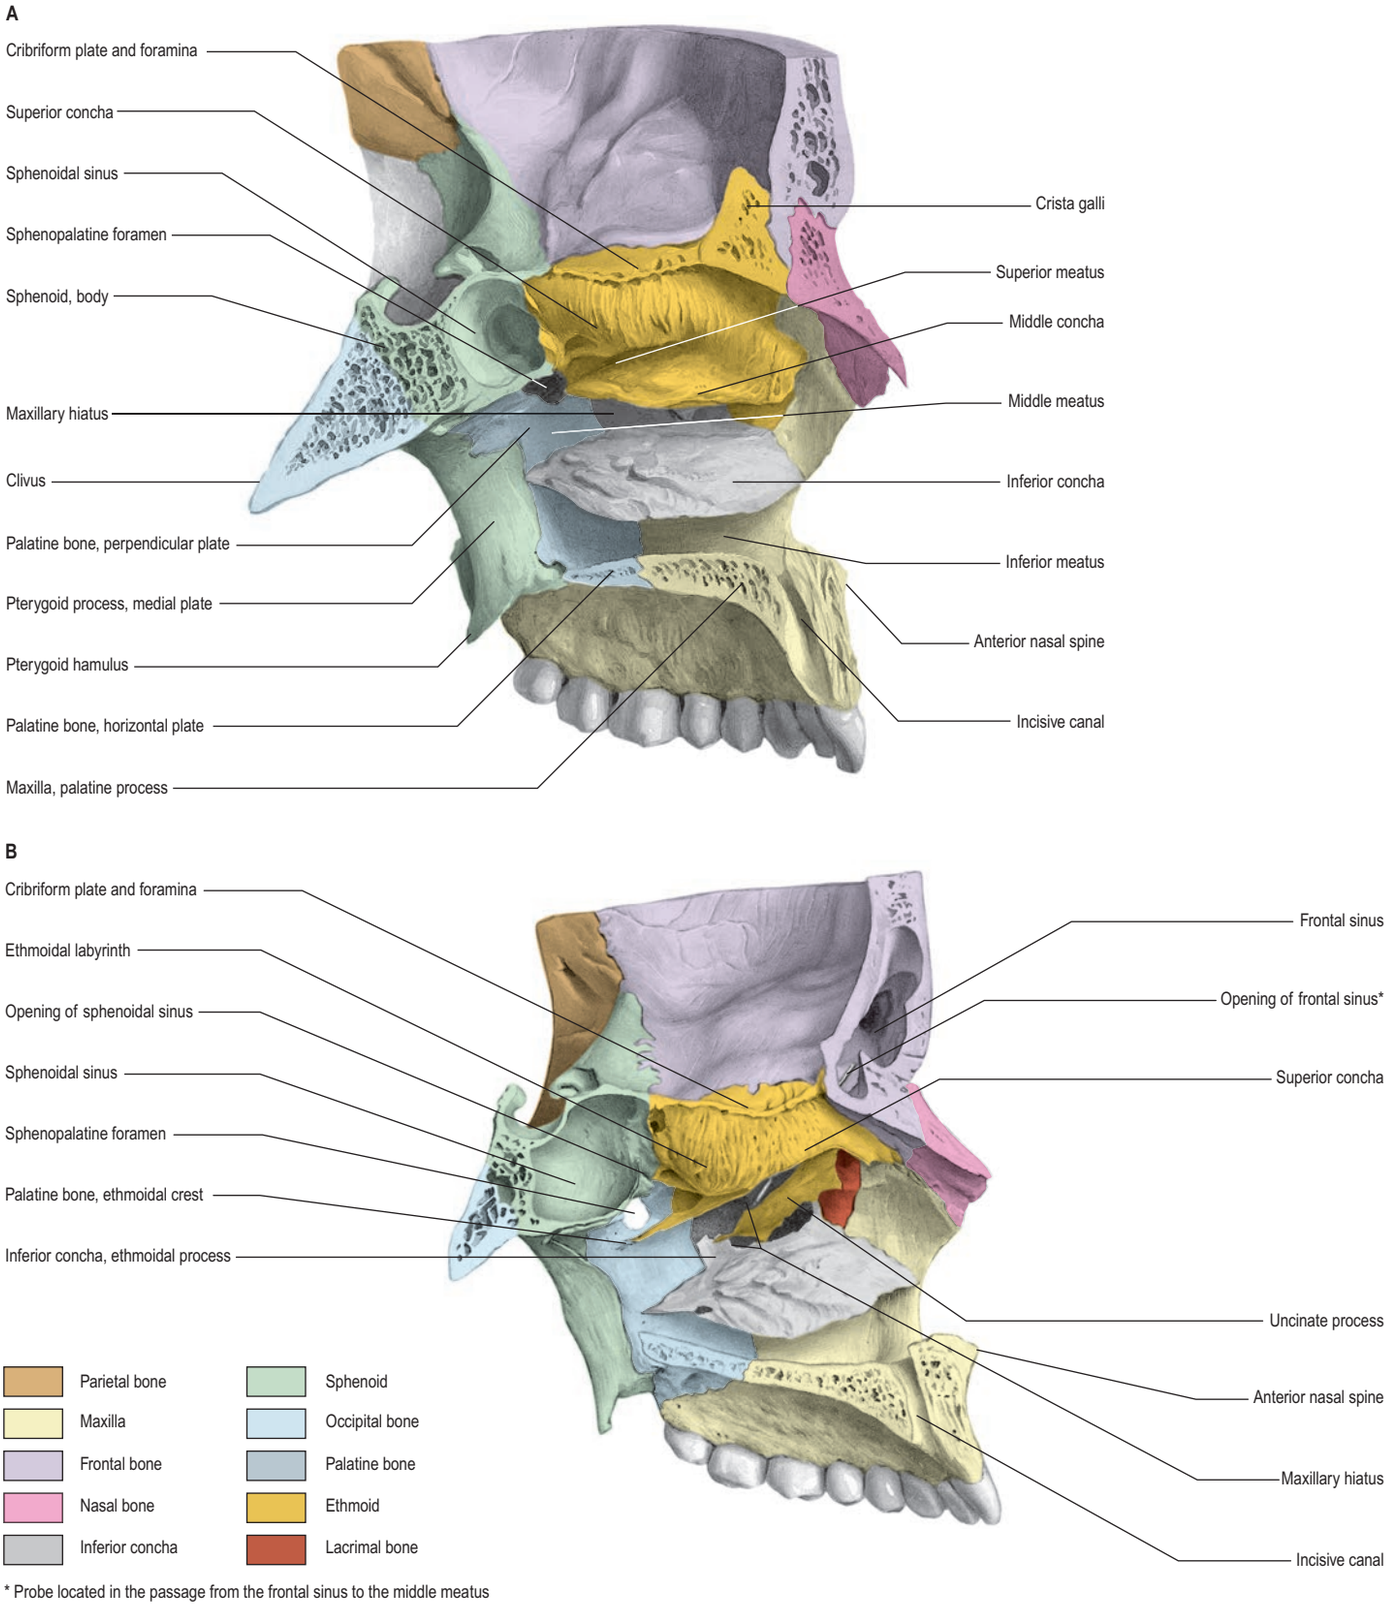
Ethmoid bone

The ethmoid bone is cuboidal and fragile (**Figs 36.3B**, **36.4–36.6**). It lies anteriorly in the cranial base and contributes to the medial walls of the orbit, the nasal septum, and the roof and lateral walls of the nasal cavity. It has a horizontal perforated cribriform plate, a median perpendicular plate, and two lateral labyrinths that contain the ethmoidal air cells.

Cribriform plate and crista galli

The cribriform plate fills the ethmoidal notch of the frontal bone and forms a large part of the nasal roof. It derives its name from the fact that it is penetrated by numerous foramina that transmit branches of the olfactory nerves and their associated meninges. A thick, smooth, triangular, median process, the crista galli, projects upwards from the centre of the cribriform plate. The falx cerebri is attached to its thin and curved posterior border, while its shorter, thick, anterior border articulates with the frontal bone by two small alae, so completing the foramen caecum. Its sides are generally smooth but may show slight bulges that are related to underlying ethmoidal air cells. On both sides of the crista galli, the cribriform plate is narrow and depressed, and is related to the gyrus rectus and the olfactory bulb that lie above it. On each side of the crista anteriorly, there is a small slit occupied by dura mater. Just anterolateral to the slit, a foramen transmits the anterior ethmoidal nerve and vessels to the nasal cavity. A groove runs forwards to the foramen caecum from the anterior ethmoidal canal.

Perpendicular plate



The perpendicular plate is thin, flat, quadrilateral and median. It descends from the cribriform plate to form the upper part of the nasal septum, usually deviating slightly from the midline. Its anterior border articulates with the nasal spine of the frontal bone and the crests of the nasal bones, and its posterior border articulates with the crest of the body of the sphenoid bone above and the vomer below. The thick inferior border is attached to the nasal septal cartilage. Its surfaces are smooth, except for above, where numerous grooves and canals that transmit filaments of the olfactory nerves lead to medial foramina in the cribriform plate.

Ethmoidal labyrinths

The ethmoidal labyrinths consist of thin-walled ethmoidal air cells between two vertical plates. The lateral surface (orbital plate) of the labyrinth is part of the medial orbital wall. The air cells are arranged in anterior and posterior groups separated by the basal lamella (the lateral attachment of the middle concha (turbinate) to the lamina papyracea). Historically the ethmoidal air cells sinuses were subdivided into anterior, middle and posterior ethmoidal air cells, but the nomenclature was inconsistent and confusing, and for clinical purposes, the middle group was incorporated into the anterior group (Stammberger and Kennedy 1995) (Ch. 39). On average, there are 11 anterior ethmoidal air cells, and 7 posterior. In the disarticulated bone, many air cells are open, but in life, and in the articulated skull, they are closed by proximity to adjoining bones, except where they open into the nasal cavity. The superior surface is crossed by two grooves that are converted into the anterior and posterior ethmoidal canals by the frontal bone and shows open air cells that are covered by the edges of the ethmoidal notch of the frontal bone. On the posterior surface, open air cells are covered by the sphenoidal conchae and the orbital process of the palatine bone. The posterior ethmoidal air cells are covered by a thin, smooth, oblong orbital plate that articulates superiorly with the orbital plate of the frontal bone, inferiorly with the maxilla and orbital process of the palatine bone, anteriorly with the lacrimal bone, and posteriorly with the sphenoid bone. The walls of the air cells lying anterior to the orbital plate are completed by the lacrimal bone and frontal process of the maxilla.

A thin, curved uncinate process, variable in size, projects posteroinferiorly from the labyrinth. The upper edge of this process is a medial boundary of the hiatus semilunaris in the middle meatus. The uncinate process appears in the medial wall of the maxillary sinus as it crosses the ostium of the maxillary sinus to articulate with the ethmoidal process of the inferior nasal concha.

The medial surface of the labyrinth forms part of the lateral nasal wall. It appears as a thin lamella that descends from the inferior surface of the cribriform plate and ends as the convoluted middle nasal concha. Superiorly, the surface contains numerous vertical grooves that transmit bundles of olfactory nerves. Posteriorly, it is divided by the narrow, oblique superior meatus, bounded above by the thin, curved superior nasal concha. Posterior ethmoidal air cells open into the superior meatus. The convex surface of the middle nasal concha extends along the entire medial surface of the labyrinth, anteroinferior to the superior meatus. Its lower edge is thick, and its lateral surface is concave and forms part of the middle meatus. The ethmoidal bulla (bulla ethmoidalis) consists of a group of the largest and least variable anterior ethmoidal cells on the lateral wall of the middle meatus, and opens into the meatus, either on the bulla or above it. A curved infundibulum extends up and forwards from the middle meatus and communicates with the anterior ethmoidal sinuses. It typically ascends as the frontonasal duct to include the drainage point for the frontal sinus. (The ethmoidal air cells are described further in Chapter 39.)

* Probe located in the passage from the frontal sinus to the middle meatus

In **B**, the middle concha in the lateral wall of the nasal cavity has been removed to reveal the uncinate process. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Ossification

The ethmoid bone ossifies in the cartilaginous nasal capsule from three centres: one in the perpendicular plate, and one in each labyrinth. The latter two appear in the orbital plates between postmenstrual weeks 13 and 20 and extend into the ethmoidal conchae. At birth, the labyrinths, although ill-developed, are partially ossified, and the remainder are cartilaginous. The perpendicular plate begins to ossify from the median centre during the first year, and fuses with the labyrinths early in the second year. The cribriform plate is ossified partly from the perpendicular plate and partly from the labyrinths. The crista galli ossifies during the second year. The parts of the ethmoid bone unite to form a single bone at around 3 years of age. Ethmoidal air cells begin to develop at about postmenstrual weeks 9–12, and are therefore present at birth; however,

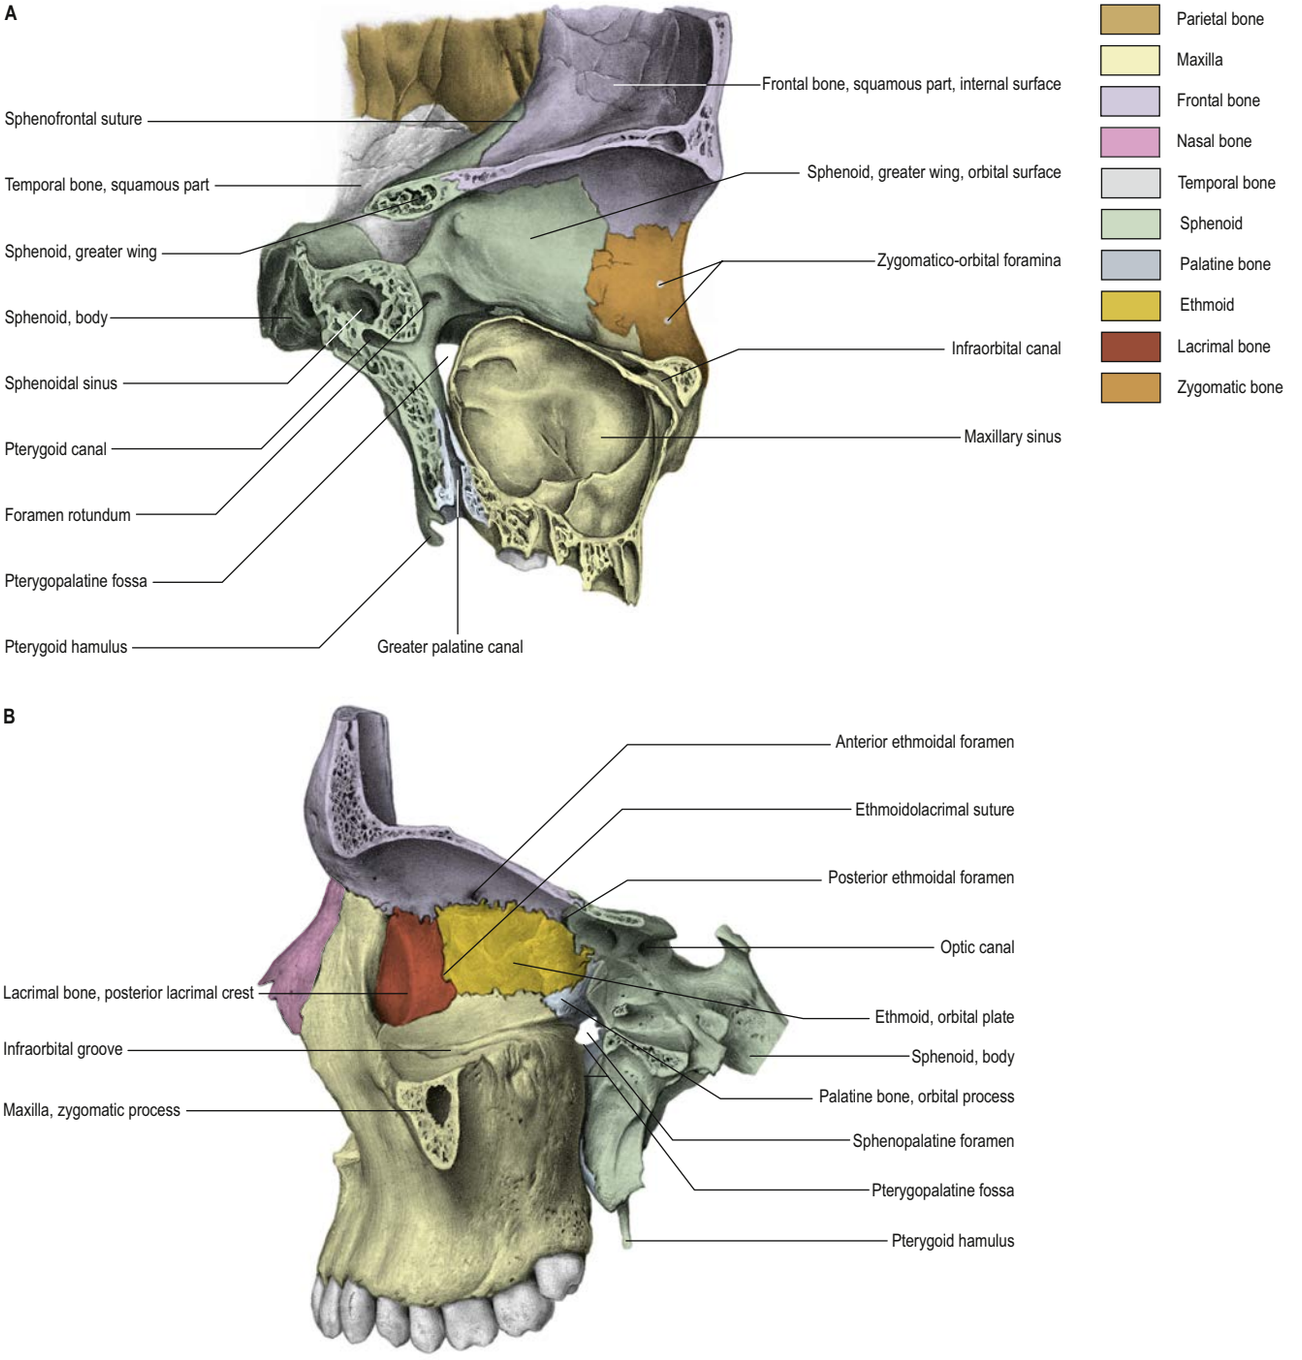


Fig. 36.6 A, Sagittal view of the facial skeleton, showing the bones forming the lateral wall of the left orbit and the maxillary air sinus. **B**, The bones forming the medial wall and the floor of the left orbit. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

they are difficult to visualize radiographically until the end of the first year. They grow slowly and have almost reached adult size by the age of 12 years.

Inferior nasal concha

The inferior nasal conchae are curved horizontal laminae in the lateral nasal walls (see Fig. 36.5). Each has two surfaces (medial and lateral), two borders (superior and inferior) and two ends (anterior and posterior). The medial surface is convex, much perforated, and longitudinally grooved by vessels. The lateral surface is concave and part of the inferior meatus. The superior border, thin and irregular, may be divided into three regions: an anterior region articulating with the conchal crest of the maxilla; a posterior region articulating with the conchal crest of the palatine bone; and a middle region with three processes, which are variable in size and form. The lacrimal process is small and pointed and lies towards the front. It articulates apically with a descending process from the lacrimal bone, and at its margins with the edges of the nasolacrimal groove on the medial surface of the maxilla, thereby helping to complete the nasolacrimal canal. Most posteriorly, a thin ethmoidal process ascends to articulate with the uncinate process of the ethmoid bone. An intermediate thin maxillary process curves inferolaterally to articulate with the medial surface of the maxilla at the opening of the maxillary sinus. The inferior border is thick and spongiose, especially in its mid part. The anterior and posterior ends of the inferior nasal concha are more or less tapered, the posterior more so than the anterior.

Ossification

The inferior nasal concha ossifies from one centre that appears at about postmenstrual weeks 17–20 in the incurved lower border of the

cartilaginous lateral wall of the nasal capsule. The inferior concha loses continuity with the nasal capsule during ossification.

Lacrimal bone

The lacrimal bones are the smallest and most fragile of the cranial bones and lie anteriorly in the medial walls of the orbits (**Figs 36.5B**, **36.6B**). Each has two surfaces (medial and lateral) and four borders (anterior, posterior, superior and inferior). The lateral (orbital) surface is divided by a vertical posterior lacrimal crest. Anterior to the crest, the anterior edge of a vertical groove articulates with the posterior border of the frontal process of the maxilla to complete the fossa that houses the lacrimal sac. The medial wall of the groove is prolonged by a descending process that contributes to the formation of the nasolacrimal canal by articulating with the lips of the nasolacrimal groove of the maxilla and the lacrimal process of the inferior nasal concha. A smooth part of the medial orbital wall lies behind the posterior lacrimal crest; the lacrimal part of orbicularis oculi is attached to this surface and crest. The surface ends inferiorly in the lacrimal hamulus, which together with the maxilla completes the upper opening of the nasolacrimal canal. The hamulus can appear as a separate lesser lacrimal bone. The anteroinferior region of the medial (nasal) surface is part of the middle meatus. Its posterosuperior part articulates with the ethmoid to complete some of the anterior ethmoidal air cells. The anterior border of the lacrimal bone articulates with the frontal process of the maxilla, the posterior border with the orbital plate of the ethmoid bone, the superior border with the frontal bone, and the inferior border with the orbital surface of the maxilla.

Ossification

The lacrimal bone ossifies from a centre that appears at about postmenstrual week 12 in mesenchyme around the nasal capsule. In later life, the lacrimal bone is subject to patchy erosion.

Nasal bone

The nasal bones are small, oblong, variable in size and form, and placed side by side between the frontal processes of the maxillae, jointly forming the nasal bridge (see Figs 36.4, 36.5, 36.6B). Each nasal bone has two surfaces (external and internal) and four borders (superior, inferior, lateral and mesial). The external surface has a descending concavo-convex profile and is transversely convex. It is covered by procerus and nasalis and perforated centrally by a small foramen that transmits a vein. The internal surface, transversely concave, bears a longitudinal groove that houses the anterior ethmoidal nerve. The superior border, thick and serrated, articulates with the nasal part of the frontal bone. The inferior border, thin and notched, is attached to the lateral nasal cartilage. The lateral border articulates with the frontal process of the maxilla. The medial border, thicker above, articulates with its fellow and projects behind as a vertical crest, so forming a small part of the nasal septum. It articulates from above with the nasal spine of the frontal bone, the perpendicular plate of the ethmoid bone, and the nasal septal cartilage.

Ossification

The nasal bone ossifies from a centre that appears about postmenstrual week 12 in the mesenchyme overlying the cartilaginous anterior part of the nasal capsule.

Vomer

The vomer is thin, flat and almost trapezoid (see Fig. 36.4). It forms the posteroinferior part of the nasal septum and presents two surfaces and four borders. Both surfaces are marked by grooves for nerves and vessels. A prominent groove for the nasopalatine nerve and vessels lies obliquely in an anteroinferior plane. The superior border is thickest, and possesses a deep furrow between projecting alae, which fits and articulates with the rostrum of the body of the sphenoid bone. The alae articulate with the sphenoidal conchae, the vaginal processes of the medial pterygoid plates of the sphenoid bone, and the sphenoidal processes of the palatine bones. Where each ala lies between the body of the sphenoid and the vaginal process, its inferior surface helps to form the vomerovaginal canal. The inferior border articulates with the median nasal crests of the maxilla and palatine bones. The anterior border is the longest and articulates in its upper half with the perpendicular plate of the ethmoid bone. Its lower half is cleft to receive the inferior margin of the nasal septal cartilage. The concave posterior border is thick and bifid superiorly and thin inferiorly and separates the posterior nasal apertures. The anterior extremity of the vomer articulates with the posterior margin of the maxillary incisor crest and descends between the incisive canals.

Inability to identify the vomer during antenatal ultrasound scanning in the first and early second trimesters of pregnancy has been suggested as a marker for trisomy 13 or 21, with a diagnostic accuracy of 0.985 (Mihailovic et al 2012).

Ossification

The nasal septum is initially a plate of cartilage, part of which is ossified superiorly to form the perpendicular plate of the ethmoid. Its anteroinferior region persists as septal cartilage. The vomer is ossified in a layer of connective tissue that covers the cartilage posteroinferiorly on each aspect. At about postfertilization week 8, two centres appear flanking the midline. In postmenstrual week 12 these unite below the cartilage to form a deep groove for the nasal septal cartilage. Union of the bony lamellae progresses anterosuperiorly while the intervening cartilage is absorbed. By puberty, the lamellae are almost united, but evidence of their bilaminar origin remains in the everted alae and anterior marginal groove.

Zygomatic bone

Each zygomatic bone forms the prominence of a cheek, contributes to the floor and lateral wall of the orbit, and the walls of the temporal and infratemporal fossae and completes the zygomatic arch. Each is roughly quadrangular and is described as having three surfaces, five borders and two processes (**Fig. 36.7**).

The lateral (facial) surface is convex and is pierced near its orbital border by the zygomaticofacial foramen that is often double and occasionally absent: when present, it transmits the zygomaticofacial nerve and

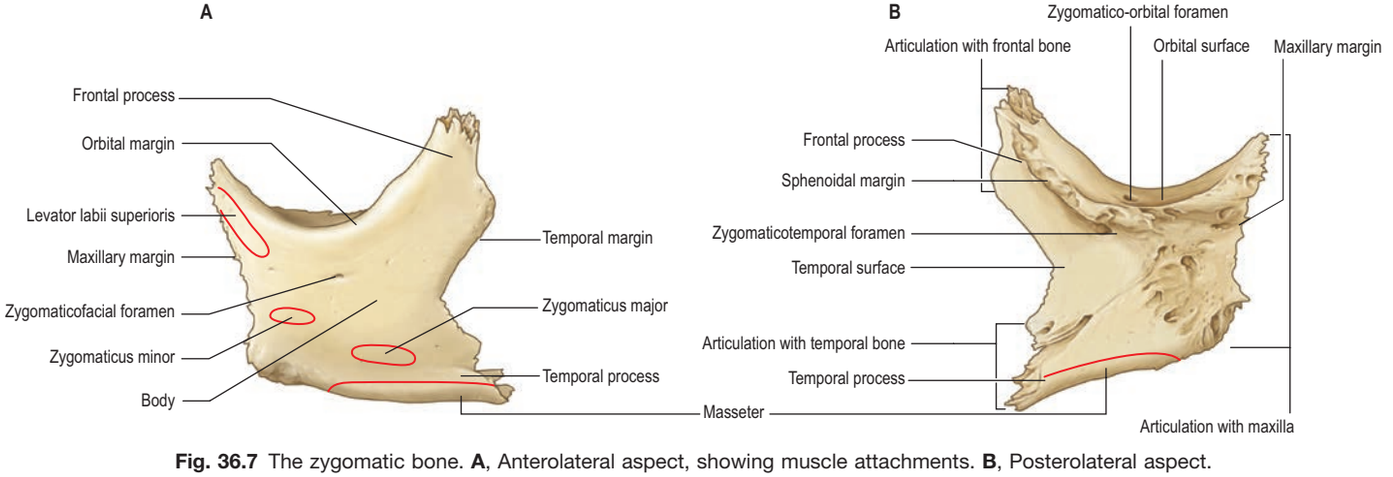

Fig. 36.7 The zygomatic bone. **A**, Anterolateral aspect, showing muscle attachments. **B**, Posterolateral aspect.

vessels. This surface gives attachment to zygomaticus major posteriorly and zygomaticus minor anteriorly. The posteromedial (temporal) surface has a rough anterior area for articulation with the zygomatic process of the maxilla and a smooth, concave posterior area that extends up posteriorly on its frontal process as the anterior aspect of the temporal fossa. It also extends back on the medial aspect of the temporal process as an incomplete lateral wall for the infratemporal fossa. The zygomaticotemporal foramen pierces this surface near the base of the frontal process. The smooth and concave orbital surface forms the anterolateral part of the floor and adjoining lateral wall of the orbit and extends up on the medial aspect of its frontal process. It usually bears zygomatico-orbital foramina that represent the openings of canals leading to the zygomaticofacial and zygomaticotemporal foramina.

The smoothly concave anterosuperior (orbital) border forms the inferolateral circumference of the orbital opening and separates the orbital and lateral surfaces of the bone. The anteroinferior (maxillary) border articulates with the maxilla. Its medial end tapers to a point above the infraorbital foramen. A part of levator labii superioris is attached at this surface. The posterosuperior (temporal) border is sinuous, convex above and concave below, and is continuous with the posterior border of the frontal process and upper border of the zygomatic arch. The temporal fascia is attached to this border. There is often a small, easily palpable, marginal tubercle below the frontozygomatic suture. The posteroinferior border is roughened for the attachment of masseter. The serrated posteromedial border articulates with the greater wing of the sphenoid bone superiorly, and the orbital surface of the maxilla inferiorly. Between these serrated regions a short, concave, nonarticular part usually forms the lateral edge of the inferior orbital fissure: this part is occasionally absent, in which case the fissure is completed by the articulation of the maxilla and sphenoid (or with a small sutural bone between them).

The frontal process, thick and serrated, articulates superiorly with the zygomatic process of the frontal bone and posteriorly with the greater wing of the sphenoid. A tubercle of varying size and form, Whitnall's tubercle, is usually present on its orbital aspect, within the orbital opening and about 1 cm below the frontozygomatic suture. This tubercle provides attachment for the lateral palpebral ligament, the suspensory ligament of the eye, and part of the aponeurosis of levator palpebrae superioris (Ch. 44). The temporal process, directed backwards, has an oblique, serrated end that articulates with the zygomatic process of the temporal bone to complete the zygomatic arch.

Ossification

The zygomatic bone ossifies from one centre that appears in fibrous tissue about postfertilization week 8. The bone is sometimes divided by a horizontal suture into a larger upper and smaller lower part.

Maxilla

The maxillae jointly form the whole of the upper jaw. Each bone forms the greater part of the floor and lateral wall of the nasal cavity, and of the floor of the orbit; contributes to the infratemporal and pterygopalatine fossae; and bounds the inferior orbital and pterygomaxillary fissures. Each maxilla has a body and four processes, namely: the zygomatic, frontal, alveolar and palatine processes (see Fig. 36.6; **Fig. 36.8**).

Body

The body of the maxilla is roughly pyramidal, and has anterior, infratemporal (posterior), orbital and nasal surfaces that enclose the maxillary sinus.

Anterior surface

The anterior surface faces anterolaterally and displays inferior elevations overlying the roots of teeth. There is a shallow incisive fossa above the incisors to which depressor septi is attached. A slip of orbicularis oris is attached to the alveolar border below this fossa, and nasalis is attached superolateral to it. Lateral to the incisive fossa is a larger, deeper canine fossa; levator anguli oris is attached to the bone of this fossa. The incisive and canine fossae are separated by the canine eminence overlying the socket of the canine tooth. The infraorbital foramen lies above the fossa and transmits the infraorbital vessels and nerve. Above the foramen, a sharp border separates the anterior and orbital surfaces of the bone and contributes to the infraorbital margin. Levator labii superioris is attached here above the infraorbital foramen and levator anguli oris is attached below it. Medially, the anterior surface ends at a deeply concave nasal notch, terminating in a pointed process that, with its contralateral fellow, forms the anterior nasal spine. Nasalis and depressor septi are attached to the anterior surface near the notch.

Infratemporal surface

The infratemporal surface is concave and faces posterolaterally, forming the anterior wall of the infratemporal fossa. It is separated from the anterior surface by the zygomatic process and a ridge (jugal crest) that ascends to it from the first molar socket. Near its centre are the openings of two or three alveolar canals that transmit posterior superior alveolar vessels and nerves. Posteroinferior is the maxillary tuberosity, roughened superomedially where it articulates with the pyramidal process of the palatine bone. A few fibres of medial pterygoid are attached here. Above the tuberosity, the smooth anterior boundary of the pterygopalatine fossa is grooved by the maxillary nerve as it passes laterally and slightly upwards into the infraorbital groove on the orbital surface.

Orbital surface

The orbital surface is smooth and triangular and forms most of the floor of the orbit. Anteriorly, its medial border bears a lacrimal notch, behind which it articulates with the lacrimal bone, the orbital plate of the ethmoid and, posteriorly, with the orbital process of the palatine bone. Its posterior border is smoothly rounded and forms most of the anterior edge of the inferior orbital fissure. The infraorbital groove lies centrally. The anterior border is part of the orbital margin and it articulates medially with the lacrimal crest of the frontal process of the maxilla. The infraorbital groove transmits the infraorbital vessels and nerve, and begins midway on the posterior border, where it is continuous with a groove on the posterior surface. It passes forwards into the infraorbital canal, which opens on the anterior surface below the infraorbital margin. Near its midpoint, the infraorbital canal gives off a small lateral branch, the canalis sinuosus, that transmits the anterior superior alveolar nerve and vessels. The canalis sinuosus descends in the orbital floor lateral to the infraorbital canal, curves medially in the anterior wall of the maxillary sinus, and then passes below the infraorbital foramen to the margin of the anterior nasal aperture in front of the anterior end of the inferior concha. It follows the lower margin of the aperture and opens near the nasal septum in front of the incisive canal. The site of the attachment of inferior oblique may be indicated by a small depression in the bone at the anteromedial corner of the orbital surface, lateral to the lacrimal groove.

Nasal surface

The nasal surface displays posterosuperiorly a large, irregular maxillary hiatus that leads into the maxillary sinus. Parts of air sinuses that are completed by articulation with the ethmoid and lacrimal bones lie at the upper border of the hiatus. The smooth concave surface below the hiatus is part of the inferior meatus. Posteriorly, the surface is roughened where it articulates with the perpendicular plate of the palatine bone. This surface is traversed by a groove that descends forwards from the mid-posterior border and is converted into a greater palatine canal by the perpendicular plate. Anterior to the hiatus, a deep nasolacrimal groove, continuous above with the lacrimal groove, makes up about two-thirds of the circumference of the nasolacrimal canal. The rest is contributed by the descending part of the lacrimal bone and the lacrimal process of the inferior nasal concha. The nasolacrimal canal conveys the nasolacrimal duct to the inferior meatus. More anteriorly, an oblique conchal crest articulates with the inferior nasal concha. The concavity below it is part of the inferior meatus, while the surface above it is part of the atrium of the middle meatus.

Zygomatic process

Anterior, infratemporal and orbital surfaces of the maxilla converge at a pyramidal projection, the zygomatic process. Anteriorly, this process merges into the facial surface of the body of the maxilla; posteriorly, it is concave and continuous with the infratemporal surface; superiorly, it is roughly serrated for articulation with the zygomatic bone; and inferiorly, a bony arched ridge, the zygomatico-alveolar ridge or jugal crest, separates the facial (anterior) and infratemporal surfaces.

Frontal process

The frontal process projects posterosuperiorly between the nasal and lacrimal bones. Its lateral surface is divided by a vertical anterior lacrimal crest that gives attachment to the medial palpebral ligament and is continuous below with the infraorbital margin. A small, palpable tubercle at the junction of the crest and orbital surface is a guide to the lacrimal sac. The smooth area anterior to the lacrimal crest merges below with the anterior surface of the body of the maxilla. Parts of orbicularis oculi and levator labii superioris alaeque nasi are attached here. Behind the

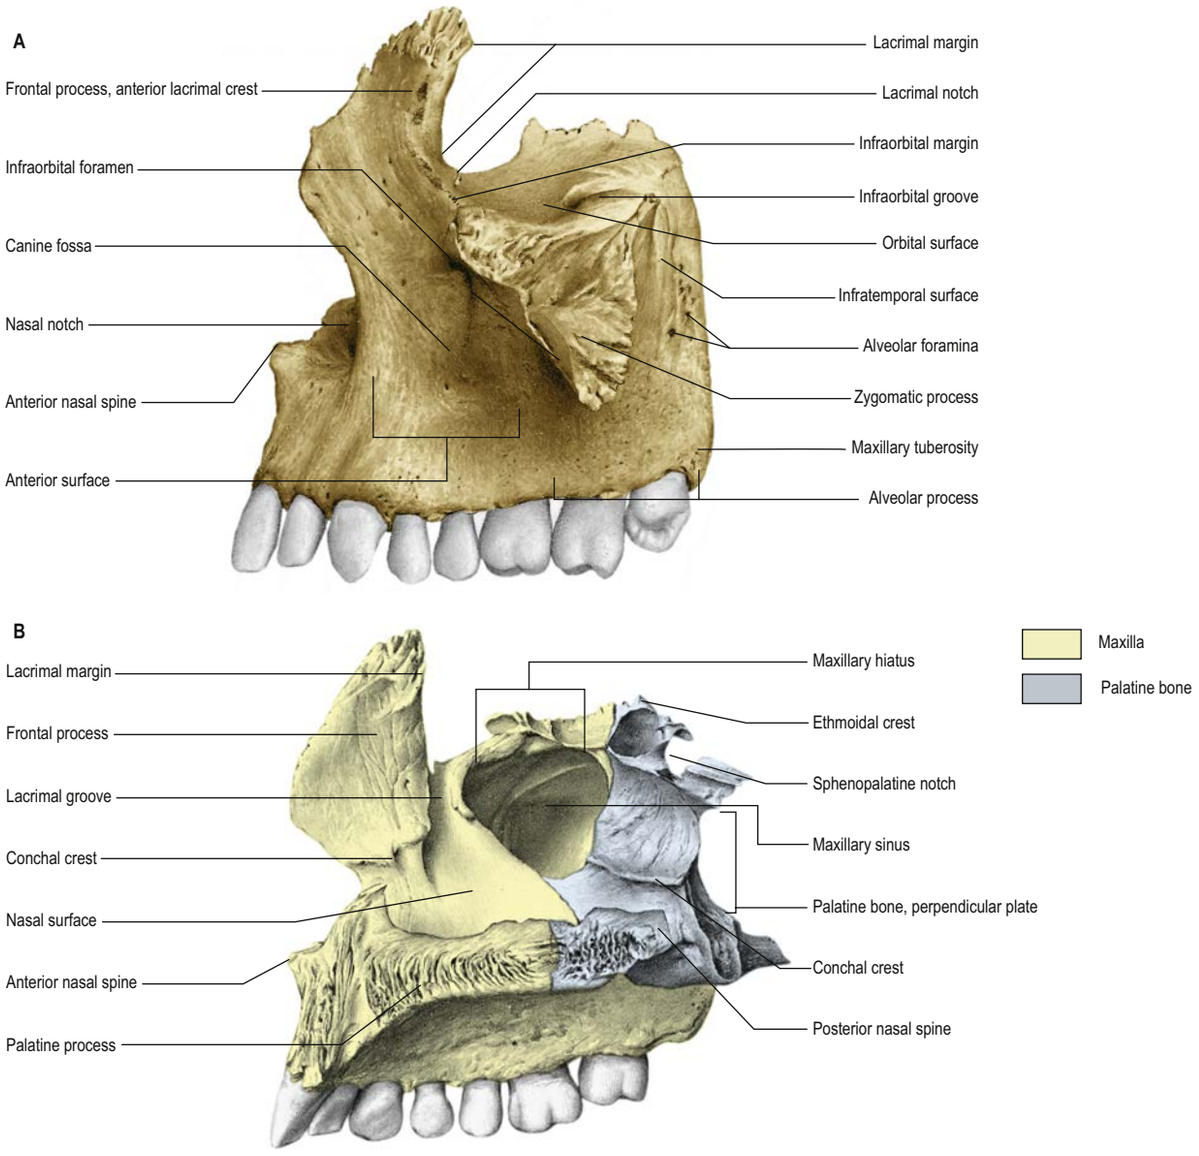

Fig. 36.8 A, The maxilla, lateral view. **B**, The maxilla and palatine bone, medial view. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

crest, a vertical groove combines with a groove on the lacrimal bone to complete the lacrimal fossa. The medial surface is part of the lateral nasal wall. A rough subapical area articulates with the ethmoid and closes the anterior ethmoidal air cells. Below this, an oblique ethmoidal crest articulates posteriorly with the middle nasal concha, and anteriorly underlies the agger nasi, a ridge anterior to the concha on the lateral nasal wall. The ethmoidal crest forms the upper limit of the atrium of the middle meatus. The frontal process articulates above with the nasal part of the frontal bone, its anterior border articulates with the nasal bone and its posterior border articulates with the lacrimal bone.

Alveolar process

The alveolar process is thick and arched, wide posteriorly, and socketed for the roots of the upper teeth. The eight sockets on each side vary according to the tooth type. The socket for the canine is deepest, the sockets for the molars are widest and subdivided into three by septa, those for the incisors and second premolar are single, and the socket for the first premolar is usually double. Buccinator is attached to the external alveolar aspect as far forwards as the first molar. In articulated maxillae, the processes form the alveolar arch. Occasionally, a variably prominent maxillary torus is present in the midline of the palate.

Palatine process

The palatine process is thick and horizontal and projects medially from the lowest part of the medial aspect of the maxilla. It forms a large part of the nasal floor and hard palate and is much thicker anteriorly. Its inferior surface is concave and uneven, and with its contralateral fellow it forms the anterior three-quarters of the osseous (hard) palate. The palatine process displays numerous vascular foramina and depressions for palatine glands; posterolaterally, two grooves transmit the greater palatine vessels and nerves. The infundibular incisive fossa is placed between the two maxillae, behind the incisor teeth. The median intermaxillary palatal suture runs posterior to the fossa, and although a little uneven, is usually relatively flat on its oral aspect. Its bony margins are sometimes raised into a prominent longitudinal palatine torus. Two lateral incisive canals, each ascending into its half of the nasal cavity, open in the incisive fossa and transmit the terminations of the greater palatine artery and nasopalatine nerve. Two additional median openings, anterior and posterior incisive foramina, are occasionally present; they transmit the nasopalatine nerves, the left nerve usually passes through the anterior foramen, and the right nerve usually passes through the posterior foramen. On the inferior palatine surface, a fine groove (the incisive suture), extending anterolaterally from the incisive fossa to the interval between the lateral incisor and canine teeth, is prominent in young skulls and can be observed in adult skulls. The superior surface of the palatine process is smooth and concave transversely, and forms most of the nasal floor. The incisive canal lies anteriorly, near its median margin. The lateral border is continuous with the body of the maxilla. The medial border, thicker anteriorly, is raised into a nasal crest that, with its contralateral fellow, forms a groove for the vomer. Anteriorly, this ridge rises higher as an incisor crest, prolonged forwards into a sharp process that, with its fellow, forms an anterior nasal spine. The posterior border is serrated for articulation with the horizontal plate of the palatine bone.

Maxillary sinus

The maxillary sinus is the largest of the paranasal sinuses and is situated in the body of the maxilla. It is described in detail in Chapter 39.

Ossification

The maxilla and premaxilla have primary ossification centres from postfertilization week 7 and three further centres in postfertilization week 8. The pattern of spread of ossification can initially leave an unmineralized zone roughly corresponding to a site where a premaxillary suture can occur. However, this deficiency is soon ossified, and there is no evidence of a separate centre of ossification for the incisor-bearing portion of the maxilla (premaxilla).

The maxillary sinus appears as a shallow groove on the nasal aspect at about postmenstrual weeks 13–16. Though small at birth, the sinus is identifiable radiologically. After birth, it enlarges with the growing maxilla, though it is only fully developed following the eruption of the permanent dentition. The infraorbital vessels and nerve are, for a time, in an open groove in the orbital floor; the anterior part of the groove is subsequently converted into a canal by a lamina that grows in from the lateral side.

At birth, the transverse and sagittal maxillary dimensions are greater than the vertical. The frontal process is prominent, but the body is little more than an alveolar process because the alveoli reach almost to the orbital floor. In adults, the vertical dimension is the greatest, reflecting the development of the alveolar process and enlargement of the sinus. When teeth are lost, the bone reverts towards its infantile shape; its height diminishes, the alveolar process is absorbed, and the lower parts of the bone contract and become reduced in thickness at the expense of the labial wall.

Palatine bone

The palatine bones are posteriorly placed in the nasal cavity, between the maxillae and the pterygoid processes of the sphenoid bones. They contribute to the floor and lateral walls of the nose, to the floor of the orbit and the hard palate, to the pterygopalatine and pterygoid fossae, and to the inferior orbital fissures. Each has two plates (horizontal and perpendicular), arranged as an L-shape, and three processes (pyramidal, orbital and sphenoidal) (**Fig. 36.9**).

Horizontal plate

The horizontal plate is quadrilateral, with two surfaces (nasal and palatine) and four borders (anterior, posterior, lateral and medial). The nasal surface, transversely concave, forms the posterior nasal floor. The palatine surface articulates with its contralateral fellow to form the posterior quarter of the bony palate. There is often a curved palatine crest near its posterior margin. The posterior border is thin and concave; the expanded tendon of tensor veli palatini is attached to it and to its adjacent surface posterior to the palatine crest. Medially, articulating with its contralateral fellow, the posterior border forms a median posterior nasal spine to which musculus uvulae is attached. The anterior border is serrated and articulates with the palatine process of the maxilla. The lateral border is continuous with the perpendicular plate of the palatine bone and is marked by a greater palatine groove. The medial border is thick and serrated, and articulates with its contralateral fellow in the midline, forming the posterior part of the nasal crest that articulates with the posterior part of the lower edge of the vomer.

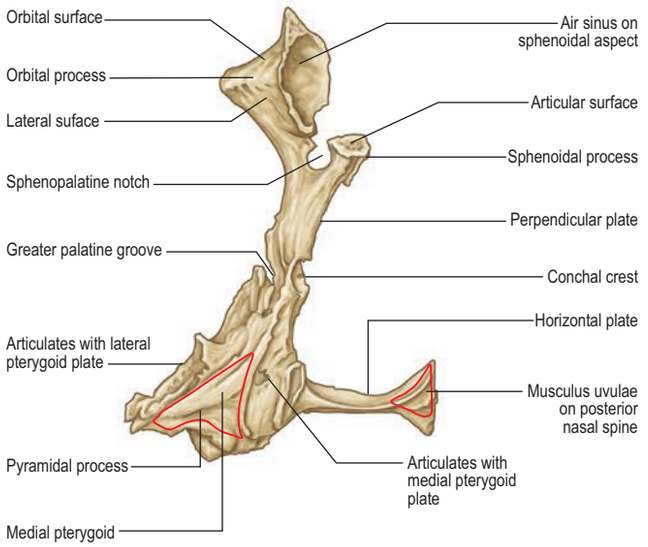

Fig. 36.9 The palatine bone, posterior view.

Perpendicular plate

The perpendicular plate is thin and oblong and has two surfaces (nasal and maxillary) and four borders (anterior, posterior, superior and inferior) (see Figs 36.8B, 36.9). The nasal surface bears two crests (conchal and ethmoidal) and shows areas that contribute to the inferior, middle and superior meatuses. Inferiorly, the nasal surface is concave where it contributes to part of the inferior meatus. Superiorly, a horizontal conchal crest articulates with the inferior concha. Above the conchal crest, the surface presents a shallow depression that forms part of the middle meatus; it is limited superiorly by an ethmoidal crest for the middle nasal concha, above which a narrow, horizontal groove forms part of the superior meatus.

The maxillary surface is largely rough and irregular and articulates with the nasal surface of the maxilla. Posterosuperiorly, it forms a smooth medial wall to the pterygopalatine fossa. Its anterior area, also smooth, overlaps the maxillary hiatus from behind to form a posterior part of the medial wall of the maxillary sinus. A deep, obliquely descending greater palatine groove (converted into a canal by the maxilla) lies posteriorly on this maxillary surface and transmits the greater palatine vessels and nerve.

The anterior border is thin and irregular. Level with the conchal crest, a pointed lamina projects below and behind the maxillary process of the inferior concha; it articulates with it and so appears in the medial wall of the maxillary sinus. The posterior border articulates via a serrated suture with the medial pterygoid plate. It is continuous above with the sphenoidal process of the palatine bone and expands below into its pyramidal process. Orbital and sphenoidal processes project from the superior border and are separated by the sphenopalatine notch, which is converted into a foramen by articulation with the body of the sphenoid. This foramen connects the pterygopalatine fossa to the posterior part of the superior meatus and transmits sphenopalatine vessels and the posterior superior nasal nerves. The inferior border is continuous with the lateral border of the horizontal plate and bears the lower end of the greater palatine groove anterior to the pyramidal process.

Pyramidal process

The pyramidal process slopes down posterolaterally from the junction of the horizontal and perpendicular palatine plates into the angle between the pterygoid plates of the sphenoid bone. On its posterior surface, a smooth, grooved triangular area, limited on each side by rough articular furrows that articulate with the pterygoid plates, completes the lower part of the pterygoid fossa. Anteriorly, the lateral surface articulates with the maxillary tuberosity. This area gives attachment to fibres of the superficial head of medial pterygoid. Posteriorly, a smooth triangular area appears low in the infratemporal fossa between the tuberosity and the lateral pterygoid plate. The inferior surface, near its union with the horizontal plate, bears the lesser palatine foramina that transmit the lesser palatine nerves and vessels.

Orbital process

The orbital process is directed superolaterally from in front of the perpendicular plate and has a constricted 'neck'. It encloses an air sinus and presents three articular and two non-articular surfaces. Of the articular surfaces, the oblong anterior (maxillary) surface faces down and anterolaterally and articulates with the maxilla. The posterior (sphenoidal) surface is directed up and posteromedially and bears the opening of an air sinus. It usually communicates with the sphenoidal sinus and is completed by a sphenoidal concha. The medial (ethmoidal) surface faces anteromedially and articulates with the labyrinth of the ethmoid bone. The sinus of the orbital process sometimes opens on the surface and communicates with the posterior ethmoidal air cells. More rarely, it opens on both the ethmoidal and sphenoidal surfaces, and communicates with the posterior ethmoidal air cells and the sphenoidal sinus.

Of the non-articular surfaces, the triangular superior (orbital) surface is directed superolaterally to the posterior part of the orbital floor. The lateral surface is oblong, faces the pterygopalatine fossa, and is separated from the orbital surface by a rounded border that forms a medial part

of the lower margin of the inferior orbital fissure. This surface may present a groove, directed superolaterally, for the maxillary nerve, and is continuous with the groove on the upper posterior surface of the maxilla. The border between the lateral and posterior surfaces descends anterior to the sphenopalatine notch.

Sphenoidal process

The sphenoidal process is a thin plate that is smaller and lower than the orbital process, and is directed superomedially. Its superior surface articulates with the sphenoidal concha and, above it, with the root of the medial pterygoid plate. It carries a groove that contributes to the formation of the palatovaginal canal. The concave inferomedial surface forms part of the roof and lateral wall of the nasal cavity. Posteriorly, the lateral surface articulates with the medial pterygoid plate, while its smooth anterior region forms part of the medial wall of the pterygopalatine fossa. The posterior border articulates with the vaginal process of the medial pterygoid plate. The anterior border is the posterior edge of the sphenopalatine notch. The medial border articulates with the ala of the vomer.

Ossification

The palatine bone ossifies in mesenchyme from one centre in the perpendicular plate that appears during postfertilization week 8. From this centre, ossification spreads into all parts. At birth, the height of the perpendicular plate equals the width of the horizontal plate, but in adults it is almost twice as great, a change in proportions that accords with those that occur in the maxilla.

Fractures of the facial skeleton

Trauma to the face is common; outcomes are related to the mechanism of the injury in terms of its severity and to delays in treatment. Both soft and hard tissues are affected. Moderate to severe injuries produce facial skeletal disruption that compromises masticatory and orbital function. Inadequate skeletal support of soft tissues contributes to facial asymmetry and the additional loss of soft tissues and subsequent scarring merely compound this. Some fractures pass through foramina, damage branches of the trigeminal nerve and result in sensory deficits. Fracture configurations vary according to the amount of energy absorbed and local anatomical factors that constitute sites of weakness. The direction and magnitude of the applied forces determine the displacement of these fractures, which are modified according to muscle attachments and the state of the dentition, e.g. an unerupted mandibular third molar may produce a weak point at the mandibular angle.

Lateral pterygoid frequently displaces a fractured mandibular condyle medially. Masseter, temporalis and medial pterygoid can stabilize fractures of the mandible when vertically or horizontally favourable, but displace those that are vertically and horizontally unfavourable. Severe injuries to the middle third of the face may result in craniofacial dysjunction, the middle third sliding inferiorly down the angulated and strong anterior skull base, causing an apparent lengthening of the face and a dish-faced appearance. Airway obstruction may result from this downward and backward displacement. Fractures of the anterior mandible may cause loss of support of the muscles controlling the anterior tongue position and may also contribute to loss of the airway.

Although the fractures caused by severe injuries are often complex, it is convenient to describe them as arising in the upper, middle and lower thirds of the face, even though fractures may involve one or more of these areas. Upper third fractures involve the frontal bones. Middle third fractures involve the nasoethmoidal complex, orbit, zygomatic complex and maxilla. Lower third fractures correspond to fractures of the mandible.

MUSCLES OF THE FACE

Craniofacial muscles are associated with the orbital margins and eyelids, external nose and nostrils, lips, cheeks and mouth, pinna, scalp and cervical skin, and collectively are often called, not very accurately, 'muscles of facial expression' (Fig. 36.17). Their organization differs from that of muscles in most other regions of the body because there is no deep membranous fascia beneath the skin of the face, and many small slips of muscle that are attached to the facial skeleton insert directly into the skin.

Although these muscles produce movements of the facial skin that reflect emotions, it is usually argued that their primary function is to act as sphincters and dilators of the facial orifices and that the function of facial expression has developed secondarily. Embryologically, they are derived from the mesenchyme of the second branchial arch and so are innervated by the facial nerve. Topographically and functionally, the muscles of facial expression may be subdivided into epicranial, circumorbital and palpebral, nasal, and buccolabial groups (Fig. 36.18).

Epicranial muscle group

Epicranius

Epicranius consists of occipitofrontalis and temporoparietalis.

Occipitofrontalis

Occipitofrontalis covers the dome of the skull from the highest nuchal lines to the eyebrows. It is a broad, musculofibrous layer and consists of four thin, muscular quadrilateral parts, two occipital and two frontal, connected by the epicranial aponeurosis. Each occipital part (occipitalis) arises by tendinous fibres from the lateral two-thirds of the highest nuchal line of the occipital bone and the adjacent region of the mastoid part of the temporal bone to extend forward and join the aponeurosis. The gap between the two occipital parts is occupied by an extension of the epicranial aponeurosis. Each frontal part (frontalis) is adherent to the superficial fascia, particularly of the eyebrows. Although frontalis has no bony attachments of its own, its fibres blend with those of adjacent muscles, procerus, corrugator supercilii and orbicularis oculi, and ascend to join the epicranial aponeurosis anterior to the coronal suture.

Vascular supply Occipitofrontalis is supplied by branches of the superficial temporal, ophthalmic, posterior auricular and occipital arteries.

Innervation The occipital part of occipitofrontalis is supplied by the posterior auricular branch of the facial nerve. The frontal part is supplied by the temporal branches of the facial nerve.

Actions Acting from above, the frontal parts raise the eyebrows and the skin over the root of the nose (e.g. as in expressions of surprise or horror). Acting from below, the frontal parts draw the scalp forwards, throwing the forehead into transverse wrinkles. The occipital parts draw the scalp backwards. Acting alternately, the occipital and frontal parts can move the entire scalp backwards and forwards.

Variations A thin muscular slip, transversus nuchae, is sometimes present. It arises from the external occipital protuberance or from the superior nuchal line, either superficial or deep to trapezius and is frequently inserted with auricularis posterior but may blend with the posterior edge of sternocleidomastoid.

Epicranial aponeurosis

The epicranial aponeurosis covers the upper part of the cranium and, with the epicranial muscle, forms a continuous fibromuscular sheet that extends from the occiput to the eyebrows. Posteriorly, between the occipital

Fractures in the upper third of the face are almost invariably comminuted and are often associated with fractures of the middle third of the face. Fractures of the frontal bone may involve the frontal sinuses and/or orbital roof. If the frontonasal duct is traumatized, its drainage may be impaired predisposing to ascending intracranial infection and mucocele development within the frontal sinuses (Eljamel and Foy 1990; **Fig. 36.10**). This risk may be minimized with frontonasal stents or frontonasal duct and frontal sinus obliteration with autogenous bone graft. Fractures that involve both the anterior and the posterior walls of the frontal sinus also carry a risk of early and delayed intracranial infection, and it is often necessary to obliterate the frontal sinuses or cranialize the frontal sinuses in order to prevent this complication. Cranialization of the frontal sinuses involves the removal of the posterior wall and all frontal sinus mucosa, typically through a frontal craniotomy approach. Fractures of the posterior wall of the frontal sinus may be associated with dural tears (and cerebrospinal rhinorrhoea) that must be repaired at the same time. Fractures involving the orbital roof may be associated with displacement of the globe of the eye, diplopia and supraorbital nerve injury.

The middle third of the face is defined as that area bounded above by a transverse line connecting the two zygomaticofrontal sutures, passing through the frontomaxillary and frontonasal sutures, and limited below by the occlusal plane of the maxillary teeth. Posteriorly, the region is limited by the sphenoethmoidal junction, but it includes the free margins of the pterygoid plates inferiorly. Fractures of the middle third of the facial skeleton (Le Fort 1901) may involve the maxillae, palatine bones, zygomatic bones, zygomatic processes of the temporal bones, nasal bones, vomer, ethmoid bone together with its nasal conchae, and the body and greater and lesser wings of the sphenoid bone. A classification system that subdivides the fractures into central block fractures and those that involve the lateral middle third is now largely of historical value but finds use as an initial description that is later elaborated by defining extensions of the fracture pattern into the upper third and the cranium.

Central middle third of face

The majority of the skeleton of the central middle third is composed of wafer-thin sheets of cortical bone with stronger reinforcements, i.e. the palate and alveolar process; the lateral rim of the piriform aperture extending upwards (via the canine fossa) to the medial orbital rim, and finally to the glabella; the zygomatic buttress and its connections to the inferior and lateral orbital margins and the zygomatic arch; and the orbital rims and the pterygoid plates. Whatever the fracture configuration, pterygoid plate disruption is seen in all examples of maxillary fracture. The strength lies in the facial surface of the skeleton, which, although thin in most areas, is cross-braced. The design is ideally suited to transmit occlusal forces vertically to the cranial base.

Central middle third fractures may involve the nasoethmoidal complex in isolation or as part of a more complex Le Fort pattern of injury. Le Fort I, II or III fractures inevitably involve the infratemporal fossa. The bones of the midface transmit the forces of impact directly to the cranium. The most important strut related to the infratemporal and pterygopalatine fossae is the pterygomaxillary strut. Fractures involving this strut may extend elsewhere to involve the cranial base and orbit. The associated soft tissue damage that accompanies these fractures may damage nerves, blood vessels and muscles. Injuries to the maxillary or mandibular divisions of the trigeminal nerve or the chorda tympani nerve result in altered sensation to the oral cavity, face and jaws, including impaired taste. Fractures extending into the orbit may result in decreased visual acuity, ophthalmoplegia and neural damage to motor nerves. Direct damage to muscles may result in problems with chewing, swallowing, speech, middle ear function and eye movements. Injuries involving the pterygopalatine or otic ganglia interfere with lacrimation, nasal secretions and salivation. Facial deformity with lack of nasal projection, asymmetry and occlusal disturbance and vertical and anteroposterior malposition of the globe, are frequent outcomes of middle third fractures.

Nasoethmoidal complex Fractures can involve the osteocartilaginous framework of the nose in isolation or as part of complex injuries that also involve the paranasal sinuses and/or the orbits (**Fig. 36.11**).

Simple fractures involve the nasal bones and/or frontal process of the maxilla. Only if there is displacement of the bones is a closed reduction of the fracture required. The terminal branch of the anterior ethmoidal nerve and its accompanying vessels are at risk when injuries involve the dorsum of the nose.

Complex nasal injuries may include nasofrontal suture disjunction, nasolacrimal and frontonasal duct injury, and fracture of the ethmoidal complex (Markowitz et al 1991). The skeletal foundation of the nasoethmoidal complex consists of a strong triangular-shaped frame. However, all these structures are fragile and any force sufficient to fracture the frame results in severe comminution and displacement. The ethmoidal air cells act as a crumple zone protecting the cranial base from mechanical forces. A severe impact delivered to the midface, particularly over the bridge of the nose, may result in these structures being driven backwards between the orbits and may result in traumatic hypertelorism, producing an increase in distance between the pupils. Associated displacement of the medial canthal ligaments results in traumatic telecanthus. Increased intercanthal distance may be corrected using microplates, stainless steel

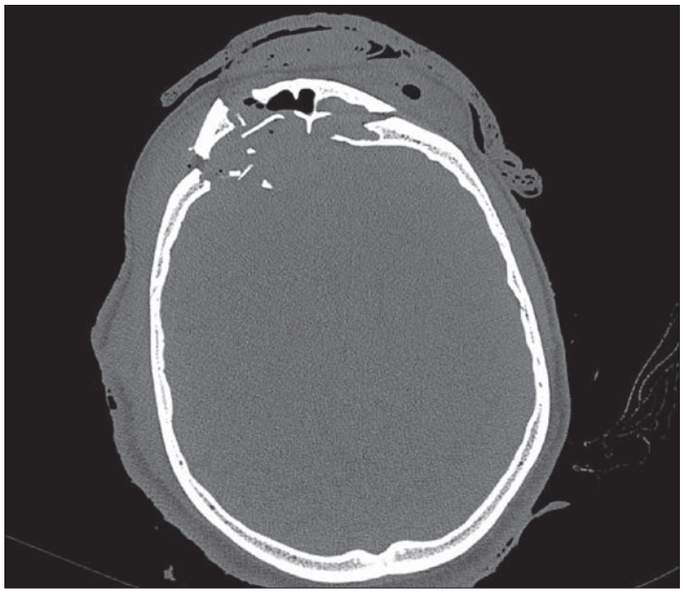

Fig. 36.10 An axial CT of a compound craniofacial fracture with disruption of the anterior and posterior walls of the frontal sinus, torn dura and intracranial bone. Treatment is directed at establishing a safe sinus, i.e. sealing off the frontonasal duct and removing all traces of sinus epithelium. It is also important to establish an intact fronto-orbital bar, to enable an accurate scaffold on which to attach the root of the nose and midface, if implicated in the fracture pattern, and to assure good cosmesis.

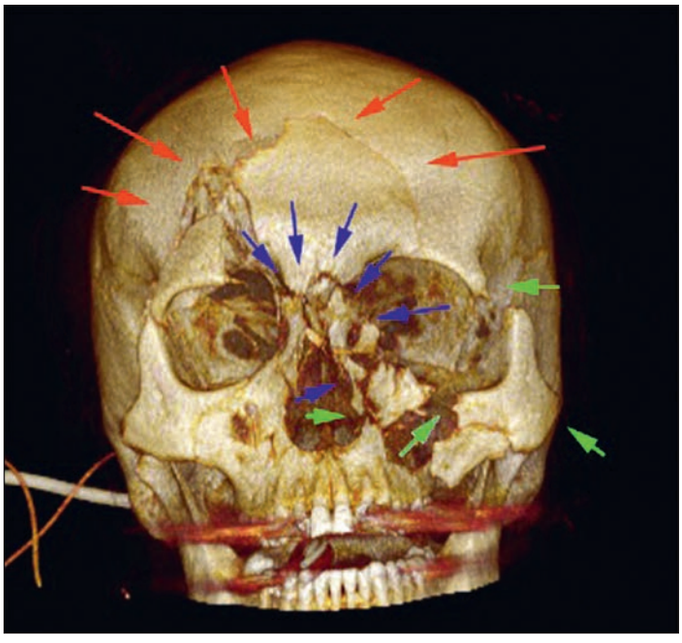

Fig. 36.11 An extended naso-orbito-ethmoid (NOE) fracture. The frontal sinus and frontal bone fracture (red arrows) need to be reconstructed to provide a stable platform for the NOE. The NOE fracture (blue arrows) extends into the anterior maxilla and blends with the extended comminuted zygomatic fracture (green arrows).

wire and acrylic canthal splints. Damage to the lacrimal system requires approximation of the severed canalicular ends or dacryocystorhinostomy. Comminution of the cribriform plates of the ethmoid bone may result in dural tears and cerebrospinal rhinorrhoea. Nasoethmoidal fractures are often combined with more extensive fractures of the frontal bone. The complexity of the injury has implications for subsequent facial reconstruction (Fig. 36.12).

Le Fort I fractures (Guerin's fracture) Le Fort I fractures consist of a horizontal fracture line above the level of the floor of the nose involving the lower third of the nasal septum. The mobile segment consists of the palate, the alveolar process and the lower thirds of the pterygoid plates.

Le Fort II fractures (pyramidal fracture) Le Fort II fractures are pyramidal fractures involving the maxillary bones. From the nasal bridge, the fracture enters the medial wall of the orbit to involve the lacrimal bone and then crosses the inferior orbital rim, usually at the junction of the medial one-third and lateral two-thirds, and often involves the infraorbital foramen. The fracture line then runs beneath the zygomaticomaxillary suture, traversing the lateral wall of the maxillary sinus to extend posteriorly and horizontally across the pterygoid plates. The zygomatic bones and arches remain attached to the skull.

Le Fort III fractures Le Fort III fractures separate the entire midfacial skeleton from the cranial base. The fracture extends through the nasal base, continues posteriorly across the ethmoid bone and then crosses the lesser wing of the sphenoid and, on occasion, involves the optic foramen. Usually, it slopes down medially, passing below the optic foramen to reach the pterygomaxillary fissure and pterygopalatine fossa. From the base of the inferior orbital fissure the fracture runs laterally and upwards, separating the greater wing of the sphenoid from the zygomatic bone to reach the frontozygomatic suture. It also extends downwards and backwards across the pterygopalatine fossa to involve the root of the pterygoid plates. The zygomatic arch is usually fractured at the zygomaticotemporal suture (Le Fort 1901). Open reduction and internal fixation are conducted through aesthetically favourable incisions in the hairline, upper eyelid, oral cavity and lower eyelid (subciliary and transconjunctival) (Fig. 36.13).

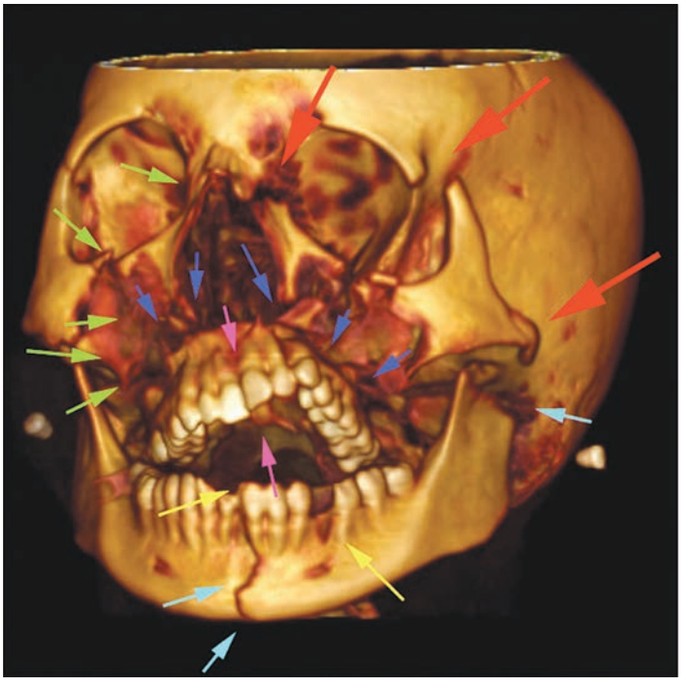

Fig. 36.12 A typical high-energy pan-facial injury. This injury demonstrates several complicated levels of Le Fort type maxillary fracture. The red arrows demonstrate the Le Fort III pattern (although the major fragment is further comminuted). The green arrows demonstrate the Le Fort II pattern, and the dark blue arrows demonstrate the Le Fort I pattern, although the maxilla is itself fractured sagittally (purple arrows). There are also bilateral condylar neck fractures and a mandibular symphysial fracture (light blue arrows). Note the avulsed lower left premolar and dental fracture of the right incisor (yellow arrows). Exclusion of inhaled dental teeth and fragments is important.

Fig. 36.13 Various examples of plating configurations and titanium alloplastic reconstructions. The aim of surgery is to reconstruct anatomy in order to provide a scaffold on which to overlay the soft tissues.

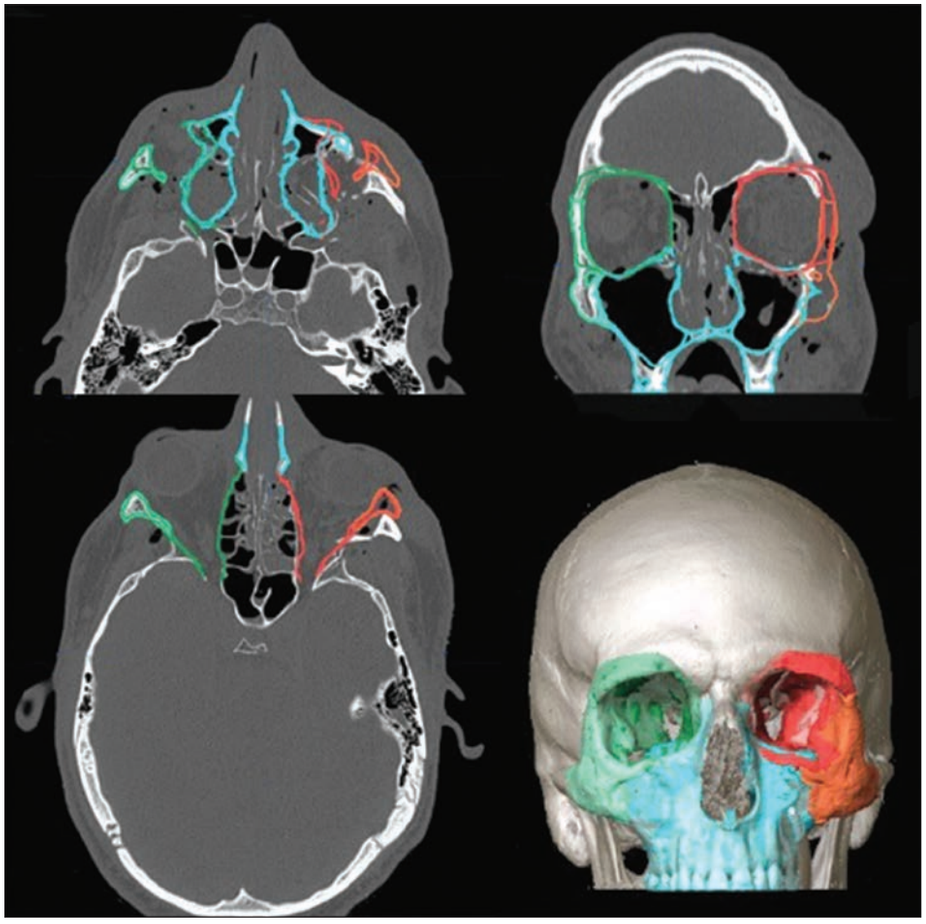

Fig. 36.14 A typical left zygomatic fracture. In this case, navigation planning takes the normal green right side and mirrors to the left. The red and orange outlines indicate where the bone should be. Axial and coronal CTs plus volume rendered reconstruction.

Lateral middle third of face

Fractures of the lateral middle third involve the zygomaticomaxillary complex (Fig. 36.14). The zygomatic bone forms the prominence of the cheek. Since the most common cause of a zygomatic fracture is a blow from a fist, depressed fractures of the zygomaticomaxillary complex are a common injury. These injuries may be sustained in isolation or in association with orbital blowout fractures. Isolated zygomatic arch fractures from a well-directed lateral blow are also common. Classic zygomatic complex fractures involve the zygomaticomaxillary, zygomaticotemporal, zygomaticofrontal and sphenozygomatic sutures. The fracture line extends from the lateral wall of the orbit laterally into the infratemporal fossa at the zygomaticofrontal suture. From this point, it extends inferiorly to join the most lateral aspect of the inferior orbital fissure and continues inferiorly along the posterior surface of the zygomatic buttress, where it communicates with the lateral bulge of the maxillary sinus (antrum). It then runs around the zygomatic buttress, high in the buccal sulcus in the upper molar region to extend upwards towards the infraorbital foramen. It finally runs laterally along the floor of the orbit to reach the lateral extension of the inferior orbital fissure. Clinical signs may include facial asymmetry, infraorbital nerve paraesthesia/anaesthesia, limitation of mouth opening (if there is impingement of the coronoid process by a depressed arch fracture) and signs of orbital blowout fracture (see below).

As zygomatic fractures involve the maxillary sinus (the lateral wall of which is frequently comminuted) and the infratemporal fossa, there is potential for spread of infection between these structures and then via foramina in the cranial base to the middle cranial fossa. Patients with zygomatic complex fractures must be advised to refrain from sneezing or nose-blowing, which may force air from the sinus into the surrounding tissues (surgical emphysema) or into the orbit, resulting in proptosis of the eye. While the zygoma may be reduced transorally (the Keen approach), or via the brow (Dingman approach), or a cheek-hook technique (Poswillo approach), it is perhaps the Gillies temporal approach that is worthy of mention here because it exploits the anatomy of the region (Gillies et al 1927). The incision is hidden in the hairline and the approach depends on the fact that the superior temporal fascia is attached to the superior temporal line of the skull superiorly and the zygomatic arch inferiorly, and that temporalis runs under the arch. An incision through the temporalis fascia, but not through the muscle, allows a metal elevator to be passed from the hairline to the zygomatic arch and body. Outward traction, coupled with rotation, allows precise localization of the bone.

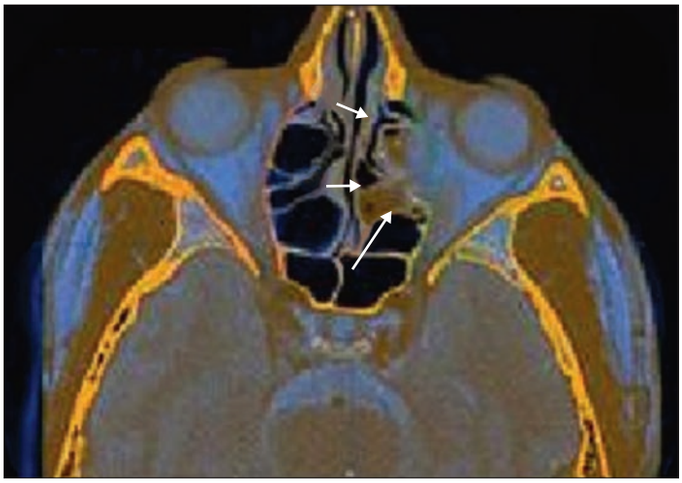

Fig. 36.15 Image fusion of computed tomography and magnetic resonance imaging, showing an extensive left medial orbital wall fracture (arrows). There is obvious herniation of orbital contents and disruption of the soft tissue contents of the orbit.

Orbital fractures The orbit is invariably involved in fractures of the zygomatic bone and in Le Fort II and III fractures and can also be involved in fractures of the frontal bone and extensive nasal complex injuries. Direct blunt trauma to the globe may result in displacement of the globe and fracture of the thin orbital floor (or medial wall) without associated rim involvement and is known as a 'blowout' fracture (Ahmas et al 2006). This protective mechanism of injury helps to maintain the integrity of the globe in preference to the orbital walls. There may be associated herniation of periorbital fat (Fig. 36.15) and/or inferior rectus, resulting in restriction of eye movement, diplopia, ipsilateral lowering of pupillary height, and enophthalmos (due to increased orbital volume) (Manson et al 1986). Fortunately, the optic foramen, situated

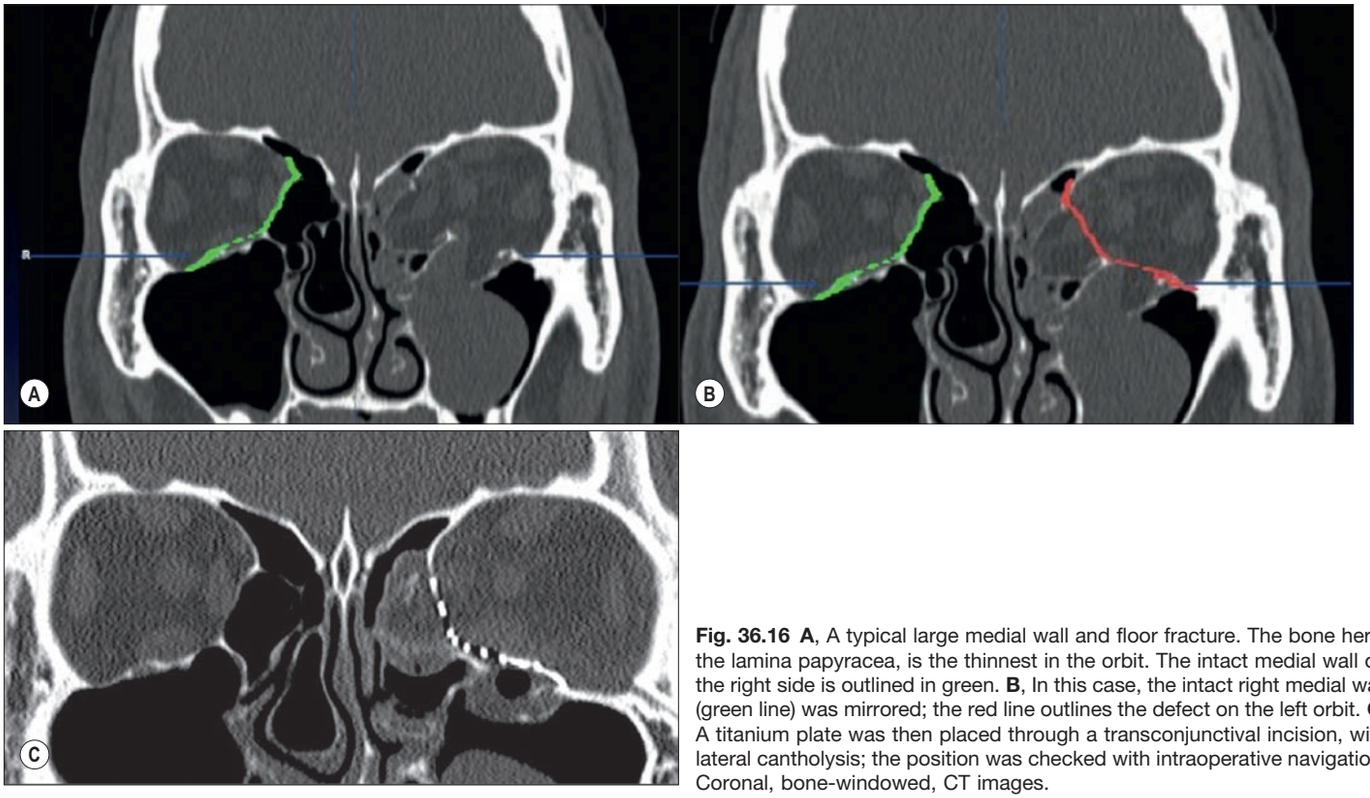

Fig. 36.16 **A**, A typical large medial wall and floor fracture. The bone here, the lamina papyracea, is the thinnest in the orbit. The intact medial wall on the right side is outlined in green. **B**, In this case, the intact right medial wall (green line) was mirrored; the red line outlines the defect on the left orbit. **C**, A titanium plate was then placed through a transconjunctival incision, with lateral cantholysis; the position was checked with intraoperative navigation. Coronal, bone-windowed, CT images.

within the lesser wing of the sphenoid bone, is surrounded by dense bone and is only rarely involved in fractures, which means that direct injury to the optic nerve is unusual. The orbital floor is normally repaired by the insertion of an alloplastic or autogenous graft (**Fig. 36.16**) (Ellis and Tan 2003).

The mandible is essentially a tubular bone bent into a blunt V shape (Ch. 37). This basic configuration is modified by sites of muscle attachment, principally masseter and medial pterygoid at the angle, and temporalis at the coronoid process. The presence of teeth, particularly those with long roots such as the canines, or of unerupted teeth, produces lines of weakness in the mandible. When the teeth are lost or fail to develop, the subsequent progressive resorption of the alveolar bone means that the mandible reverts to its underlying tubular structure. Like all tubular bones, the strength of the mandible resides in a dense cortical plate, thickened anteriorly and at its lower border, which means that the mandible is strongest anteriorly in the midline and is progressively weaker posteriorly towards the condylar processes. Again, like all tubular bones, the mandible has great resistance to compressive forces, but it fractures at sites of tensile strain. The mandible is liable to particular patterns of distribution of tensile strain when forces are applied to it. Anterior forces applied to the mental symphysis, or over the body of the mandible, lead to strain at the condylar necks and also along the lingual cortical plates on the contralateral side in the molar region. The mandible therefore often fractures at two sites and isolated fractures are relatively unusual. In order of frequency, fractures most commonly involve the neck of the condyle, the angle, the parasymphysial region and the body of the mandible.

Condylar process

The condyle is protected from direct injury by the zygomatic arches. Fractures are usually caused by transmission of force following a blow to the front of the mandible or to the contralateral mandibular body. Fractures are seen at all levels of the condyle (Loukota et al 2005). Except in children, most condylar fractures are not intracapsular but are sustained at the neck and usually run obliquely downwards and backwards from the mandibular notch. The condyle is usually displaced anteromedially (because of the attachment of lateral pterygoid to the temporomandibular joint disc, capsule and anterior border of the neck of the condyle). Most condylar fractures are managed by open reduction and early mobilization.

Angle of mandible

The majority of fractures of the mandible run posteriorly and inferiorly from the alveolar bone to the angle. The presence of a third molar tooth produces a line of weakness and a fracture line will pass through its socket. The unopposed pull of the powerful elevator muscles (masseter, medial pterygoid and temporalis) will typically displace the posterior fragment superiorly, anteriorly and medially.

Ramus and coronoid process

Fractures at the ramus exhibit very little displacement as a consequence of the splinting activity of medial pterygoid medially and masseter laterally (pterygomasseteric sling); their wide attachments to the ramus extend across the fracture lines. Similarly, the coronoid process is rarely displaced significantly because it is splinted by the tendinous insertion of temporalis.

Body of mandible

Most fractures of the body of the mandible are sustained as the result of direct trauma and tend to be concentrated in the first molar or canine region. The more anterior the site of the fracture, the more the upward displacement of the elevators is counteracted by the downward pull of geniohyoid and the anterior belly of digastric. When teeth are present, displacement is limited by the dental occlusion (i.e. further displacement is resisted by the lower and upper teeth), whereas displacement may be considerable in an edentulous patient.

Campbell's lines are five lines that are systematically traced when assessing maxillofacial radiographs. Line 1 joins the two zygomaticofrontal sutures, runs along the superior orbital margins and crosses the midline in the region of the glabella. Line 2 runs along the zygomatic bone and the inferior orbital margin, crosses the frontal process of the maxilla and lateral wall of the nose, and then passes through the nasal septum to follow a similar course to the contralateral zygomatic bone. Line 3 begins at the condyle of the mandible, passes across the mandibular notch and coronoid process of the mandible, then crosses the maxillary sinus from its lateral to medial walls and continues through the lateral wall of the nose at the level of the nasal floor; it follows a similar course on the contralateral side. Line 4 follows the occlusal plane of the upper and lower teeth, and line 5 follows the lower border of the mandible.

The cranial base, regarded clinically as the frontal, ethmoid, sphenoid and occipital bones, is a relatively solid platform inclined at an angle of 45° to the maxillary occlusal plane. Fractures of the cranial base are not readily visible on normal radiographs and are best detected on CT scans. They result in bleeding in the floor of the middle cranial fossa, which often presents as bruising over the mastoid process (Battle's sign). These fractures may be associated with dural tears and escape of cerebrospinal fluid from the nose (rhinorrhoea) or ruptured tympanic membrane (otorrhoea). If the tympanic membrane remains intact, it may appear as blue and bulging (haemotympanum).

The craniofacial skeleton has an excellent blood supply and so can be dismantled as a series of osteoplastic flaps. The surgical disarticulation of the craniofacial skeleton has been used to gain access to otherwise inaccessible sites in order to allow the surgeon to attend to pathology in the skull base, cervical spine and anterior and posterior cranial fossae. The aim is to provide increased and more direct exposure of both the pathology and the adjacent vital structures without the need to resect uninvolved structures. The craniofacial skeleton can be divided into a series of modular osteotomies that permit both independent and conjoined mobilization.

The zygomatic and nasal bones and the maxilla may be exposed, mobilized and pedicled on the overlying soft tissues either unilaterally or bilaterally. These approaches improve access to the nasal cavity, maxillary, ethmoidal and sphenoidal sinuses, the soft palate and nasopharynx, and the infratemporal fossa and pharyngeal space. The exposures may be extended to gain access to the anterior and middle cranial fossae, cavernous sinus, clivus, craniocervical junction and upper cervical vertebrae.

A variety of different access osteotomies have been described and found to be useful in specific clinical situations. Most of the osteotomies described follow the conventional patterns of facial fractures described above. The entire hemimaxilla and zygoma can be mobilized, and pedicled on the soft tissues of the face by making bone cuts that follow the lines of a Le Fort II fracture on one side. The osteotomy is completed by dividing the upper alveolus and palate just to the side of the nasal septum and perpendicular plate of the vomer. The maxilla can be mobilized at the Le Fort I level and down-fractured, pedicled on the palatoglossal muscles and soft tissue attachments, giving good access to the nasopharynx, clivus and upper cervical spine, particularly if the palate is divided in the midline.

Lateral zygomatic osteotomies may be performed to gain access to the orbital apex and infratemporal fossa. The surgical approach is from behind using a hemi- or bicoronal flap. The zygomatic complex is mobilized inferiorly, pedicled on masseter. When combined with a mandibular ramus osteotomy, access is gained to the retromaxillary area and pterygoid space as well as to the infratemporal fossa. In combination with a frontotemporal craniotomy, the zygomatic osteotomy has been used for access to the middle cranial fossa, cavernous sinus, apex of the petrous temporal bone and the interpeduncular cistern.

Dividing the lower lip in the midline and dividing the mandible either in the midline or just in front of the mental foramen, allows the hemi-mandible to be swung laterally. The technique is used to give improved access to the floor of the mouth, the base of the tongue, tonsillar fossa, soft palate, oropharynx, posterior pharyngeal wall, supraglottic larynx and pterygomandibular region. By extending the dissection laterally, access is gained to the pterygoid space, infratemporal fossa and parapharyngeal space. By dissecting more medially, access is gained to the nasopharynx, lower part of the clivus and all seven of the cervical vertebrae. A modification of the mandibular swing procedure increases access up to the skull base, by combining the classic mandibular swing with a horizontal osteotomy of the mandibular ramus above the level of the lingula.

parts of occipitofrontalis, it is attached to the external protuberance and highest nuchal line of the occipital bone. Anteriorly, it splits to enclose the frontal parts and sends a short, narrow prolongation between them. Laterally, the anterior and superior auricular muscles are attached to it; the aponeurosis is thinner and continues over the temporal fascia to the zygomatic arch. It is united to the skin lying over the cranial vault by fibrous superficial fascia, but it is connected more loosely to the underlying pericranium by areolar tissue, an arrangement that allows it to move freely, carrying with it the skin of the scalp.

Temporoparietalis

Temporoparietalis is a variably developed sheet of muscle that lies between the frontal parts of occipitofrontalis and the anterior and superior auricular muscles.

Circumorbital and palpebral muscle group

The circumorbital and palpebral group of muscles are orbicularis oculi, corrugator supercilii and levator palpebrae superioris. The first two are described here; levator palpebrae superioris is described on page 773.

Orbicularis oculi

Orbicularis oculi is a broad, flat, elliptical muscle that surrounds the circumference of the orbit and spreads into the adjacent regions of the eyelids, anterior temporal region, infraorbital cheek and superciliary region (see Fig. 36.18). It has orbital, palpebral and lacrimal parts, and a small ciliary bundle.

The orbital part arises from the nasal component of the frontal bone, the frontal process of the maxilla and from the medial palpebral ligament. The fibres form complete ellipses, without interruption on the lateral side, where there is no bony attachment. The upper orbital fibres blend with the frontal part of occipitofrontalis and corrugator supercilii. Many of them are inserted into the skin and subcutaneous tissue of the eyebrow and constitute depressor supercilii. Inferiorly and medially, the ellipses overlap or blend to some extent with adjacent muscles (levator labii superioris alaeque nasi, levator labii superioris and zygomaticus minor). At the extreme periphery, sectors of complete, and sometimes incomplete, ellipses have a loose areolar connection with the temporal extension of the epicranial aponeurosis.

The palpebral part arises from the medial palpebral ligament, mainly from its superficial surface, and from the bone immediately above and below the ligament. The fibres sweep across the eyelids anterior to the orbital septum, interlacing at the lateral commissure to form the lateral palpebral raphe. A small group of fine fibres, close to the margin of each eyelid behind the eyelashes, constitutes the ciliary bundle.

The lacrimal part arises from the upper part of the lacrimal crest and the adjacent lateral surface of the lacrimal bone. It passes laterally behind the nasolacrimal sac (where some fibres are inserted into the associated fascia) and divides into upper and lower slips. Some fibres are inserted into the tarsi of the eyelids close to the lacrimal canaliculi, but most continue across in front of the tarsi and interlace in the lateral palpebral raphe.

Vascular supply Orbicularis oculi is supplied by branches of the facial, superficial temporal, maxillary and ophthalmic arteries.

Innervation Orbicularis oculi is supplied by temporal and zygomatic branches of the facial nerve.

Actions Orbicularis oculi is the sphincter muscle of the eyelids and plays an important role in facial expression and various ocular reflexes.

C

D

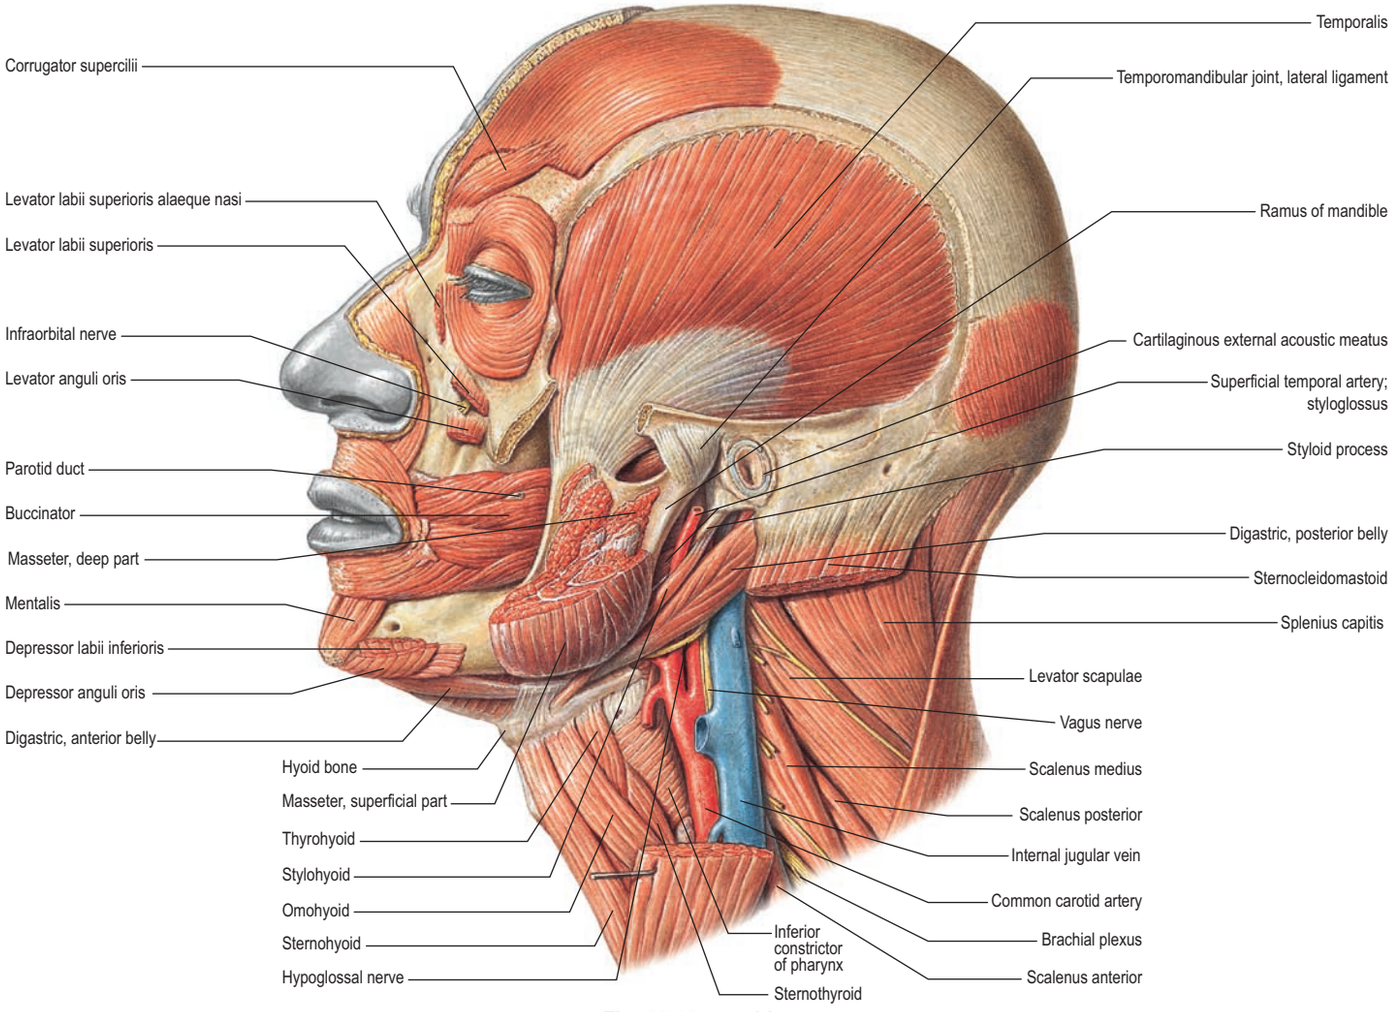

Fig. 36.18, cont'd

The orbital portion is usually activated under voluntary control. Contraction of the upper orbital fibres produces vertical furrowing above the bridge of the nose, narrowing of the palpebral fissure, and bunching and protrusion of the eyebrows, which reduces the amount of light entering the eyes. Eye closure is largely affected by lowering of the upper eyelid but there is also considerable elevation of the lower eyelid. The palpebral portion can be contracted voluntarily, to close the lids gently as in sleep, or reflexively, to close the lids protectively in blinking. The palpebral part has upper depressor and lower elevator fascicles. The lacrimal part of the muscle draws the eyelids and the lacrimal papillae medially, thereby exerting traction on the lacrimal fascia, and may aid drainage of tears by dilating the lacrimal sac. It may also influence pressure gradients within the lacrimal gland and ducts. This activity may assist in the sinuous flow of tears across the cornea, direct the lacrimal punctum into the lacus lacrimalis, and express secretions of the ciliary and tarsal glands. When the entire orbicularis oculi muscle contracts, the skin is thrown into folds that radiate from the lateral angle of the eyelids. Such folds, when permanent, cause wrinkles (often called 'crow's feet').

Corrugator supercilii

Corrugator supercilii is a small pyramidal muscle located at the medial end of each eyebrow, lying deep to the frontal part of occipitofrontalis and orbicularis oculi, with which it is partially blended (**Fig. 36.18A**). It arises from bone at the medial end of the superciliary arch and its fibres pass laterally and slightly upwards to exert traction on the skin above the middle of the supraorbital margin.

Vascular supply Corrugator supercilii is supplied by branches from adjacent arteries, mainly from the superficial temporal and ophthalmic arteries.

Innervation Corrugator supercilii is innervated by temporal branches of the facial nerve.

Actions Corrugator supercilii cooperates with orbicularis oculi to draw the eyebrows medially and downwards to shield the eyes in bright sunlight. It is also involved in frowning. The combined action of the two muscles produces mainly vertical wrinkles on the supranasal strip of the forehead.

Nasal muscle group

The nasal muscle group consists of procerus, nasalis and depressor septi and is described in Chapter 39.

Buccolabial muscle group

The shape of the mouth and the posture of the lips are controlled by a complex three-dimensional assembly of muscular slips (Yousif and Mendelson 1995). These include elevators, retractors and evertors of the upper lip (levator labii superioris alaeque nasi, levator labii superioris, zygomaticus major and minor, levator anguli oris and risorius); depressors, retractors and evertors of the lower lip (depressor labii inferioris, depressor anguli oris, and mentalis); a compound sphincter (orbicularis oris, incisivus superior and inferior); and buccinator (see Fig. 36.18).

Levator labii superioris alaeque nasi

Levator labii superioris alaeque nasi is described in Chapter 39.

Levator labii superioris

Levator labii superioris arises from the maxilla and zygomatic bone above the infraorbital foramen. Its fibres converge into the muscular substance of the upper lip between the lateral slip of levator labii superioris alaeque nasi and zygomaticus minor.

Vascular supply Levator labii superioris is supplied by the facial artery and the infraorbital branch of the maxillary artery.

Innervation Levator labii superioris is innervated by the zygomatic and buccal branches of the facial nerve.

Actions Levator labii superioris elevates and everts the upper lip. Acting with other muscles, it modifies the nasolabial furrow: in some faces, this furrow is a highly characteristic feature and is often deepened in expressions of sadness or seriousness.

Zygomaticus major

Zygomaticus major arises from the zygomatic bone, just anterior to the zygomaticotemporal suture, and passes to the angle of the mouth where it blends with the fibres of levator anguli oris, orbicularis oris and more deeply placed muscular bands.

Vascular supply Zygomaticus major is supplied by the superior labial branch of the facial artery.

Innervation Zygomaticus major is innervated by the zygomatic and buccal branches of the facial nerve.

Actions

Zygomaticus major draws the angle of the mouth upwards and laterally, as in laughing.

Zygomaticus minor

Zygomaticus minor arises from the lateral surface of the zygomatic bone immediately posterior to the zygomaticomaxillary suture, and passes downwards and medially into the muscular substance of the upper lip. Superiorly, it is separated from levator labii superioris by a narrow triangular interval and, inferiorly, it blends with this muscle.

Vascular supply Zygomaticus minor is supplied by the superior labial branch of the facial artery.

Innervation Zygomaticus minor is innervated by the zygomatic and buccal branches of the facial nerve.

Actions Zygomaticus minor elevates the upper lip, exposing the maxillary teeth. It also assists in deepening and elevating the nasolabial furrow. Acting together, the main elevators of the lip, levator labii superioris alaeque nasi, levator labii superioris and zygomaticus minor, curl the upper lip in smiling and in expressing smugness, contempt or disdain.

Levator anguli oris

Levator anguli oris arises from the canine fossa of the maxilla, just inferior to the infraorbital foramen, and inserts into and below the angle of the mouth. Its fibres mingle there with other muscle fibres (zygomaticus major, depressor anguli oris, orbicularis oris). Some superficial fibres curve anteriorly and attach to the dermal floor of the lower part of the nasolabial furrow. The infraorbital nerve and accompanying vessels enter the face via the infraorbital foramen between the origins of levator anguli oris and levator labii superioris.

Vascular supply Levator anguli oris is supplied by the superior labial branch of the facial artery and the infraorbital branch of the maxillary artery.

Innervation Levator anguli oris is innervated by the zygomatic and buccal branches of the facial nerve.

Actions Levator anguli oris raises the angle of the mouth in smiling and contributes to the depth and contour of the nasolabial furrow.

Malaris

Malaris is a thin sheet of muscle that is sometimes found covering and blending with zygomaticus major and minor and levator labii superioris. It is subject to considerable variation (Zufferey 2013). When present, it is continuous with the inferior limit of orbicularis oculi, from which it is possibly derived. Its fibres incline medially and downwards. Some of its superficial fascicles have a dermal attachment to the nasolabial ridge and sulcus, and others pass directly to the angle of the mouth and to the outer third of the upper lip to intersect with bundles of orbicularis oris.

Mentalis

Mentalis is a conical bundle of fibres lying at the side of the frenulum of the lower lip. The fibres arise from the incisive fossa of the mandible and descend to attach to the skin of the chin.

Vascular supply Mentalis is supplied by the inferior labial branch of the facial artery and the mental branch of the maxillary artery.

Innervation Mentalis is innervated by the mandibular branch of the facial nerve.

Actions Mentalis raises the base of the lower lip and wrinkles the skin of the chin. It helps in protruding and everting the lower lip in drinking and in expressing doubt or disdain.

Depressor labii inferioris

Depressor labii inferioris is a quadrilateral muscle that arises from the oblique line of the mandible, between the symphysis menti and the mental foramen. It passes upwards and medially into the skin and mucosa of the lower lip, blending with its contralateral fellow and with orbicularis oris. Below and laterally, it is continuous with platysma.

Vascular supply Depressor labii inferioris is supplied by the inferior labial branch of the facial artery and the mental branch of the maxillary artery.

Innervation Depressor labii inferioris is innervated by the mandibular branch of the facial nerve.

Actions Depressor labii inferioris draws the lower lip downwards and a little laterally in masticatory activity and may assist in eversion of the lower lip. It contributes to the expressions of irony, sorrow, melancholy and doubt.

Depressor anguli oris

Depressor anguli oris has a long, linear origin from the mental tubercle of the mandible and its continuation, the oblique line, below and lateral to depressor labii inferioris. It converges into a narrow fasciculus that blends at the angle of the mouth with orbicularis oris and risorius, and some fibres continue into levator anguli oris. Depressor anguli oris is continuous below with platysma and cervical fasciae. Some of its fibres may pass below the mental tubercle and cross the midline to interlace with their contralateral fellows, thereby forming transversus menti (the 'mental sling').

Vascular supply Depressor anguli oris is supplied by the inferior labial branch of the facial artery and the mental branch of the maxillary artery.

Innervation Depressor anguli oris is innervated by the buccal and mandibular branches of the facial nerve.

Actions Depressor anguli oris draws the angle of the mouth downwards and laterally in opening the mouth and in expressing sadness. During opening of the mouth, the mentolabial sulcus becomes more horizontal and its central part deepens.

Buccinator

Buccinator is a thin quadrilateral muscle that occupies the interval between the maxilla and the mandible and is the muscle of the cheek (Fig. 36.18D). It is attached to the outer surfaces of the alveolar processes opposite the maxillary and mandibular molar teeth, and to the anterior margin of the pterygomandibular raphe. A few fibres also arise from a fine tendinous band that bridges the interval between the maxilla and the pterygoid hamulus, between the tuberosity of the maxilla and the upper end of the pterygomandibular raphe. On its way to the soft palate, the tendon of tensor veli palatini pierces the pharyngeal wall in the small gap that lies behind this tendinous band. The posterior part of buccinator is deeply placed, internal to the mandibular ramus and in the plane of the medial pterygoid plate. Its anterior component curves out behind the third molar tooth to lie in the submucosa of the cheek and lips. The fibres of buccinator converge towards the modiolus near the angle of the mouth. Here the central (pterygomandibular) fibres intersect, those from below cross to the upper part of orbicularis oris, and those from above cross to the lower part. The highest (maxillary) and lowest (mandibular) fibres of buccinator continue forwards to enter their corresponding lips without decussation. As buccinator courses through the cheek and modiolus, substantial numbers of its fibres are diverted internally to attach to submucosa.

Relations Posteriorly, buccinator lies in the same plane as the superior pharyngeal constrictor, which arises from the posterior margin of the pterygomandibular raphe and is covered there by the buccopharyngeal fascia. Superficially, the buccal pad of fat separates the posterior part of buccinator from the ramus of the mandible, masseter and part of temporalis. Anteriorly, the superficial surface of buccinator is related to zygomaticus major, risorius, levator and depressor anguli oris, and the parotid duct. It is crossed by the facial artery, facial vein and branches of the facial and buccal nerves. The deep surface of buccinator is related to the buccal glands and mucous membrane of the mouth. The parotid duct pierces buccinator opposite the third upper molar tooth and lies on the deep surface of the muscle before opening into the mouth opposite the maxillary second molar tooth.

Vascular supply Buccinator is supplied by branches from the facial artery and the buccal branch of the maxillary artery.

Innervation Buccinator is supplied by the buccal branch of the facial nerve.

Actions Buccinator compresses the cheek against the teeth and gums during mastication and assists the tongue in directing food between the teeth. As the mouth closes, the teeth glide over the buccolabial mucosa, which must be retracted progressively from their occlusal surfaces by buccinator and other submucosally attached muscles. When the cheeks have been distended with air, the buccinators expel it between the lips, an activity important when playing wind instruments, and that accounts for the name of the muscle (Latin *buccinator* = trumpeter).

Pterygomandibular raphe

The pterygomandibular raphe is a thin band of tendinous fibres that stretches from the hamulus of the medial pterygoid plate down to the posterior end of the mylohyoid line of the mandible. It is easily palpated medially, where it is covered by the mucous membrane of the mouth. Laterally, it is separated from the ramus of the mandible by a quantity of adipose tissue. It gives attachment to the superior constrictor of the pharynx posteriorly, and the central part of buccinator anteriorly. The pterygomandibular raphe (see Figs 37.1, 37.3) is a useful anatomical landmark for the administration of inferior alveolar nerve blocks because the nerve lies lateral to it.

Orbicularis oris

Orbicularis oris is so named because it was once assumed that the oral fissure was surrounded by a series of complete ellipses of striated muscle that acted together in the manner of a sphincter. In fact, orbicularis oris consists of four substantially independent quadrants (upper, lower, left and right), each containing a larger pars peripheralis and a smaller pars marginalis that are apposed along lines that correspond externally to the lines of junction between the vermilion zone of the lip and the skin. Orbicularis oris is therefore composed of eight segments that are named systematically according to their location. Each segment resembles a fan that has its stem at the modiolus and is open in peripheral segments and almost closed in marginal segments.

Pars peripheralis

In each quadrant, the pars peripheralis has a lateral stem attached to the labial side of the modiolus over its full thickness, from apex to base, including the corresponding upper or lower cornu. Most of these stem fibres are thought to originate within the modiolus (although it is possible that some are direct continuations from the other modiolar muscles). They are reinforced directly by fibres from buccinator (upper fibres and decussating lower central fibres), levator anguli oris and the superficial part of zygomaticus major in the upper lip, and from buccinator (lower fibres and decussating upper central fibres) and depressor anguli oris in the lower lip.

The fibres of orbicularis oris enter their respective superior and inferior labial areas and diverge to form triangular muscular sheets. These are thickest at the junctions between skin and the vermilion zone and become progressively thinner as they reach the limits of the labial region. The greater part of each sheet enters the free lip, where its fibres aggregate into cylindrical bundles orientated parallel to the vermilion zone. Fibres of the direct labial tractors pass to their submucosal attachments between these cylindrical bundles and between the pars peripheralis and pars marginalis. In the upper lip, the highest fibres run near the nasolabial sulcus, a few fibres attach to the sulcus, and a few to the nasal ala and septum. In the lower lip, the lowest fibres reach and are attached to the mentolabial sulcus. A small proportion of the main body of fibres is thought to end in the labial connective tissue, dermis or submucosa as it traverses its quadrant of free lip. Most fibres continue towards the median plane and cross some 5 mm into the opposite half-lip. At this point, the fibres from the two sides interlace on their way to their dermal insertions, creating the ridges of the philtrum of the upper lip and the less marked corresponding depression in the lower lip.

Pars marginalis

The pars marginalis of orbicularis oris is developed to a unique extent in human lips where it is closely associated with speech and the production of some kinds of musical tone. In each quadrant, the pars marginalis consists of a single (occasionally double) band of thin muscle fibres lodged within the tissues of each vermilion zone. At their medial end,

the marginal fibres meet and interlace with their contralateral fellows and are then attached to the dermis of the vermilion zone a few millimetres beyond the median plane in a manner similar to pars peripheralis. At their lateral ends, the fibres converge and are attached to the deepest part of the modiolar base along a horizontal strip level with the angle of the mouth.

The relations between the pars marginalis and pars peripheralis are complex. In a full-thickness section of an upper lip at right-angles to the vermilion zone, the cylindrical bundles of the fibres of the pars peripheralis form an S shape, with an external convexity above and an internal convexity below: the classic analogy being to the shank and initial curved part of a hook. Beyond the pars peripheralis, the hook shape is completed by the blunted triangular profile of the pars marginalis that occupies the core of the vermilion zone with its base adjacent to the pars peripheralis and its apex reaching upwards and anteriorly towards the junction between the vermilion zone and the skin. In a similar section through the lower lip, the bundles of the pars peripheralis form a continuous curve that is concave towards the external surface. This is surmounted by the flattened triangular profile of the pars marginalis that curves anteriorly, its apex again nearing the vermilion/cutaneous junction. Thus, throughout the vermilion zones of both lips, the pars marginalis lies substantially anterior to the adjacent bundles of the pars peripheralis. However, as the muscles are traced laterally beyond the vermilion zone and across the angle of the mouth, this relationship alters. The pars marginalis becomes inverted as it wraps progressively around the adjacent edge of the pars peripheralis to reach its deep (submucosal) surface and maintains this position up to its attachment at the modiolar base.

Vascular supply Orbicularis oris is supplied mainly by the superior and inferior labial branches of the facial artery, the mental and infraorbital branches of the maxillary artery, and the transverse facial branch of the superficial temporal artery.

Nerve supply Orbicularis oris is supplied by the buccal and mandibular branches of the facial nerve.

Actions The actions of orbicularis oris are considered in detail in the next section.

Incisivus labii superioris

Incisivus labii superioris has a bony origin from the floor of the incisive fossa of the maxilla above the eminence of the lateral incisor tooth. Initially, it lies deep to the superior part of the pars peripheralis of orbicularis oris. Arching laterally, its fibre bundles become intercalated between, and parallel to, the orbicular bundles. Approaching the modiolus, it is segregated into superficial and deep parts: the former blends partially with levator anguli oris and is attached to the body and apex of the modiolus, and the latter is attached to the superior cornu and base of the modiolus.

Incisivus labii inferioris

Incisivus labii inferioris, an accessory muscle of the orbicularis oris muscle complex, shares many features with incisivus labii superioris. Its osseous attachment is to the floor of the incisive fossa of the mandible, lateral to mentalis and below the eminence of the lateral incisor tooth. Curving laterally and upwards, it blends to some extent with the inferior part of the pars peripheralis of orbicularis oris before reaching the modiolus, where superficial bundles are attached to the apex and body, and deep bundles are attached to the base and inferior cornu.

Platysma

Platysma is described as a muscle of the neck, but it is considered here as a contributor to the orbicularis oris muscle complex. It has mandibular, labial and modiolar parts. Pars mandibularis attaches to the lower border of the body of the mandible. Posterior to this attachment, a substantial flattened bundle separates and passes superomedially to the lateral border of depressor anguli oris where a few fibres join this muscle. The remainder continue deep to depressor anguli oris and reappear at its medial border. Here, they continue within the tissue of the lateral half of the lower lip, as a direct labial tractor, platysma pars labialis. Pars labialis occupies the interval between depressor anguli oris and depressor labii inferioris and is in the same plane as these muscles. The adjacent margins of all three muscles blend and they have similar labial attachments. Platysma pars modiolaris constitutes all the remaining bundles posterior to pars labialis, other than a few fine fascicles that end directly in buccal dermis or submucosa. Pars modiolaris is posterolateral to depressor anguli oris and passes superomedially, deep to risorius, to apical and subapical modiolar attachments.

Risorius

Risorius is a highly variable muscle that ranges in form from one or more slender bundles to a wide, thin, superficial fan. Its peripheral attachments may include some or all of the following: the zygomatic arch, parotid fascia, fascia over the masseter anterior to the parotid, fascia enclosing platysma pars modiolaris, and fascia over the mastoid process. Its fibres converge to apical and subapical attachments at the modiolus.

Vascular supply Risorius is supplied mainly by the superior labial branch of the facial artery.

Nerve supply Risorius is supplied by buccal branches of the facial nerve.

Actions Risorius pulls the angle of the mouth laterally in numerous facial activities, including grinning and laughing.

Movements of the face and lips

Direct labial tractors

Direct labial tractors, as their name suggests, pass directly into the tissues of the lips and not via the modioli. In broad terms, the force exerted by tractors is directed vertically at an approximate right-angle to the oral fissure. Their action will therefore elevate and/or evert the whole, or part, of the upper lip and depress and/or evert the whole, or part, of the lower lip. The tractors are, from medial to lateral, the labial part of levator labii superioris alaeque nasi; levator labii superioris and zygomaticus minor in the upper lip; and depressor labii inferioris and platysma pars labialis in the lower lip.

In both upper and lower lips, the tractors blend into a continuous sheet that divides into a series of superimposed coronal sheets anterior to the muscle bundles of orbicularis oris pars peripheralis as they enter the free lip. The sheets may be divided into three groups at increasing depths from the skin surface, each with a distinct zone of attachment (Fig. 36.19). The superficial group consists of a succession of bundles of fine fibres that curve anteriorly a short distance before being attached in a series of horizontal rows to the dermis between the hair follicles, sebaceous glands and sweat glands. The intermediate group is attached to the dermis of the vermilion zone that they reach by two routes. The more superficial bundles continue past the skin/vermilion junction, then curve posteriorly over orbicularis oris pars marginalis to punctate attachments on the ventral half of the dermis of the vermilion zone. The deeper bundles first pass posteriorly between pars peripheralis and pars marginalis of orbicularis oris, then curve anteriorly to punctate attachments on the dorsal half of the dermis of the vermilion zone. The deep group is closely applied to the anterior surface of orbicularis oris pars peripheralis and sends fine tractor fibres between its parallel bundles to be attached posteriorly into the submucosa and periglandular connective tissue.

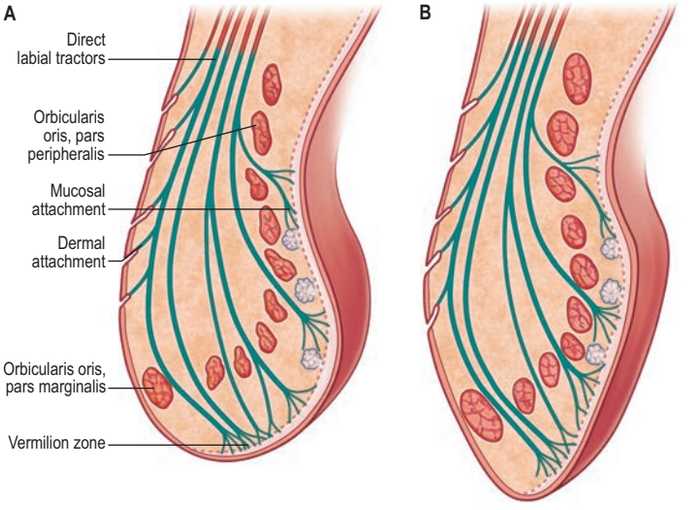

Fig. 36.19 **A**, Sagittal section of the upper lip in repose. On the left is thin skin with oblique hair follicles; on the right is thick mucosa with mucous glands and mucosal shelf; between them is the vermilion zone. **B**, As **A** but slightly contracted, forming a narrowed profile (labial cord).

Movements of the lips

The various groups of direct labial tractors may act together or individually, and their effects may involve a complete labial quadrant or be restricted to a short segment. For example, partial contraction of the superior labial tractors can result in localized elevation of a segment of the upper lip, in a postural expression reminiscent of the 'canine snarl'. Normally, the activity of the tractors is modified by the superimposed activity of orbicularis oris and the modiolar muscles: the resulting actions range from delicate adjustments of the tension and profile of the lip margins to large increases of the oral fissure with eversion of the lips.

Lip protrusion is passive in its initial stages. It may be suppressed by powerful contraction of the whole of orbicularis oris or enhanced by selective activation of parts of the direct labial tractors. However, lip movements must accommodate separation of the teeth brought about by mandibular depression at the temporomandibular joints. Beyond a certain range of mouth opening, labial movements are almost completely dominated by mandibular movements. Thus, over the last 2.5–3 cm inter-incisal distance of wide jaw separation, strong contraction of orbicularis oris cannot effect lip contact. Instead it causes full-thickness inflection of the upper and lower lips, including the vermilion zone, towards the oral cavity, wrapping them around the incisal edges, canine cusps and premolar occlusal surfaces. The involvement of the lips in speech is described in Chapter 41, but some aspects relevant to the actions of orbicularis oris pars marginalis will be described here. Contraction of marginalis is considered to alter the cross-sectional profile of the free margin of the vermilion zone such that both the gentle bulbous profile of the upper lip and the smooth posterosuperior convexity of the lower lip change to a narrow, symmetric, triangular profile. The transformed rims, whose length and tension can be delicately controlled, have been named labial cords and are known to be involved in the production of some consonantal (labial) sounds. A labial cord may also function as a 'vibrating reed' in whistling or playing a wind instrument such as the trumpet.

The modiolus and its role in facial movements

On each side of the face, a number of muscles converge towards a focus just lateral to the angle of the mouth where they interlace to form a dense, compact, mobile, fibromuscular mass called the modiolus. This can be palpated most effectively by using the opposed thumb and index finger to compress the mucosa and skin simultaneously. At least nine muscles, depending on the classification employed, are attached to each modiolus. The muscles lie in different planes, their modiolar stems are often spiralized, and most divide into two bundles, some into three or four, each of them interlacing and attaching in a distinctive way.

The shape and dimensions of the modiolus are subject to individual, age, sexual and ethnic variation. There are no precise histological boundaries because the modiolus is an irregular zone where dense, compact, interlacing tissue grades into the stems of individually recognizable muscles. It has the rough form of a blunt cone that is approximately 10 mm thick from mucosa to dermis, divided approximately equally into basal, central and apical parts. The base is roughly elliptical in outline, extending vertically 20 mm above and 20 mm below a horizontal line through the angle of the mouth and laterally a similar distance from the angle. The blunt apex of the cone is 4 mm across, centred approximately 12 mm lateral to the angle of the mouth. The central body has an oblique fibrous cleft or channel that transmits the facial artery, an arrangement that may limit the extent to which it is compressed by contraction of the buccolabial musculature. The cone shape is modified by two round-edged flanges (cornua) that extend into the lateral free lip tissues above and below the angle of the mouth.

Controlled three-dimensional mobility of the modioli enables them to integrate the activities of the cheeks, lips and oral fissure, the oral vestibule and the jaws. Such activities include biting, chewing, drinking, sucking, swallowing, changes in vestibular contents and pressure, the innumerable subtle variations involved in speech, the modulation (and occasional generation) of musical tones, production of harsher sounds in shouting and screaming, crying, and all the permutations of facial expression, ranging from mere hints to gross distortion, symmetric or asymmetric. Major modiolar movements appear to involve many, if not all, of its associated muscles, and there is little value in considering the actions of the individual muscles in isolation. While the most obvious determinant of modiolar position and mobility is the balance between the forces exerted by muscles that are directly attached to it, another influential factor is the degree of separation or 'gape' between the upper and lower teeth. Starting from the occlusal position, and with the lips maintained in contact, the teeth can be separated by approximately 1.25 cm near the midline, and the mentolabial sulcus descends by a similar distance. With further separation, the lips part, and as gape increases to its maximum, interlabial and interdental distances approach 4 cm, at which point the mentolabial sulcus has descended a further 2 cm. In this posture, the modiolus has descended about 1 cm to lie over the interdental space, into which its basal and surrounding buccal mucosa projects a few millimetres, and its cornua diverge into their respective lips at an obtuse angle to each other, the dispositions of the modiolar muscles being correspondingly modified. The general hexagonal shape of the labial area changes as the mouth and jaws open progressively. In maximal opening, the distance between the superior and inferior boundaries has increased by 3–3.5 cm at the centre; the transverse distance between its lateral angles has decreased by 1 cm and the angles are obtuse; the nasolabial sulci are longer, straighter and more vertical; and the inferior buccolabial sulci are less deep and curved. These soft tissue changes radiate from the bilateral modioli.

With the lips in contact and the teeth in tight occlusion, the modiolus can move a few millimetres in all directions. However, mobility is maximal when there is 2–3 mm clearance between the teeth: the apex of the modiolus may then move vertically upwards 10 mm, downwards 5 mm, posterolaterally 10 mm, and anteromedially 10 mm, these movements being accomplished in the curved planes of the cheek and lips. Specific movements of the modiolus may take place at any point, and along any path, within the boundaries of the envelope of movement thus defined. When the mouth is opened wide, the modiolus becomes immobile. From the neutral position, the modiolus may be displaced superficially along its apicobasal axis for up to 5–10 mm by liquids or solids in the vestibule, or by an increase in air pressure that 'balloons' the cheeks and lips.

Many activities take place in three phases. Initially, a particular modiolar muscle group becomes dominant over its antagonists and the modiolus is rapidly relocated. Next, the modiolus is transiently fixed in this new site by simultaneous contraction of modiolar muscles, principally zygomaticus major, levator anguli oris, depressor anguli oris and platysma pars modiolaris, and this provides a fixed base from which the main physiological effectors, buccinator and orbicularis oris, carry out their specific actions. These actions are usually integrated with partial separation or closure of the jaws, and with varying degrees of activity in the direct labial tractors. All these factors combine to determine the positions of the lips and oral fissure from moment to moment. Modiolar movements may be bilaterally symmetric, unilateral or asymmetric.

Muscles of mastication

Masseter and temporalis, two of the muscles of mastication, are seen on the face. Masseter covers the ramus of the mandible, and temporalis lies over the temporal fossa. These muscles are described in detail with the other main muscles of mastication in Chapter 38.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The main arterial supply to the face is derived from the facial and superficial temporal arteries, with additional supply from branches of the maxillary and ophthalmic arteries. The back of the scalp is supplied by the posterior auricular and occipital arteries. There are numerous anastomoses between the branches.

Facial artery

The facial artery arises in the neck from the external carotid artery (see Figs 33.1A, 35.8). It initially lies beneath platysma, passing onto the face at the anteroinferior border of masseter, where its pulse can be felt as it crosses the mandible. The artery is deep to skin, the fat of the cheek and, near the angle of the mouth, zygomaticus major and risorius, and superficial to buccinator and levator anguli oris. It may pass over or through levator labii superioris and pursues a tortuous course along the side of the nose towards the medial corner of the eye. At its termination, it is embedded in levator labii superioris alaeque nasi.

Occasionally, the facial artery barely extends beyond the angle of the mouth, in which case its normal territory beyond this region is taken over by an enlarged transverse facial branch from the superficial temporal artery and by branches from the contralateral facial artery. The facial vein is posterior to the artery and runs a more direct course across the face. At the anterior border of masseter, the two vessels are in contact, whereas in the neck the vein is superficial to the artery. The facial artery

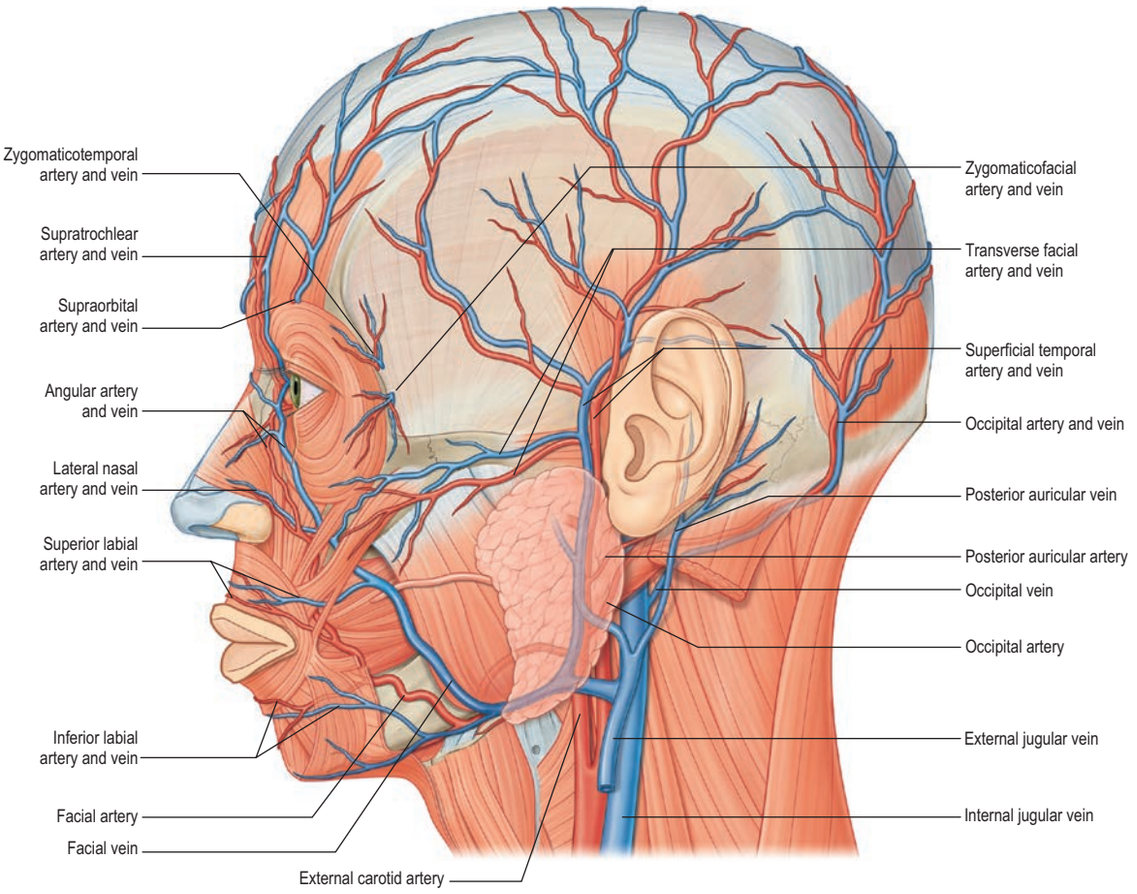

Fig. 36.20 Arteries and veins of the left side of the face, head and neck and their main branches. The infraorbital artery is shown in Fig. 33.1A.

supplies branches to the muscles and skin of the face (Fig. 36.20). Its named branches on the face are the premasseteric artery, the superior and inferior labial arteries and the lateral nasal artery. The part of the artery distal to its terminal branch is called the angular artery.

Premasseteric artery The premasseteric artery is small and inconstant. When present, it passes upwards along the anterior border of masseter and supplies the surrounding tissues.

Inferior labial artery The inferior labial artery arises near the angle of the mouth, passes upwards and forwards under depressor anguli oris, and then penetrates orbicularis oris to run sinuously near the margin of the lower lip, between the muscle and the mucous membrane. It supplies the inferior labial glands, mucous membrane and muscles, and anastomoses with its contralateral fellow and with the mental branch of the inferior alveolar artery.

Superior labial artery The superior labial artery is larger and more tortuous than the inferior labial artery. It pursues a similar course along the superior labial margin, between the mucous membrane and orbicularis oris, anastomoses with its contralateral fellow, and supplies the upper lip. It gives off an alar branch and a septal branch that ramifies anteroinferiorly in the nasal septum.

Lateral nasal artery The lateral nasal artery is given off by the side of the nose, supplies the dorsum and ala of the nose, and anastomoses with its contralateral fellow. The lateral nasal artery can be replaced by a branch from the superior labial artery.

Superficial temporal artery

The superficial temporal artery is the smaller terminal branch of the external carotid artery (see Figs 33.1A, 36.20). It arises in the parotid gland behind the neck of the mandible, where it is crossed by temporal and zygomatic branches of the facial nerve. Initially deep, it becomes superficial as it passes over the posterior root of the zygomatic process of the temporal bone, where its pulse can be felt. It then ascends in the scalp for approximately 4 cm and divides into frontal (anterior) and parietal (posterior) branches. The artery is accompanied by corresponding veins, and by the auriculotemporal nerve that usually lies just posterior to it.

The superficial temporal artery supplies the skin and muscles at the side of the face and in the scalp, the parotid gland and the temporomandibular joint. It is occasionally biopsied when a histological diagnosis of giant cell arteritis is required. The named branches of the superficial temporal artery are the transverse facial, auricular, zygomatico-orbital, middle temporal, frontal and parietal arteries. The relative sizes of the frontal, parietal and transverse facial branches vary: the frontal and parietal branches may be absent, whereas the transverse facial branch may replace a shortened transverse facial artery arising from the facial artery.

Transverse facial artery The transverse facial artery arises before the superficial temporal artery emerges from the parotid gland. It traverses the gland, crosses masseter between the parotid duct and the zygomatic arch (accompanied by one or two facial nerve branches), and divides into numerous branches that supply the parotid gland and duct, masseter and adjacent skin. The branches anastomose with the facial, masseteric, buccal, lacrimal and infraorbital arteries, and can have a direct origin from the external carotid artery.

Auricular artery The branches of the auricular artery are distributed to the lobule and lateral surface of the auricle and to the external acoustic meatus.

Zygomatico-orbital artery The zygomatico-orbital artery may arise independently from the superficial temporal artery or from its middle temporal or parietal branches. It runs close to the upper border of the zygomatic arch, between the two layers of temporal fascia, to the lateral orbital angle. It supplies orbicularis oculi and anastomoses with the lacrimal and palpebral branches of the ophthalmic artery. A well-developed zygomatico-orbital artery can be associated with a delayed division of the superficial temporal artery into frontal and parietal branches.

Middle temporal artery The middle temporal artery arises just above the zygomatic arch and perforates the temporal fascia to supply temporalis. It anastomoses with the deep temporal branches of the maxillary artery.

Frontal (anterior) branch The frontal branch passes upwards towards the frontal tuberosity and supplies the muscles, skin and pericranium in this region. It anastomoses with its contralateral fellow and with the supraorbital and supratrochlear branches of the ophthalmic artery.

Parietal (posterior) branch The parietal branch is larger than the frontal branch of the superficial temporal artery. It curves upwards and backwards, remains superficial to the temporal fascia, and anastomoses with its contralateral fellow and with the posterior auricular and occipital arteries.

Facial branches of the maxillary artery

The maxillary artery is the larger of the two terminal branches of the external carotid artery. It has three branches that supply the face, namely the mental, buccal and infraorbital arteries (see Figs 33.1A, 33.2A).

Mental artery The mental artery arises from the first part of the maxillary artery as a terminal branch of the inferior alveolar artery. It emerges on to the face from the mandibular canal at the mental foramen, supplies muscles and skin in the chin region, and anastomoses with the inferior labial and submental arteries.

Buccal artery The buccal artery is a branch of the second part of the maxillary artery. It emerges onto the face from the infratemporal fossa, crosses buccinator to supply the cheek, and anastomoses with the infraorbital artery and with branches of the facial artery.

Infraorbital artery The infraorbital artery arises from the third part of the maxillary artery. It runs through the infraorbital foramen and onto the face, supplying the lower eyelid, the lateral aspect of the nose and the upper lip. The infraorbital artery has extensive anastomoses with the transverse facial and buccal arteries and with branches of the ophthalmic and facial arteries.

Facial branches of the ophthalmic artery

The ophthalmic artery is a branch of the internal carotid artery (see Fig. 44.13). Its supratrochlear, supraorbital, lacrimal, medial palpebral and external (dorsal) nasal branches supply the face (see Fig. 36.20).

Supratrochlear artery The supratrochlear artery emerges from the orbit onto the face at the frontal notch. It supplies the medial parts of the upper eyelid, forehead and scalp, and anastomoses with the supraorbital artery and with its contralateral fellow.

Supraorbital artery The supraorbital artery leaves the orbit through the supraorbital notch or foramen. It divides into superficial and deep branches that supply the skin and muscle of the upper eyelid, forehead and scalp. It anastomoses with the supratrochlear artery, the frontal branch of the superficial temporal and its contralateral fellow. At the supraorbital margin, it often sends a branch to the diploë of the frontal bone and can also supply the mucoperiosteum in the frontal sinus.

Lacrimal artery The lacrimal artery appears on the face at the upper lateral corner of the orbit and supplies the lateral part of the eyelids. Within the orbit, it gives off a zygomatic artery that divides into zygomaticofacial and zygomaticotemporal arteries. The zygomaticofacial artery passes through the lateral wall of the orbit to emerge onto the face at the zygomaticofacial foramen and supplies the region overlying the prominence of the cheek. The zygomaticotemporal artery also passes through the lateral wall of the orbit, via the zygomaticotemporal foramen, and supplies the skin over the non-beard part of the temple. The lacrimal artery anastomoses with the deep temporal branch of the maxillary artery and the transverse facial branch of the superficial temporal artery.

Medial palpebral arteries Superior and inferior medial palpebral arteries arise from the ophthalmic artery below the trochlea. They descend behind the nasolacrimal sac to enter the eyelids, where each divides into two branches that course laterally along the edges of the tarsal plates, forming the superior and inferior arches and supplying the eyelids. They anastomose with branches of the supraorbital, zygomatico-orbital and lacrimal arteries. The inferior arch also anastomoses with the facial artery.

External (dorsal) nasal artery The external nasal artery is a terminal branch of the anterior ethmoidal artery that arises from the ophthalmic artery. It emerges at the junction of the nasal bone and the lateral nasal cartilage and supplies the skin covering the external nose.

Occipital artery

The occipital artery arises in the neck from the external carotid artery (see Fig. 35.8). It runs in a groove on the temporal bone, medial to the mastoid process. Accompanied by the greater occipital nerve, the occipital artery enters the posterior scalp by piercing the investing layer of deep cervical fascia that connects the cranial attachments of trapezius and sternocleidomastoid. Tortuous branches run between the skin and the occipital belly of occipitofrontalis, anastomosing with the contralateral occipital, posterior auricular and superficial temporal arteries, as well as with the transverse cervical branch of the subclavian artery. These branches supply the occipital belly of occipitofrontalis and the skin and pericranium associated with the scalp as far forwards as the vertex. The artery may give off a meningeal branch that traverses the parietal foramen.

Posterior auricular artery

The posterior auricular artery arises in the neck from the external carotid artery and ascends between the auricle and mastoid process. It supplies the cranial surface of the auricle via its auricular branch, and the occipital belly of occipitofrontalis and the scalp behind and above the auricle via its occipital branch. The posterior auricular artery anastomoses with the occipital artery.

Veins

The veins of the face are subject to considerable variations; the following description concerns those that are relatively constant (see Fig. 36.20).

Supratrochlear vein

The supratrochlear vein starts on the forehead from a venous network connected to the frontal tributaries of the superficial temporal vein. Veins from this network form a single trunk that descends to the bridge of the nose, near the midline and parallel with its contralateral fellow. The veins are joined by a nasal arch across the nose and then diverge, each joining a supraorbital vein to form the facial vein near the medial canthus of the eye.

Supraorbital vein

The supraorbital vein begins near the zygomatic process of the frontal bone, connecting with branches of the superficial and middle temporal veins. It passes medially above the orbital opening, pierces orbicularis oculi and unites with the supratrochlear vein near the medial canthus of the eye to form the facial vein. A branch passes through the supraorbital notch, where it receives veins from the frontal sinus and frontal diploë, and subsequently connects with the superior ophthalmic vein.

Facial vein

The facial vein is the main vein draining the face. After receiving the supratrochlear and supraorbital veins, it travels obliquely downwards by the side of the nose, passes under zygomaticus major, risorius and platysma, descends to the anterior border of masseter and then passes over the surface of the muscle. It crosses the body of the mandible and runs down in the neck to drain into the internal jugular vein. The facial vein initially lies behind the more tortuous facial artery but it crosses the artery at the lower border of the mandible. The uppermost segment of the facial vein, above its junction with the superior labial vein, is also called the angular vein; any infection of the mouth or face can potentially spread via the angular veins to the cavernous sinuses, resulting in thrombosis.

Tributaries Near its origin, the facial vein connects with the superior ophthalmic vein, both directly and via the supraorbital vein, and so is linked to the cavernous sinus. The facial vein receives tributaries from the side of the nose and, below this, an important deep facial vein from the pterygoid venous plexus. It also receives the inferior palpebral, superior and inferior labial, buccinator, parotid and masseteric veins, and other tributaries that join it below the mandible.

Superficial temporal vein

A widespread venous network across the scalp receives branches from the supratrochlear, supraorbital, posterior auricular and occipital veins. Anterior and posterior tributaries from this network unite above the zygomatic arch to form the superficial temporal vein on each side. The

vein accompanies its artery, usually lying behind it, crosses the posterior root of the zygoma and enters the parotid gland, where it joins the maxillary vein to form the retromandibular vein.

Tributaries The tributaries are the parotid veins, rami draining the temporomandibular joint, anterior auricular, transverse facial and middle temporal veins. The middle temporal vein receives the orbital vein (formed by the lateral palpebral veins), pierces the temporal fascia and then passes back between the layers of the fascia to join the superficial temporal vein just above the level of the zygomatic arch.

Buccal, mental and infraorbital veins

The buccal, mental and infraorbital veins drain the cheek and chin regions and pass into the pterygoid venous plexus.

Posterior auricular and occipital veins

The posterior auricular vein arises in a parieto-occipital network that also drains into tributaries of the occipital and superficial temporal veins. It descends behind the auricle to join the posterior division of the retromandibular vein in, or just below, the parotid gland, to form the external jugular vein. It receives a stylomastoid vein and tributaries from the cranial surface of the auricle, drains the region of the scalp behind the ear and drains into the external jugular vein. The occipital vein begins in a posterior network in the scalp, pierces the cranial attachment of trapezius, turns into the suboccipital triangle and joins the deep cervical and vertebral veins. It may be joined by a vein draining the diploë in the occipital bone and then passes to either the internal jugular, posterior auricular, deep cervical or vertebral veins. Emissary veins connect the occipital vein to the intracranial venous sinuses via the mastoid and parietal foramina and through the posterior condylar canal and occipital protuberances.

Lymphatic drainage

Lymph vessels from the frontal region above the root of the nose drain to the submandibular nodes (Fig. 36.21; see Fig. 35.15). Vessels from the rest of the forehead, temporal region, upper half of the lateral auricular aspect and anterior wall of the external acoustic meatus drain to the superficial parotid nodes that lie just anterior to the tragus, either on or deep to the parotid fascia. These nodes also drain lateral vessels from the eyelids and skin of the zygomatic region, and their efferent vessels pass to the upper deep cervical nodes. A strip of scalp above the auricle, the upper half of the cranial aspect and margin of the auricle, and the posterior wall of the external acoustic meatus all drain to the upper deep cervical and posterior auricular nodes. The posterior auricular nodes are superficial to the mastoid attachment of sternocleidomastoid and deep to auricularis posterior and drain to the upper deep cervical nodes. The auricular lobule, floor of the external acoustic meatus and skin over the mandibular angle and lower parotid region all drain to the superficial cervical or upper deep cervical nodes. Superficial cervical nodes lie along the external jugular vein superficial to sternocleidomastoid. Some efferents pass round the anterior border of sternocleidomastoid to the upper deep cervical nodes, while others follow the external jugular vein to the lower deep cervical nodes in the subclavian triangle.

The occipital region of the scalp drains partly to the occipital nodes, and partly to a vessel that runs along the posterior border of sternocleidomastoid to the lower deep cervical nodes. Occipital nodes are commonly superficial to the upper attachment of trapezius but occasionally lie in the superior angle of the posterior triangle.

There are usually three submandibular nodes, internal to the deep cervical fascia in the submandibular triangle. One lies at the anterior pole of the submandibular gland, and two flank the facial artery as it reaches the mandible. Other nodes are often embedded in the gland or deep to it. Submandibular nodes drain a wide area, including vessels from the submental, buccal and lingual groups of nodes, and their efferents pass to the upper and lower deep cervical nodes. The external nose, cheek, upper lip and lateral parts of the lower lip drain directly to the submandibular nodes; the afferent vessels may have a few buccal nodes along their course and near the facial vein. The mucous membrane of the lips and cheek drains to the submandibular nodes, and the lateral part of the cheek drains to the parotid nodes. The central part of the lower lip, buccal floor and tip of the tongue all drain to the submental nodes lying on mylohyoid between the anterior bellies of the digastric muscles. These nodes receive afferents bilaterally, some decussating across the chin and their efferents pass to the submandibular and jugulo-omohyoid nodes.

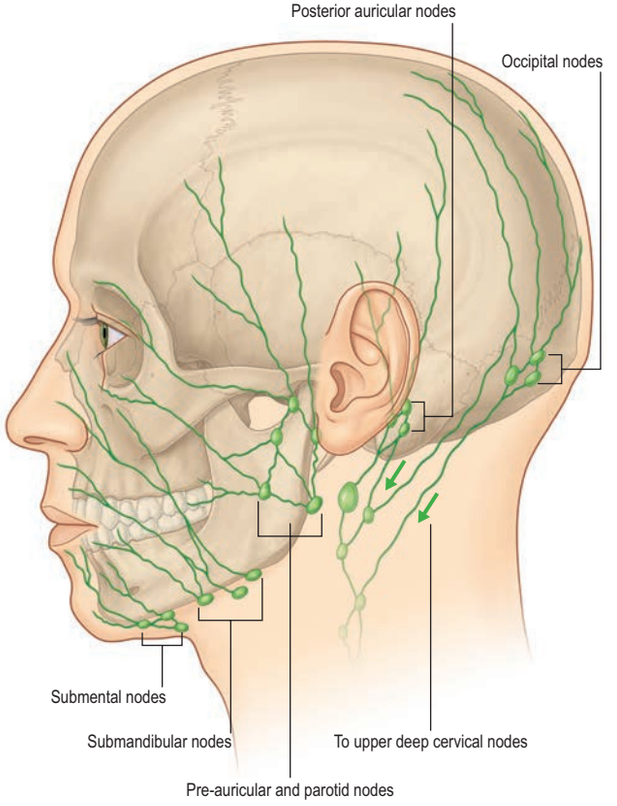

Fig. 36.21 Lymphatic drainage of the face and scalp. Arrows indicate the direction of flow. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

INNERVATION

The numerous muscles of facial expression are supplied by the facial nerve, and the two muscles of mastication that relate to the face are innervated by the mandibular division of the trigeminal nerve. The sensory innervation is primarily from the three divisions of the trigeminal nerve, with smaller contributions from the cervical spinal nerves. The detailed innervation of the auricle is considered in Chapter 42.

Trigeminal nerve

Three large areas of the face can be mapped out to indicate the peripheral nerve fields associated with the three divisions of the trigeminal nerve. The fields are not horizontal but curve upwards, reflecting the upwards movement of the facial skin as the skull and brain develop (Fig. 36.22). Embryologically, each division of the trigeminal nerve is associated with a developing facial process that gives rise to a specific area of the adult face: the ophthalmic nerve is associated with the frontonasal process, the maxillary nerve with the maxillary process, and the mandibular nerve with the mandibular process.

Ophthalmic nerve

The cutaneous branches of the ophthalmic nerve supply the conjunctiva, skin over the forehead, upper eyelid and much of the external surface of the nose.

Supratrochlear nerve

The supratrochlear nerve is the smaller terminal branch of the frontal nerve. It runs anteromedially in the roof of the orbit, passes above the trochlea and sends a descending filament to the infratrochlear branch of the nasociliary nerve. The nerve emerges between the trochlea and the supraorbital foramen at the frontal notch, curves up on the forehead close to the bone with the supratrochlear artery, and supplies the conjunctiva and the skin of the upper eyelid. It then ascends beneath the corrugator and the frontal belly of occipitofrontalis before dividing into

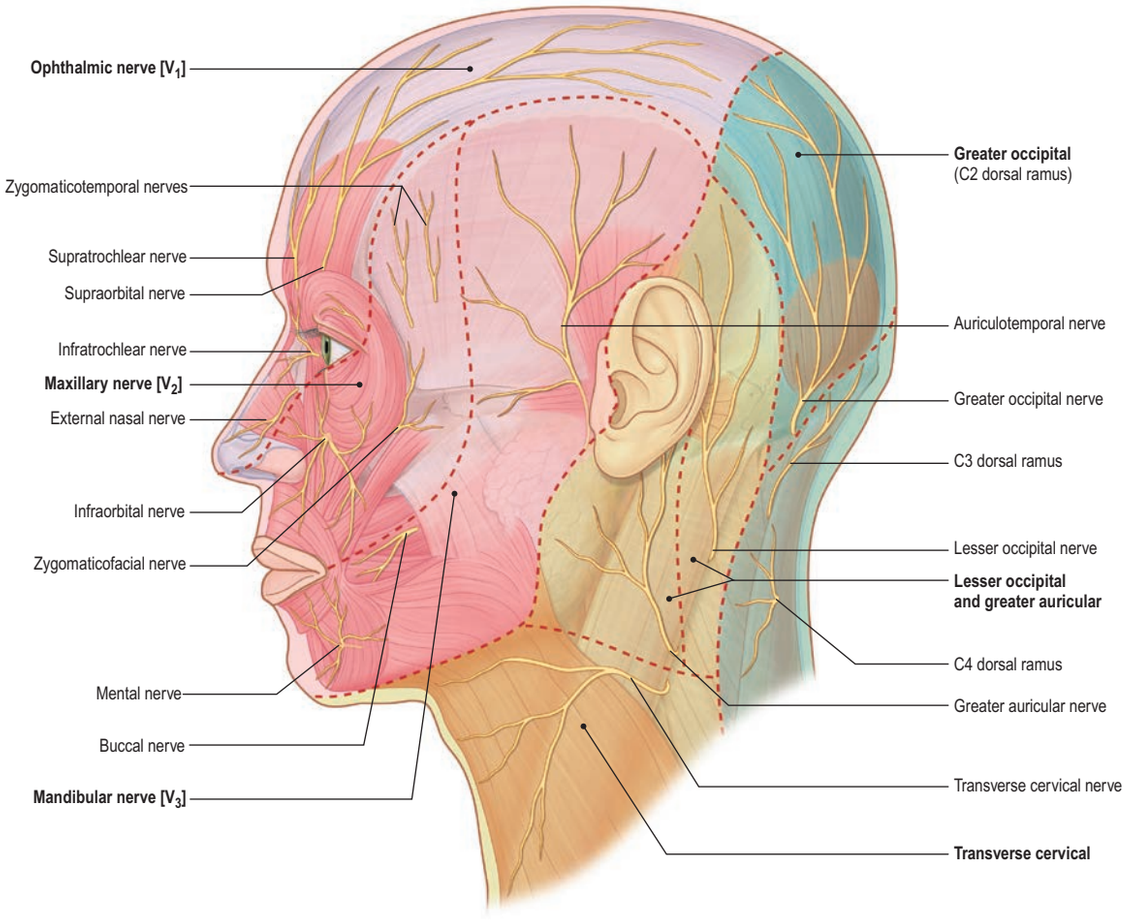

Fig. 36.22 Cutaneous innervation of the face and neck, showing dermatomes (in bold, territories outlined with dotted lines). (Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

branches that pierce these muscles to supply the skin of the lower forehead near the midline.

Supraorbital nerve

The supraorbital nerve is the larger terminal branch of the frontal nerve. It traverses the supraorbital notch or foramen and supplies palpebral filaments to the upper eyelid and conjunctiva. It ascends on the forehead with the supraorbital artery and divides into medial and lateral branches that supply the skin of the scalp nearly as far back as the lambdoid suture. These branches are at first deep to the frontal belly of occipitofrontalis: the medial branch perforates the muscle to reach the skin, while the lateral branch pierces the epicranial aponeurosis.

Lacrimal nerve

The lacrimal nerve is the smallest of the main ophthalmic branches and pierces the orbital septum to end in the lateral region of the upper eyelid, which it supplies. It anastomoses with filaments of the facial nerve. Occasionally, the lacrimal nerve is absent, in which case it is replaced by the zygomaticotemporal nerve; their relationship is reciprocal, and when the zygomaticotemporal nerve is absent it is replaced by a branch of the lacrimal nerve.

Infratrochlear nerve

The infratrochlear nerve branches from the nasociliary nerve. It leaves the orbit below the trochlea and supplies the skin of the eyelids, the conjunctiva, lacrimal sac, lacrimal caruncle and the side of the nose above the medial canthus.

External nasal nerve

The external nasal nerve is the terminal branch of the anterior ethmoidal nerve. It descends through the lateral wall of the nose and supplies the skin of the nose below the nasal bones, excluding the alar portion around the external nares.

Maxillary nerve

The maxillary nerve passes through the orbit to supply the skin of the lower eyelid, the prominence of the cheek, the alar part of the nose, part of the temple and the upper lip. It has three cutaneous branches: the zygomaticotemporal, zygomaticofacial and infraorbital nerves.

Zygomaticotemporal nerve

The zygomaticotemporal nerve traverses a canal in the zygomatic bone and emerges into the anterior part of the temporal fossa, where it ascends between the bone and temporalis before piercing the temporal fascia about 2 cm above the zygomatic arch to supply the skin of the temple. It communicates with the facial and auriculotemporal nerves. As it pierces the deep layer of the temporal fascia, it sends a slender twig between the two layers of the fascia towards the lateral angle of the eye. It was thought that this branch carried parasympathetic postganglionic fibres from the pterygopalatine ganglion to the lacrimal gland, but it is now known that these fibres usually innervate the lacrimal gland directly.

Zygomaticofacial nerve

The zygomaticofacial nerve traverses the inferolateral angle of the orbit and emerges on the face through a foramen in the zygomatic bone. It perforates orbicularis oculi to supply the skin on the prominence of the cheek and forms a plexus with zygomatic branches of the facial nerve and palpebral branches of the maxillary nerve. Occasionally, the zygomaticofacial nerve is absent.

Infraorbital nerve

The infraorbital nerve emerges onto the face at the infraorbital foramen, where it lies between levator labii superioris and levator anguli oris. It gives off palpebral, nasal and superior labial branches. The palpebral branches ascend deep to orbicularis oculi, pierce the muscle to supply the skin in the lower eyelid and join with the facial and zygomaticofacial nerves near the lateral canthus. Nasal branches supply the skin of the side of the nose and the movable part of the nasal septum and join the external nasal branch of the anterior ethmoidal nerve. Superior labial branches, are large and numerous and descend behind levator labii superioris to supply the skin of the anterior part of the cheek and upper lip. They are joined by branches from the facial nerve to form the infraorbital plexus.

Mandibular nerve

The mandibular nerve supplies the skin over the mandible, the lower lip, the fleshy part of the cheek, part of the auricle of the ear and part of the temple via the buccal, mental and auriculotemporal nerves.

Buccal nerve

The buccal nerve emerges onto the face from behind the ramus of the mandible and passes laterally in front of masseter to unite with the buccal branches of the facial nerve. It supplies the skin over the anterior part of buccinator.

Mental nerve

The mental nerve is the terminal branch of the inferior alveolar nerve. It enters the face through the mental foramen, where it is directed backwards to supply the skin of the lower lip and labial gingivae.

Auriculotemporal nerve

The auriculotemporal nerve emerges onto the face behind the temporomandibular joint and within the superior surface of the parotid gland. It ascends posterior to the superficial temporal vessels, passes over the posterior root of the zygoma, and divides into superficial temporal branches (see Figs 38.20, 38.25). The cutaneous branches of the auriculotemporal nerve supply the tragus and part of the adjoining auricle of the ear and the posterior part of the temple. The nerve may be damaged during parotid gland surgery, resulting in impaired sensation of the tragus and temple. It communicates with the temporofacial division of the facial nerve, usually by two rami that pass anterolaterally behind the neck of the mandible. These communications anchor the facial nerve close to the lateral surface of the condylar process of the mandible and limit its mobility during surgery. Communications with the temporal and zygomatic branches of the facial nerve loop around the transverse facial and superficial temporal vessels.

Facial nerve

The facial nerve emerges from the base of the skull at the stylomastoid foramen and almost immediately gives off the nerves to the posterior belly of digastric and stylohyoid together with the posterior auricular nerve that supplies the occipital belly of occipitofrontalis and some of the auricular muscles (**Fig. 36.23**).

The nerve next enters the parotid gland high up on its posteromedial surface and passes forwards and downwards behind the mandibular ramus. Within the substance of the gland, it branches into superior (temporofacial) and inferior (cervicofacial) trunks, usually just behind and superficial to the retromandibular vein. The trunks branch further to form a parotid plexus (pes anserinus). Five main terminal branches arise from the plexus, diverge within the gland and leave by its anteromedial surface, medial to its anterior margin, to supply the muscles of facial expression (see Fig. 36.23). Six distinctive anastomotic patterns were originally classified by Davis et al (1956) and these are illustrated in **Fig. 36.24**. Numerous microdissection studies have demonstrated considerable individual variation in branching patterns and anastomoses between branches, both within the parotid and on the face (e.g. Lineaweaver et al 1997, Kwak et al 2004): the account that follows is therefore an overview. In surgical terms, these anastomoses are important and presumably explain why accidental or deliberate division of a small branch often fails to result in the expected facial nerve weakness. The surface anatomy of the facial nerve is described in Chapter 33.

The temporal branch usually divides into anterior and posterior rami soon after piercing the parotidomasseteric fascia below the zygomatic arch; there is often a middle (frontal) ramus. These rami cross the arch in subcutaneous tissue lying in the subgaleal space. Their course is extremely variable.

Twigs supply intrinsic muscles on the lateral surface of the auricle and the anterior and superior auricular muscles. They communicate with the zygomaticotemporal branch of the maxillary nerve and the auriculotemporal branch of the mandibular nerve. The more anterior branches supply the frontal belly of occipitofrontalis, orbicularis oculi and corrugator and join the supraorbital and lacrimal branches of the ophthalmic nerve.

Zygomatic branches are generally multiple. They cross the zygomatic bone to the lateral canthus of the eye and supply orbicularis oculi and may also supply muscles innervated by the buccal branch. Twigs communicate with filaments of the lacrimal nerve and the zygomaticofacial branch of the maxillary nerve.

The buccal branch is usually single. It has a close relationship to the parotid duct for about 2.5 cm after emerging from the parotid gland and typically lies below the duct. Superficial branches run beneath the subcutaneous fat and the superficial musculo-aponeurotic system (SMAS). Some branches pass deep to procerus and join the infratrochlear and external nasal nerves. Upper deep branches supply zygomaticus major and levator labii superioris and form an infraorbital plexus with the superior labial branches of the infraorbital nerve. They also supply levator anguli oris, zygomaticus minor, levator labii superioris alaeque nasi and the small nasal muscles (these branches are sometimes described as lower zygomatic branches). Lower deep branches supply buccinator and orbicularis oris and communicate with filaments of the buccal branch of the mandibular nerve.

There are usually two marginal mandibular branches. They run forwards towards the angle of the mandible under platysma, and then

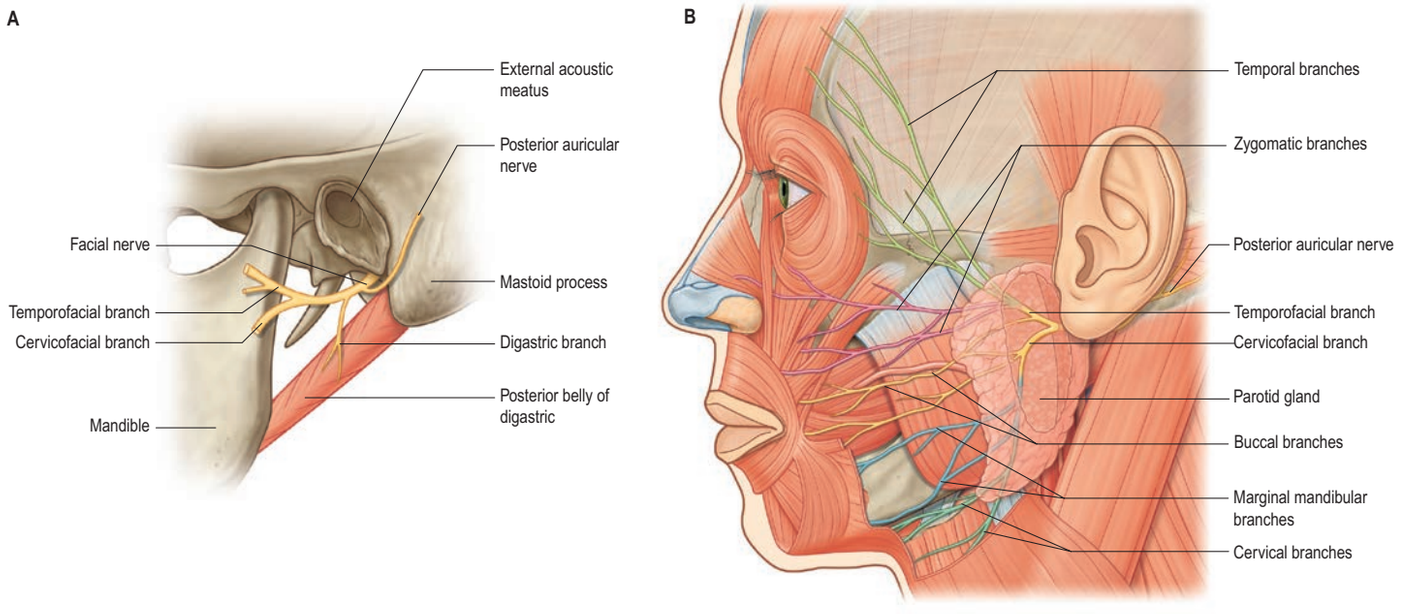

Fig. 36.23 The distribution of the facial nerve. **A**, Branches given off immediately after the nerve exits the stylomastoid foramen. **B**, Branches of the nerve on the face. London: Martin Dunitz, and from Davis RA, Anson BJ, Budinger JM et al 1956 Surgical anatomy of the facial nerve and parotid gland based upon a study of 350 cervicofacial halves. Surg Gynecol Obstet 102:385–412, with permission from the American College of Surgeons.)

turn upwards across the body of the mandible to pass under depressor anguli oris. The branches supply risorius and the muscles of the lower lip and chin. Filaments communicate with the mental nerve. The marginal mandibular branch has an important surgical relationship with the inferior border of the mandible.

The cervical branch emerges from the lower part of the parotid gland and runs anteroinferiorly under platysma to the anterior neck. Typically single, it supplies platysma and communicates with the transverse cutaneous cervical nerve.

Cutaneous branches of the facial nerve accompany the auricular branch of the vagus and probably supply small areas on both aspects of the auricle, in the depression of the concha and over its eminence.

Lesions of the facial nerve

Facial paralysis may be due to an upper motor neurone lesion (when frontalis is partially spared because of the bilateral cortical representation of the muscles of the upper part of the face) or a lower motor neurone lesion (when all branches may be involved). Lower motor neurone facial paralysis is most commonly idiopathic (Bell's palsy). There are a large number of other recognized causes that include geniculate herpes zoster (Ramsay Hunt syndrome), malignant tumours of the parotid gland and temporal bone. Iatrogenic damage also accounts for a significant number of palsies, most often acquired in vestibular schwannoma, parotid and middle ear or mastoid surgery (Robinson and Baiungo 2018).

Cervical spinal nerves

Cervical spinal nerves have cutaneous branches that supply areas of skin in the face and scalp (see Fig. 36.22). The named branches are the great auricular and lesser occipital nerves that are part of the cervical plexus and described on page 573 (see Fig. 35.1B), and the greater occipital nerve that is described on page 862 (see Figs 46.78, 47.8).

PAROTID SALIVARY GLAND

The paired parotid glands are the largest of the salivary glands. Each has an average weight of 25 g and is an irregular, lobulated, yellowish mass, lying largely below the external acoustic meatus between the mandible and sternocleidomastoid. The gland also projects forwards onto the surface of masseter (**Fig. 36.23B**). Sometimes, a small and often detached part called the accessory parotid gland (pars accessoria or socia parotidis) lies between the zygomatic arch above and the parotid duct below (Fromer 1977). The overall shape of the parotid gland is variable. Viewed laterally, it is often roughly triangular in outline, whereas other glands are more or less of even width throughout with rounded upper and lower poles.

In its usual inverted pyramidal form, the parotid gland presents superior, superficial, anteromedial and posteromedial surfaces and tapers inferiorly to a blunt apex. The small concave superior surface is related to the cartilaginous part of the external acoustic meatus and posterior aspect of the temporomandibular joint. Here, the auriculotemporal nerve curves round the neck of the mandible, embedded in the parotid capsule. The apex overlaps the posterior belly of digastric and the carotid triangle to a variable extent. The superficial surface is covered by skin and superficial fascia that contains the facial branches of the great auricular nerve, superficial parotid lymph nodes and the posterior border of platysma. It extends upwards to the zygomatic arch, backwards to overlap sternocleidomastoid, downwards to its apex posteroinferior to the mandibular angle, and forwards to lie on masseter below the parotid duct. The anteromedial surface is grooved by the posterior border of the mandibular ramus. It covers the posteroinferior part of masseter, the lateral aspect of the temporomandibular joint and the adjoining part of the mandibular ramus. It passes forwards, medial to the ramus of the mandible, to reach medial pterygoid. The gland may therefore be subdivided into a larger superficial part and a smaller part, the deep 'lobe', deep to the ramus, the two being joined by an isthmus. Branches of the facial nerve emerge on the face from the anterior margin of this surface.

The posteromedial surface is moulded to the mastoid process, sternocleidomastoid, posterior belly of the digastric, and the styloid process and its associated muscles. The external carotid artery grooves this surface before entering the gland, and the internal carotid artery and internal jugular vein are separated from the gland by the styloid process and its associated muscles (**Fig. 36.25**). The anteromedial and posteromedial surfaces meet at a medial margin that may project so deeply that it contacts the lateral wall of the pharynx.

Deep lobe tumours The deep 'lobe' of the gland extends behind the mandibular ramus, where its deep surface lies immediately lateral to

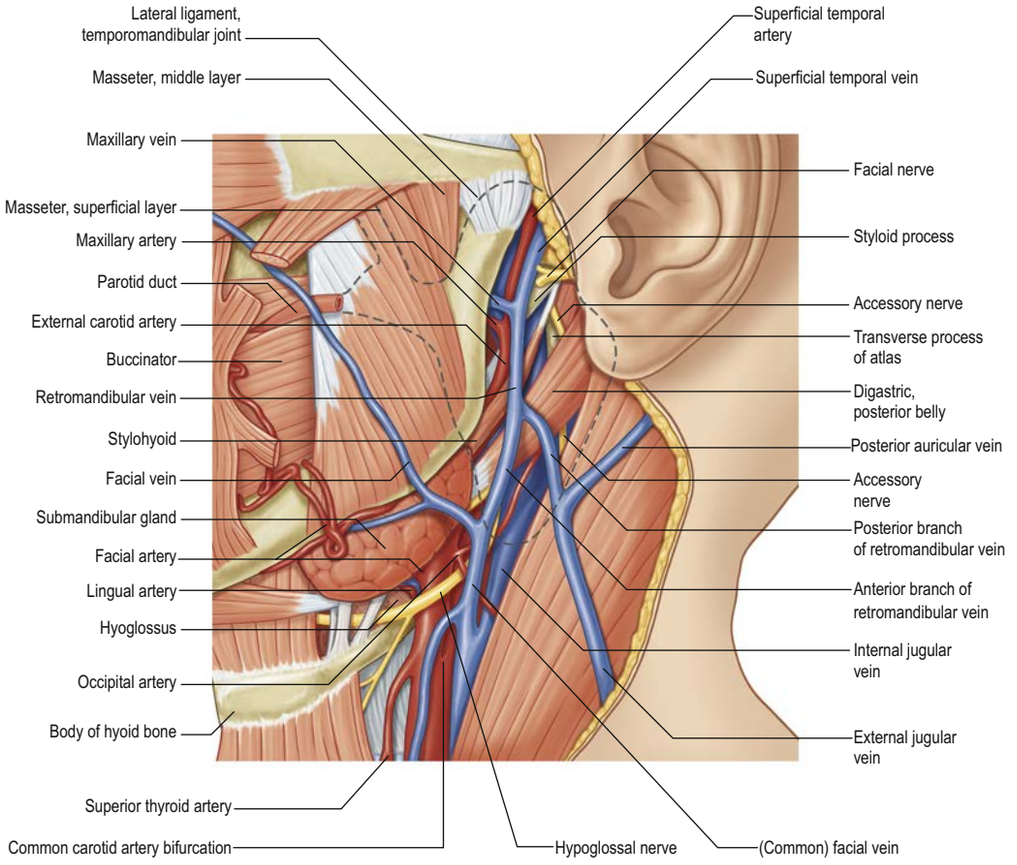

Fig. 36.25 The principal immediate deep relations of the parotid gland. The outline of the parotid gland is indicated by the interrupted black line.

the superior constrictor of the pharynx. When a parotid tumour, either benign or malignant, develops in the deep 'lobe', the mass presents as a swelling in the lateral wall of the oropharynx and not as a facial swelling.

Structures within the parotid gland

The external carotid artery, retromandibular vein and facial nerve, either in part or in whole, traverse the gland and branch within it (Langdon 1998). The external carotid artery enters the posteromedial surface and divides into the maxillary artery, which emerges from the anteromedial surface, and the superficial temporal artery, which gives off its transverse facial branch in the gland and ascends to leave its upper limit (see Fig. 36.23). The posterior auricular artery may also branch from the external carotid artery within the gland, leaving by its posteromedial surface.

The retromandibular vein, formed by the union of the maxillary and superficial temporal veins (which enter near the points of exit of the corresponding arteries), is superficial to the external carotid artery. It descends in the parotid gland and emerges behind the apex of the gland, where it usually divides into an anterior branch that passes forwards to join the facial vein, and a posterior branch that joins the posterior auricular vein to form the external jugular vein. Occasionally, it is not connected to the external jugular vein, which is then small, and the anterior jugular vein is enlarged.

Parotid capsule

The parotid gland is enclosed within an unyielding parotid capsule derived from the investing layer of deep cervical fascia. Acute inflammation of the parotid gland (acute sialadenitis) may cause exquisite pain in the pre-auricular region as a result of capsular stretch and stimulation of the great auricular nerve. The pain is usually exacerbated at mealtimes when the gustatory stimulus to the gland results in further turgor within the capsule. Causes of acute sialadenitis include parotid duct obstruction (calculus, mucus plug and duct stricture) and mumps.

Parotid duct

The average dimensions of the parotid duct are 5 cm long and 3 mm wide (narrower at its oral orifice). The duct begins by the confluence of two main tributaries within the anterior part of the parotid gland. It appears at the anterior border of the upper part of the gland and passes horizontally across masseter, approximately midway between the angle of the mouth and the zygomatic arch (**Fig. 36.18C**; see Figs 36.25, 37.40A). If the duct arises lower down, it may run obliquely upwards. It crosses masseter, turning medially at its anterior border at almost a right angle, and traverses the buccal fat pad and buccinator opposite the crown of the maxillary third molar tooth. The duct then runs obliquely forwards for a short distance between buccinator and the oral mucosa before it opens on a small papilla opposite the crown of the maxillary second molar tooth. The submucosal passage of the duct serves as a valvular mechanism, preventing inflation of the gland with raised intraoral pressures. While crossing masseter, the duct lies between the upper and lower buccal branches of the facial nerve and may receive the accessory parotid duct.

The accessory part of the gland (Fromer 1977) and the transverse facial artery lie above the parotid duct; the buccal branch of the mandibular nerve, emerging from beneath temporalis and masseter, lies just below, at the anterior border of masseter. The parotid duct may be crossed by anastomosing branches between the zygomatic and buccal branches of the facial nerve.

The ramifications of the ductal systems, their patterns and calibres, can be demonstrated radiographically by injecting a radiopaque substance into the parotid duct via a cannula. In a lateral parotid sialogram, the main duct can be seen to be formed near the centre of the posterior border of the mandibular ramus by the union of two or three ducts that ascend or descend, respectively at right-angles to the main duct. As it crosses the face, the main duct also receives from above five or six ductules from the accessory parotid gland (**Fig. 36.26**). As it curves round the anterior border of masseter, it is often compressed and its shadow is attenuated. Deep lacerations of the cheek, where the integrity of the parotid duct is in doubt, should be explored and repaired using microsurgical techniques to prevent saliva leaking into the soft tissues of the cheek and subsequent sialocele formation.

Vascular supply and lymphatic drainage

The parotid gland receives its arterial supply from the external carotid artery and its branches within and near the gland. The veins drain to the external jugular vein via local tributaries.

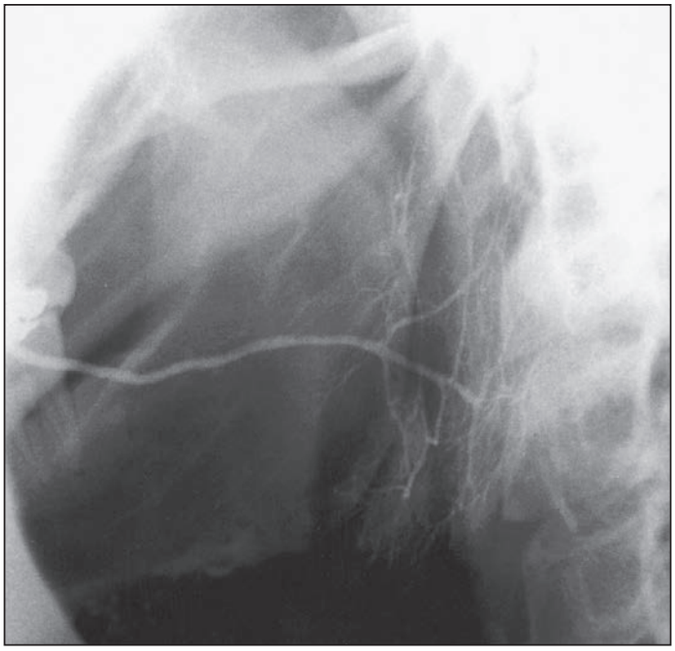

Fig. 36.26 An oblique lateral radiograph showing a normal parotid duct outlined after injection of radio-opaque contrast medium (sialogram). Note that here the main duct is formed by the union of three smaller ducts at the posterior border of the ramus of the mandible. (Courtesy of Dr N Drage.)

Lymph drains to nodes in the skin overlying the parotid gland (pre-auricular nodes) and in the substance of the gland itself. There are usually 10 lymph nodes present in the gland, the majority lying in the superficial part of the gland above the plane related to the facial nerve. Lymph from these parotid nodes drains to the upper deep cervical lymph nodes.

Innervation

Preganglionic nerves travel in the lesser petrosal branch of the glossopharyngeal nerve and synapse in the otic ganglion (see Fig. 33.7). Postganglionic secretomotor fibres reach the gland via the auriculotemporal nerve.

Gustatory sweating

Gustatory sweating (syndrome or auriculotemporal sweating) may occasionally develop after parotid surgery or trauma to the capsule of the gland. It is thought to reflect aberrant innervation of sweat glands on the face by regenerating parasympathetic secretomotor axons that would previously have innervated the parotid gland. Frey's syndrome is characterized by sweating, warmth and redness of the face as a result of salivary stimulation in response to the smell or taste of food. The management of Frey's syndrome is difficult. Denervation by tympanic neurectomy or auriculotemporal nerve avulsion has been advocated but is rarely curative and has been superseded by the subcutaneous infiltration of purified botulinum toxin into the affected area or the use of antiperspirants.

Microstructure of the salivary glands is described in Chapter 37.

CHAPTER
37

Mouth

The mouth extends from the lips and cheeks externally to the anterior pillars of the fauces internally, where it continues into the oropharynx. The mouth can be subdivided into the vestibule external to the teeth and the oral cavity proper internal to the teeth (**Fig. 37.1**). The palate forms the roof of the mouth and separates the oral and nasal cavities. The floor of the mouth is formed by the mylohyoid muscles and is occupied mainly by the tongue. The lateral walls of the mouth are defined by the cheeks and retromolar regions. Three pairs of major salivary glands (parotid, submandibular and sublingual) and numerous minor salivary glands (labial, buccal, palatal, lingual) open into the mouth. The muscles in the mouth and oral cavity are associated with the lips, cheeks, floor of the mouth and tongue. The muscles of the lips and cheeks are described with the face in Chapter 36. The muscles of the soft palate are described with the pharynx in Chapter 40 (Berkovitz and Moxham 2002).

The mouth is concerned primarily with the ingestion and mastication of food, which is mainly the function of the teeth. The mouth is also associated with phonation and ventilation.

CHEEKS

The external features of the cheeks are described in Chapter 36. Internally, the mucosa of the cheek is tightly adherent to buccinator and is thus stretched when the mouth is opened and wrinkled when closed. Ectopic sebaceous glands may be evident as yellow patches (Fordyce spots). Their numbers increase in puberty and in later life.

Few structural landmarks are visible. The parotid duct drains into the cheek opposite the maxillary second molar tooth at a small parotid papilla. A hyperkeratinized line (the linea alba) may be seen at a position related to the occlusal plane of the teeth. In the retromolar region, a fold of mucosa containing the pterygomandibular raphe extends from the upper to the lower alveolus. The entrance to the pterygomandibular space (which contains the lingual and inferior alveolar nerves) lies lateral to this fold and medial to the ridge produced by the anterior border of the ramus of the mandible; this is the site for injection for an inferior alveolar nerve block, commonly used to anaesthetize the ipsilateral lower teeth and gums.

Vascular supply and innervation

The cheek receives its arterial blood supply principally from the buccal branch of the maxillary artery, and is innervated by cutaneous branches of the maxillary division of the trigeminal nerve, via the zygomaticofacial and infraorbital nerves, and by the buccal branch of the mandibular division of the trigeminal nerve.

LIPS

The external features of the lips are described in Chapter 36. The central part of the lips contains orbicularis oris. Internally, the labial mucosa is smooth and shiny, and shows small elevations caused by underlying mucous glands.

The position and activity of the lips are important in controlling the degree of protrusion of the incisors. With normal (competent) lips, the tips of the maxillary incisors lie below the upper border of the lower lip, and this arrangement helps to maintain the 'normal' inclination of

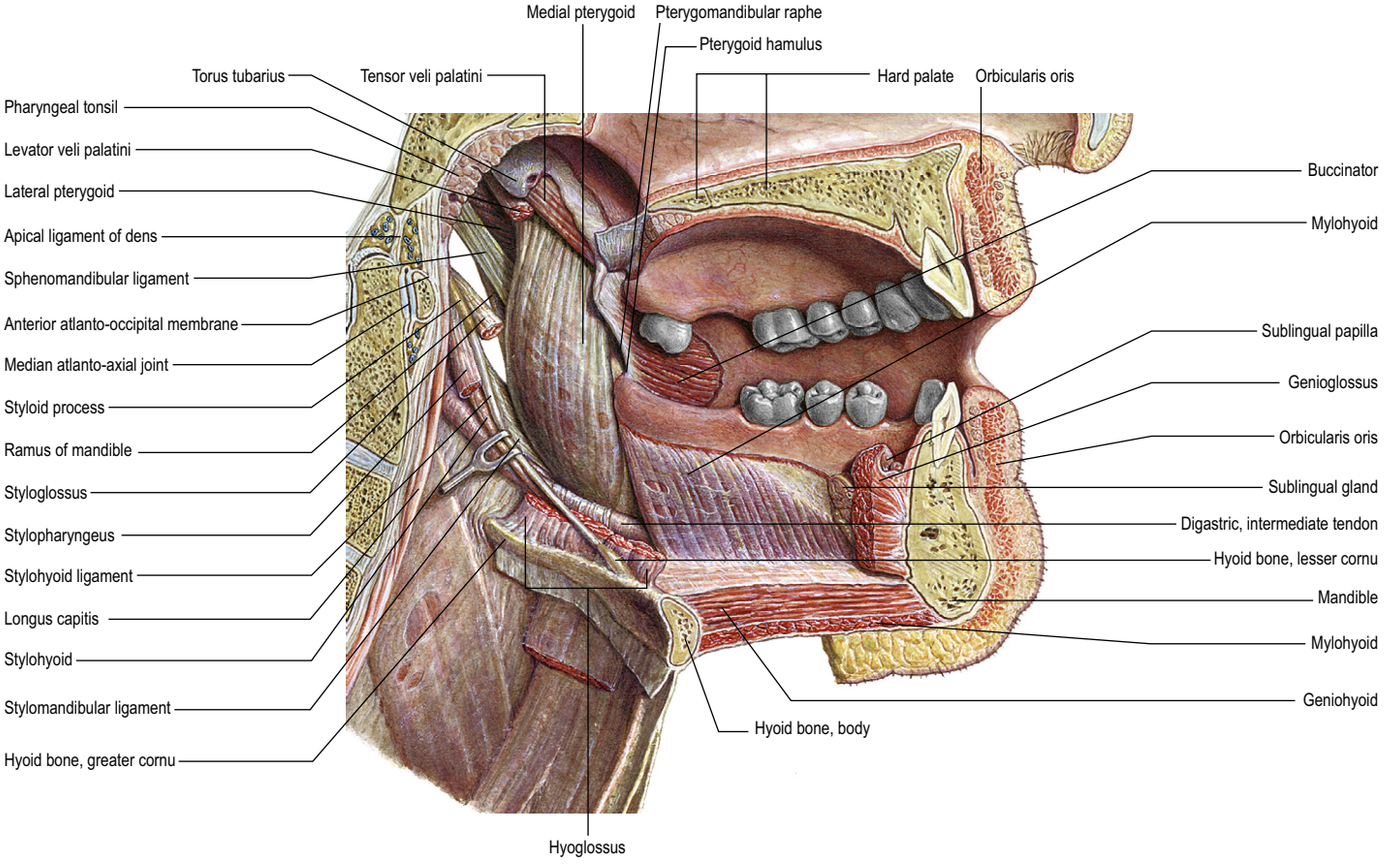

Fig. 37.1 The oral cavity. The tongue and soft palate have been removed. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

the incisors. When the lips are incompetent, the maxillary incisors may not be so controlled and the lower lip may even lie behind them, thus producing an exaggerated proclination of these teeth. A tight, or overactive, lip musculature may be associated with retroclined maxillary incisors. The lips are kept moist both by tongue deposition of saliva and by numerous minor salivary glands within them. These glands are liable to trauma by the teeth, particularly in the lower lip; this can produce a mucocele as a result of either extravasation of saliva into the submucosal tissues or retention of saliva within the gland or its duct.

Vascular supply and innervation

The lips are mainly supplied by the superior and inferior labial branches of the facial artery. The upper lip is innervated by superior labial branches of the infraorbital nerve, and the lower lip is innervated by the mental branch of the mandibular division of the trigeminal.

ORAL VESTIBULE

The oral vestibule is a slit-like space between the lips or cheeks on one side and the teeth on the other. When the teeth occlude, the vestibule is a closed space that only communicates with the oral cavity proper in the retromolar regions behind the last molar tooth on each side. Where the mucosa that covers the alveolus of the jaw is reflected on to the lips and cheeks, a trough or sulcus is formed, which is called the fornix vestibuli. A variable number of sickle-shaped folds containing loose connective tissue run across the fornix vestibuli. In the midline, these are the upper and lower labial frenula. Other folds may traverse the fornix near the canines or premolars. The folds in the lower fornix are said to be more pronounced than those in the upper fornix (**Fig. 37.2**).

The upper labial frenulum is normally attached well below the alveolar crest. A large frenulum with an attachment near or on the crest may be associated with a midline gap (diastema) between the maxillary first incisors. This can be corrected by simple surgical removal of the frenulum (frenulectomy) because it contains no structures of clinical importance. Prominent frenula may compromise the stability of dentures.

ORAL MUCOSA

The oral mucosa is continuous with the skin at the labial margins (vermilion border) and with the pharyngeal mucosa at the oropharyngeal isthmus. It varies in structure, function and appearance in different regions of the oral cavity and is traditionally divided into lining, masticatory and specialized mucosae (Presland and Dale 2000).

Lining mucosa

The lining mucosa is red in colour, and covers the soft palate, ventral surface of the tongue, floor of the mouth, alveolar processes excluding the gingivae, and the internal surfaces of the lips and cheeks. It has a non-keratinized stratified squamous epithelium, which overlies a loosely fibrous lamina propria, and the submucosa contains some fat deposits and collections of minor mucous salivary glands. The oral mucosa covering the alveolar bone – which supports the roots of the teeth – and the necks (cervical region) of the teeth is divided into two main components. That portion lining the lower part of the alveolus is loosely attached to the periosteum via a diffuse submucosa and is termed the alveolar mucosa. It is delineated from the masticatory gingival mucosa, which covers the upper part of the alveolar bone and the necks of the teeth, by a well-defined junction, the mucogingival junction. The alveolar mucosa appears dark red; the gingival appears pale pink (see Fig. 37.2). These colour differences relate to differences in the type of keratinization and the proximity to the surface of underlying small blood vessels, which may sometimes be seen coursing beneath the alveolar mucosa.

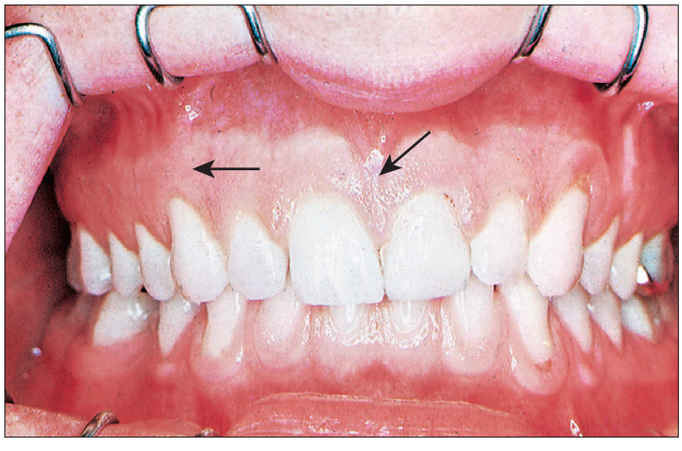

Fig. 37.2 An anterior view of the dentition in centric occlusion, with the lips retracted. Note the pale pink, stippled gingivae and the red, shiny, smooth alveolar mucosa. The degree of overbite is rather pronounced, and the gingiva and its epithelial attachment have receded on to the root of the upper left canine. Note the frena (arrows).

Masticatory mucosa and the gingivae

Masticatory mucosa (mucosa that is subjected to masticatory stress) is bound firmly to underlying bone or to the necks of the teeth, and forms a mucoperiosteum in the gingivae and palatine raphe. Gingival, palatal and dorsal lingual mucosae are keratinized or parakeratinized (Schroeder and Listgarten 1997).

The gingivae may be further subdivided into the attached gingivae and the free gingivae. Attached gingivae are firmly bound to the periosteum of the alveolus and to the teeth, whereas free gingivae, which constitute approximately a 1 mm margin of the gingivae, lie unattached around the cervical region of each tooth. The free gingival groove between the free and attached gingivae corresponds roughly to the floor of the gingival sulcus that separates the inner surface of the attached gingivae from the enamel. The interdental papilla is that part of the gingivae that fills the space between adjacent teeth. The surface of the attached gingivae is characteristically stippled, although there is considerable inter-individual variation in the degree of stippling, and variation according to age, sex and the health of the gingivae. The free gingivae are not stippled. A mucogingival line delineates the attached gingivae on the buccal surface of the upper and lower jaws (see Fig. 37.2) and the lingual surface of the lower jaw from the alveolar mucosa. There is no corresponding obvious division between the attached gingivae and the remainder of the palatal mucosa because this whole surface is orthokeratinized masticatory mucosa, which is pink.

A submucosa is absent from the gingivae and the midline palatine raphe, but is present over the rest of the hard palate. Posterolaterally, it is thick where it contains mucous salivary glands and the greater palatine nerves and vessels, and it is anchored to the periosteum of the maxillae and palatine bones by collagenous septa.

Vascular supply and lymphatic drainage

The gingival tissues derive their blood supply from the maxillary and lingual arteries. The buccal gingivae around the maxillary cheek teeth are supplied by gingival and perforating branches from the posterior superior alveolar artery and by the buccal branch of the maxillary artery. The labial gingivae of anterior teeth are supplied by labial branches of the infraorbital artery and by perforating branches of the anterior superior alveolar artery. The palatal gingivae are supplied primarily by branches of the greater palatine artery.

The buccal gingivae associated with the mandibular cheek teeth are supplied by the buccal branch of the maxillary artery and by perforating branches from the inferior alveolar artery. The labial gingivae around the anterior teeth are supplied by the mental artery and by perforating branches of the incisive artery. The lingual gingivae are supplied by perforating branches from the inferior alveolar artery and by its lingual branch, and by the main lingual artery, a branch of the external carotid artery.

No accurate description is available concerning the venous drainage of the gingivae, although it may be assumed that buccal, lingual, greater palatine and nasopalatine veins are involved. These veins run into the pterygoid plexuses (apart from the lingual veins, which may pass directly into the internal jugular veins).

The lymph vessels of the labial and buccal gingivae of the maxillary and mandibular teeth unite to drain into the submandibular nodes, though in the labial region of the mandibular incisors they may drain into the submental lymph nodes. The lingual and palatal gingivae drain into the jugulodigastric group of nodes, either directly or indirectly through the submandibular nodes.

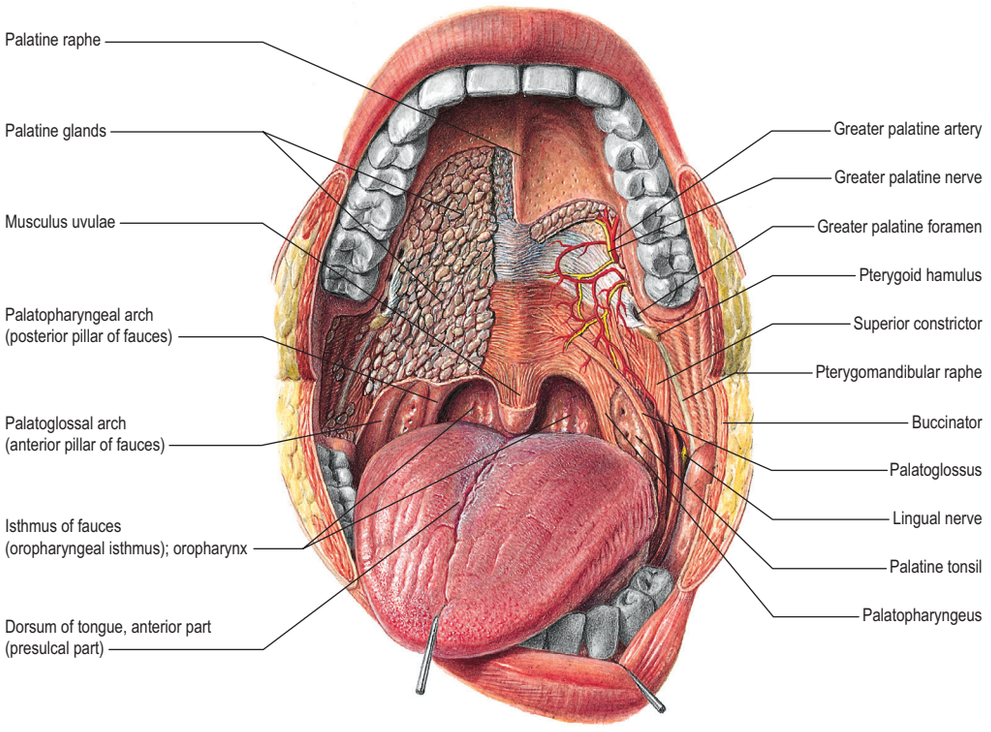

Fig. 37.3 The oral cavity, oropharyngeal isthmus and muscles of the palate. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Innervation

The nerves supplying the gingivae in the upper jaw come from the maxillary nerve via its greater palatine, nasopalatine, anterior, middle and posterior superior alveolar branches (see Table 37.2). Surgical division of the nasopalatine nerve, e.g. during the removal of an ectopic canine tooth, causes no obvious sensory deficit in the anterior part of the palate, which suggests that the territory of the greater palatine nerve reaches as far forwards as the gingivae lingual to the incisor teeth or that the nerve has large regenerative potential. The mandibular nerve innervates the gingivae in the lower jaw by its inferior alveolar, lingual and buccal branches.

OROPHARYNGEAL ISTHMUS

The oropharyngeal isthmus lies between the soft palate and the dorsum of the tongue, and is bounded on both sides by the palatoglossal arches. Each palatoglossal arch runs downwards, laterally and forwards, from the soft palate to the side of the tongue, and consists of palatoglossus and its covering mucous membrane (**Fig. 37.3**). The approximation of the arches shuts off the mouth from the oropharynx, and is essential for deglutition.

FLOOR OF THE MOUTH

The floor of the mouth is a small, horseshoe-shaped region situated beneath the movable part of the tongue and above the muscular diaphragm formed by the mylohyoid muscles. The fascia of the floor of the mouth lies immediately beneath the oral mucosa and is attached around the inner arc of the mandible, fusing centrally with the connective tissue on the ventral surface of the tongue (Mills et al 2019). The sublingual glands and submandibular ducts are enveloped by the fascial layer, fibres of the anterior part of genioglossus are suspended beneath it, and branches of the lingual nerve, located superficially on the ventral surface of the tongue, lie immediately deep to the fascia. Normal movements of the anterior part of the tongue create tension in the central region of the fascia and elevate it into a midline fold, the lingual frenulum (**Figs 37.4C,D**). Restricted movements of the tongue are commonly attributed to the lingual frenulum tethering the tongue, a condition called ankyloglossia (known colloquially as a 'tongue tie'). Historically, the tongue-tied frenulum has been divided to aid speech but the evidence for this procedure is scanty: there is some evidence that frenotomy may aid breast feeding (NICE 2005, Webb et al 2013).

The lingual frenulum is frequently and erroneously referred to as a 'cord' or 'submucosal band' of connective tissue, whereas the fascial fibres that form the frenulum exhibit a basket-weave orientation across the midline and there are no deep extensions into either genioglossus or the median septum of the tongue (Mills et al 2019). There is therefore no anatomical indication to make deep incisions into muscle when performing a frenotomy, with the attendant risk of iatrogenic injury to the lingual nerve.

The submandibular salivary ducts open into the mouth at the sublingual papilla (caruncle), which is a large, centrally positioned protuberance at the base of the tongue. The sublingual folds lie on either side of the sublingual papilla and cover the underlying submandibular ducts and sublingual salivary glands. The blood supply of the floor of the mouth is described with the blood supply of the tongue. The main muscle forming the floor of the mouth is mylohyoid, with geniohyoid lying immediately above it.

Mylohyoid

Mylohyoid lies superior to the anterior belly of digastric and, with its contralateral fellow, forms a muscular floor for the oral cavity. It is a flat, triangular sheet attached to the whole length of the mylohyoid line of the mandible (**Fig. 37.4A**; see Figs 37.1, 37.10, 37.14). The mylohyoid line is of variable length, sometimes ending before the lower third molar (wisdom) tooth. The posterior fibres of mylohyoid pass medially and slightly downwards to the front of the body of the hyoid bone near its lower border. The middle and anterior fibres from each side decussate in a median fibrous raphe that stretches from the symphysis menti to the hyoid bone. The median raphe is sometimes absent, in which case the two muscles form a continuous sheet, or it may be fused with the anterior belly of digastric. In about one-third of subjects, there is a hiatus in the muscle through which a process of the sublingual gland protrudes. The mylohyoid hiatus is the pathway for a plunging ranula.

Relations The inferior (external) surface is related to platysma, the anterior belly of digastric the superficial part of the submandibular gland, the facial and submental vessels, and the mylohyoid vessels and nerve. The superior (internal) surface is related to geniohyoid, part of hyoglossus and styloglossus, the hypoglossal and lingual nerves, the submandibular ganglion, the sublingual gland, the deep part of the submandibular gland and its duct, the lingual and sublingual vessels, and, posteriorly, the mucous membrane of the mouth (see Fig. 37.14).

Vascular supply Mylohyoid receives its arterial supply from the sublingual branch of the lingual artery, the maxillary artery, via the mylohyoid branch of the inferior alveolar artery, and the submental branch of the facial artery.

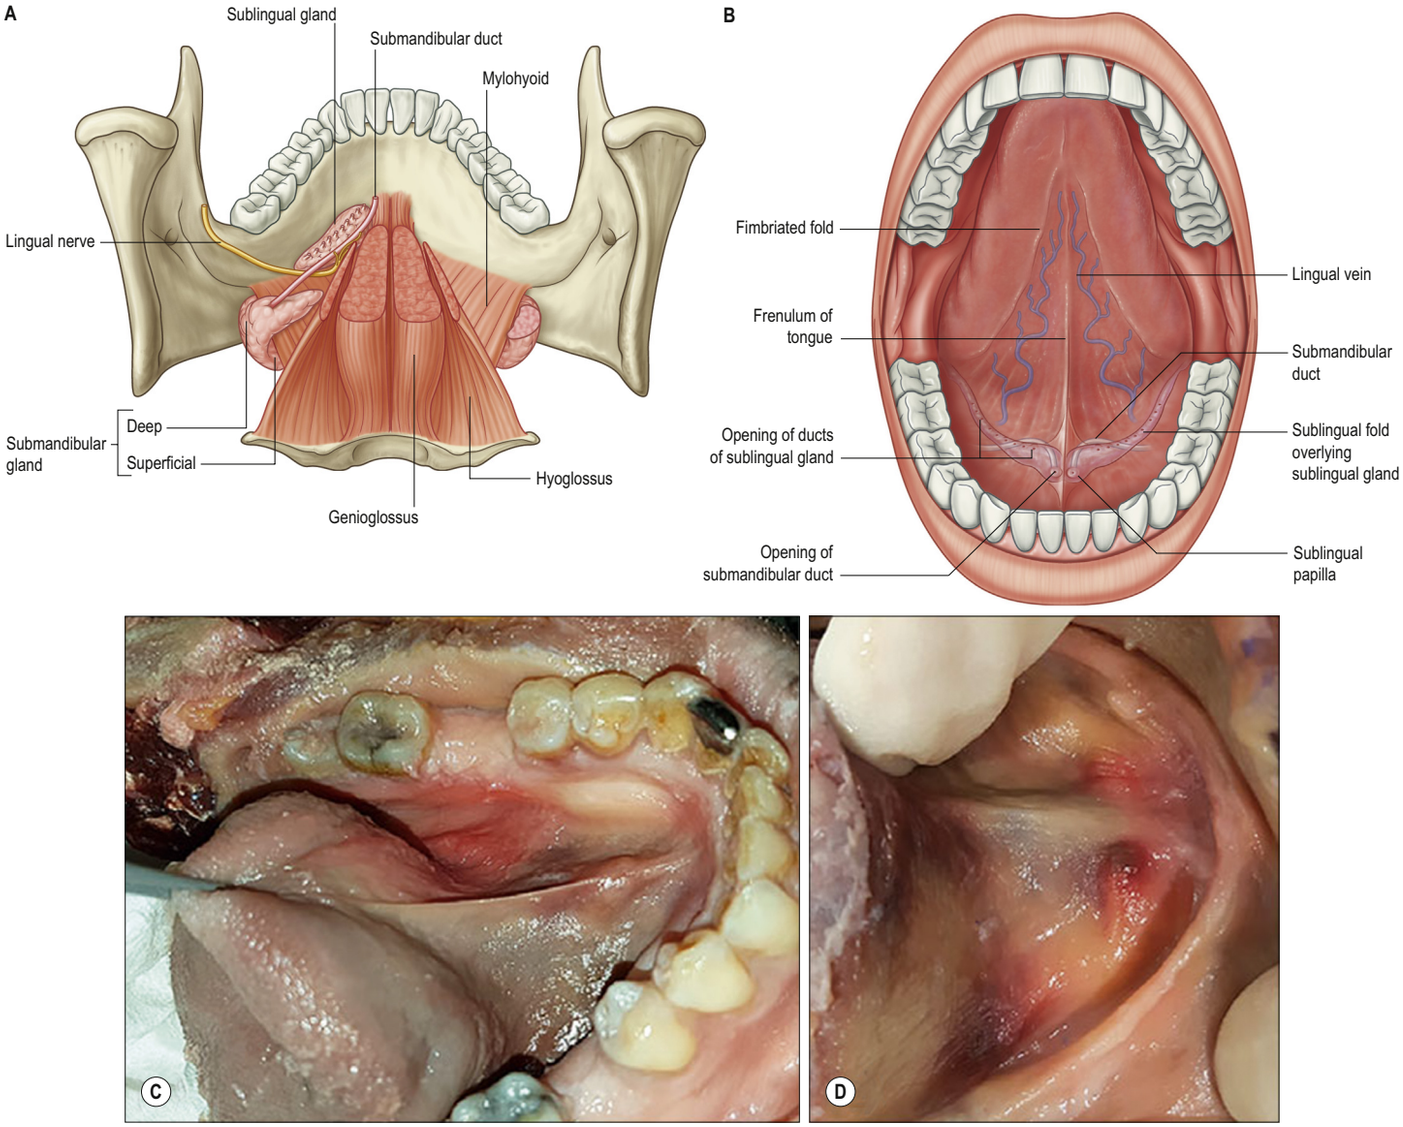

Fig. 37.4 The floor of the mouth. **A**, View from above when the bulk of the tongue musculature has been removed. Innervation. Mylohyoid is supplied by the mylohyoid branch of the inferior alveolar nerve, which can sometimes also supply accessory innervation to the posterior mandibular teeth.

Actions. Mylohyoid elevates the floor of the mouth in the first stage of deglutition. It may also elevate the hyoid bone or depress the mandible.

Geniohyoid

Geniohyoid is a narrow muscle that lies above the medial part of mylohyoid (see Figs 37.9–37.11). It arises from the inferior mental spine (genial tubercle) on the back of the symphysis menti, and runs backwards and slightly downwards to attach to the anterior surface of the body of the hyoid bone. The paired muscles are contiguous and may occasionally fuse with each other or with genioglossus.

Vascular supply. The blood supply to geniohyoid is derived from the lingual artery (sublingual branch).

Innervation. Geniohyoid is supplied by the first cervical spinal nerve, through the hypoglossal nerve.

Actions. Geniohyoid elevates the hyoid bone and draws it forwards, and therefore acts partly as an antagonist to stylohyoid. When the hyoid bone is fixed, geniohyoid depresses the mandible.

PALATE

The palate forms the roof of the mouth and is divisible into two regions, namely: the hard palate in front and soft palate behind.

Soft palate

The soft palate is described with the pharynx in Chapter 40.

Hard palate

The hard palate is formed by the palatine processes of the maxillae and the horizontal plates of the palatine bones (see Figs 36.8B, 36.9, 37.16A). The hard palate is bounded in front and at the sides by the tooth-bearing alveolus of the upper jaw and is continuous posteriorly with the soft palate. It is covered by a thick mucosa bound tightly to the underlying periosteum. In its more lateral regions, it also possesses a submucosa containing the main neurovascular bundle. The mucosa is covered by keratinized stratified squamous epithelium, which shows regional variations and may be ortho- or parakeratinized.

The periphery of the hard palate consists of gingivae. A narrow ridge, the palatine raphe, devoid of submucosa, runs anteroposteriorly in the midline. An oval prominence, the incisive papilla, lies at the anterior extremity of the raphe. It covers the incisive fossa at the oral opening of the incisive canal and also marks the position of the fetal nasopalatine canal. Irregular transverse ridges or rugae, each containing a core of dense connective tissue, radiate outwards from the palatine raphe in the anterior half of the hard palate; their pattern is unique to the individual.

The submucosa in the posterior half of the hard palate contains minor mucous-type salivary glands. They secrete via numerous small ducts, which often drain into a larger duct that opens bilaterally at the paired palatine foveae. These depressions, sometimes a few millimetres deep, flank the midline raphe at the posterior border of the hard palate. They provide a useful landmark for the extent of an upper denture; they cause an overextended denture to become unstable when the soft palate moves during deglutition and mastication. The upper surface of the hard palate is the floor of the nasal cavity and is covered by ciliated respiratory epithelium.

Vascular supply and lymphatic drainage

The palate derives its blood supply principally from the greater palatine artery, a branch of the third part of the maxillary artery. The greater palatine artery descends with its accompanying nerve in the palatine canal, where it gives off two or three lesser palatine arteries, which are transmitted through the lesser palatine canals and foramina to supply the soft palate and tonsil, and anastomose with the ascending palatine branch of the facial artery. The greater palatine artery emerges on to the oral surface of the palate at the greater palatine foramen adjacent to the second maxillary molar and runs in a curved groove near the alveolar border of the hard palate to the incisive canal. It ascends this canal and anastomoses with septal branches of the nasopalatine artery to supply the gingivae, palatine glands and mucous membrane.

The veins of the hard palate accompany the arteries and drain largely to the pterygoid plexus.

Innervation

The sensory nerves of the hard palate are the greater palatine and nasopalatine branches of the maxillary nerve, which all pass through the pterygopalatine ganglion. The greater palatine nerve descends through the greater palatine canal, emerges on the hard palate from the greater palatine foramen, runs forwards in a groove on the inferior surface of

the bony palate almost to the incisor teeth and supplies the gums and the mucosa and glands of the hard palate (see Fig. 37.3). It also communicates with the terminal filaments of the nasopalatine nerve. As it leaves the greater palatine canal, it supplies palatine branches to both surfaces of the soft palate. The lesser (middle and posterior) palatine nerves, which are much smaller, descend through the greater palatine canal and emerge through the lesser palatine foramina in the tubercle of the palatine bone to supply the uvula, tonsil and soft palate. The nasopalatine nerves enter the palate at the incisive foramen and are branches of the maxillary nerve that pass through the pterygopalatine ganglion to supply the anterior part of the hard palate behind the incisor teeth.

Fibres conveying taste impulses from the palate probably pass via the palatine nerves to the pterygopalatine ganglion, and travel through it without synapsing to join the nerve of the pterygoid canal and the greater petrosal nerve to the facial ganglion, where their cell bodies are situated. The central processes of these neurones traverse the sensory root of the facial nerve (nervus intermedius) to pass to the gustatory nucleus in the nucleus of the tractus solitarius. Parasympathetic postganglionic secretomotor fibres from the pterygopalatine ganglion run with the nerves to supply the palatine mucous glands.

TONGUE

The tongue is a highly muscular organ of deglutition, taste and speech. It is partly oral and partly pharyngeal in position, and is attached by its muscles to the hyoid bone, mandible, styloid processes, soft palate and the pharyngeal wall. It has a root, an apex, a curved dorsum and an inferior surface. Its mucosa is normally pink and moist, and is attached closely to the underlying muscles. The dorsal mucosa is covered by numerous papillae, some of which bear taste buds. Intrinsic muscle fibres are arranged in a complex interlacing pattern of longitudinal, transverse, vertical and horizontal fasciculi, and this allows great mobility. Fasciculi are separated by a variable amount of adipose tissue, which increases posteriorly. The root of the tongue is attached to the hyoid bone and mandible, and between them it is in contact inferiorly with geniohyoid and mylohyoid. The dorsum (posterosuperior surface) is generally convex in all directions at rest. It is divided by a V-shaped sulcus terminalis into an anterior, oral (presulcal) part that faces upwards, and a posterior, pharyngeal (postsulcal) part that faces posteriorly. The anterior part forms about two-thirds of the length of the tongue. The two limbs of the sulcus terminalis run anterolaterally to the palatoglossal arches from a median depression, the foramen caecum, which marks the site of the upper end of the embryonic thyroid diverticulum (thyroglossal duct).

The oral (presulcal) and pharyngeal parts of the tongue differ in their mucosa, innervation and developmental origins.

Oral (presulcal) part

The oral (presulcal) part of the tongue is located in the floor of the oral cavity. It has an apex touching the incisor teeth, a margin in contact with the gums and teeth, and a superior surface (dorsum) related to the hard and soft palates. On each side, in front of the palatoglossal arch, there are four or five vertical folds, the foliate papillae, which represent vestiges of larger papillae found in many other mammals. The mucosa on the inferior (ventral) surface is smooth, purplish and reflected on to the oral floor and gums; it is connected to the oral floor anteriorly by the lingual frenulum. The deep lingual vein, which is visible, lies lateral to the frenulum on either side. The plica fimbriata (fimbriated fold), a fringed mucosal ridge directed anteromedially towards the apex of the tongue, lies lateral to the vein (see Fig. 37.4B). This part of the tongue develops from the lingual swellings of the mandibular arch and from the tuberculum impar, and this embryological derivation explains its sensory innervation.

The dorsal mucosa has a longitudinal median sulcus and is covered by filiform, fungiform and circumvallate papillae (**Fig. 37.5**). It is somewhat thicker than the ventral and lateral mucosae, is directly adherent to underlying muscular tissue with no discernible submucosa, and is covered by numerous papillae. The dorsal epithelium consists of a superficial stratified squamous epithelium, which varies from non-keratinized stratified squamous epithelium posteriorly, to fully keratinized epithelium overlying the filiform papillae more anteriorly. These features probably reflect the fact that the apex of the tongue is subject to greater dehydration than the posterior and ventral parts and is subject to more abrasion during mastication. The underlying lamina propria is a dense fibrous connective tissue, with numerous elastic fibres, and is continuous with similar tissue extending between the fasciculi of the lingual muscles. It contains numerous vessels and nerves from which the papillae are supplied, and also large lymph plexuses and lingual glands.

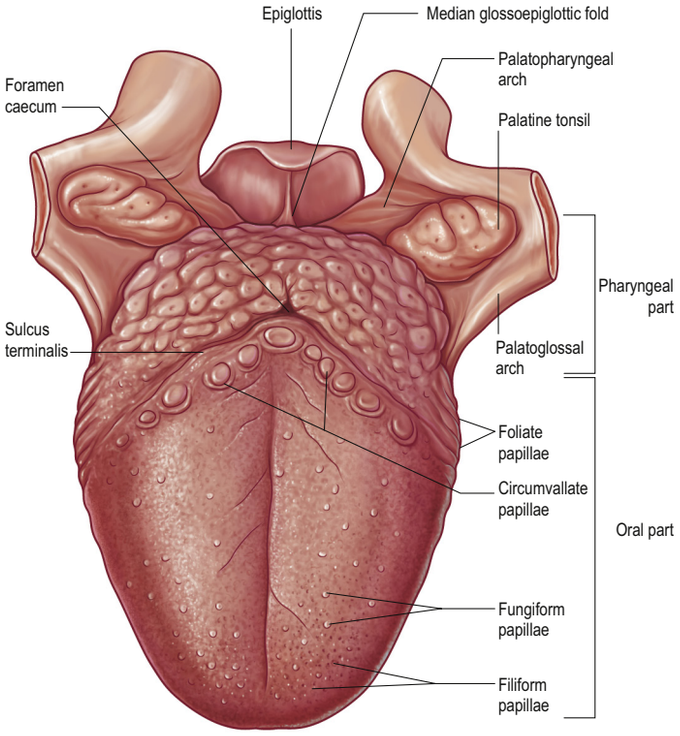

Fig. 37.5 The dorsum of the tongue, adjoining palatoglossal and palatopharyngeal arches, and epiglottis. The palatine tonsils lie in the tonsillar recesses between the palatoglossal and palatopharyngeal arches.

Lingual papillae

Lingual papillae are projections of the mucosa covering the dorsal surface of the tongue (see Fig. 37.5). They are limited to the presulcal part of the tongue, produce its characteristic roughness and increase the area of contact between the tongue and the contents of the mouth. There are four principal types, filiform, fungiform, foliate and circumvallate papillae, and all except the filiform papillae bear taste buds. Papillae are more visible in the living when the tongue is dry.

Filiform papillae

Filiform papillae are minute, conical or cylindrical projections that cover most of the presulcal dorsal area, and are arranged in diagonal rows that extend anterolaterally, parallel with the sulcus terminalis, except at the lingual apex, where they are transverse. They have irregular cores of connective tissue and their epithelium, which is keratinized, may split into whitish fine secondary processes (**Fig. 37.6**). Their functions appear to be to increase the friction between the tongue and food, and to facilitate the movement of particles by the tongue within the oral cavity.

Fungiform papillae

Fungiform papillae occur mainly on the lingual margin but also irregularly on the dorsal surface, where they may occasionally be numerous (see Fig. 37.6). They differ from filiform papillae because they are larger, rounded and deep red in colour, this last reflecting their thin, non-keratinized epithelium and highly vascular connective tissue core. Each usually bears one or more taste buds on its apical surface.

Foliate papillae

Foliate papillae lie bilaterally in two zones at the sides of the tongue near the sulcus terminalis, each formed by a series of red, leaf-like mucosal ridges, covered by a non-keratinized epithelium. They bear numerous taste buds (see Fig. 37.5).

Tori are benign, localized overgrowths of bone found in both the upper (torus palatinus) and lower (torus mandibularis) jaws. Torus palatinus is more common in females, while torus mandibularis is slightly more common in males. Incidence varies from about 0.5% to over 65%: tori are less frequent in Caucasians and more frequent in Eskimos, Mongoloids and other Asian groups. Aetiology is unclear, but torus palatinus may have a hereditary basis (autosomal dominant) (García-García et al 2010).

In the upper jaw, the enlargement is typically seen in the midline. In the lower jaw, it is usually on the lingual aspect in the canine/premolar region and may be unilateral or bilateral. A torus mandibularis may also affect the buccal surface of the mandible. Tori vary considerably in size, and tend to increase in size with age. They may be related to functional adaptations: there is some evidence that their incidence is decreased when fewer teeth are present in the jaws. No treatment is necessary unless they interfere with the construction of satisfactory removable dentures.

Remnants of the nasopalatine ducts or of epithelium persisting during the fusion of palatine processes may proliferate and give rise to non-neoplastic cysts that most often develop in the anterior midline of the hard palate.

Circumvallate papillae

Circumvallate papillae are large cylindrical structures, varying in number from 8 to 12, which form a V-shaped row immediately in front of the sulcus terminalis on the dorsal surface of the tongue (see Fig. 37.5). Each papilla, 1–2 mm in diameter, is surrounded by a slight circular mucosal elevation (vallum or wall), which is separated from the papilla by a circular sulcus (Figs 37.7–37.8). The papilla is narrower at its base than its apex and the entire structure is generally covered with non-keratinized stratified squamous epithelium. Numerous taste buds are scattered in both walls of the sulcus, and small serous glands (of von Ebner) open into the sulcal base.

Muscles

The tongue is divided by a median fibrous septum that is attached to the body of the hyoid bone. There are extrinsic and intrinsic muscles in each half, the former extending outside the tongue and moving it bodily, the latter wholly within it and altering its shape. The extrinsic musculature consists of four pairs of muscles, namely: genioglossus, hyoglossus, styloglossus (and chondroglossus) and palatoglossus.

Genioglossus

Genioglossus is triangular in sagittal section, lying near and parallel to the midline. It arises from a short tendon attached to the superior genial tubercle behind the mandibular symphysis, above the origin of geniohyoid. From this point, it fans out backwards and upwards (Fig. 37.9). The inferior fibres of genioglossus are attached by a thin aponeurosis to the upper anterior surface of the hyoid body near the midline (a few fasciculi passing between hyoglossus and chondroglossus to blend with the middle constrictor of the pharynx). Intermediate fibres pass backwards into the posterior part of the tongue, and superior fibres ascend forwards to enter the whole length of the ventral surface of the tongue from root to apex, intermingling with the intrinsic muscles. The muscles of opposite sides are separated posteriorly by the lingual septum. Anteriorly, they are variably blended by decussation of fasciculi across the midline.

Genioglossus is regarded as the main upper airway dilator muscle. EMG studies have revealed respiratory-related activities in the muscle that appear to be modulated by changes in airway pressure during quiet breathing and by changes in head and jaw posture: this behaviour may be part of a reflex mechanism to maintain airway patency (Cheng et al 2008, Cai et al 2016).

The attachment of the genioglossi to the genial tubercles prevents the tongue from sinking back and obstructing respiration; anaesthetists pull the mandible forwards to obtain the full benefit of this connection. In infants and children, 'chin lift' and 'jaw thrust' are standard resuscitative manoeuvres that rely on this anatomical arrangement to relieve obstruction of the pharynx by the tongue falling back.

Vascular supply. Genioglossus is supplied by the sublingual branch of the lingual artery and the submental branch of the facial artery.

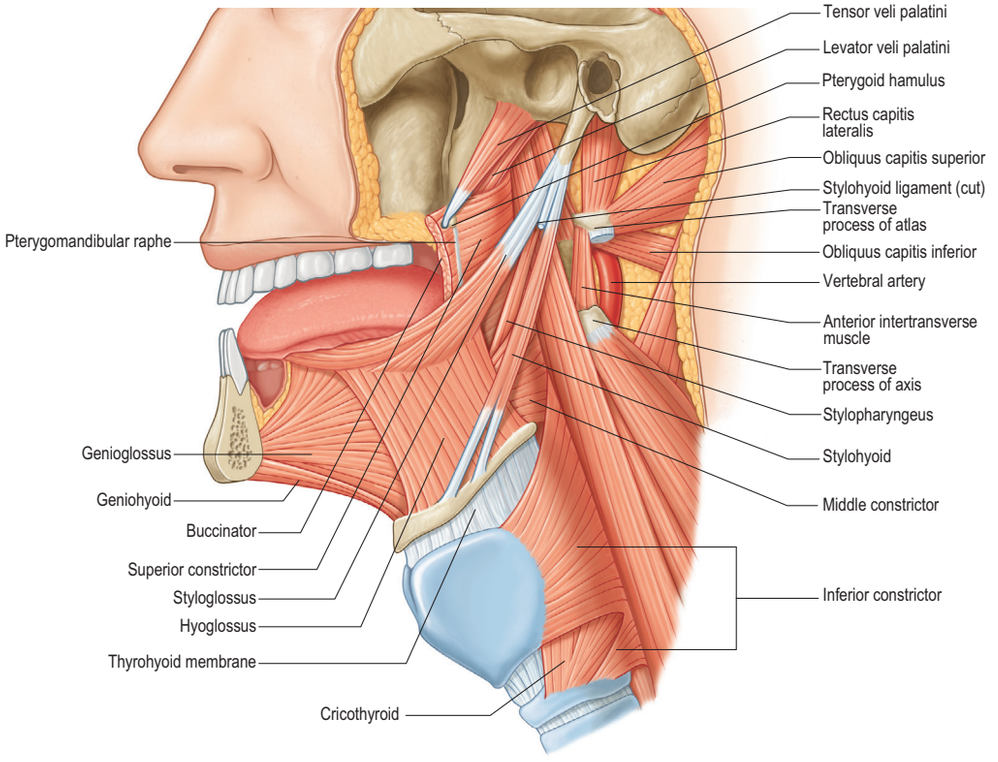

Fig. 37.9 Muscles of the tongue and pharynx. Palatoglossus is not shown here but is depicted in (Fig. 40.3A).

Innervation. Genioglossus is innervated by the hypoglossal nerve.

Actions. Genioglossus brings about the forward traction of the tongue to protrude its apex from the mouth. Acting bilaterally, the two muscles depress the central part of the tongue, making it concave from side to side. Acting unilaterally, genioglossus pushes the tongue to the contralateral side.

Hyoglossus

Hyoglossus is thin and quadrilateral, and arises from the whole length of the greater cornu and the front of the body of the hyoid bone (see Fig. 37.9). It passes vertically up to enter the side of the tongue between styloglossus laterally and the inferior longitudinal muscle medially. Fibres arising from the body of the hyoid overlap those from the greater cornu.

Relations. Hyoglossus is related at its superficial surface to the digastric tendon, stylohyoid, styloglossus and mylohyoid, the lingual nerve and submandibular ganglion, the sublingual gland, the deep part of the submandibular gland and duct, the hypoglossal nerve and the deep lingual vein. By its deep surface it is related to the stylohyoid ligament, genioglossus, the middle constrictor and the inferior longitudinal muscle of the tongue, and the glossopharyngeal nerve. Posteroinferiorly, it is separated from the middle constrictor by the lingual artery. This part of the muscle is in the lateral wall of the pharynx, below the palatine tonsil. Passing deep to the posterior border of hyoglossus are, in descending order: the glossopharyngeal nerve, stylohyoid ligament and lingual artery.

Vascular supply. Hyoglossus is supplied by the sublingual branch of the lingual artery and the submental branch of the facial artery.

Innervation. Hyoglossus is innervated by the hypoglossal nerve.

Actions. Hyoglossus depresses the tongue.

Chondroglossus

Sometimes described as a part of hyoglossus, this muscle is separated from it by some fibres of genioglossus, which pass to the side of the pharynx. It is about 2 cm long, and arises from the medial side and base of the lesser cornu and the adjoining part of the body of the hyoid. It ascends to merge into the intrinsic musculature between hyoglossus and genioglossus. A small slip occasionally springs from the cartilago triticea and enters the tongue with the posterior fibres of hyoglossus.

Vascular supply, innervation and actions. These are similar to those described for hyoglossus.

Styloglossus

Styloglossus is the shortest and smallest of the three muscles attached to the styloid process (see Fig. 37.9). It arises from the anterolateral aspect of the styloid process near its apex, and from the styloid end of the stylomandibular ligament (Mérida-Velasco et al 2006). Passing downwards and forwards, it divides at the side of the tongue into a longitudinal part, which enters the tongue dorsolaterally to blend with the inferior longitudinal muscle in front of hyoglossus, and an oblique part, overlapping hyoglossus and decussating with it.

Vascular supply. Styloglossus is supplied by the sublingual branch of the lingual artery.

Innervation. Styloglossus is innervated by the hypoglossal nerve.

Actions. Styloglossus draws the tongue up and backwards.

Stylohyoid ligament

The stylohyoid ligament is a fibrous cord that extends from the tip of the styloid process to the lesser cornu of the hyoid bone (see Fig. 37.9). It gives attachment to some fibres of styloglossus and the middle constrictor of the pharynx, and is closely related to the lateral wall of the oropharynx. Below it is overlapped by hyoglossus. The ligament is derived embryologically from the second branchial arch. It may be partially calcified.

Palatoglossus

Palatoglossus is closely associated with the soft palate in function and innervation, and is described with the other palatal muscles (Ch. 40).

Intrinsic muscles

The intrinsic muscles of the tongue are the bilateral superior and inferior longitudinal, the transverse and the vertical (**Fig. 37.10**).

Superior longitudinal

The superior longitudinal muscle constitutes a thin stratum of oblique and longitudinal fibres lying beneath the mucosa of the dorsum of the tongue. It extends forwards from the submucous fibrous tissue near the epiglottis and from the median lingual septum to the lingual margins. Some fibres are inserted into the mucous membrane (see Fig. 37.11B).

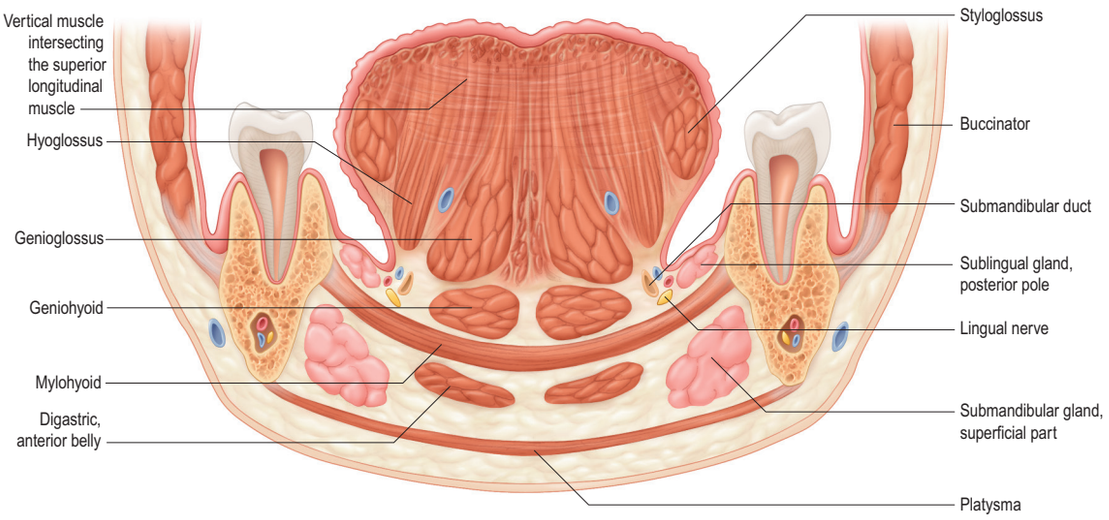

Fig. 37.10 A coronal section through the tongue, the mouth and the body of the mandible opposite the lower first molar tooth.

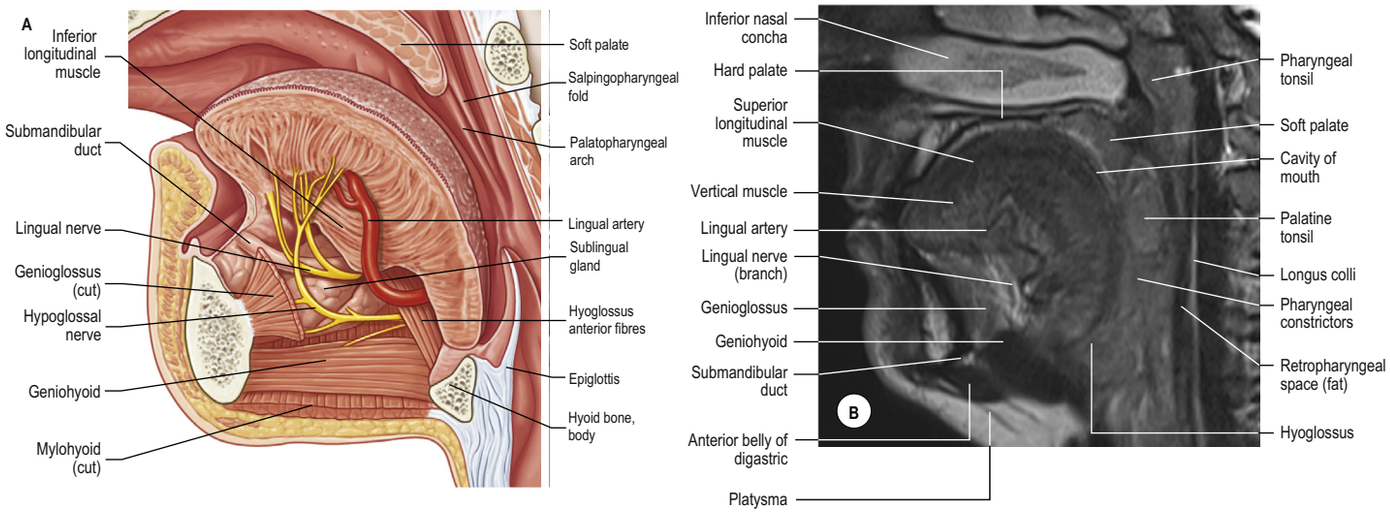

Fig. 37.11 A, The left half of the tongue, viewed from the medial side, showing the lingual artery and ramifications of the hypoglossal and lingual nerves. **B**, Sagittal T2-weighted MRI showing the lingual artery and muscles of the tongue.

Inferior longitudinal

The inferior longitudinal muscle is a narrow band of muscle close to the inferior lingual surface between genioglossus and hyoglossus. It extends from the root of the tongue to the apex. Some of its posterior fibres are connected to the body of the hyoid bone. Anteriorly, it blends with styloglossus (see Fig. 37.11A).

Transverse

The transverse muscles pass laterally from the median fibrous septum to the submucous fibrous tissue at the lingual margin, blending with palatopharyngeus.

Vertical

The vertical muscles extend from the dorsal to the ventral aspects of the tongue in the anterior borders (see Fig. 37.11B).

Vascular supply of intrinsic muscles. The intrinsic muscles are supplied by the lingual artery.

Innervation of intrinsic muscles. All intrinsic lingual muscles are innervated by the hypoglossal nerve.

Actions. The intrinsic muscles are presumed to largely function as muscular hydrostats, altering the shape of the tongue (Sanders et al 2013). Thus, contraction of the superior and inferior longitudinal muscles tend to shorten the tongue, but the former also turns the apex and sides upwards to make the dorsum concave, while the latter pulls the apex down to make the dorsum convex. The transverse muscle narrows and elongates the tongue, while the vertical muscle makes it flatter and wider. Acting alone or in pairs and in endless combination, the intrinsic muscles give the tongue precise and highly varied mobility, important not only in alimentary function but also in speech.

Vascular supply and lymphatic drainage

Lingual artery

The tongue and the floor of the mouth are supplied chiefly by the lingual artery, which arises from the anterior surface of the external carotid artery. It passes between hyoglossus and the middle constrictor of the pharynx to reach the floor of the mouth, accompanied by the

lingual veins and the glossopharyngeal nerve. At the anterior border of hyoglossus, the lingual artery bends sharply upwards (Fig. 37.11). It is covered by the mucosa of the tongue and lies between genioglossus medially and the inferior longitudinal muscle laterally. Near the tip of the tongue, it anastomoses with its contralateral fellow; this contribution is important in maintaining the blood supply to the tongue in any surgical resection of the tongue. The branches of the lingual artery form a rich anastomotic network, which supplies the musculature of the tongue, and a very dense submucosal plexus. Named branches of the lingual artery in the floor of the mouth are the dorsal lingual, sublingual and deep lingual arteries.

Dorsal lingual arteries

The dorsal lingual arteries are usually two or three small vessels. They arise medial to hyoglossus and ascend to the posterior part of the dorsum of the tongue. The vessels supply its mucous membrane and the palatoglossal arch, tonsil, soft palate and epiglottis. They anastomose with their contralateral fellows.

Sublingual artery

The sublingual artery arises at the anterior margin of hyoglossus. It passes forwards between genioglossus and mylohyoid to the sublingual gland, and supplies the gland, mylohyoid and the buccal and gingival mucous membranes. One branch pierces mylohyoid and joins the submental branches of the facial artery. Another branch courses through the mandibular gingivae to anastomose with its contralateral fellow. A single artery arises from this anastomosis and enters a small foramen (lingual foramen) on the mandible, situated in the midline on the posterior aspect of the symphysis immediately above the genial tubercles.

Deep lingual artery

The deep lingual artery is the terminal part of the lingual artery and is found on the inferior surface of the tongue near the lingual frenulum.

In addition to the lingual artery, the tonsillar and ascending palatine branches of the facial and ascending pharyngeal arteries also supply tissue in the root of the tongue. In the region of the valleculae, epiglottic branches of the superior laryngeal artery anastomose with the inferior dorsal branches of the lingual artery.

Lingual veins

The lingual veins are formed from the union of the dorsal lingual and deep lingual veins and the vena comitans of the hypoglossal nerve. The veins draining the tongue follow two routes. Dorsal lingual veins drain the dorsum and sides of the tongue, join the lingual veins accompanying the lingual artery between hyoglossus and genioglossus, and empty into the internal jugular vein near the greater cornu of the hyoid bone. The deep lingual vein begins near the tip of the tongue and runs back just beneath the mucous membrane on the inferior surface of the tongue. It joins a sublingual vein from the sublingual salivary gland near the anterior border of hyoglossus and forms the vena comitans nervi hypoglossi, which runs back with the hypoglossal nerve between mylohyoid and hyoglossus to join the facial, internal jugular or lingual vein. The lingual veins usually join the facial and retromandibular veins (anterior division) to form the common facial vein, which drains into the internal jugular vein.

Lymphatic drainage

The mucosa of the pharyngeal part of the dorsal surface of the tongue contains many lymphoid follicles aggregated into dome-shaped groups: the lingual tonsils. Each group is arranged around a central deep crypt, or invagination, which opens on to the surface epithelium. The ducts of mucous glands open into the bases of the crypts. Small isolated follicles also occur beneath the lingual mucosa. The lymphatic drainage of the tongue can be divided into three main regions: marginal, central and dorsal. The anterior region of the tongue drains into marginal and central vessels, and the posterior part of the tongue behind the circumvallate papillae drains into the dorsal lymph vessels. The more central regions may drain bilaterally, and this must be borne in mind when planning to remove malignant tumours of the tongue that are approaching the midline. If the tumour has a propensity for lymphatic spread, both cervical chains may be involved.

Marginal vessels

Marginal vessels from the apex of the tongue and the lingual frenulum area descend under the mucosa to widely distributed nodes. Some vessels pierce mylohyoid as it contacts the mandibular periosteum to enter either the submental or anterior or middle submandibular nodes, or else to pass anterior to the hyoid bone to the jugulo-omohyoid node. Vessels arising in the plexus on one side may cross under the frenulum to end in contralateral nodes. Efferent vessels of median submental nodes pass bilaterally. Some vessels pass inferior to the sublingual gland and accompany the companion vein of the hypoglossal nerve to end in jugulodigastric nodes. One vessel often descends further to reach the jugulo-omohyoid node, and passes either superficial or deep to the intermediate tendon of digastric.

Vessels from the lateral margin of the tongue cross the sublingual gland, pierce mylohyoid and end in the submandibular nodes. Others end in the jugulodigastric or jugulo-omohyoid nodes. Vessels from the posterior part of the lingual margin traverse the pharyngeal wall to the jugulodigastric lymph nodes (Fig. 37.12).

Central vessels

The regions of the lingual surface draining into the marginal or central vessels are not distinct. Central lymphatic vessels ascend between the fibres of the two genioglossi; most pass between the muscles and diverge to the right or left to follow the lingual veins to the deep cervical nodes, especially the jugulodigastric and jugulo-omohyoid nodes. Some pierce mylohyoid to enter the submandibular nodes.

Dorsal vessels

Vessels draining the postsulcal region and the circumvallate papillae run posteroinferiorly. Those near the median plane may pass bilaterally. They turn laterally, joining the marginal vessels, and all pierce the pharyngeal wall, passing around the external carotid arteries to reach the jugulodigastric and jugulo-omohyoid lymph nodes. One vessel may descend posterior to the hyoid bone, perforating the thyrohyoid membrane to end in the jugulo-omohyoid node.

Innervation

All of the muscles of the tongue, with the exception of palatoglossus, are supplied by the hypoglossal nerve. Palatoglossus is supplied via the pharyngeal plexus (Ch. 40).

The sensory innervation of the tongue reflects its embryological development: the anterior two-thirds (presulcal part) is derived from first arch mesenchyme and the posterior one-third (postsulcal part) is derived from third arch mesenchyme. The nerve of general sensation to the anterior two-thirds is the lingual nerve. Taste sensation travels in the chorda tympani branch of the facial nerve. The nerve supplying both general and taste sensation to the posterior third is the glossopharyngeal nerve. An additional area in the region of the valleculae is supplied by the internal laryngeal branch of the vagus nerve.

Proprioceptive nerve endings have been observed in the tongue, although the precise nerve pathways await full clarification. Anaesthetizing the lingual nerve does not appear to affect tongue movement, suggesting that proprioception does not pass along this nerve either directly or via the chordae tympani. Loss of proprioceptive nerve endings following section of the hypoglossal nerve suggests that the proprioceptive pathway involves the hypoglossal nerve directly or indirectly via its connections with the upper three cervical spinal nerves.

Hypoglossal nerve

The course of the hypoglossal nerve in the neck is described in Chapter 35. After crossing the loop of the lingual artery a little above the tip of the greater cornu of the hyoid, it inclines upwards and forwards on hyoglossus, passing deep to stylohyoid, the tendon of digastric and the posterior border of mylohyoid. Between mylohyoid and hyoglossus, the hypoglossal nerve lies below the deep part of the submandibular gland, the submandibular duct and the lingual nerve, with which it communicates. It then passes on to the lateral aspect of genioglossus, continuing forwards in its substance as far as the tip of the tongue (Fig. 37.11A). It distributes fibres to styloglossus, hyoglossus and genioglossus and to the intrinsic muscles of the tongue. Cadaveric tongues stained using Sihler's stain (a whole mount nerve staining technique that renders a large specimen transparent while counterstaining all nerves) or acetylcholinesterase or silver stains show the basic mammalian intralingual pattern of hypoglossal nerve distribution but with notable differences, even from non-human primates. Thus, many muscle fibres, particularly in the transverse group of intrinsic muscles, contain multiple *en grappe* motor end-plates (suggesting that they are some variant of slow tonic muscle fibres). Presumably, these specializations facilitate the fine motor control of tongue shape that is required in speech and swallowing (Mu and Sanders 2010) (Fig. 37.13). If the nerve suffers either iatrogenic or pathological damage, the tongue, on protrusion, will deviate towards the affected side and there may also be wasting of the muscles on the affected side.

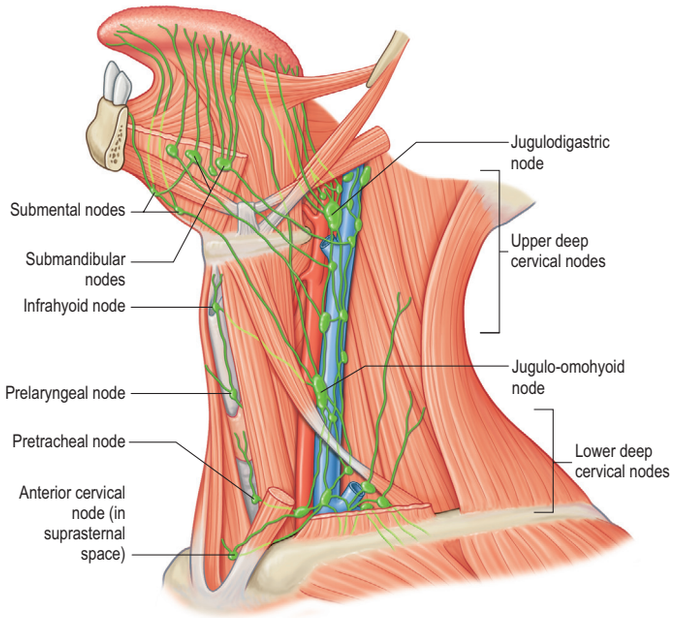

Fig. 37.12 Lymphatic drainage of the tongue: sternocleidomastoid has been removed to expose the chain of deep cervical lymph nodes.

Lingual nerve

The lingual nerve is sensory to the mucosa of the floor of the mouth, mandibular lingual gingivae and mucosa of the presulcal part of the tongue (excluding the circumvallate papillae). It also carries postganglionic parasympathetic fibres from the submandibular ganglion to the sublingual and anterior lingual glands.

The lingual nerve arises from the posterior trunk of the mandibular nerve in the infratemporal fossa (see Fig. 38.23), where it is joined by the chorda tympani branch of the facial nerve and often by a branch of the inferior alveolar nerve. It then passes below the mandibular attachment of the superior pharyngeal constrictor and pterygomandibular raphe, closely applied to the periosteum of the medial surface of the mandible. Here it lies opposite the distal (posterior) root of the third molar tooth, where it is covered only by the gingival mucoperiosteum. In about 1 in 7 cases, the lingual nerve may be located above the lingual bony plate and is susceptible to damage during surgery in the region. It next passes medial to the mandibular attachment of mylohyoid, which carries it progressively away from the mandible, and separates it from the alveolar bone covering the mesial root of the third molar tooth. The lingual nerve then passes downwards and forwards on the deep surface of mylohyoid (i.e. the surface nearer the mucosa covering the floor of the mouth), crossing the lingual sulcus beneath the mucosa. In this position, it lies on the deep portion of the submandibular gland, which bulges over the top of the posterior border of mylohyoid. It passes below the submandibular duct, which crosses it from medial to lateral, and curves upwards, forwards and medially to enter the tongue by medial and lateral branches (see Fig. 37.11; **Fig. 37.14**). Within the tongue, the medial branch sends small branches to the medial part of the ventrolateral tongue, and the lateral branch runs along the lateral border of the tongue and sends larger branches to innervate the mucosa of the anterior tip of the tongue. The lingual nerve is connected to the submandibular ganglion (see Fig. 38.23) by two or three branches. It forms connecting loops with twigs of the hypoglossal nerve at the anterior margin of hyoglossus (Fitzgerald and Law 1958) and within the tongue (Zur et al 2004).

The lingual nerve is at risk during surgical removal of (impacted) lower third molars: patients occasionally develop lingual sensory disturbance postoperatively but this is rarely persistent (Renton 2011). The nerve is also at risk during operations to remove the submandibular salivary gland because the duct must be dissected from the lingual nerve, and because its connection to the submandibular ganglion pulls it into the operating field.

Glossopharyngeal nerve

The glossopharyngeal nerve is distributed to the posterior third of the tongue and the circumvallate papillae. It communicates with the lingual nerve. The course of the glossopharyngeal nerve in the neck is described in Chapter 35.

Taste

The sense of taste is dependent on scattered groups of sensory cells, the taste buds, which occur in the oral cavity and pharynx, and are particularly plentiful on the lingual papillae of the dorsal lingual mucosa.

Taste buds

Taste buds are microscopic barrel-shaped epithelial structures found on all types of lingual papillae (except filiform papillae). They contain chemosensory taste receptor cells in synaptic contact with the terminals of gustatory nerves (the facial, glossopharyngeal or vagus nerves). Taste buds are most abundant on the posterior parts of the tongue, especially around the walls of the circumvallate papillae and their surrounding sulci, where there is an average of 250 taste buds for each of the 8–12 papillae (see Fig. 37.7). Over 1000 taste buds are distributed over the sides of the tongue, particularly over the more posterior folds of the foliate papillae, whereas they are rare, and sometimes even absent, on fungiform papillae. Taste buds have been described on the fetal epiglottis and lingual aspect of the soft palate but most disappear from these sites during postnatal development.

Microstructure of taste buds

Each taste bud is a barrel-shaped cluster of 50–150 fusiform cells, which lies within an oval cavity in the epithelium and converges apically on a gustatory pore, a 2 μm wide opening on the mucosal surface. The whole structure is about 70 μm in height by 40 μm across and is separated by a basal lamina from the underlying lamina propria (see Fig. 37.8B). A small fasciculus of afferent nerve fibres penetrates the basal lamina and spirals around the sensory cells. Chemical substances dissolved in the oral saliva diffuse through the gustatory pores of the taste buds to reach the taste receptor cell membranes, where they cause membrane depolarization. At the ultrastructural level, four distinct cell types have been described within the taste bud: the relatively undifferentiated type IV cells are distinguished by their basal position and the presence of intermediate filaments; type I cells have a dark appearance, while types II and III cells are lighter. Types I and III cells may form synapses with intragemmal nerves. The exposed parts of the receptor cells bear numerous apical microvilli which provide a large surface area for contact with the chemicals dissolved in the saliva.

Innervation of taste buds

Individual gustatory nerves may diverge to innervate widely separated taste buds, or they may innervate more than one sensory cell in each bud. The terminals of several different nerve fibres may converge on individual taste buds. Nerve fibres either branch in the periphery of a taste bud to form a perigemmal plexus, or form an intragemmal plexus within the bud itself. Perigemmal fibres contain various neuropeptides including calcitonin gene-related peptide (CGRP) and substance P, and appear to represent free sensory endings. Intragemmal fibres branch within the taste bud and each forms a series of synapses with the bases of the taste receptor cells.

The gustatory nerve for the anterior part of the tongue, excluding the circumvallate papillae, is the chorda tympani, which travels via the lingual nerve. Taste buds in the inferior surface of the soft palate are innervated mainly by the facial nerve but may also be supplied by the glossopharyngeal nerve. Taste buds in the circumvallate papillae, pharyngeal (postsulcal) part of the tongue and in the palatoglossal arches and the oropharynx are innervated by the glossopharyngeal nerve, and those in the extreme pharyngeal part of the tongue and epiglottis are innervated by the internal laryngeal branch of the vagus.

Central connections

On entering the brainstem, gustatory afferents constitute the tractus solitarius and terminate in the rostral third of the nucleus solitarius of the medulla oblongata.

Taste discrimination

It is difficult to separate the perceptions of taste and smell because the oral and nasal cavities are continuous. Indeed, much of what is perceived as 'taste' is more properly described as 'flavour' and is the result of airborne odorants from the oral cavity that pass through the nasopharynx to the olfactory area above it (Linden 1998).

Perceived sensations of taste are the results of the central processing of a complex pattern of responses from taste receptor cells located in the taste buds on the surface of the tongue. Five canonical tastes, bitter (typically quinine), sweet (typically sugars), umami (typically monosodium glutamate), sour (typically acids) and salty are detected on the tongue (Smith and Margolskee 2006, Kapsimali and Barlow 2012, Liman et al 2014). There are three major classes of taste cells: Type I cells degrade or absorb neurotransmitters and some may transduce salty taste. Type II cells are receptors that bind sweet, bitter, or umami compounds: they do

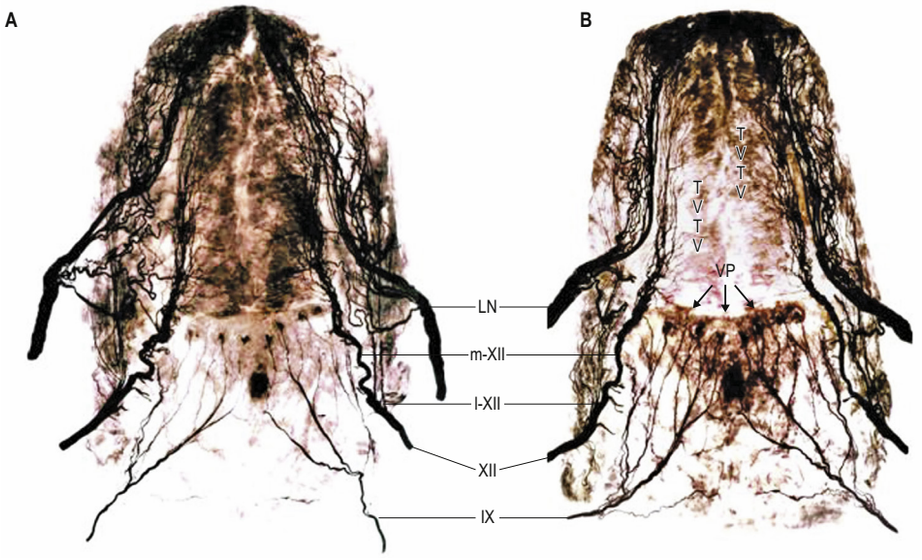

Fig. 37.13 A–B, Entire nerve maps of an adult human tongue, Sihler's stain. Several muscles, including genioglossus and the posterior transverse (T) and vertical (V) intrinsic muscles, were removed in order to track individual nerves. The hypoglossal nerve (XII) and its lateral (l-XII) and medial (m-XII) branches lie between the lingual (LN) and glossopharyngeal (IX) nerves in the posterior part of the tongue. The lateral branch is derived from the main trunk of the hypoglossal nerve as either a short single branch (left side in **A**) or multiple branches (right side in **A** and both sides in **B**). Other abbreviations: VP, vallate papillae. (With permission from Mu L, Sanders I 2010 Human tongue neuroanatomy: nerve supply and motor endplates. Clin Anat 23:777–91.)

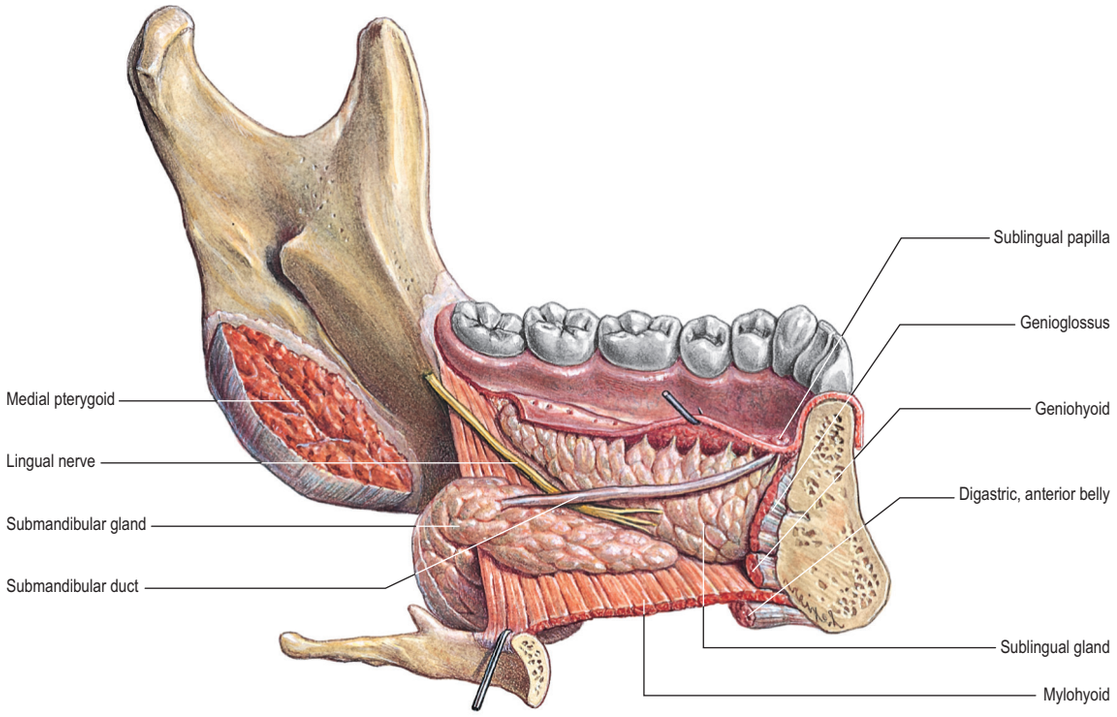

Fig. 37.14 The lingual nerve, submandibular duct, and submandibular and sublingual salivary glands in the floor of the mouth; lingual aspect, left side. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

not form ultrastructurally identifiable synapses but gustatory afferents are closely apposed to them. Each type II cell expresses taste GPCRs specific for only one taste quality. Type III (presynaptic) cells express proteins associated with synapses and form synaptic junctions with nerve terminals (Chaudhari and Roper 2010). Bitter chemicals are detected by a small family of receptors structurally related to rhodopsin: they may detect either one or a few specific bitter chemicals or many bitter chemicals. The tastes of sweet and umami are evoked by a relatively small number of molecules that signal either calorie-rich (sweet) or protein-rich foods (umami) and are sensed by a single type of GPCR, a heterodimer of a common subunit and a unique subunit. The structurally divergent receptors for sugars, bitter chemicals and amino acids all employ a common canonical phosphoinositide-based signalling pathway. In humans, salty taste is generated mainly by sodium ions and is amiloride-insensitive: it appears to be mediated by a nonselective cation pathway that as yet is less well documented than in experimental animals. In newborn infants, oral sucrose has been shown to reduce procedural pain from single events; the mechanism of this nociceptive effect is not yet fully understood (Stevens et al 2013).

The taste bud complex is an extremely dynamic system in which there is a rapid turnover of receptor cells: the lifespan of receptor cells produced by the division of epithelial stem cells (basal cells) is approximately 10 days. The gustatory nerves are therefore continually sprouting new processes, forming new synapses with young cells, and retracting synaptic connections with dying cells. It has been calculated that at any one time less than one-third of the cells in a single taste bud are fully innervated. An intact nerve supply is necessary for the normal survival and function of taste buds. If the nerve supply is interrupted, the taste buds degenerate and slough off, although they will reappear and can return to normal function following nerve regeneration.

Autonomic innervation of the tongue

The parasympathetic secretomotor innervation of the various lingual mucous glands is via the chorda tympani branch of the facial nerve, which synapses in the submandibular ganglion; postganglionic branches are distributed to the lingual mucosa either via the lingual nerve or via plexuses around the lingual arteries.

The postganglionic sympathetic supply to lingual glands and vessels arises from the carotid plexus (fibres derived from neurones in the superior cervical ganglion) and enters the tongue through plexuses around the lingual arteries. Isolated neurones, perhaps postganglionic parasympathetic neurones, have been reported in the postsulcal region and presumably innervate glandular tissue and vascular smooth muscle.

TEETH

Introduction and terminology

Humans have two generations of teeth: the deciduous (primary) dentition (Fig. 37.15) and the permanent (secondary) dentition. The first deciduous teeth erupt into the mouth at about 6 months after birth and all of the deciduous teeth have erupted by 3 years of age. The first permanent molar erupts around 6 years, and thence the deciduous teeth are exfoliated one by one, to be replaced by their permanent successors. A complete permanent dentition is present when the third molars erupt at around the age of 18–21 years. In the complete deciduous dentition, there are 20 teeth, 5 in each jaw quadrant. In the complete permanent dentition, there are 32 teeth, 8 in each jaw quadrant (Berkovitz et al 2009).

There are three basic tooth forms in both dentitions: incisiform, caniniform and molariform. Incisiform teeth (incisors) are cutting teeth and have thin, blade-like crowns. Caniniform teeth (canines) are piercing or tearing teeth and have a single, stout, pointed, cone-shaped crown. Molariform teeth (molars and premolars) are grinding teeth and possess a number of cusps on an otherwise flattened biting surface. Premolars are bicuspid teeth that are restricted to the permanent dentition and replace the deciduous molars.

The tooth-bearing region of the jaws can be divided into four quadrants: the right and left maxillary and mandibular quadrants. A tooth may thus be identified according to the quadrant in which it is located (e.g. a right maxillary tooth or a left mandibular tooth). In both the deciduous and permanent dentitions, the incisors may be distinguished according to their relationship to the midline. Thus, the incisor nearest the midline is the central (first) incisor and the incisor that is more laterally positioned is termed the lateral (second) incisor. The permanent premolars and the permanent and deciduous molars can also be distinguished according to their mesiodistal relationships. The molar most mesially positioned is designated the first molar, and the one behind it is the second molar. In the permanent dentition, the tooth most distally positioned is the third molar. The mesial premolar is the first premolar, and the premolar behind it is the second premolar.

The terminology used to indicate tooth surfaces is shown in Fig. 37.16B. The aspect of teeth adjacent to the lips or cheeks is termed labial or buccal, that adjacent to the tongue being lingual (or palatal in the maxilla). Labial and lingual surfaces of an incisor meet medially at a mesial surface and distally at a distal surface, terms that are also used to describe the equivalent surfaces of premolar and molar (postcanine) teeth. On account of the curvature of the dental arch, mesial surfaces of postcanine teeth are directed anteriorly and distal surfaces are directed posteriorly. Thus, the point of contact between the central incisors is the datum point for mesial and

Fig. 37.15 The primary dentition. An anterior view of the complete deciduous (primary) dentition at age 3 years. (Courtesy of Miss Victoria Clark.)

Natal and/or neonatal teeth (teeth present at birth and teeth erupted within the first month of life, respectively) are rare, with an incidence of 1 in 3000 births. More than 90% of natal and neonatal teeth are prematurely erupted deciduous mandibular incisors, while less than 10% are supernumerary. Several syndromes have been associated with natal teeth, namely: Ellis–van Creveld, Hallermann–Streiff, Jadassohn–Lewandowski and Pierre Robin syndromes. Histological features are failure of root formation, a large vascular pulp, irregular dentine formation and a failure of cementum formation (Mhaske et al 2013).

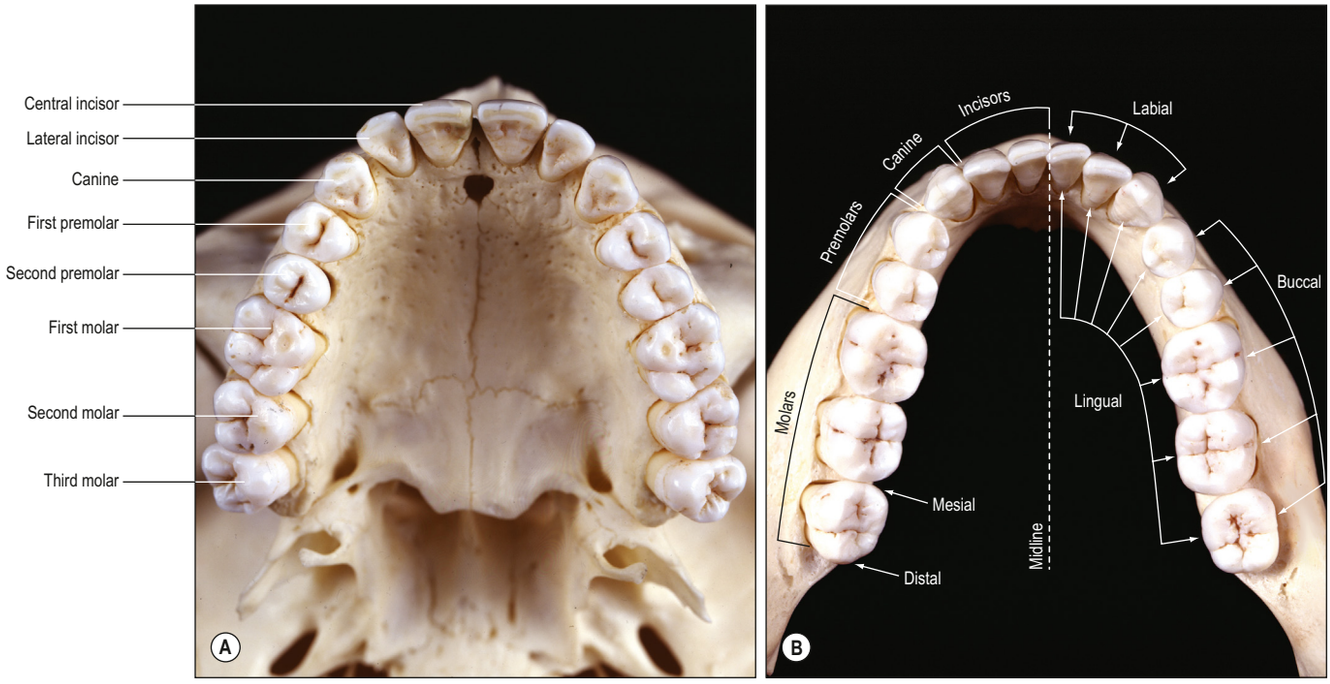

Fig. 37.16 The permanent teeth: occlusal aspect. **A**, The upper dental arch. **B**, The lower dental arch. The terminology employed for the identification of teeth according to their location is shown in the lower jaw; the same terminology is used to describe the teeth in the upper jaw.

distal. The biting or occlusal surfaces of postcanine teeth are tuberculated by cusps that are separated by fissures forming a pattern characteristic of each tooth. The biting surface of an incisor is the incisal edge.

Tooth morphology

There are two incisors, a central and a lateral, in each half jaw or quadrant (Figs 37.16–37.17). In labial view, the crowns are trapezoid, and the maxillary incisors (particularly the central) are larger than the mandibular. On eruption, the biting or incisal edges initially have three tubercles or mamelons, which are rapidly removed by wear. In mesial or distal view, their labial profiles are convex while their lingual surfaces are concavo-convex (the convexity near the cervical margin is caused by a low ridge or cingulum, which is prominent only on upper incisors). The roots of incisors are single and rounded in maxillary teeth, but flattened mesiodistally in mandibular teeth. The upper lateral incisor may be congenitally absent or may have a reduced form (peg-shaped lateral incisor).

Behind each lateral incisor is a canine tooth with a single cusp (hence the American term cuspid) instead of an incisal edge. The maxillary canine is stouter and more pointed than the mandibular canine, whose cusp tip is inclined lingually. The canine root, which is the longest of any tooth, produces a bulge (canine eminence) on the alveolar bone externally, particularly in the upper jaw. Although canines usually have single roots, those of the lower jaw may sometimes be bifid.

Distal to the canines are two premolars, each with a buccal and lingual cusp (hence the term bicuspid). The occlusal surfaces of the maxillary premolars are oval (the long axis is buccopalatal) and a mesiodistal fissure separates the two cusps. In buccal view, premolars resemble the canines but are smaller. The maxillary first premolar has two roots (one buccal, one palatal) but may have one root, or very rarely three roots (two buccal and one palatal); this makes the tooth more likely to fracture on removal. The maxillary second premolar usually has one root. The occlusal surfaces of the mandibular premolars are more circular or squarer than those of the upper premolars. The buccal cusp of the mandibular first premolar towers above a diminutive lingual cusp to which it is connected by a ridge separating the mesial and distal occlusal pits. In the mandibular second premolar, a mesiodistal fissure usually separates a buccal from two smaller lingual cusps. Each lower premolar has one root, but very rarely the root of the first is bifid. Rarely, lower second premolars fail to develop.

Posterior to the premolars are three molars whose size decreases distally. Each has a large rhomboid (upper jaw) or rectangular (lower jaw) occlusal surface with four or five cusps. The maxillary first molar has a cusp at each corner of its occlusal surface, and the mesiopalatal cusp is connected to the distobuccal by an oblique ridge. A smaller cusplet or tubercle (cusplet of Carabelli) usually appears on the mesiopalatal cusp (most commonly in Caucasian groups). The tooth has three widely separated

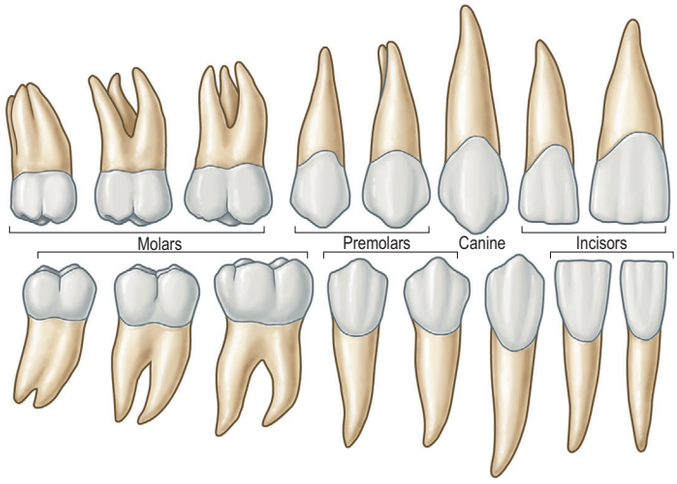

Fig. 37.17 The permanent upper and lower teeth of the right side: labial and buccal surfaces.

roots: two buccal, of which the mesiobuccal is larger and broader and the distobuccal is rounder and smaller, and one large palatal. Their proximity to the maxillary air sinus is thought to be the reason first molar roots are wide apart and second and third molar roots are converged. The smaller maxillary second molar has a reduced or occasionally absent distopalatal cusp. Its three roots show varying degrees of fusion. The maxillary third molar, the smallest, is very variable in form. It usually has three cusps (the distopalatal being absent) and commonly the three roots are fused.

The mandibular first molar has three buccal and two lingual cusps on its rectangular occlusal surface, the smallest cusp being distal. The cusps of this tooth are all separated by fissures. It has two widely separated roots: one mesial and one distal. The smaller mandibular second molar is like the first, but has only four cusps (it lacks the distal cusp of the first molar) and its two roots are closer together. The mandibular third molar is smaller still and, like the upper third molar, is variable in form. Its crown may resemble that of the lower first or second molar and its roots are frequently fused. One or more third molars (upper or lower) often fail to develop.

The cementum-covered roots of teeth lie in sockets or alveoli, to which they are anchored by the periodontal ligament. The five permanent teeth in each quadrant in front of the molars generally have a single root except for the upper first premolar that has two roots, one buccal and one palatal. The roots are rounded in cross-section and taper towards the apex. The roots of the lower incisors are flattened

mesiodistally. The upper permanent molars have three roots (two buccal and one palatal) while the lower molars have two roots, one mesial and one distal. The roots of the molar teeth tend to shorten and fuse as one passes from the first to the third molars. When a tooth first erupts, only about two-thirds of the root has formed and it takes a further three years for the root to complete its formation.

The unmineralized central core of the root contains the vital dental pulp, where it is known as the root canal. Generally, there is one canal present in each root. Exceptions to this are the mesiobuccal root of upper molars, which normally has two canals and the mesial root of lower molars which also usually has two canals.

If the pulp becomes infected following dental caries, one form of treatment may require the pulp to be removed and replaced by an inert material (root canal therapy). Clearly, it is important to know the number of root canals present in the tooth so that each is filled during the procedure. Three-dimensional radiographs are now available to aid assessment. Should an abscess develop at the apex of a tooth, the important structures related to each tooth must be considered if extraction becomes necessary to avoid iatrogenic complications. Among the most important of these are the maxillary sinus for the upper premolars and molars, the mental nerve for lower premolars and the lingual and inferior alveolar nerves for the lower third molars. The same structures must be avoided when placing dental implants.

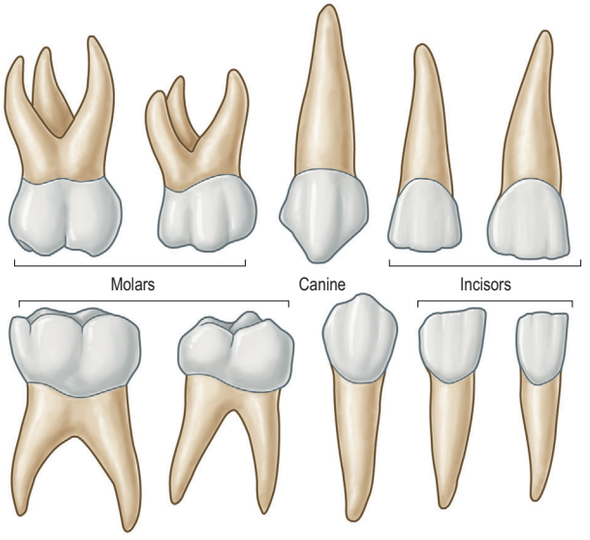

Fig. 37.18 The deciduous upper and lower teeth of the right side; labial and buccal surfaces.

Deciduous teeth

The incisors, canine and premolars of the permanent dentition replace two deciduous incisors, a deciduous canine and two deciduous molars in each jaw quadrant (Figs 37.18–37.19). The deciduous incisors and canine are shaped like their successors but are smaller and whiter and become extremely worn in older children. The deciduous second molars resemble the first permanent molars rather than their successors, the premolars. The upper first deciduous molar has a triangular occlusal surface (its rounded 'apex' is palatal), and a fissure separates a double buccal cusp from the palatal cusp. The lower first deciduous molar is long and narrow; its two buccal cusps are separated from its two lingual cusps by a zigzagging mesiodistal fissure. Both deciduous molars have large buccal protuberances on their mesial aspect. Upper deciduous molars have three roots (fusion of the palatal and distobuccal root is commonplace), and lower deciduous molars have two roots. These roots diverge more than those of permanent teeth because each developing premolar tooth crown is accommodated directly under the crown of its deciduous predecessor. The roots of deciduous teeth are progressively resorbed by osteoclast-like cells (odontoclasts) prior to being shed.

Fig. 37.19 **A**, Upper deciduous dentition: note the channels (arrows) leading to the developing permanent teeth. **B**, Lower deciduous dentition. (With permission from Berkovitz BKB, Moxham BJ 1994 Color Atlas of the Skull. London: Mosby.)

Eruption of teeth

Information on the sequence of development and eruption of teeth into the oral cavity (Fig. 37.20) is important in clinical practice and also in forensic medicine and archaeology. Dental development is one of the best indicators of chronological age when no record of birth exists (Garn et al 1965). The tabulated data provided in Table 37.1 are largely based on European-derived populations and there is evidence of ethnic variation. When a permanent tooth erupts, about two-thirds of the root is formed and it takes about another 3 years for the root to be completed. For deciduous teeth, root completion is more rapid. The developmental stages of initial calcification and crown completion are less affected by environmental influences than is eruption, the timing of which may be modified by several factors such as early tooth loss and severe malnutrition.

Fig. 37.21 shows the panoramic appearance of the dentition seen with orthopantomograms at the time of birth and at 2½, 6½, 10 and 16 years of age.

Dental alignment and occlusion

It is possible to bring the jaws together so that the teeth meet or occlude in many positions. When opposing occlusal surfaces meet with maximal 'intercuspation' (i.e. maximum contact), the teeth are said to be in centric occlusion. In this position, the lower teeth are normally opposed symmetrically and lingually with respect to the upper. Some important features of centric occlusion in a normal (idealized) dentition may be noted. Each lower postcanine tooth is slightly in front of its upper equivalent and the lower canine occludes in front of the upper. Buccal cusps of the lower postcanine teeth lie between the buccal and palatal cusps of the upper teeth. Thus, the lower postcanine teeth are slightly lingual and mesial to their upper equivalents. Lower incisors bite against the palatal surfaces of upper incisors, the latter normally obscuring about one-third of the crowns of the lower. This vertical overlap of incisors in centric occlusion is the overbite. The extent to which upper incisors are anterior to lowers is termed the overjet. In the most habitual jaw position, the resting posture, the teeth are slightly apart, the gap between them being the freeway space or interocclusal clearance. During mastication, especially with lateral jaw movements, the food is comminuted, which facilitates the early stages of digestion.

The ideal occlusion is a rather subjective concept. If there is an ideal occlusion, it can only presently be defined in broad functional terms. Therefore, the occlusion can be considered 'ideal' when the teeth are aligned such that the masticatory loads are within physiological range and act through the long axes of as many teeth in the arch as possible; mastication involves alternating bilateral jaw movements (and not habitual, unilateral biting preferences as a result of adaptation to occlusal interference); lateral jaw movements occur without undue mechanical interference; in the rest position of the

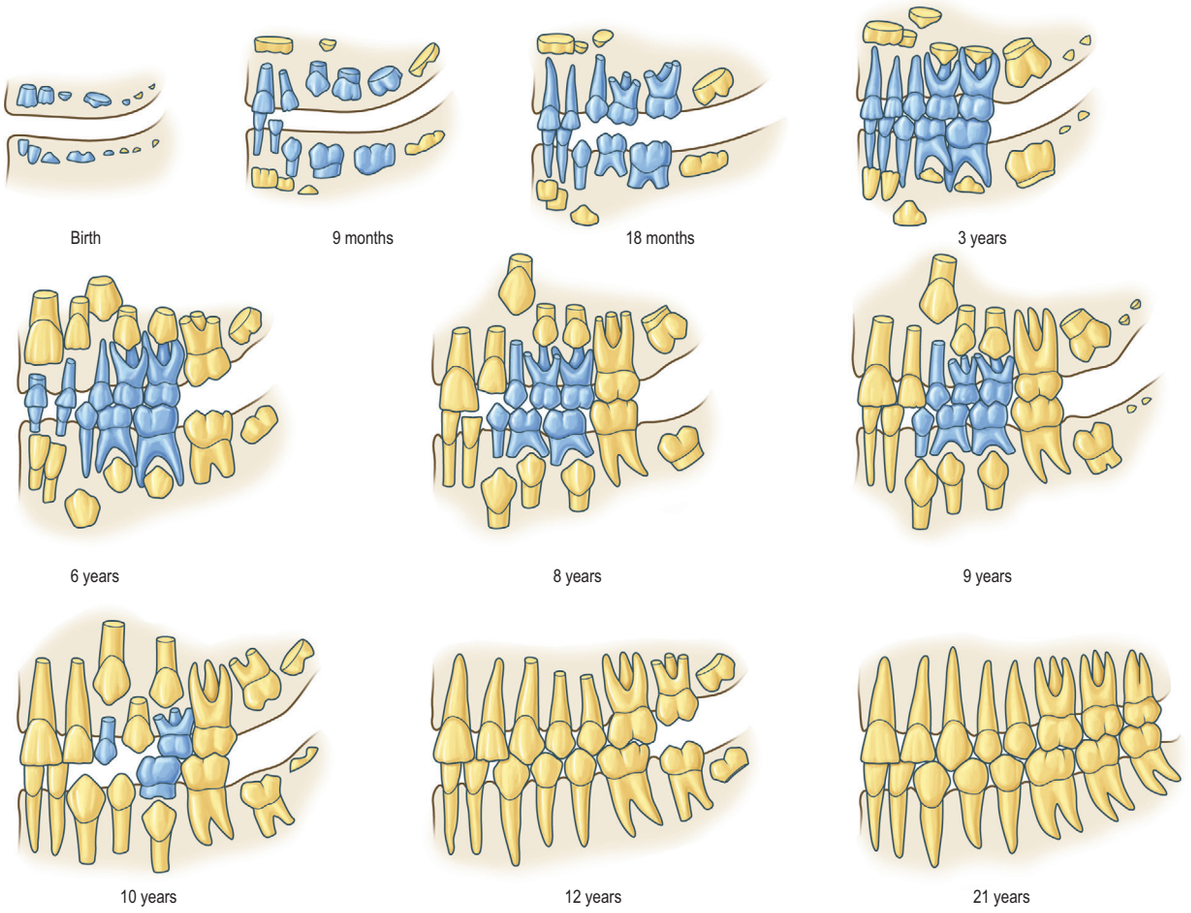

Fig. 37.20 The development of the deciduous (blue) and permanent (yellow) teeth. (Modified with permission from Schour I, Massler M 1941 The development of the human dentition. J Am Dent Assoc 28:1153–60.)

jaw, the gap between teeth (the freeway space) is correct for the individual concerned; and the tooth alignment is aesthetically pleasing to its possessor.

Variations from the ideal occlusion may be termed malocclusions (although these could be regarded as normal, since they are more commonly found in the population: the majority of the population in the USA has some degree of occlusal 'disharmony'). However, the majority of malocclusions should be regarded as anatomical variations rather than abnormalities, as they are rarely involved in masticatory dysfunction or pain, although they may be aesthetically displeasing.

Variations in tooth number, size and form

Available with the Gray's Anatomy e-book.

General arrangement of dental tissues

A tooth consists of a crown covered by very hard translucent enamel and a root covered by yellowish bone-like cementum (Fig. 37.26A). These meet at the neck or cervical margin. A longitudinal ground section (Fig. 37.26B) reveals that the body of a tooth is mostly dentine with an enamel covering over 2 mm thick, while the cementum is much thinner. The dentine surrounds a central pulp cavity, expanded at its coronal end into a pulp chamber and narrowed in the root as a pulp canal, opening at or near its tip by an apical foramen, occasionally multiple. The pulp is a soft connective tissue, continuous with the periodontal ligament via the apical foramen. It contains vessels for the support of the dentine and sensory nerves.

The root is surrounded by alveolar bone, its cementum separated from the osseous socket (alveolus) by the connective tissue of the periodontal ligament, approximately 0.2 mm thick (Fig. 37.27). Coarse bundles of collagen fibres, embedded at one end in cementum, cross the periodontal ligament to enter the osseous alveolar wall, these inserting bundles of collagen being termed Sharpey's fibres. Near the cervical margin, the tooth, periodontal ligament and adjacent bone are covered by the gingiva. On its internal surface, the gingiva is attached to the tooth surface by the junctional epithelium, a zone of profound clinical importance because just above it is a slight recess, the gingival sulcus. As the sulcus is not necessarily self-cleansing, dental plaque may accumulate in it and this predisposes to periodontal disease.

Enamel

Enamel is an extremely hard and rigid material that covers the crowns of teeth. It is a heavily mineralized epithelial cell secretion, containing 95–96% by weight crystalline apatites (88% by volume) and less than 1% organic matrix. The organic matrix comprises mainly unique enamel proteins, amelogenins and non-amelogenins such as enamelins and tuftelins. Although comprising a very small percentage of the weight and volume of enamel, the organic matrix permeates the whole of enamel. As its formative cells are lost from the surface during tooth eruption, enamel is incapable of further growth. Repair is limited to the remineralization of minute carious lesions.

Enamel reaches a maximum thickness of 2.5 mm over cusps and thins at the cervical margins. It is composed of closely packed enamel prisms or rods. In longitudinal section, enamel prisms extend from close to the enamel–dentine junction to within 20 µm of the surface, where they are generally replaced by prismless (non-prismatic, aprismatic) enamel (Fig. 37.28A). In cross-section, the prisms are mainly horseshoe-shaped and are arranged in rows that are staggered, such that the tails of the prisms in one row lie between the heads of the prism in the row above (prism pattern 3) (Fig. 37.28B) and the tails are directed rootwards. The appearance of prism boundaries results from sudden changes in crystallite orientation. Prisms have a diameter of approximately 5 µm, and are packed with flattened hexagonal hydroxyapatite crystals, far larger than those found in collagen-based mineralized tissues.

Two types of incremental lines are visible in enamel: short-term and long-term. At intervals that average 4 µm – with a range of 2–3 µm at the enamel–dentine junction and 4–6 µm in outer enamel – along its length, each prism is crossed by a line, probably reflecting diurnal swelling and shrinking in diameter during its growth. This short-term daily growth line is known as a cross-striation (Fig. 37.28C). The longer-term incremental lines pass from the enamel–dentine junction obliquely to the surface, where they end in shallow furrows, perikymata, visible on newly erupted teeth (Fig. 37.28D). Each line, known as an enamel stria (of Retzius) (Fig. 37.28E), usually represents a period of between 7 and 9 days of enamel growth with a modal value of 9 days. This is known as

The incidence of variation in number and form, which is often related to ethnicity, is rare in deciduous teeth but not uncommon in the permanent dentition. One or more teeth may fail to develop, a condition known as hypodontia. Conversely, additional or supernumerary teeth may form, producing hyperdontia (Fig. 37.22). The third permanent molar is the most frequently missing tooth. In declining order of incidence, other missing teeth are the maxillary lateral incisors, maxillary or mandibular second premolars, mandibular central incisors and maxillary first premolars.

Malformations of teeth can be related to variations in number, size and shape.

Variations in number

Anodontia refers to a complete absence of teeth and this condition is very rare but may be found in some cases of ectodermal dysplasia. More commonly in ectodermal dysplasia a few teeth are present, often malformed. Areas where the teeth are absent lack alveolar process so there is little bone naturally available to receive an implant.

Hypodontia. refers to the condition where just one or two teeth are absent. The most frequently affected teeth are the permanent third molars, then the permanent maxillary second incisors, followed by the second premolars. Having seen the important part played by certain transcription factors during organogenesis, it is not surprising to find in both mice and humans that an absence of teeth has been associated with mutations in *Pax1* and *Msx1* genes.

Hyperdontia. describes an increase in tooth number and affects the maxillary arch much more commonly than the mandibular dentition. The extra teeth are usually situated on the palatal aspect of the permanent incisors or distal to the molars. More rarely, additional premolars develop. Supernumerary teeth in the incisor region can often impede the eruption of the permanent teeth (Figs 37.23–37.24) and indeed this is often the first indication of their presence. A supernumerary tooth situated between the central incisors is known as a mesiodens. Teeth may be unusually large (macrodontia) or small (microdontia), e.g. the crowns of maxillary central incisors may be abnormally wide mesiodistally. A common variant of the maxillary lateral incisor has a small, peg-shaped crown. Epidemiological studies reveal that hyperdontia tends to be associated with macrodontia, and hypodontia with microdontia (Fig. 37.25), the most severely affected individuals representing the extremes of a continuum of variation. Together with family studies, this indicates that the causation is multifactorial, combining polygenic and environmental influences.

Fig. 37.22 A plaster cast of the maxilla of a 25-year-old male showing 1 supplemental premolar and 12 peg-shaped supernumerary teeth on the palatal side of the permanent teeth. (With permission from Berkovitz BKB, Holland GR, Moxham BJ 2009 Oral Anatomy, Histology and Embryology, 4th ed. Edinburgh: Mosby. Courtesy of Royal College of Surgeons of England.)

Some differences in the form of teeth display geographical variation and are of anthropological and forensic interest. Mongoloid dentitions tend to have shovel-shaped maxillary incisors with enlarged palatal marginal ridges. The additional cusp of Carabelli is commonly found on the mesiopalatal aspect of maxillary first permanent or second deciduous molars in Caucasian but rarely in Mongoloid dentitions. In African races, the mandibular second permanent molar often has five rather than four cusps.

Variation in size

Microdontia is the term given to describe a tooth very much reduced in size. Microdontia generally affects individual teeth, usually the maxillary second incisor and the third molar. Occasionally, however, many teeth in the same dentition may be affected, in which case the teeth may be spaced apart. Microdontia may accompany clefts of the lip or palate, Ehlers–Danlos syndrome, hypopituitary disorders and ectodermal disorders. A frequent variation in shape is the peg-shaped maxillary lateral incisor.

Where a tooth is unusually large, the condition is referred to as macrodontia (megadontia) and usually affects individual teeth.

Variation in shape

Abnormal tooth shapes may be seen as a result of congenital syphilis. The incisors may be notched (Hutchinson's incisors) and the molars may have numerous small protrusions on the enamel surface (mulberry molars).

Gemination, fusion and concrescence of teeth

Gemination refers to a situation during development where a tooth germ splits to give the appearance of a large, double tooth. The tooth count in such situations is normal.

Rarely during development, there is **fusion** and union of two adjacent tooth germs. Although in both gemination and fusion, the appearance can suggest a 'double' tooth, in fusion the total number of teeth is one fewer than normal.

Concrescence. is caused by hypercementosis of adjacent roots as the fusion happens after the teeth are formed. It is rarely noticed until one of the teeth is due for extraction when it is found that the other tooth is displaced as well and surgical separation is necessary. It particularly affects second and third molar teeth.

Odontomes

During development a tooth germ may form a tumour-like mass of hard tissue called an odontome which may be asymptomatic or associated with a localized swelling. An odontome may be found in the anterior region of the maxilla, where its presence may prevent eruption of an anterior tooth, or it may be encountered in the posterior region of the jaws, where it may prevent a posterior tooth from erupting. When the odontome consists of many small, discrete, simple, tooth-like structures (denticles), each containing the normal arrangement of dental tissues, it is referred to as a compound odontome. Where the calcified mass bears no resemblance to rudimentary teeth and the dental tissues are arranged haphazardly, it is termed a complex odontome.

An invaginated odontome has been termed 'dens in dente' ('tooth within a tooth): it results either from downward proliferation of a portion of the internal enamel epithelium of the enamel organ into the dental papilla or from retarded growth of part of the tooth germ. It presents on the fully erupted tooth as an extremely deep pit and most commonly affects the permanent maxillary second incisor. The full range of dental tissues (including cementum and bone from incorporation of the dental follicle) may be associated with the 'infolded' organ.

Ameloblastomas

During tooth development, components of the enamel organ may undergo abnormal proliferation to form a tumour. In its simplest form this odontogenic tumour may appear as a benign cyst, often multilocular, that is most commonly seen in the mandible between the ages of 30 and 50 years. Histologically, its main component is strands of epithelial tissue that may resemble pre-ameloblasts, with the nuclei showing a reversal of polarity.

TABLE 37.1 Chronology of the human dentition

Dentition	Tooth	First evidence of calcification (weeks *in utero* for deciduous teeth)	Crown completed (postnatal years)	Eruption (postnatal years)	Root completed (years)
Deciduous upper	i1	14	1½ months	10 (8–12) months	1½
	i2	16	2½ months	11 (9–13) months	2
	C	17	9 months	19 (16–22) months	3¼
	m1	15½	6 months	16 (13–19) months	2½
	m2	19	11 months	29 (25–33) months	3
Deciduous lower	i1	14	2½ months	8 (6–10) months	1½
	i2	16	3 months	13 (10–16) months	1½
	C	17	9 months	20 (17–23) months	3¼
	m1	15½	5½ months	16 (14–18) months	2¼
	m2	18	10 months	27 (23–31) months	3
Permanent upper	I1	3–4 months	4–5	7–8	10
	I2	10–12 months	4–5	8–9	11
	C	4–5 months	6–7	11–12	13–15
	P1	1½–1¾ years	5–6	10–11	12–13
	P2	2–2¼ years	6–7	10–12	12–14
	M1	At birth	2½–3	6–7	9–10
	M2	2½–3 years	7–8	12–13	14–16
	M3	7–9 years	12–16	17–21	18–25
Permanent lower	I1	3–4 months	4–5	6–7	9
	I2	3–4 months	4–5	7–8	10
	C	4–5 months	6–7	9–10	12–14
	P1	1¾–2 years	5–6	10–12	12–13
	P2	2¼–2½ years	6–7	1–12	13–14
	M1	At birth	2½–3	6–7	9–10
	M2	2½–3 years	7–8	11–13	14–15
	M3	8–10 years	12–16	17–21	18–25

an individual's periodicity and it is constant in all teeth from the same individual. Periodicities of 6, 10, 11 and perhaps even 12 days have been reported, but collectively they account for less than 10% of the observed periodicities in large samples of teeth (Reid and Dean 2006).

A prominent striation, the neonatal line, is formed in teeth whose mineralization spans birth. Neonatal lines are present in the enamel and dentine of teeth mineralizing at the time of birth (all the deciduous teeth and the first permanent molars) and are therefore of forensic importance, indicating that an infant has survived for a few days after birth. They reflect a disturbance in mineralization during the first few days after birth. Other accentuated lines can be observed throughout enamel growth; these are generally reflections in disturbances in ameloblast secretion caused by illness or nutritional deficiencies. In serious cases, these disturbances will manifest as hypoplasia (enamel thinning on the tooth surface).

Dentine

Dentine is a yellowish avascular tissue that forms the bulk of a tooth. It is a tough and compliant composite material, with a mineral content of 70% dry weight (largely crystalline hydroxyapatite with some calcium carbonate) and 20% organic matrix (type I collagen, glycosaminoglycans and phosphoproteins). Its conspicuous feature is the regular pattern of microscopic dentinal tubules, 3 µm in diameter, which extend from the pulpal surface to the enamel–dentine junction. The tubules show lateral and terminal branching near the enamel–dentine junction (Fig. 37.29A) and may project a short distance into the enamel (enamel spindles). Each tubule encloses a single cytoplasmic process of an odontoblast whose cell body lies in a pseudostratified layer that lines the pulpal surface. Processes are believed to extend the full thickness of dentine in newly erupted teeth, but in older teeth they may be partly withdrawn and occupy only the pulpal third, while the outer regions contain probably only extracellular fluid. The diameter of the dentine tubule is narrowed by deposition of peritubular dentine. This is different from normal dentine (intertubular dentine) because it is more highly mineralized and lacks a collagenous matrix. Peritubular dentine can therefore be identified by microradiography (Fig. 37.29B). In time, it may completely fill the tubule, a process that gives rise to translucent dentine and that commences in the apical region of the root.

The outermost zone (10–20 µm) of dentine differs in the crown and the root. In the crown, it is referred to as mantle dentine and differs in the orientation of its collagen fibres. In the root, the peripheral zone presents a granular layer – with less overall mineral – beyond which is a hyaline layer that lacks a tubular structure and may function to produce a good bond between the cementum and dentine.

Dentine is formed slowly throughout life, and so there is always an unmineralized zone of predentine at the surface of the mineralized dentine, adjacent to the odontoblast layer at the periphery of the pulp. Biochemical changes within the mineralizing matrix mean that predentine stains differently to the matrix of the mineralized dentine. The predentine–dentine border is generally scalloped, because dentine mineralizes both linearly and as microscopic spherical aggregates of crystals (calcospherites). Dentine, like enamel, is deposited incrementally, and exhibits both short- and long-term incremental lines (Dean 2000). Long-term lines are known as Andresen lines and in the mid-axial region are approximately 20 µm apart; they represent increments of about 6–12 days (Fig. 37.29C). Daily incremental lines (von Ebner lines) in the mid-axial plane are typically 4 µm apart; they are considerably closer together (1–2 µm apart) at the enamel–dentine junction and in root dentine. Where mineralization spans birth (i.e. all deciduous teeth and usually the first permanent molars), a neonatal line is formed in dentine similar to that which is seen in enamel, and it signals the abrupt change in both environment and nutrition that occurs at birth. As with enamel, disturbances in growth of dentine will exhibit as accentuated lines, commonly called contour lines of Owen.

Primary dentine formation proceeds at a steady but declining rate as first the crown and then the root is completed. A slow and intermittent deposition of dentine (regular secondary dentine) continues throughout life and further reduces the size of the pulp chamber; it is distinguished from primary dentine by the reduction and less regular arrangement of dentinal tubules within it. The presence of the odontoblast process means that dentine is a vital tissue. It responds to adverse external stimuli – such as rapidly advancing caries, excessive wear or tooth breakage – by forming poorly mineralized dead tracts, in which the odontoblasts of the affected region die and the tubules remain empty (tertiary dentine). A dead tract may be sealed from the pulp by a thin zone of sclerosed dentine and the deposition of irregular (tertiary) dentine by newly differentiated pulp cells (Fig. 37.30).

Dental pulp

Dental pulp provides the nutritive support for the synthetic activity of the odontoblast layer. It is a well-vascularized, soft, loose connective tissue, enclosed by dentine and continuous with the periodontal ligament via apical and accessory foramina. Several thin-walled arterioles enter by the apical foramen and run longitudinally within the pulp to an extensive subodontoblastic plexus. Blood flow rate per unit volume of tissue is greater in the pulp than in other oral tissues, and tissue fluid pressures within the pulp appear to be unusually high.

As well as typical connective tissue cells, pulp uniquely contains the cell bodies of odontoblasts whose long processes occupy the dentinal tubules. Pulp also has dendritic antigen-presenting cells. Approximately 60% of pulpal collagen is type I, and the bulk of the remainder is type III. As dentine deposition increases with age, the pulp recedes until the whole of the crown may be removed without accessing the pulp.

Dental pulp is extensively innervated by postganglionic vasoconstrictor sympathetic nerve fibres from the superior cervical ganglion, which enter with the arterioles, and by myelinated (Aδ) and unmyelinated (C) sensory nerve fibres from the trigeminal ganglion, which traverse the pulp longitudinally and ramify as a plexus (Raschkow's plexus) beneath the odontoblast layer (Figs 37.31–37.32). Here, any myelinated nerve fibres lose their myelin sheaths and continue into the odontoblast layer, and some enter the dentinal tubules, especially the region beneath the cusps. Stimulation of dentine, whether by thermal, mechanical or osmotic means, evokes a pain response. Pulp nerves release numerous neuropeptides such as CGRP, substance P and neuropeptide Y that maintain homeostasis within the pulp.

Cementum

Cementum is a bone-like tissue that covers the dental roots, and is 50% by weight mineralized (mainly hydroxyapatite crystals). However, unlike bone, cementum is avascular and lacks nerves. The cementum generally overlaps the enamel slightly, although it may meet it end on. Occasionally, the two tissues may fail to meet, in which case dentine is exposed in the mouth. If the exposed dentinal tubules remain patent, then the teeth may be sensitive to stimuli such as cold water. In older teeth, the root may become exposed in the mouth as a consequence of occlusal drift and gingival recession, and cementum is often abraded away by incorrect tooth brushing and dentine is exposed.

Like bone, cementum is perforated by Sharpey's fibres, which represent the attachment bundles of collagen fibres in the periodontal ligament (extrinsic fibres). New layers of cementum, which are deposited incrementally throughout life to compensate for tooth movements, incorporate new Sharpey's fibres. Incremental lines are irregularly spaced. The first (primary) cementum to be formed is thin (up to 200 μm) and acellular, and contains only extrinsic fibres. Cementum formed later (secondary cementum) towards the root apex is produced more rapidly and contains cells, the cementocytes, lying in lacunae joined by canaliculi. The latter are mainly directed towards their source of nutrients from the periodontal ligament. This cementum contains mainly intrinsic collagen fibres of cementoblastic origin, which lie parallel to the surface. Varying arrangements of layering between cellular and acellular cement occur. With increasing age, cellular cement may reach a thickness of a millimetre or more around the apices and at the branching of the roots, where it compensates for the loss of enamel by attrition. Cementum is not remodelled but small areas of resorption with evidence of repair may be seen.

Periodontal ligament

The principal functions of the periodontal ligament are to support the teeth, generate the force of tooth eruption and provide sensory information about tooth position and forces to facilitate reflex jaw activity during chewing movements. The periodontal ligament is a soft, dense, fibrous connective tissue 0.2 mm wide, which contains cells associated with the development and maintenance of alveolar bone (osteoblasts and osteoclasts) and of cementum (cementoblasts and odontoclasts). It also contains a network of epithelial cells (epithelial cell rests of Malassez, ERM cells), which are embryological remnants of an epithelial root sheath. Although their function remains speculative, ERM cells have been implicated in root development and protection against root resorption, and in reparative/regenerative functions of the pulp and periodontal tissues such as apexogenesis and periodontal healing (Keinan and Cohen 2013). Proliferation of ERM cells may play a role in the evolution of odontogenic cysts and tumours.

The majority of collagen fibres of the periodontal ligament are arranged as variously orientated dense fibre bundles that connect alveolar bone and cementum, and which may help to resist movement in specific directions (Fig. 37.33). About 80% of the collagen in the periodontal ligament is type I, most of the remainder being type III. The rate of turnover of collagen is probably the highest of any site in the

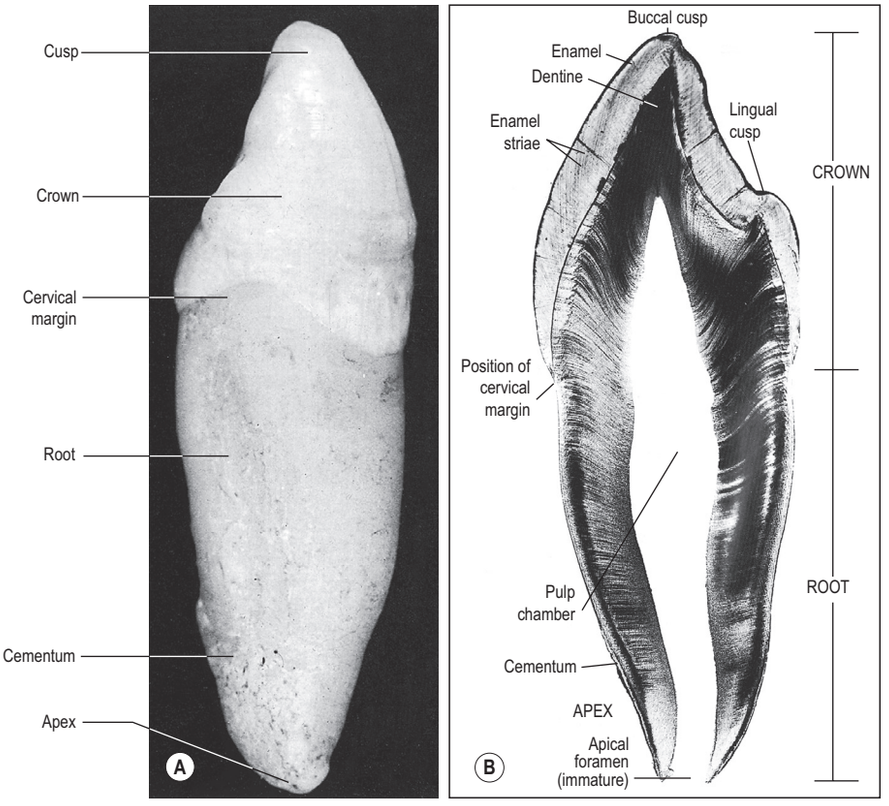

Fig. 37.26 The principal parts of a tooth. **A**, An extracted upper right canine tooth viewed from its mesial aspect. The root is covered by cementum (partially removed), and the curved cervical margin is convex towards the cusp of the tooth. **B**, Ground section of a young (permanent) lower first premolar tooth sectioned in the buccolingual longitudinal plane, photographed with transmitted light. The enamel striae are incremental lines of enamel growth (compare with Fig. 37.31). Within the dentine, the lines of the dentinal tubules are visible, forming S-shaped curves in the apical region but straighter in the root.

body, for reasons that are as yet unclear. A very small volume of fibres are oxytalan (pre-elastin) fibres. Fibroblast density in human periodontal ligament tissue decreases with age (Krieger et al 2013).

The periodontal ligament is innervated by autonomic and sensory nerve fibres, the former carrying vasomotor information and the latter carrying nociceptive and proprioceptive information. Three types of nerve endings have been identified: free nerve endings (originating from myelinated and unmyelinated nerve fibres); Ruffini-like endings (mostly found at the apical part of the periodontal ligament); and lamellated corpuscles (for further reading, see Huang et al (2011)). The periodontal ligament has a rich blood supply; the vessels tend to lie towards the bone side of the periodontal ligament and the capillaries are fenestrated (see below for further details).

Alveolar bone

That part of the maxilla or mandible that supports and protects the teeth is known as alveolar bone. An arbitrary boundary at the level of the root apices of the teeth separates the alveolar processes from the body of the mandible or the maxilla (Fig. 37.34). Like bone in other sites, alveolar bone functions as a mineralized supporting tissue, gives attachment to muscles, provides a framework for bone marrow and acts as a reservoir for ions, especially calcium. It is dependent on the presence of teeth for its development and maintenance, and requires functional stimuli to maintain bone mass. Where teeth are congenitally absent – as in anodontia, for example – it is poorly developed, and it atrophies after tooth extraction, which can cause difficulties in the prosthodontic rehabilitation of patients.

The alveolar tooth-bearing portion of the jaws consists of outer and inner alveolar plates. The individual sockets are separated by plates of bone termed the interdental septa, while the roots of multirooted teeth are divided by inter-radicular septa. The compact layer of bone that lines the tooth socket has been called either the cribriform plate, on account of its content of vascular (Volkmann's) canals, which pass from the alveolar bone into the periodontal ligament; or bundle bone, because numerous bundles of Sharpey's fibres pass into it from the periodontal ligament (Fig. 37.35).

In clinical radiographs, the bone lining the alveolus commonly appears as a continuous dense white line about 0.5–1 mm thick: the lamina dura (Fig. 37.36). However, this appearance gives a misleading impression of the density of alveolar bone; the X-ray beam passes tangentially through the socket wall, and so the radiopacity of the lamina dura is an indication of the quantity of bone the beam has passed through, rather than the degree of mineralization of the bone. Superimposition also obscures the Volkmann's canals. Chronic infections of the dental pulp spread into the periodontal ligament, which leads to resorption of the lamina dura around the root apex (see Fig. 37.36). The presence of a continuous lamina dura around the apex of a tooth therefore usually indicates a healthy apical region (except in acute infections where resorption of bone has not yet begun).

On the labial and buccal aspects of upper teeth, the two cortical plates usually fuse, and there is very little cancellous bone between them, except where the buccal bone thickens over the molar teeth near the root of the zygomatic arch. It is easier and more convenient to extract upper and lower teeth by widening the tooth socket in a buccal direction due to its thinness. Anteriorly in the lower jaw, labial and lingual plates are thin, but in the molar region the buccal plate is thickened as the external oblique line. Near the lower third molar, the lingual bone is much

thinner than the buccal and it is important to realize that the lingual nerve is easily damaged by poor technique during tooth extraction.

Vascular supply and lymphatic drainage of the teeth and supporting structures

The main arteries to the teeth and their supporting structures are derived from the maxillary artery, one of the two terminal branches of the external carotid artery. The upper teeth are supplied by branches from the superior alveolar arteries, and the lower teeth by branches from the inferior alveolar arteries.

Superior alveolar arteries

The upper jaw is supplied by posterior, middle and anterior superior alveolar (dental) arteries. The posterior superior alveolar artery usually arises from the third part of the maxillary artery in the pterygopalatine fossa. It descends on the infratemporal surface of the maxilla, and divides to give branches that enter the alveolar canals to supply molar and premolar teeth, adjacent bone and the maxillary sinus, and other branches that continue over the alveolar process to supply the gingivae. The middle and anterior superior alveolar arteries are branches from the infraorbital artery.

The infraorbital artery often arises with the posterior superior alveolar artery. It enters the orbit posteriorly through the inferior orbital fissure and runs in the infraorbital groove and canal with the infraorbital nerve. When the small middle superior alveolar artery is present, it runs down the lateral wall of the maxillary sinus and forms anastomotic arcades with the anterior and posterior vessels, terminating near the canine tooth. The anterior superior alveolar artery curves through the canalis sinuosus to supply the upper incisor and canine teeth and the mucous membrane in the maxillary sinus. The canalis sinuosus swerves laterally from the infraorbital canal and inferomedially below it in the wall of the maxillary sinus, following the rim of

the anterior nasal aperture, between the alveoli of canine and incisor teeth and the nasal cavity. It ends near the nasal septum where its terminal branch emerges. The canal may be up to 55 mm long.

Inferior alveolar artery

The inferior alveolar (dental) artery, a branch of the first part of the maxillary artery, descends in the infratemporal fossa posterior to the inferior alveolar nerve. Here, it lies between bone laterally and the sphenomandibular ligament medially. Before entering the mandibular foramen it gives off a mylohyoid branch, which pierces the sphenomandibular ligament to descend with the mylohyoid nerve in its groove on the inner surface of the ramus of the mandible. The mylohyoid artery ramifies superficially on the muscle and anastomoses with the submental branch of the facial artery. The inferior alveolar artery then traverses the mandibular canal with the inferior alveolar nerve to supply the mandibular molars and premolars, and divides into the incisive and mental branches near the first premolar.

The incisive branch continues below the incisor teeth (which it supplies) to the midline, where it anastomoses with its fellow, although few anastomotic vessels cross the midline. In the canal, the arteries supply the mandible, tooth sockets and teeth via branches that enter the minute hole at the apex of each root to supply the pulp. The mental artery leaves the mental foramen and supplies the chin; it anastomoses with the submental and inferior labial arteries. Near its origin, the inferior alveolar artery has a lingual branch, which descends with the lingual nerve to supply the lingual mucous membrane. The pattern of branching of the inferior alveolar artery reflects that of the nerves of the same name.

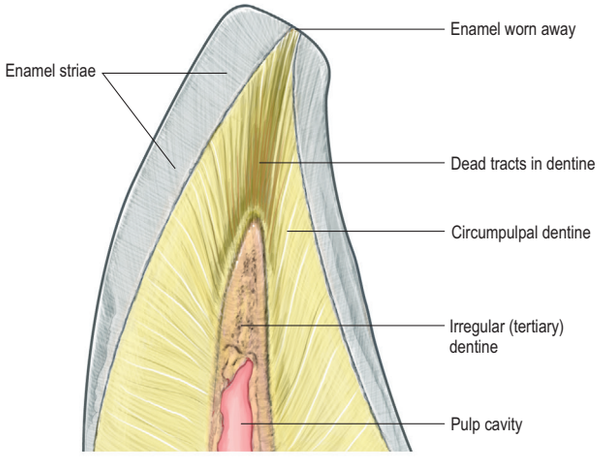

Fig. 37.30 Longitudinal ground section of an incisor tooth.

Arterial supply of periodontal ligaments

The periodontal ligaments supporting the teeth are supplied by dental branches of the alveolar arteries. One branch enters the alveolus apically and sends two or three small rami into the dental pulp through the apical foramen, and other rami into the periodontal ligament. Interdental arteries ascend in the interdental septa, sending branches at right-angles into the periodontal ligament, and terminate by communicating with gingival vessels that also supply the cervical part of the ligament. The periodontal ligament therefore receives its blood from three sources: from the apical region; ascending interdental arteries; and descending vessels from the gingivae. These vessels anastomose with each other, which means that when the pulp of a tooth is removed during endodontic treatment, the attachment tissues of the tooth remain vital.

Venous drainage of the teeth

Veins accompanying the superior alveolar arteries drain the upper jaw and teeth anteriorly into the facial vein, or posteriorly into the pterygoid venous plexus. Veins from the lower jaw and teeth collect either into larger vessels in the interdental septa or into plexuses around the root apices and thence into several inferior alveolar veins. Some of these veins drain through the mental foramen to the facial vein; others drain via the mandibular foramen to the pterygoid venous plexus.

Lymphatic drainage of the teeth

The lymph vessels from the teeth usually run directly into the ipsilateral submandibular lymph nodes. Lymph from the mandibular incisors, however, drains into the submental lymph nodes. Occasionally, lymph from the molars may pass directly into the jugulodigastric group of nodes.

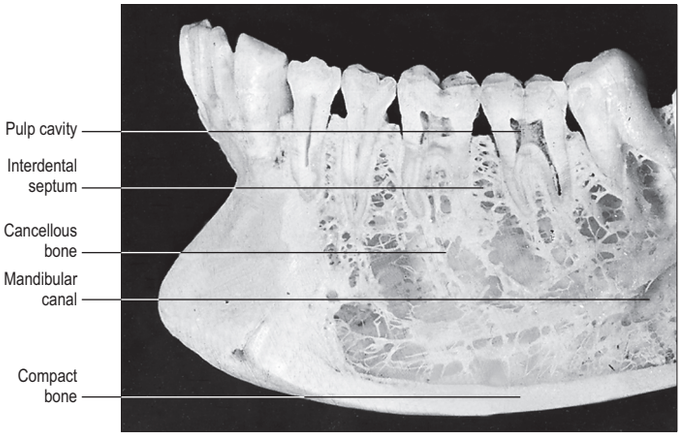

Fig. 37.34 The anterior part of the left side of the mandible; superficial bone has been removed on the buccal side to show the roots of a number of teeth, some of which have also been sectioned vertically. Note the cortical plate of compact bone lining the sockets of the teeth (the lamina dura of radiographs; see Fig. 37.37), and the flat table of bone surmounting the interdental bone septa. In this specimen, the mandibular canal is widely separated from the roots of the teeth, a variable condition.

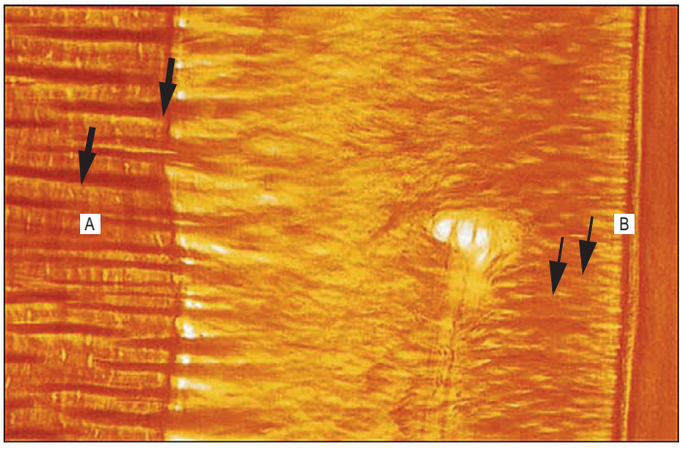

Fig. 37.35 Decalcified section of a root of a tooth showing Sharpey's fibres from the periodontal ligament entering alveolar bone (A). The Sharpey's fibres in bone (thick arrows) are seen to be thicker, but less numerous, than those entering the cementum (B) on the tooth surface (thin arrows). Van Gieson stain. (With permission from Berkovitz BKB, Holland GR, Moxham BJ 2009 Oral Anatomy, Embryology and Histology, 4th ed. Edinburgh: Mosby.)

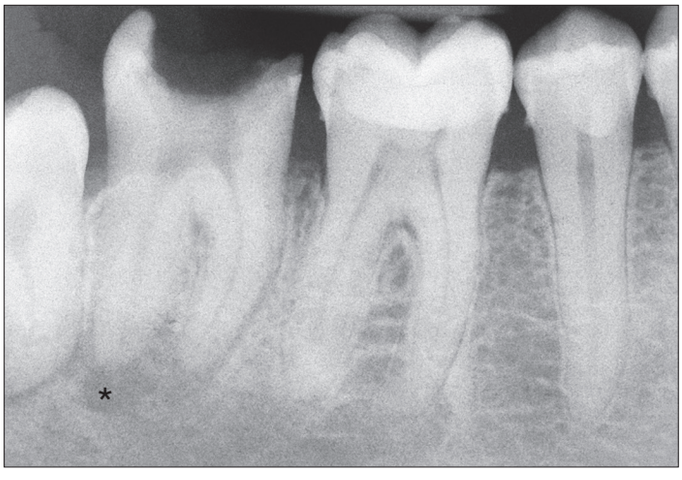

Fig. 37.36 A bite-wing radiograph of teeth and surrounding bone. Note the different radiopacities of enamel and dentine. In a healthy tooth, such as the first molar illustrated here, the lamina dura is complete and appears as a radiopaque line. In the case of the adjacent second molar tooth, in which the bulk of the crown has been lost due to dental caries, an abscess (*) has formed at the base of the tooth and, as a result, the lamina dura has lost its continuity. (Courtesy of Ms Nadine White.)

Innervation of the teeth

The regional innervation of the teeth and gingivae is shown in Table 37.2. The teeth in the upper jaw are supplied by the superior alveolar nerves, while those in the lower jaw are supplied by the inferior alveolar nerve (Rodella et al 2012).

Superior alveolar nerves

The teeth in the upper jaw are supplied by the three superior alveolar (dental) nerves that arise from the maxillary nerve in the pterygopalatine fossa or in the infraorbital groove and canal. The posterior superior alveolar (dental) nerve leaves the maxillary nerve in the pterygopalatine fossa and runs anteroinferiorly to pierce the infratemporal surface of the maxilla, at which point it is possible to perform a local anaesthetic block that will anaesthetize the pulps of the premolar and molar ipsilateral teeth; it then descends under the mucosa of the maxillary sinus. After supplying the lining of the sinus, the nerve divides into small branches that link up as the molar part of the superior alveolar plexus, supplying twigs to the molar teeth. It also supplies a branch to the upper gingivae and the adjoining part of the cheek.

The middle superior alveolar (dental) nerve arises from the infraorbital nerve as it runs in the infraorbital groove, and runs downwards and forwards in the lateral wall of the maxillary sinus. It ends in small branches that link up with the superior dental plexus, supplying small rami to the upper premolar teeth. This nerve is variable, and it may be duplicated or triplicated, or absent.

The anterior superior alveolar (dental) nerve leaves the lateral side of the infraorbital nerve near the midpoint of its canal and traverses the canalis sinuosus in the anterior wall of the maxillary sinus. It curves first under the infraorbital foramen, then passes medially towards the nose, and finally turns downwards and divides into branches to supply the incisor and canine teeth. It assists in the formation of the superior dental plexus and it gives off a nasal branch, which passes through a minute canal in the lateral wall of the inferior meatus to supply the mucous membrane of the anterior area of the lateral wall as high as the opening of the maxillary sinus, and the floor of the nasal cavity. It communicates with the nasal branches of the pterygopalatine ganglion and finally emerges near the root of the anterior nasal spine to supply the adjoining part of the nasal septum.

Inferior alveolar (dental) nerve

The course of the inferior alveolar nerve in the infratemporal fossa is described in Chapter 38. Just before entering the mandibular canal, the inferior alveolar nerve gives off a small mylohyoid branch that pierces the sphenomandibular ligament and enters a shallow groove on the medial surface of the mandible, following a course roughly parallel to its parent nerve. It passes below the origin of mylohyoid to lie on the superficial surface of the muscle, between it and the anterior belly of digastric, both of which it supplies. It gives a few filaments to supply the skin over the point of the chin.

In the mandibular canal, the inferior alveolar nerve runs downwards and forwards, generally below the apices of the teeth until below the first and second premolars, where it divides into terminal incisive and mental branches. The incisive branch continues forwards in a bony canal or in a plexiform arrangement, giving off branches to the first premolar, canine and incisor teeth, and the associated labial gingivae. The lower central incisor teeth receive a bilateral innervation, fibres probably crossing the midline within the periosteum to re-enter the bone via numerous canals in the labial cortical plate.

The mental nerve passes upwards, backwards and outwards to emerge from the mandible via the mental foramen between and just below the apices of the premolar teeth. It immediately divides into three branches, two of which pass upwards and forwards to form an incisor plexus labial to the teeth, supplying the gingiva (and probably the periosteum). From this plexus and the dental branches, fibres turn downwards and then lingually to emerge on the lingual surface of the mandible on the posterior aspect of the symphysis or opposite the premolar teeth, probably communicating with the lingual or mylohyoid nerve. The third branch of the mental nerve passes through the intermingled fibres of depressor anguli oris and platysma to supply the skin of the lower lip and chin. Branches of the mental nerve also communicate with terminal filaments of the mandibular branch of the facial nerve.

Variations in the fascicular organization of the inferior alveolar nerve are clinically important when extracting impacted third molars. The nerve may appear as a single bundle lying a few millimetres below the roots of the teeth, or it may lie much lower and almost reach the lower border of the bone, so that it gives off a variable number of large rami that pass anterosuperiorly towards the roots before dividing to supply the teeth and interdental septa. Only rarely is it plexiform. The nerve may lie on the lingual or buccal side of the mandible (slightly more commonly on the buccal side). Even when the third molar tooth is in a normal position, the nerve may be so intimately related to it that it grooves its root. Exceptionally, the nerve may be similarly related to the second molar.

TABLE 37.2 Innervation of the teeth and gingivae

Maxilla	Nasopalatine nerve			Greater palatine nerve					Palatal gingivae
	Anterior superior alveolar nerve			Middle superior alveolar nerve		Posterior superior alveolar nerve			Teeth
	Infraorbital nerve			Posterior superior alveolar nerve and buccal nerve					Buccal gingivae
	1	2	3	4	5	6	7	8	Tooth position
	Mental nerve				Buccal nerve and perforating branches of inferior alveolar nerve				Buccal gingivae
Mandible	Incisive nerve				Inferior alveolar nerve				Teeth
	Lingual nerve and perforating branches of inferior alveolar nerve								Lingual gingivae

Pain sensation in teeth

The teeth are supplied by nociceptors that generate pain sensation of a very high order. The mechanism underlying this sensitivity is of considerable clinical significance and is controversial. Currently, the most widely accepted view is that fluid movements through the dentine tubules stimulate nerve endings at the periphery of the dental pulp (hydrodynamic hypothesis).

Local analgesia

Available with the *Gray's Anatomy* e-book

SALIVARY GLANDS

Salivary glands are compound, tubuloacinar exocrine glands whose ducts open into the oral cavity. They secrete saliva, a fluid that lubricates food to assist deglutition, moistens the buccal mucosa, which is important for speech, and provides an aqueous solvent necessary for taste and a fluid seal for sucking and suckling. Salivary glands also secrete digestive enzymes, e.g. salivary amylase, and antimicrobial agents, e.g. immunoglobulin A (IgA), lysozyme and lactoferrin, into saliva. Most salivary IgA is derived from the blood by passive leakage mainly via gingival crevicular epithelium (Brandtzaeg 2013). Conditions in which there is a significant decrease in the production of saliva (xerostomia) may result in periodontal inflammation and dental caries. An illustration of the position of the major salivary glands and their ducts is given in Fig. 37.40.

The major salivary glands are the paired parotid, submandibular and sublingual glands. In addition, there are numerous minor salivary glands scattered throughout the mouth.

Approximately 0.5 l of saliva is secreted per day. Salivary flow rates are typically 0.3 ml/min when unstimulated, and rise to 1.5–2 ml/min when stimulated. Flow rate is negligible during sleep. In the unstimulated state, the parotid gland contributes 20%, the submandibular gland 65%, and the sublingual and minor salivary glands 15% of the daily output of saliva: when stimulated, the parotid contribution rises to 50%. Parasympathetic impulses usually evoke most of the fluid secretion into saliva, mainly acting through M3 muscarinic cholinergic receptors. Sympathetic impulses elicit exocytosis of protein storage granules in acinar cells in some experimental animals, but the sparse sympathetic (adrenergic) innervation of human sublingual and minor salivary glands is mainly associated with the vasculature and not the parenchyma (Proctor and Carpenter 2007, Proctor 2016). Several aquaporins (transmembrane protein channels) are expressed in salivary glands, including the acinar and ductal cells involved in the formation of saliva: AQP5 appears to play a major role in saliva secretion (Delporte et al 2016).

The failure of complete anaesthesia to the mandibular teeth following an inferior alveolar nerve block, which is meant to anaesthetize the nerve before its entrance into the mandibular canal, indicates that there are alternative pathways for sensory nerves to the teeth. Knowledge of these alternative pathways is important in helping clinicians to obtain complete dental anaesthesia. These alternative pathways involve anatomical variation in the distribution of the inferior alveolar nerve, the buccal branch of the mandibular nerve, the mylohyoid nerve, the lingual nerve, the deep temporal nerves and the cervical plexus. The inferior alveolar nerve may give multiple branches before entering the mandibular canal, one or more of which may escape anaesthesia following inferior alveolar nerve block. They may then re-enter the mandible via small accessory foramina in the retromolar region to supply sensation to the molar teeth (**Fig. 37.37**). The buccal branch of the mandibular nerve, which supplies the buccal gingivae of the molar teeth, may also possess a branch that passes through a small retromolar foramen to supply the molar teeth. The mylohyoid nerve is primarily a motor nerve supplying mylohyoid and the anterior belly of the digastric, but it carries sensory fibres that may enter the mandible via one or more small retromental foramina in the vicinity of the genial tubercles to supply some sensation to the anterior teeth. Communications exist between the inferior alveolar and lingual nerves. If the lingual nerve is not anaesthetized during an inferior alveolar nerve block, this pathway could account for any remaining sensation in the teeth. Although the deep temporal nerves are primarily motor, it has been suggested that terminal branches may pass from the substance of temporalis to enter the mandible through foramina in the retromolar region to supply some sensation to molar teeth. In the cervical plexus, the great auricular nerve, formed by the anterior primary rami of the second and third cervical spinal nerves, supplies skin over the angle of the mandible. It is possible that this nerve may provide a branch that penetrates the mandible to supply one or more of the cheek teeth.

If a successful inferior alveolar nerve block does not completely anaesthetize teeth in a jaw quadrant, additional local injections of anaesthetic solution around the tooth in question may be necessary to block the alternative pathways described above. In addition, there is the possibility of overlap across the midline involving the incisive and mylohyoid nerves. In children, there is evidence to suggest that the lingula is variable in position and its position from the occlusion plane increases with age. It is therefore not considered an appropriate landmark for inferior alveolar nerve block (Ezoddini Ardakani et al 2010).

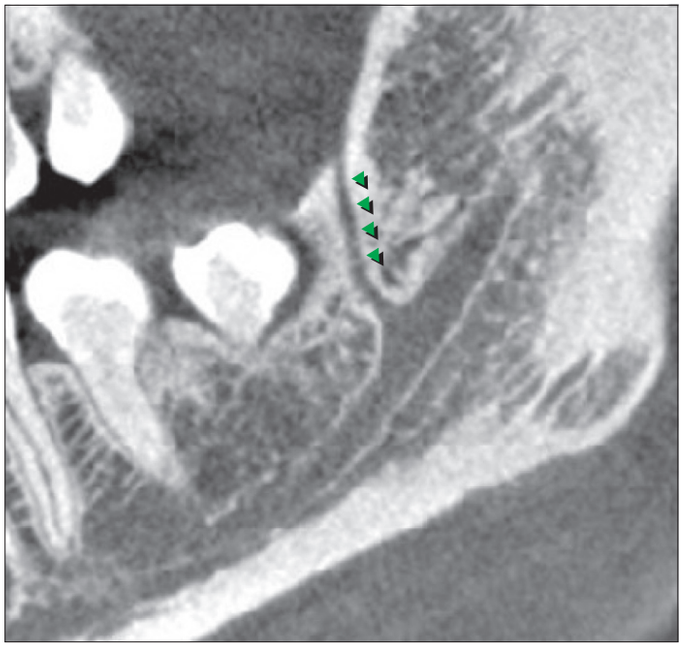

Fig. 37.37 A bifid inferior alveolar canal in which a branch of the inferior alveolar nerve enters the mandible through an accessory foramen in the retromolar region (arrowed) to supply sensation to the molar teeth. (Courtesy of Dr Clare Gleeson.)

Impacted mandibular third molars In many subjects, there is a disproportion between the size of the teeth and the size of the jaws, such that there is insufficient space for all the teeth to erupt. As the third mandibular molar teeth (the wisdom teeth) are the last to erupt, they are often impeded in their eruption and either become impacted or remain unerupted deeply within the jaw bone. If the tooth is completely covered by bone and mucosa, it is very unlikely to cause any symptoms, and the subject remains unaware of its presence unless the tooth is seen on a routine dental radiograph. Very rarely, the surrounding dental follicle may undergo cystic degeneration, which can 'hollow out' the jaw, usually the mandible, to a considerable degree. The developing cyst may displace the tooth as it expands and the tooth may end up as far away as the condylar neck or coronoid process.

More commonly, the erupting wisdom tooth erupts partially before impacting against the distal aspect of the second molar. When this occurs, symptoms are common due to recurrent soft tissue inflammation and infection around the partially erupted tooth caused by food impaction. This condition is known as pericoronitis and, if the infecting organism is virulent, the infection may rapidly spread into the adjacent tissue spaces as described elsewhere (see below and Ch. 38). The tooth only merits surgical removal if the patient suffers a severe bout or multiple bouts of pericoronitis. Surgery is not immediately indicated because it is associated with a degree of morbidity: the lingual and inferior alveolar nerves, which are often in close proximity to the tooth, may be damaged during its removal. The lingual nerve passes across the surface of the periosteum lingually to the lower wisdom tooth, separated from the tooth only by a cortical plate of bone no thicker than an eggshell. Damage to this nerve results in altered sensation (paraesthesia) to the ipsilateral side of the tongue and floor of mouth.

A major problem when extracting mandibular third molar teeth, especially if they are impacted, is possible damage to the inferior alveolar nerve. Indeed, surgical treatment may only necessitate the removal of the crown, leaving behind the roots (after suitable root filling). Maxillary third molars are only rarely impacted because they erupt posteroinferiorly. A clear radiograph is required before any tooth extraction is undertaken in order to alert the dental surgeon to any problems that may be encountered. For example, although the inferior alveolar nerve and its accompanying vessels generally lie beneath the roots of the third permanent molar in the mandibular canal, the neurovascular bundle may occupy a higher position, close to the roots, and may even run between the roots. This may be evident in routine periapical or orthopantomograph radiographs as a constriction or deviation of the mandibular canal or as a radiolucent canal overlying the roots of the third molar (**Fig. 37.38**). In this situation, the inferior alveolar nerve is at risk during extraction of third molars; damage to the nerve may result in paraesthesia in the distribution of the mental nerve, with consequent altered sensation or numbness in the lower lip. The root of a mandibular premolar may occasionally be unusually long and may be in close relationship to the mental nerve, which may then be at risk during extraction of this tooth.

Routine radiographs are no longer considered satisfactory for revealing the close relationship of the inferior alveolar nerve to the third molars; cone beam computed tomography (CBCT) is the method of choice to show this relationship in three dimensions. CBCT is also routinely used prior to insertion of a dental implant to determine not only the exact position of the inferior alveolar nerve and its mental branch but also the topography of the surrounding bone, to establish whether it is suitable for receiving a dental implant.

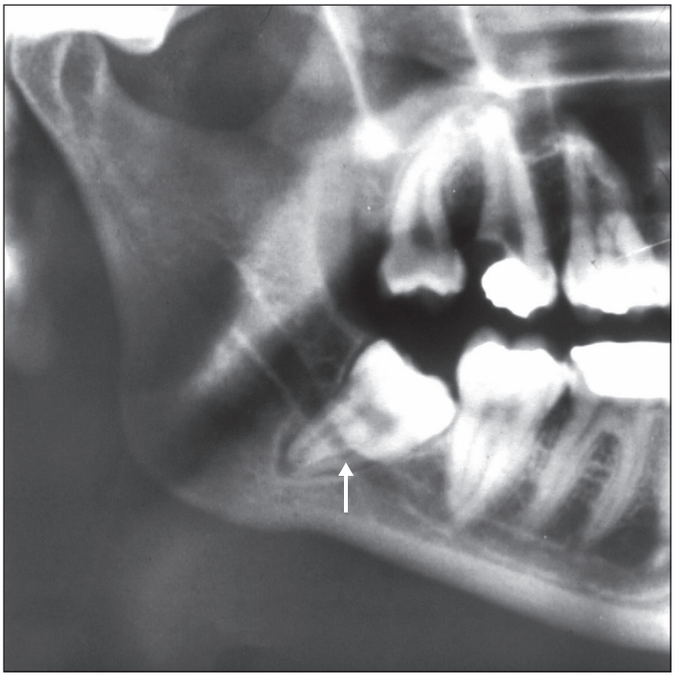

Fig. 37.38 A radiograph showing that the mandibular canal containing the inferior alveolar canal and its contents (arrow) are closely related to the roots of the impacted permanent mandibular third molar. (With permission from Berkovitz BKB, Holland GR, Moxham BJ 2009 Oral Anatomy, Histology and Embryology, 4th ed. Edinburgh, Mosby.)

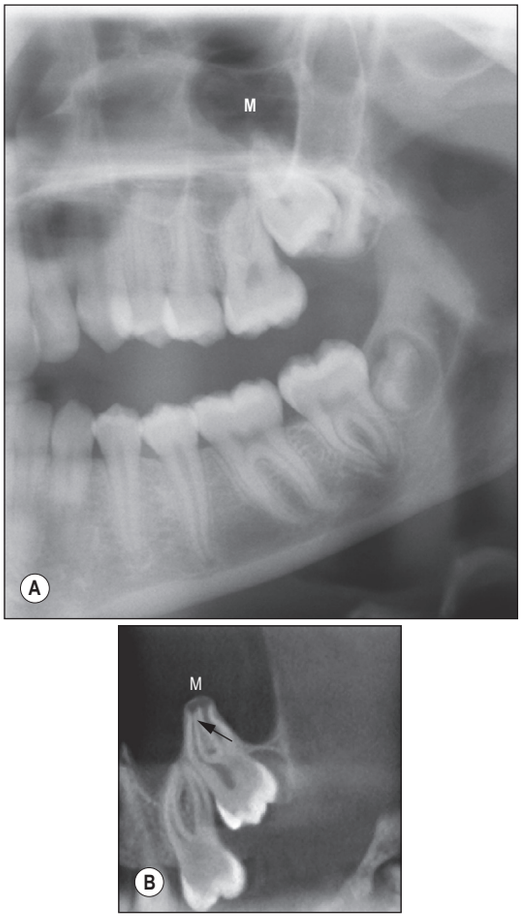

Fig. 37.39 A, A routine orthopantomogram showing the roots of the permanent maxillary molar teeth and the maxillary sinus (M): the precise relationship of the root apices to the floor of the maxillary sinus is unclear. **B**, Cone beam computed tomography of the same patient shown in **A**; the image in the sagittal plane clearly shows the two buccal root apices (arrow) of the permanent maxillary second molar tooth invaginating into the maxillary sinus (M). (Courtesy of Dr J Davies.)

It is technically possible to achieve profound regional anaesthesia by depositing local anaesthetic solution adjacent to the trigeminal nerve trunks or their branches within the infratemporal fossa. These injections can either be performed transorally (posterior superior alveolar nerve block, maxillary nerve block, inferior alveolar nerve block, lingual nerve block and mandibular nerve block) or, rarely, by an external route through the skin of the face (maxillary nerve block, inferior alveolar nerve block and mandibular nerve block).

In the case of the mandible, the anterior teeth can be anaesthetized by simple diffusion techniques, as the bone is relatively thin. However, this is not adequate for the cheek teeth due to the increased thickness of the bone. In this case, the inferior alveolar nerve has to be anaesthetized before it enters the inferior alveolar canal. The needle has to be placed within the pterygomandibular space to achieve a successful inferior alveolar nerve block. The lingual nerve is also usually blocked, as it lies close to the inferior alveolar nerve. Because of the other structures within the infratemporal fossa, it is important for the operator to have a detailed knowledge of the anatomy in this region in order to understand, and therefore try to avoid, the complications that may arise. Any damage to blood vessels in the infratemporal fossa, including the pterygoid venous plexus, can lead to haematoma formation. In extreme cases, bleeding can track through the inferior orbital fissure, resulting in a retrobulbar haematoma, which can lead to loss of visual acuity or blindness. Intravascular injection of local anaesthetic solution (which usually contains adrenaline (epinephrine)) can have profound systemic effects, and for this reason an aspirating syringe is always used to check that the needle has not entered a vessel prior to injection (vessels in this area that theoretically may be entered include the maxillary and internal carotid arteries). If the needle is placed too medially, it may enter medial pterygoid; if directed too laterally, it may penetrate temporalis. In either case, there will be a lack of anaesthesia, followed later by trismus. If the needle is placed too deeply, anaesthetic solution may cause a temporary facial nerve palsy resulting from conduction block in the facial nerve in the region of the parotid gland. Local anaesthetic solution may enter the orbit via the inferior orbital fissure and give orbital symptoms, the most likely being a temporary paralysis of the abducens nerve with loss of activity of lateral rectus.

The root apices of the maxillary cheek teeth are close to, and may even invaginate, the maxillary sinus. The permanent tooth most commonly involved is the upper second molar, followed by the first molar; less frequently, premolars and the third molar may be involved. The likelihood of cavitation of the maxillary sinus increases significantly after tooth extraction. During removal of fractured root apices in this region, care must therefore be taken to ensure that the root fragment is not pushed into the sinus. Similarly, during root canal treatment, care must be taken to ensure that any filling material is not pushed into the sinus. When routine radiographs fail to provide sufficient definition of the close relationship between the floor of the maxillary sinus and root apices, CBCT may be necessary to provide additional detail (Fig. 37.39).

Parotid gland

The parotid gland is the largest salivary gland and is almost entirely serous. The parotid duct runs through the cheek and drains into the mouth opposite the maxillary second permanent molar tooth. The parotid gland is described in detail in Chapter 36. A sialogram of the parotid duct is illustrated in Fig. 37.40A,B.

Submandibular salivary gland

The submandibular gland is irregular in shape and about the size of a walnut. It is a mixed serous and mucous tubuloacinar gland (predominantly serous). It has a larger superficial and a smaller deep part that are continuous with each other around the posterior border of mylohyoid.

Superficial part of the submandibular gland

The superficial part of the gland is situated in the digastric triangle, where it reaches forwards to the anterior belly of digastric and back to the stylomandibular ligament, by which it is separated from the parotid gland. Above, it extends medial to the body of the mandible. Below, it usually overlaps the intermediate tendon of digastric and the insertion of stylohyoid. This part of the submandibular gland presents inferior, lateral and medial surfaces, and is partially enclosed between two layers of deep cervical fascia that extend from the greater cornu of the hyoid bone. The superficial layer is attached to the lower border of the mandible and covers the inferior surface of the gland. The deep layer is attached to the mylohyoid line on the medial surface of the mandible and covers the medial surface of the gland.

The inferior surface, covered by skin, platysma and deep fascia, is crossed by the facial vein and the cervical branch of the facial nerve. Near the mandible, the submandibular lymph nodes are in contact with the gland and some may be embedded within it.

The lateral surface is related to the submandibular fossa on the medial surface of the body of the mandible and the mandibular attachment of medial pterygoid. The facial artery grooves its posterosuperior part, lies at first deep to the gland and then emerges between its lateral surface and the mandibular attachment of the medial pterygoid to reach the lower border of the mandible.

The medial surface is related anteriorly to mylohyoid, from which it is separated by the mylohyoid nerve and vessels and branches of the submental vessels. More posteriorly, it is related to styloglossus, the stylohyoid ligament and the glossopharyngeal nerve, which separate it from the pharynx. In its intermediate part, the medial surface is related to hyoglossus, from which it is separated by styloglossus, the lingual nerve, submandibular ganglion, hypoglossal nerve and deep lingual vein (sequentially from above down). Below, the medial surface is related to the stylohyoid muscle and the posterior belly of digastric.

Deep part of the submandibular gland

The deep part of the gland extends forwards to the posterior end of the sublingual gland. It lies between mylohyoid inferolaterally, hyoglossus and styloglossus medially, the lingual nerve superiorly, and the hypoglossal nerve and deep lingual vein inferiorly (see Figs 37.14, 37.40A).

Vascular supply and lymphatic drainage

The arteries supplying the gland are branches of the facial and lingual arteries. The lymph vessels drain into the deep cervical group of lymph nodes (particularly the jugulo-omohyoid node), interrupted by the submandibular nodes.

Innervation

The secretomotor supply to the submandibular gland is derived from the submandibular ganglion (parasympathetic). The vasomotor supply is derived from the superior cervical ganglion (sympathetic).

Submandibular ganglion

The submandibular ganglion is a small, fusiform body that lies on the upper part of hyoglossus, superior to the deep part of the submandibular gland and inferior to the lingual nerve, to which it is connected by several filaments. The posterior filament is the motor, parasympathetic root that conveys preganglionic fibres from the superior salivatory nucleus in the brainstem via the facial, chorda tympani and lingual nerves to the ganglion, where they synapse. Five or six postganglionic secretomotor branches from the ganglion supply the submandibular gland and its duct, and the sublingual and anterior lingual glands, by travelling either through the anterior filaments that connect the

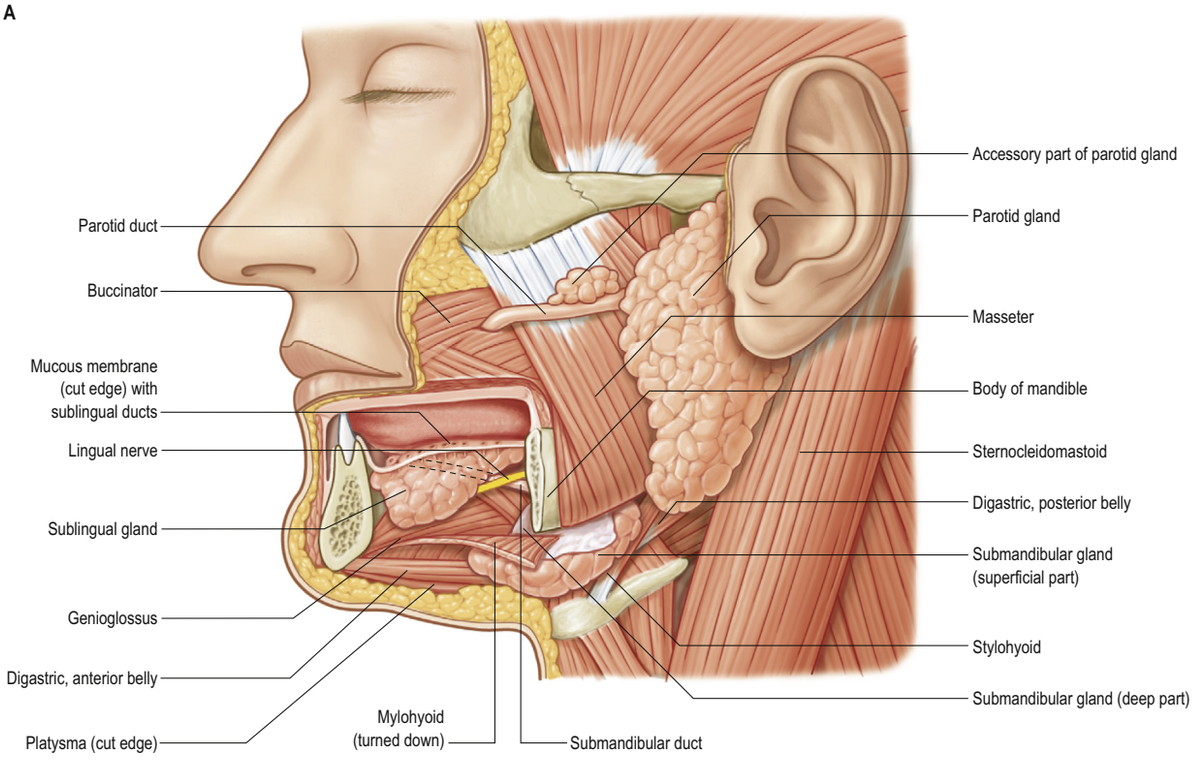

Fig. 37.40 A, The salivary glands of the left side. The cranial region of the superficial part of the submandibular gland has been excised and mylohyoid has been cut and turned down to expose a portion of the deep part of the gland. (B–C, *continued online*)

submandibular gland to the lingual nerve or along adjacent blood vessels to their targets. Neuronal cell bodies and small ganglia have been described in the interlobular connective tissue stroma of human submandibular ganglia, close to salivary parenchymal cells and blood vessels (Tosios et al 2010). The sympathetic root is derived from the plexus on the facial artery and consists of postganglionic fibres from the superior cervical ganglion that traverse the submandibular ganglion without synapsing. These fibres are vasomotor to the blood vessels of the submandibular and sublingual glands. Sensory fibres derived from the lingual nerve may also pass through the ganglion.

Submandibular duct

The submandibular duct is about 5 cm long and has a thinner wall than the parotid duct. It begins from numerous tributaries in the superficial part of the gland and emerges from the medial surface of this part of the gland behind the posterior border of mylohyoid. It traverses the deep part of the gland, and then passes at first up and slightly back for approximately 5 mm, this sharp bend over the free edge of mylohyoid being known as the genu of the duct. It then runs forwards between mylohyoid and hyoglossus, passing between the sublingual gland and genioglossus to open in the floor of the mouth on the summit of the sublingual papilla at the side of the frenulum of the tongue (see Figs 37.4, 37.14). It lies between the lingual and hypoglossal nerves on hyoglossus but, at the anterior border of the muscle, it is crossed laterally by the lingual nerve, terminal branches of which ascend on its medial side. As the duct traverses the deep part of the gland, it receives small tributaries draining this part of the gland. It has been suggested previously that the genu of the duct predisposes to the stasis of saliva and thereby encourages salivary stone (sialolith) formation, but this is somewhat controversial and largely unproven.

Like the parotid gland, the duct system of the submandibular gland can be visualized by sialography (**Fig. 37.41**).

Sublingual salivary gland

The sublingual gland is the smallest of the main salivary glands. It is a mixed serous and mucous tubuloacinar gland in which mucous cells predominate. Each sublingual gland is narrow, flat, shaped like an almond, and weighs approximately 4 g. It lies on mylohyoid and is covered by the mucosa of the floor of the mouth, which is raised as a sublingual fold (see Figs 37.4, 37.14). The deep part of the submandibular gland lies behind; the sublingual fossa of the mandible is lateral; genioglossus is medial and separated from the sublingual gland by the lingual nerve and submandibular duct.

The sublingual gland is made up two parts. A posterior part, which is not always present, is referred to as the greater sublingual gland, from which a main duct (Bartholin's duct) arises to drain either directly onto the sublingual papilla or to join the submandibular duct. This duct may be visualized occasionally in a submandibular sialogram (see Fig. 37.41). An anterior, lesser sublingual gland is always present and consists of a mass of small glands, numbering from 7 to 15, from which a short main duct drains onto the sublingual fold.

Vascular supply, lymphatic drainage and innervation

The arterial supply to the sublingual gland is from the sublingual branch of the lingual artery and the submental branch of the facial artery. Lymphatic drainage is to the submental nodes.

Secretomotor parasympathetic innervation is from the chorda tympani nerve via the submandibular ganglion.

Ranula

Available with the *Gray's Anatomy* e-book

Minor salivary glands

The minor salivary glands of the mouth include the labial, buccal, palatoglossal, palatal and lingual glands. The labial and buccal glands contain both mucous and serous elements. The palatoglossal glands are mucous glands and are located around the pharyngeal isthmus. The palatal glands are mucous glands and occur in both the soft and hard palates. The anterior and posterior lingual glands are mainly mucous. The anterior glands are embedded within muscle near the ventral surface of the tongue and open by means of four or five ducts near the lingual frenulum, and the posterior glands are located in the root of the tongue. The deep posterior lingual glands are predominantly serous. Serous glands (of von Ebner) occur around the circumvallate papillae; their secretion is watery, and they probably assist in gustation by spreading taste stimuli over the taste buds and then washing them away.

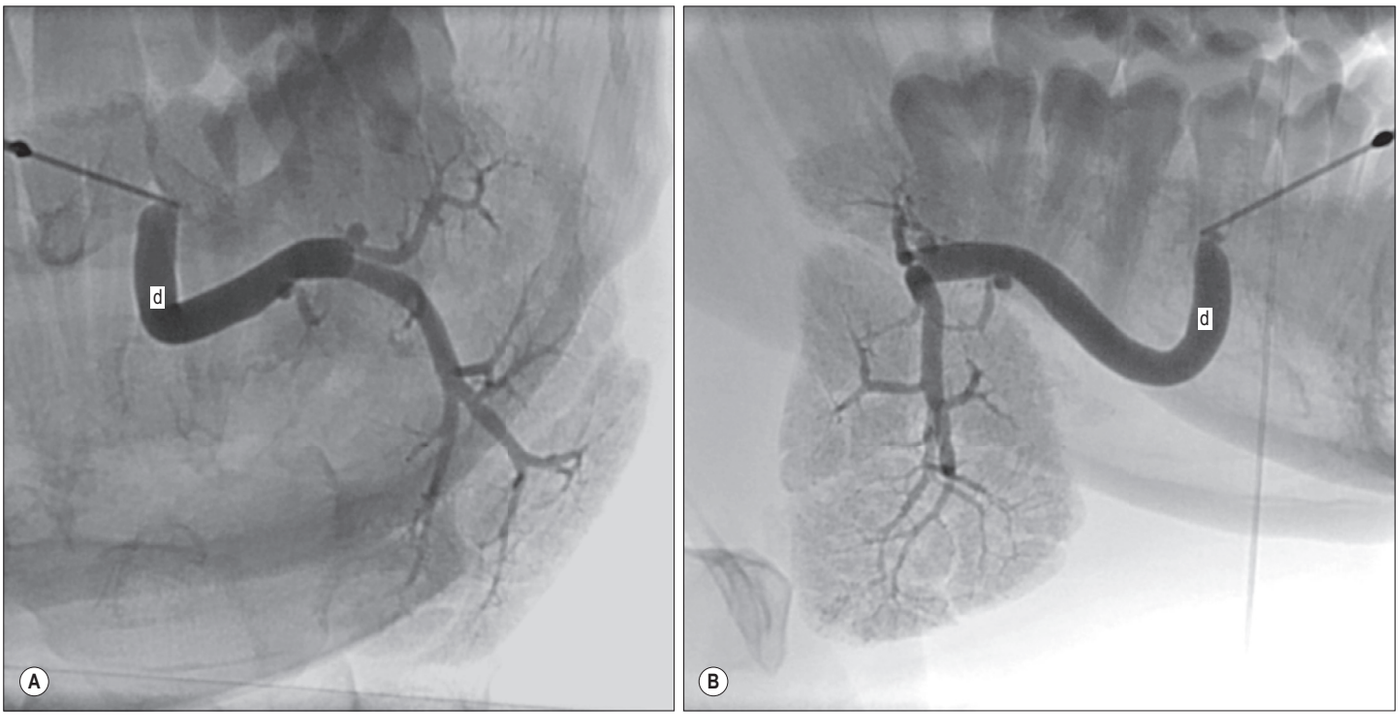

Fig. 37.41 A normal left submandibular sialogram. **A**, Frontal view; **B**, oblique view from the opposite side of the jaw. The main duct (d) has been cannulated in the floor of the mouth in order to fill the gland with contrast medium.

Microstructure

Salivary glands have numerous lobes composed of smaller lobules separated by dense connective tissue that is continuous with the capsule of the gland, and contains excretory (collecting) ducts, blood vessels, lymph vessels, nerve fibres and small ganglia. Each lobule has a single duct, whose branches terminate at dilated secretory 'end-pieces', which are tubular or acinar in shape (**Fig. 37.43**). Their primary secretion is modified as it flows through intercalated, striated and excretory ducts into one or more main ducts that discharge saliva into the oral cavity. They contain a variable amount of intralobular adipose tissue; adipocytes are particularly numerous in the parotid gland.

The secretory end-pieces of the human parotid gland are almost exclusively serous acini (**Fig. 37.44A**); mucous tubules or acini are rare. In the submandibular gland, secretory units are predominantly serous acini, with some mucous tubules and acini (**Fig. 37.44B**). Mucous tubules are often associated with groups of serous cells at their blind ends, appearing as crescent-shaped serous demilunes in routine histological preparations. However, this appearance is a fixation artefact, as tissue prepared by rapid freezing methods lacks serous demilunes and the serous secretory cells align with mucous cells around a common lumen (Yamashina et al 1999). In the sublingual gland, mucous tubules and acini predominate (**Fig. 37.44C**) but serous cells also occur, as acini or as serous demilunes.

Serous cells are approximately pyramidal in shape. Their nuclei vary in shape and position, but are more rounded and situated less basally than in mucous cells. Apically, the cytoplasm is filled by proteinaceous secretory (zymogen) granules with high amylase activity. Additionally, serous cells secrete kallikrein, lactoferrin and lysozyme, an antibacterial enzyme whose synthesis has been localized in particular to the serous demilunes of the submandibular and sublingual glands, and which is important in the defence against oral pathogens. In the human parotid and submandibular glands, zymogen granules also show a positive periodic acid–Schiff staining reaction, which indicates the presence of polysaccharides, and some texts refer to these cells as seromucous. Mucous cells are cylindrical and have flattened, basal nuclei. Their apical cytoplasm is typically packed with large, pale-staining and electron-translucent secretory droplets. The histological appearance of serous and mucous cells will vary according to the stage in the secretory cycle.

Ducts

Intercalated, striated (both intralobular) and extralobular collecting ducts lead consecutively from the secretory end-pieces. The lining cells of intercalated ducts are flat nearest the secretory end-piece but become cuboidal. Intercalated ducts function primarily as a conduit for saliva but, together with the striated ducts, may also modify its content of electrolytes and secrete IgA. Striated ducts are lined by a low columnar epithelium and are so called because their lining cells have characteristic basal striations. The latter are regions of highly infolded basal plasma membrane, between which lie columns of vertically aligned mitochondria. The nuclei are consequently displaced by the basal striations from a typical ductal basal position to a central or even apical location (see Fig. 37.44). Infolding of the basal plasma membrane and local abundance of mitochondria are typical features of epithelial cells that actively transport electrolytes. Here, the cells transport potassium and bicarbonate into saliva; they produce a hypotonic saliva by reabsorbing sodium and chloride ions in excess of water. Striated ducts modify electrolyte composition and secrete IgA (Ch. 4), lysozyme and kallikrein. The intralobular ductal system of the sublingual gland is less well developed than that of the parotid and submandibular glands.

Collecting ducts are metabolically relatively inert conduits that run within interlobular connective tissue septa in the glands. They transport saliva to the main duct, which opens on to the mucosal surface of the buccal cavity. The lining epithelium of collecting ducts varies. It may be pseudostratified columnar, stratified cuboidal or columnar in the larger ducts, and has a distinct basal layer. It becomes a stratified squamous epithelium near the buccal orifice.

Myoepithelial cells

Myoepithelial cells are contractile cells that lie between the basal laminae and the epithelial cells proper and extend numerous cytoplasmic processes around the serous acini and intercalated ducts (Ogawa 2003). They express both an epithelial and a smooth muscle

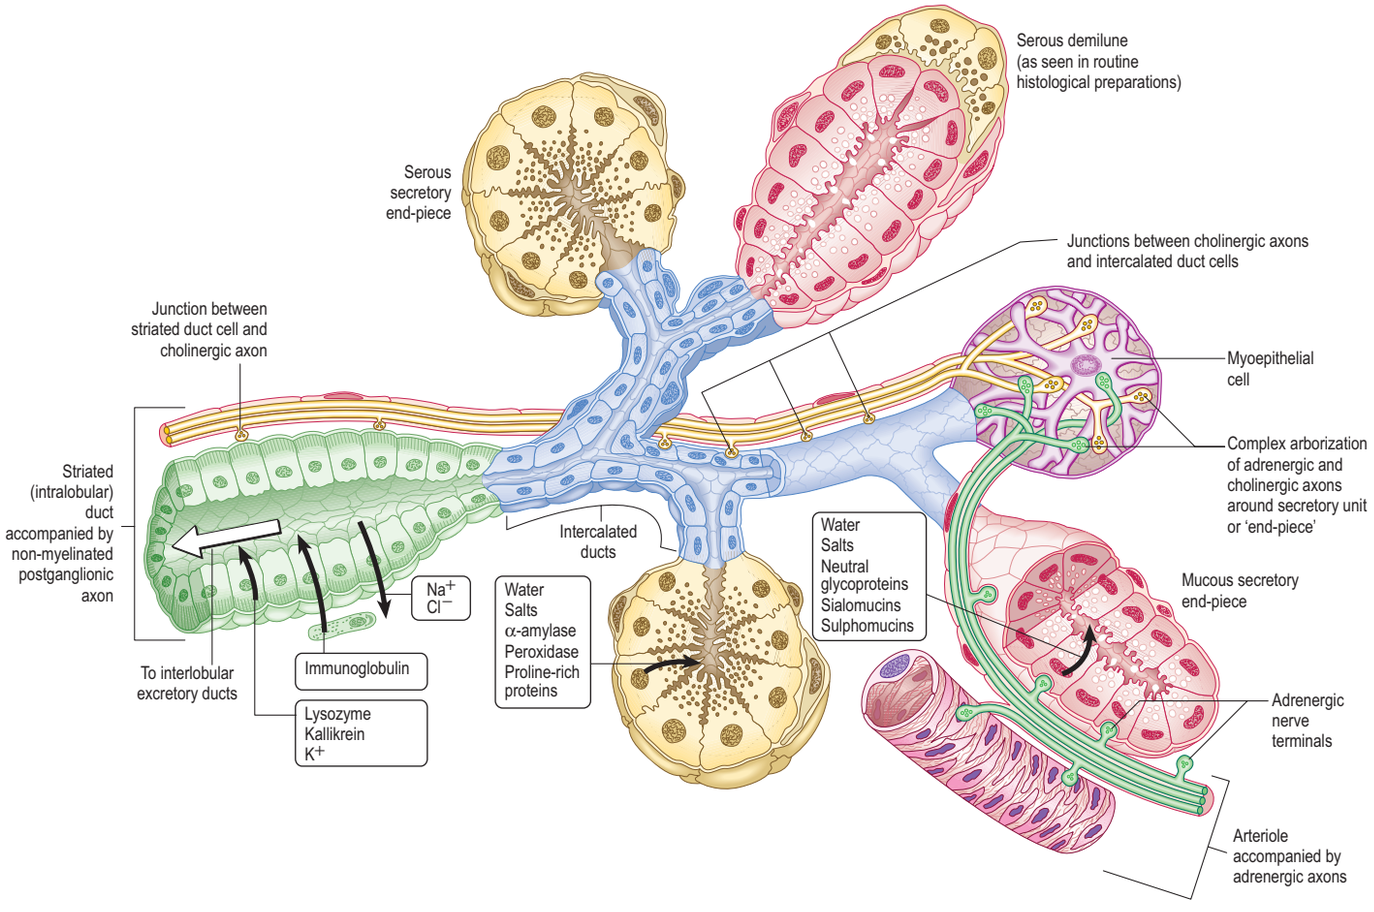

Fig. 37.43 The architecture of a generalized salivary gland. Solid black arrows indicate the direction of transport of salivary components, and the open white arrow the direction of salivary flow. The innervation of the ducts, secretory units and arterioles is shown.

If the ducts draining any salivary gland become obstructed, the gland itself is at risk of developing a retention cyst where the retained secretions dilate the gland itself rather like a balloon. This phenomenon is seen mostly in the minor salivary glands that line the lips and oral cavity, where it is known as a mucocele. Trauma, such as persistent lip biting, results in scarring of the overlying oral mucosa and obstruction of the small drainage duct. When trauma occurs in the floor of the mouth and obstructs the drainage duct/s of the sublingual gland, the resulting retention cyst is known as a ranula. (Ranula is the Latin name for a frog and is used here because the tense cystic swelling is said to resemble the throat of a croaking frog.)

A ranula usually presents as a large, tense, bluish swelling anteriorly in the floor of the mouth just to one side of the midline, which often displaces the tongue (**Fig. 37.42**). Occasionally, the developing retention cyst herniates through a midline dehiscence where the two mylohyoid muscles fail to meet in the midline anteriorly, and then the ranula may present as a submental swelling or as a combined submental and floor-of-mouth swelling, a 'plunging' ranula (Harrison et al 2013). The treatment for a ranula is excision of the sublingual gland responsible.

phenotype, being immunoreactive for high molecular weight cytokeratins (CK5/6, 34_E12 and CK14) and smooth muscle markers (actin, myosin, and calponin) (Shah et al 2016). Myoepithelial cells associated with ducts are more fusiform in shape and are aligned along the length of the duct.

Although stimulated by the autonomic nervous system, the precise functional role of myoepithelial cells in salivary secretion awaits clarification (Garrett 1998, Proctor 2016). Functional studies clearly indicate that myoepithelial activity can accelerate the initial outflow of saliva, reduce luminal volume, contribute to the secretory pressure, support the underlying parenchyma, reduce back-permeation of fluid and help salivary flow to overcome increases in peripheral resistance (although, if this is excessive, it may lead to sialectatic damage of striated ducts, thereby increasing overall permeability).

Basal cells

A population of basal cells is present in the striated and collecting ducts (Riva et al 1992). They are sparsely distributed in the striated ducts and more densely distributed in the collecting ducts, in which they form a continuous layer as the ducts pass further towards the hilum. A small population of basal cells is found on the abluminal surface of ductal cells associated with both striated and collecting ducts. These cells can be distinguished from other parenchymal cells by a combination of their morphology, their co-expression of cytokeratin 14 and the anti-apoptotic factor cl-2, and a proliferative index of about 3%, which is the highest of any cell in the region. Basal cells have been implicated as potential stem cells during turnover and/or cell regeneration in salivary glands and during metaplasia, when oncocytes and sebaceous cells may appear. However, some cell division is seen in all parenchymal cell types, including myoepithelial cells, and all these cells may be involved in salivary gland regeneration. (For further reading on salivary gland regeneration see Holmberg and Hoffman 2014.)

Lymph nodes

Lymph nodes are situated both on the surface and within the parotid gland, but are not found within the other salivary glands.

Control of salivary gland activity

The observed wide and rapid variation in the composition, quantity and rate of salivary secretion in response to various stimuli suggests an elaborate control mechanism. Secretion may be continuous but at a low resting level, and may also occur spontaneously. It is mainly a response to the drying of the oral and pharyngeal mucosae. A rapid increase can be superimposed on the resting level, e.g. during mastication or when stimulated by the autonomic innervation. The controlled variation in the activity of the many types of salivary effector cells (serous, seromucous and mucous secretory cells, myoepithelial cells, epithelial cells of all the ductal elements and the smooth muscle of local blood vessels) affects the quantity and quality of saliva. There is no clear evidence that circulating hormones evoke secretion directly at physiological levels but they may alter the response of glandular cells to neural stimuli.

The control of salivation depends on reflex nerve impulses. The afferent inputs to the reflex arc pass to brainstem salivatory centres, especially from taste and mechanoreceptors in the mouth. A variety of other sensory modalities in and around the mouth are also involved, e.g. smell, for certain aspects of submandibular secretion in humans. The afferent input is integrated centrally by the salivatory centres, which are themselves influenced by higher centres. The latter may provide facilitatory or inhibitory influences, which presumably explains why the mouth becomes dry under stress. The efferent drive to the glands passes via parasympathetic and sympathetic outputs from the centres. Relatively little is known about the connections of the preganglionic parasympathetic neurones in the salivatory centres, and virtually nothing is known about either the central location of the sympathetic preganglionic neurones, or the output pathways. No peripheral inhibitory mechanisms exist in the glands (Garrett et al 1999).

The typical pattern of innervation is shown in Fig. 37.43, but details vary in different glands and with age. Only the more constant features are illustrated and described here. Cholinergic nerves often accompany ducts and arborize freely around secretory end-pieces, but adrenergic nerves usually enter glands along arteries and ramify with them. The main secretomotor nerves are predominantly unmyelinated axons; the few myelinated axons that have been seen are presumably either preganglionic efferent or visceral afferent. Within the glands, the nerve fibres intermingle, such that cholinergic and adrenergic axons often lie in adjacent invaginations of one Schwann cell. Secretion and vasoconstriction are mediated via separate sympathetic axons. A single parasympathetic axon may, through serial *en passant* terminals, induce vasodilation, secretion and myoepithelial contraction.

Secretory end-pieces are usually the most densely innervated structures in the gland; individual cells often have both cholinergic and adrenergic innervation. Secretion of water and electrolytes, which creates the foundation for the volume of saliva secreted, is the outcome of a complex set of processes that is largely induced by parasympathetic impulses. Secretion of protein is an ongoing constitutive process wherever it occurs. The regulated exocytosis of pre-packaged proteins, which is the principal source of protein secretion into saliva, depends on the relative levels of activity in sympathetic and parasympathetic fibres.

The ductal elements of salivary glands can markedly modify the composition of saliva. They are less densely innervated than secretory

end-pieces but their activity is also under neural control. Adrenal aldosterone promotes resorption of sodium and release of potassium into saliva by striated ductal cells, as it does in kidney tubules. Myoepithelial contraction is stimulated mainly by adrenergic innervation but there may be an additional role for cholinergic axons.

Age changes in salivary glands

A wide range of age changes has been documented in salivary glands. In neonates, acini and ducts are immature and widely separated by abundant vascular connective tissue. After the age of 6 months, glandular structure is more compact and there are numerous lymphocytic foci (Scott 1979). Over the age of 50 years, the amount of glandular tissue decreases and the amount of fibrous tissue, adipocytes, inflammatory cells and oncocytes increases. An increase in duct volume has also been described, although it may in part reflect shrinkage of acini, giving the appearance of duct-like forms (Scott 1986).

With such a significant loss of parenchyma (in both major and minor glands), it might be assumed that there would be a reduction in the amount of saliva produced in the aged population, giving rise to the clinical condition of xerostomia (dry mouth). However, in healthy, unmedicated individuals, this is not the case. This could be interpreted as the result of salivary glands being able to produce more saliva than is needed but is more likely to be a secondary effect related to the increased use of medication (many drugs depress salivary production and many, such as antidepressants and antihistamines, are anticholinergic). Saliva is important in the maintenance of oral health; decreased secretion from the salivary glands results in an increased incidence in oral conditions such as periodontal disease, dental caries and candidal infections ('thrush').

TISSUE SPACES AROUND THE JAWS

The dissemination of infection in soft tissues is influenced by the natural barriers presented by bone, muscle and fascia. However, the tissue spaces around the jaws are primarily defined by muscles, principally mylohyoid, buccinator, masseter, medial pterygoid, superior constrictor and orbicularis oris (**Fig. 37.45**). None of these 'spaces' are actually empty and they should merely be regarded as potential spaces that are normally occupied by loose connective tissue. It is only when inflammatory products such as hyaluronase destroy the loose connective tissue that a definable space is produced.

The spaces are paired except for the submental, sublingual and palatal spaces.

Potential tissue spaces around the lower jaw

The important potential tissue spaces of the lower jaw are the submental, submandibular, sublingual, buccal, submasseteric, parotid, pterygomandibular, peritonsillar, parapharyngeal and retropharyngeal spaces (see Fig. 37.45) (Langdon et al 2002).

The submental and submandibular spaces are located below the inferior border of the mandible beneath mylohyoid, in the suprahyoid region of the neck. The submental space lies beneath the chin in the midline, between the mylohyoid muscles and the investing layer of deep cervical fascia. It is bounded laterally by the two anterior bellies of the digastric muscles. The submental space communicates posteriorly with the two submandibular spaces. The submandibular space is situated between the anterior and posterior bellies of the digastric muscle and communicates with the sublingual space around the posterior free border of mylohyoid. The sublingual space lies in the floor of the mouth, above the mylohyoid muscles, and is continuous across the midline; it communicates with the submandibular spaces over the posterior free borders of the mylohyoid muscles, helped by the submandibular gland's slight extension over this edge.

The remaining tissue spaces are illustrated in **Fig. 37.45B**. The buccal space is located in the cheek, on the lateral side of buccinator. The submasseteric spaces are a series of spaces between the lateral surface of the ramus of the mandible and masseter; they are formed because the fibres of masseter have multiple insertions on to most of the lateral surface of the ramus. The pterygomandibular space lies between the medial surface of the ramus of the mandible and medial pterygoid, and the parotid space lies behind the ramus of the mandible, in and around the parotid gland. The parapharyngeal space is bounded by the superior constrictor of the pharynx and the medial surface of medial pterygoid. It is restricted to the infratemporal region of the head and the suprahyoid region of the neck, and communicates with the retropharyngeal space, which itself extends into the retrovisceral space in the lower part of the neck (the tissue spaces of the neck are described in Chapter 35 and those of the pharynx in Chapter 40). The peritonsillar space lies around the palatine tonsil between the pillars of the fauces, and is part of the intrapharyngeal space. It is bounded by the medial surface of the superior constrictor of the pharynx and its mucosa.

Potential tissue spaces around the upper jaw

The tissue spaces of the upper jaw, the canine (infraorbital), palatal and infratemporal spaces, are usually associated with spread of infection from the teeth. The canine space associated with the canine fossa lies between levator labii superioris and the zygomaticus muscles. The palatal space is not truly a tissue space in the hard palate, since the mucosa there is firmly bound to the periosteum. However, inflammation can strip away some of this periosteum to produce a well-circumscribed abscess. The infratemporal space is the upper extremity of the pterygomandibular space and is closely related to the maxillary tuberosity and therefore the upper molars.

Dental abscess

Abscesses developing in relation to the apices of roots ultimately penetrate the surrounding bone where it is thinnest. The position of the resultant swelling in the soft tissues is largely determined by the relationship between muscle attachments and the sinus (the path taken by the infected material) in the bone. Thus, in the lower incisor region, because the labial bone is thin, abscesses generally appear as a swelling in the labial sulcus, above the attachment of mentalis. The abscess may open below mentalis, when it will point beneath the chin. If an abscess from a lower postcanine tooth opens below the attachment of buccinator, the swelling is in the face; if it opens above, the swelling is in the buccal sulcus of the mouth. If an abscess opens lingually above mylohyoid, the swelling is in the lingual sulcus; if it is below, the swelling is in the neck. Third molar abscesses tend to track into the neck rather than the mouth because mylohyoid ascends posteriorly and the termination of its attachment is variable, sometimes terminating before the position of the third molar and thereby allowing relatively unhindered access into the tissue spaces of the neck.

Apart from canine teeth, which have long roots, abscesses on upper teeth usually open buccally below, rather than above, the attachment of buccinator. Because its root apex is occasionally curved towards the palate, abscesses of the upper lateral incisors may track into the palatal submucosa. Abscesses of upper canines often open facially just below the orbit. Here, the swelling may obstruct drainage in the angular part of the facial vein, which has no valves, and it is therefore possible for infected material to travel via the angular and ophthalmic veins into the cavernous sinus, potentially causing a cavernous sinus thrombosis. Abscesses on the palatal roots of upper molars usually open on the palate. Upper second premolars and first and second molars are related to the maxillary sinus. When this is large, the root apices of these teeth may be separated from its cavity solely by the lining mucosa. Sinus infections may stimulate the nerves entering the teeth, simulating toothache in the ipsilateral premolars and molars; this phenomenon is known as referred pain. Upper first premolars and third molars may be closely related to the maxillary sinus.

With loss of teeth, alveolar bone is extensively resorbed. Thus, in the edentulous mandible, the mental nerve, originally inferior to premolar roots, may lie near the crest of the bone. In the edentulous maxilla, the sinus may enlarge to approach the oral surface of the bone. Both of these facts are of importance when planning surgery in this area.

Severe systemic infections during the time the teeth are developing may lead to faults in enamel, which are visible as horizontal lines (cf. Harris's growth lines).

CHAPTER
38

Infratemporal and pterygopalatine fossae and temporomandibular joint

INFRATEMPORAL FOSSA

The infratemporal fossa lies deep to the ramus of the mandible. It communicates with the temporal fossa superiorly deep to the zygomatic arch; the orbit anteriorly through the inferior orbital fissure; the pterygopalatine fossa medially through the pterygomaxillary fissure; the middle fossa through the foramina ovale and spinosum. It contains lateral and medial pterygoid, the mandibular division of the trigeminal nerve, the chorda tympani (facial nerve), the otic ganglion, the maxillary artery and the pterygoid venous plexus.

The infratemporal fossa has a roof and anterior, lateral and medial walls, and is open to the neck posteroinferiorly, which means that it has no anatomical floor. Approximately 80% of the roof is formed by the infratemporal surface of the greater wing of the sphenoid. The remainder is formed by the infratemporal surface of the temporal bone, ending at the articular eminence of the temporomandibular joint and the spine of the sphenoid on the deep medial aspect. The roof contains the foramina ovale and spinosum. The anterior wall is formed by the posterior surface of the maxilla, ending inferiorly at the maxillary tuberosity. The inferior orbital fissure forms the upper limit of the anterior wall, meeting the pterygomaxillary fissure at right-angles. The medial wall is formed anteriorly by the lateral pterygoid plate of the pterygoid process of the sphenoid, and more posteromedially by the pharynx and tensor and levator veli palatini. It contains the pterygomaxillary fissure, across which structures pass between the infratemporal and pterygopalatine fossae (Fig. 38.1). The lateral wall is formed by the medial surface of the ramus of the mandible.

Lateral pterygoid provides a key to understanding the relationships of structures within the infratemporal fossa. This muscle lies in the roof of the fossa and runs anteroposteriorly in a more or less horizontal plane from the region of the pterygoid plates to the mandibular condyle. Branches of the mandibular nerve and the main origin of medial pterygoid are deep relations and the maxillary artery is superficial. The buccal branch of the mandibular nerve passes between the two heads of lateral pterygoid. Medial pterygoid and the lingual and inferior alveolar nerves emerge below its inferior border, and the deep temporal nerves and vessels emerge from its upper border. The pterygoid venous plexus lies around and within lateral pterygoid and is important in the spread of infection.

Bones

The sphenoid bone, the paired maxillae and temporal bones, the palatine bones and the mandible collectively provide the skeletal framework to the infratemporal and pterygopalatine regions. The mandible and the two temporal bones articulate at the right and left temporomandibular joints. The disarticulated maxilla and palatine bone are described in Chapter 36, the temporal bone is described in Chapter 42, and the sphenoid and mandible are described here.

Sphenoid

The sphenoid lies in the base of the skull between the frontal, temporal and occipital bones. It has a central body, paired greater and lesser wings that spread laterally from the body, and two pterygoid processes that descend from the junction of the body and greater wings (Fig. 38.3).

Body

The body of the sphenoid is cuboidal. It contains two air sinuses separated by a septum. Its cerebral (superior) surface articulates anteriorly with the cribriform plate of the ethmoid bone via the smooth jugum sphenoidale, which is related to the overlying gyri recti and olfactory tracts. The jugum is bounded behind by the anterior border of the sulcus chiasmaticus leading laterally to the optic canals. The tuberculum sellae is posterior; behind it is the deeply concave sella turcica that houses the hypophysis cerebri within the hypophysial fossa. The anterior edge of the sella turcica is completed laterally by two middle clinoid processes. Posteriorly, the sella turcica is bounded by a square dorsum sellae with superior angles that bear variable posterior clinoid processes. The diaphragma sella and the tentorium cerebelli are attached to the clinoid processes. On each side, below

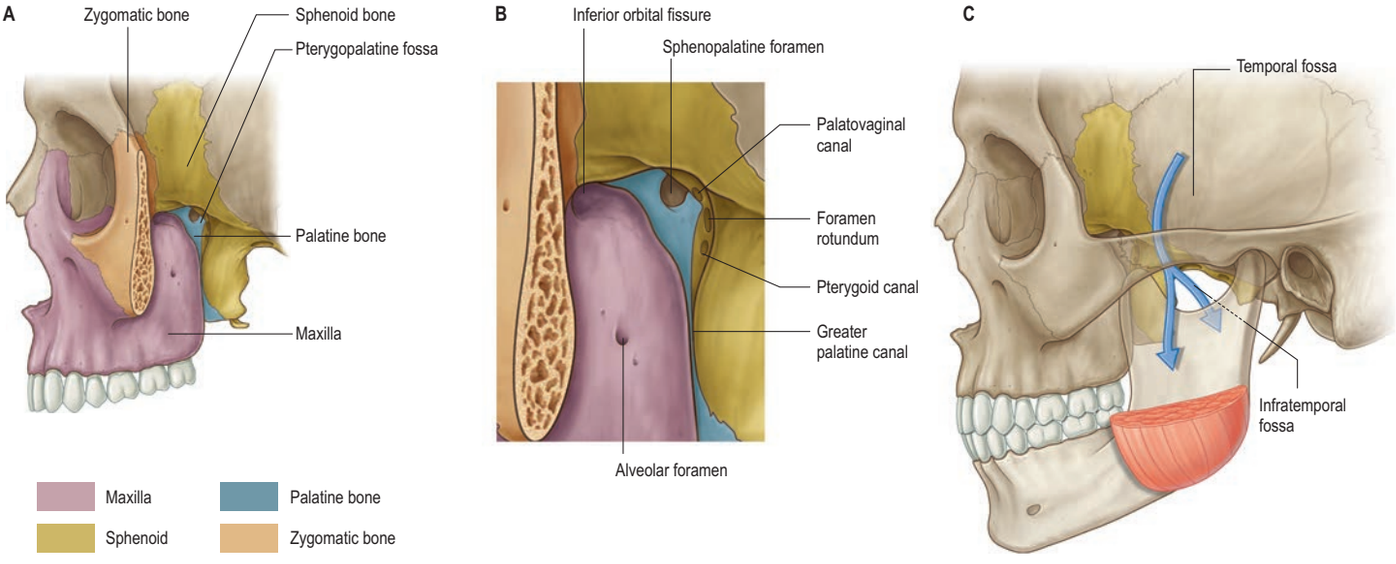

Fig. 38.1 **A**, The pterygopalatine fossa after detachment of the mandible and removal of the zygomatic arch. **B**, Anteromedial view. **C**, Lateral view; the arrows show that the floor of the temporal fossa is open medially to the infratemporal fossa and laterally to the region containing the masseter. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

There is a lack of consensus in the surgical literature with regard to both the boundaries and contents of the infratemporal fossa. Thus, the fossa is sometimes defined as the anatomical space beneath the floor of the middle fossa, incorporating the remainder of the subcranial temporal bone as part of the roof, with the exception of the glenoid fossa of the temporomandibular joint. In this description, the fossa is limited posteriorly by the prevertebral fascia and includes the internal carotid artery, the internal jugular vein, the lower cranial nerves, the cervical sympathetic trunk, and the styloid process with its attached muscles and ligaments. Alternatively, the 'extended' infratemporal fossa is said to consist of the parapharyngeal and masticator spaces (**Fig. 38.2**) (Bejjani et al 1998, Falcon et al 2010, Hosseini et al 2012, Joo et al 2013).

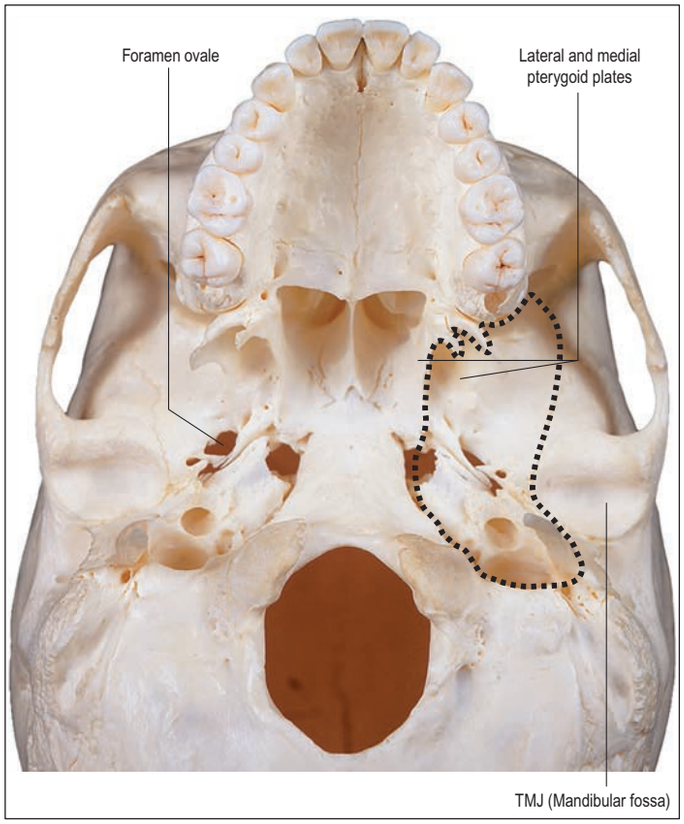

Fig. 38.2 The 'extended' infratemporal fossa. The boundaries of the infratemporal fossa are delineated by the dotted line. Note that the lateral pterygoid plate and pharyngotympanic tube constitute the medial wall of the fossa, and that the temporomandibular joint (TMJ) forms part of its lateral wall. The carotid and jugular foramina lie in the posterior part of this extended infratemporal fossa. (Adapted with permission from Berkovitz BKB, Moxham BJ, Telling D 1994 Color Atlas of the Skull, London, Mosby, and Hosseini SMS, Razfar A, Carrau RL et al 2012 Endonasal transpterygoid approach to the infratemporal fossa: correlation of endoscopic and multiplanar CT anatomy. Head and Neck 34:313–20.)

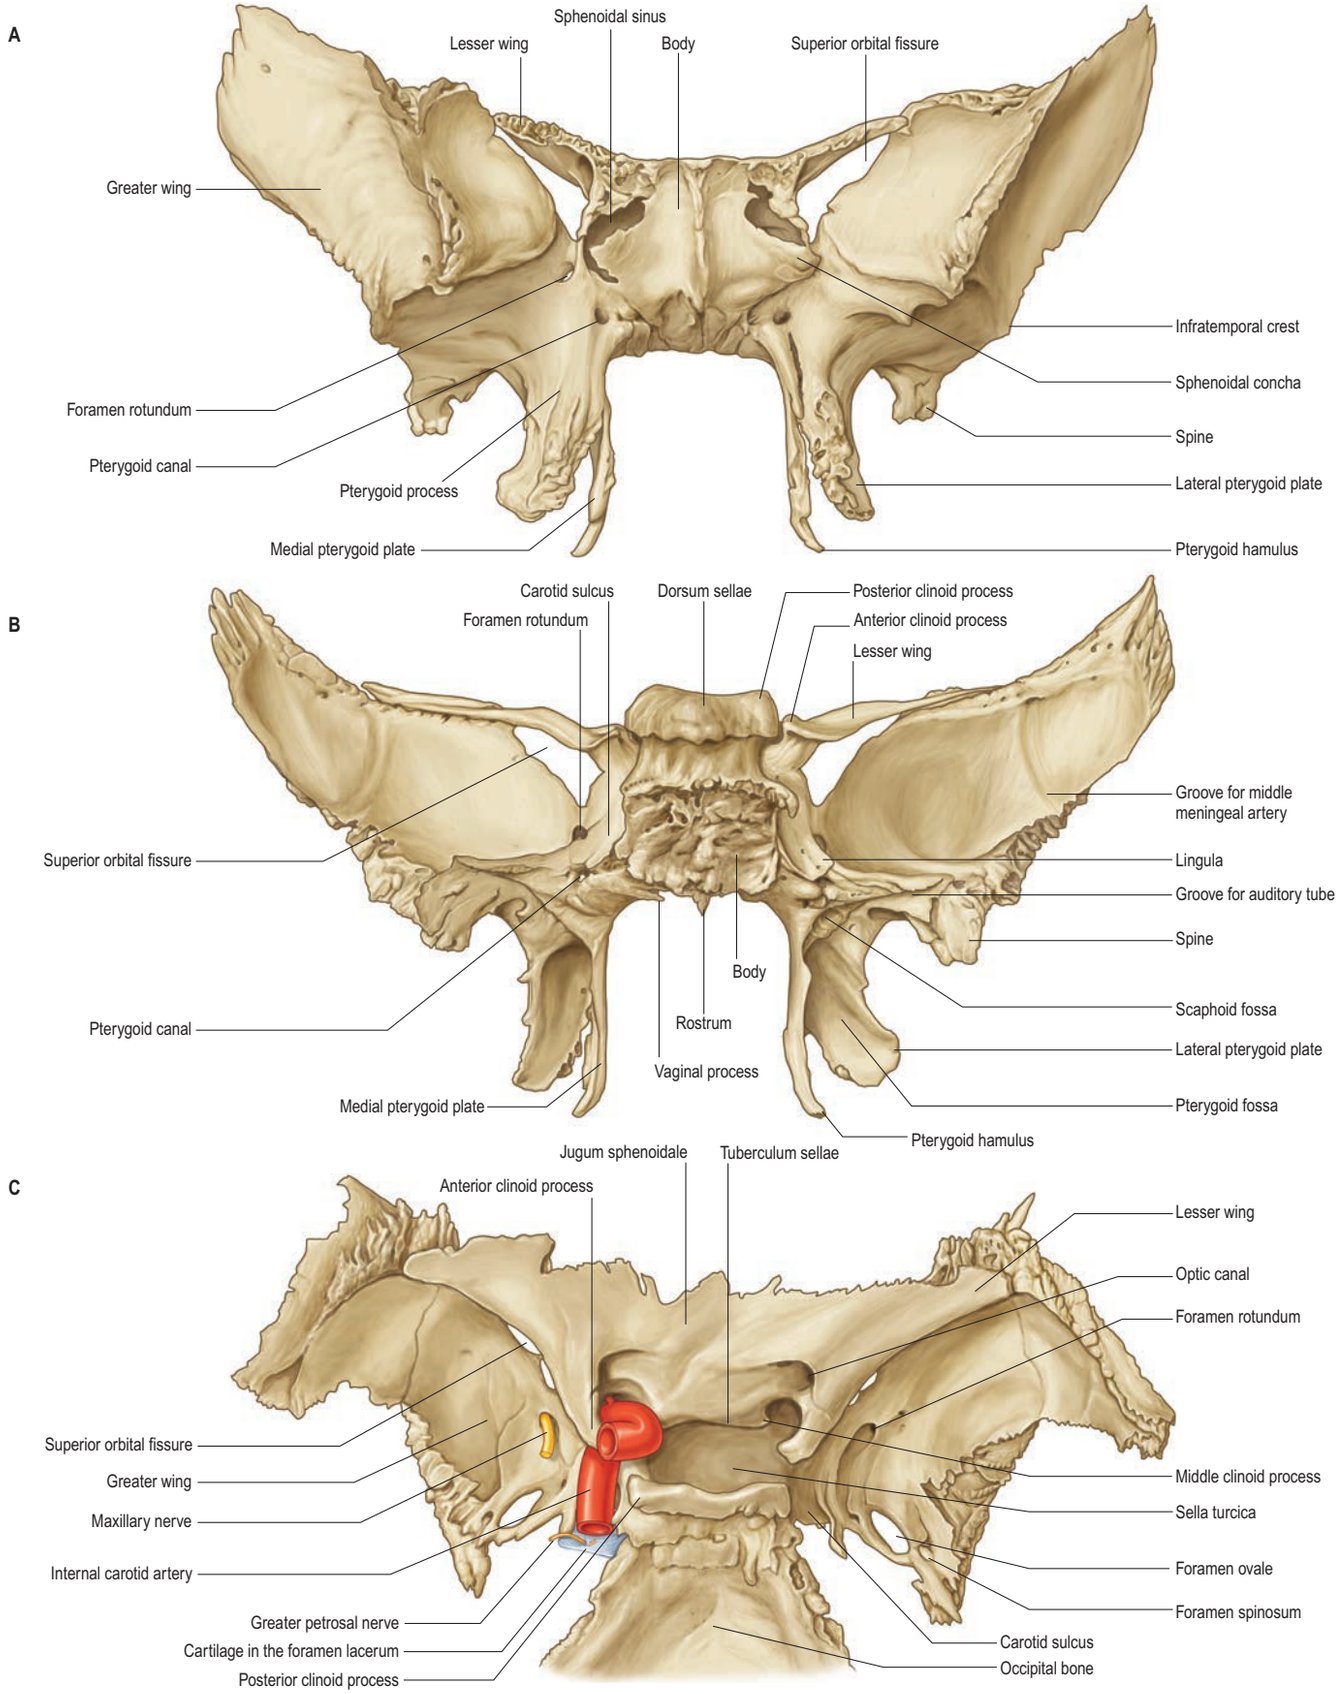

Fig. 38.3 The sphenoid bone. **A**, Anterior view. **B**, Posterior view. **C**, Superior view. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

the dorsum sellae, a small petrosal process articulates with the apex of the petrous part of the temporal bone. The body of the sphenoid slopes directly into the basilar part of the occipital bone posterior to the dorsum sellae and together these bones form the clivus. In the growing child, this is the site of the spheno-occipital synchondrosis: premature closure of this joint gives rise to the skull appearances seen in achondroplasia.

The lateral surfaces of the body are united with the greater wings and the medial pterygoid plates. A broad carotid sulcus accommodates both the internal carotid artery and the cranial nerves associated with the cavernous sinus above the root of each wing. The sulcus is deepest posteriorly and is overhung medially by the petrosal part of the temporal bone. Its sharp lateral margin, the lingula, continues back over the posterior opening of the pterygoid canal.

A median triangular bilaminar sphenoidal crest on the anterior surface of the body of the sphenoid makes a small contribution to the nasal septum. The anterior border of the crest articulates with the perpendicular plate of the ethmoid bone, and a sphenoidal sinus opens on either side of it. In the articulated state, the sphenoidal sinuses are closed anteroinferiorly by the sphenoidal conchae that are almost inevitably destroyed when disarticulating a dried skull. Each half of the anterior surface of the body of the sphenoid possesses a superolateral depressed area joined to the ethmoidal labyrinth that completes the posterior ethmoidal sinuses; a lateral margin that articulates with the orbital plate of the ethmoid above and the orbital process of the palatine bone below; and an inferomedial, smooth, triangular area that forms the posterior nasal roof. The orifice of a sphenoidal sinus lies near the superior angle of this triangular area.

The inferior surface of the body of the sphenoid bears a median triangular sphenoidal rostrum, embraced above by the diverging lower margins of the sphenoidal crest. The narrow anterior end of the rostrum fits into a fissure between the anterior parts of the alae of the vomer, and the posterior ends of the sphenoidal conchae flank the rostrum, articulating with its alae. A thin vaginal process projects medially from the base of the medial pterygoid plate on each side of the posterior part of the rostrum, behind the apex of the sphenoidal concha.

Greater wings

The greater wings of the sphenoid curve broadly superolaterally from the body. Posteriorly, each is triangular, fitting the angle between the petrous and squamous parts of the temporal bone at a sphenosquamosal suture. The cerebral surface contributes to the anterior part of the middle cranial fossa. Deeply concave, its undulating surface is adapted to the anterior gyri of the temporal lobe of the cerebral hemisphere. The foramen rotundum lies anteromedially and transmits the maxillary nerve. The foramen ovale, posterolateral to the foramen rotundum, transmits the mandibular nerve, accessory meningeal artery and sometimes the lesser petrosal nerve, although the latter nerve may have its own canaliculus innominatus medial to the foramen spinosum. When present, a small emissary sphenoidal foramen (foramen of Vesalius) transmits a small vein from the cavernous sinus, and can lie medial to the foramen ovale (on one or both sides). The foramen spinosum lies behind the foramen ovale and transmits the middle meningeal artery and meningeal branch of the mandibular nerve.

The lateral surface is vertically convex and divided by a transverse infratemporal crest into temporal (upper) and infratemporal (lower) surfaces. Temporalis is attached to the temporal surface. The infratemporal surface is directed downwards and, with the infratemporal crest, is the site of attachment of the upper fibres of lateral pterygoid. It contains the foramen ovale and foramen spinosum. The small downward-projecting spine of the sphenoid lies posterior to the foramen spinosum; the sphenomandibular ligament is attached to its tip. The medial side of the spine bears a faint anteroinferior groove for the chorda tympani nerve and appears in the lateral wall of the sulcus for the pharyngotympanic tube. A ridge passes downwards to the front of the lateral pterygoid plate, medial to the anterior end of the infratemporal crest, and forms a posterior boundary of the pterygomaxillary fissure.

The quadrilateral orbital surface of the greater wing faces anteromedially and forms the posterior part of the lateral wall of the orbit. It has a serrated upper edge that articulates with the orbital plate of the frontal bone, and a serrated lateral margin that articulates with the zygomatic bone. Its smooth inferior border is the posterolateral edge of the inferior orbital fissure, and its sharp medial margin forms the inferolateral edge of the superior orbital fissure, on which a small tubercle gives partial attachment to the common anular ocular tendon. Below the medial end of the superior orbital fissure, a grooved area forms the posterior wall of the pterygopalatine fossa that is pierced by the foramen rotundum.

The irregular margin of the greater wing, from the body of the sphenoid to the spine, is an anterior limit of the medial half of the foramen lacerum. It contains the posterior aperture of the pterygoid canal and its lateral half articulates with the petrous part of the temporal bone at a sphenopetrosal synchondrosis. The sulcus tubae inferior to the synchondrosis contains the cartilaginous pharyngotympanic (auditory) tube. Anterior to the spine of the sphenoid the concave squamosal margin is serrated, bevelled internally below and externally above, for articulation with the squamous part of the temporal bone. The tip of the greater wing, bevelled internally, articulates with the sphenoidal angle of the parietal bone at the pterion. Medial to this, a triangular rough area articulates with the frontal bone; its medial angle is continuous with the inferior boundary of the superior orbital fissure, and its anterior angle joins the zygomatic bone by a serrated articulation. Fractures of the zygomatic bone preferentially pass through this articulation with the greater wing because it is a line of weakness in the lateral orbit.

Lesser wings

The lesser wings of the sphenoid are triangular pointed plates that protrude laterally from the anterosuperior regions of the body. The superior surface of each wing is smooth and related to the frontal lobe of the cerebral hemisphere. The inferior surface is a posterior part of the orbital roof and upper boundary of the superior orbital fissure and overhangs the middle cranial fossa. The posterior border projects into the lateral fissure of the cerebral hemisphere. The medial end of the lesser wing forms the anterior clinoid process: the anterior and middle clinoid processes are sometimes united to form a caroticoclinoid foramen. The lesser wing is connected to the body by a thin, flat anterior root and a thick, triangular posterior root (the optic strut), between which lies the optic canal. The optic strut extends from the base of the anterior clinoid process to the body and separates the optic canal from the superior orbital fissure. The optic canal is bounded by the body of the sphenoid medially, the lesser wing superiorly, and the optic strut inferiorly and laterally.

Superior orbital fissure

The superior orbital fissure connects the cranial cavity with the orbit. It is bounded medially by the body of the sphenoid; above by the lesser wing of the sphenoid; below by the medial margin of the orbital surface of the greater wing; and laterally, between the greater and lesser wings, by the frontal bone. The contents of the superior orbital fissure are described in Chapter 44 (see Fig. 44.4).

Pterygoid processes

The pterygoid processes descend perpendicularly from the junctions of the greater wings and body. Each consists of a medial and lateral plate with upper parts that are fused anteriorly. The plates are separated below by the angular pterygoid fissure: the margins of the fissure articulate with the pyramidal process of the palatine bone and diverge behind. Medial pterygoid lies in the cuneiform pterygoid fossa between the plates. Above is the small, oval, shallow scaphoid fossa, formed by division of the upper posterior border of the medial plate. Part of tensor veli palatini is attached to the fossa. The anterior surface of the root of the pterygoid process is broad and triangular: it forms the posterior wall of the pterygopalatine fossa and is pierced by the anterior opening of the pterygoid canal.

Lateral pterygoid plate

The lateral pterygoid plate is broad, thin and everted. The lateral surface forms part of the medial wall of the infratemporal fossa and the lower part of lateral pterygoid is attached to it. The medial surface is the lateral wall of the pterygoid fossa and most of the deep head of medial pterygoid is attached to it. The upper part of its anterior border is a posterior boundary of the pterygomaxillary fissure, and the lower part articulates with the palatine bone. The posterior border is free.

Medial pterygoid plate

The medial pterygoid plate is narrower and longer than the lateral. Its lower end is continued into an unciform projection, the pterygoid hamulus, which curves laterally. The pterygomandibular raphe is attached to the hamulus, and the tendon of tensor veli palatini winds around the hamulus. The lateral surface forms the medial wall of the pterygoid fossa and the medial surface provides a lateral boundary for the posterior nasal aperture. The medial plate is prolonged above on the inferior aspect of the body of the sphenoid as a thin vaginal process that articulates anteriorly with the sphenoidal process of the palatine bone and medially with the ala of the vomer. The plate articulates with the posterior border of the perpendicular plate of the palatine bone in the lower part of its anterior margin. Inferiorly, it bears a furrow that is converted anteriorly into the palatovaginal canal by the sphenoidal process of the palatine bone. The palatovaginal canal transmits pharyngeal branches of the maxillary artery and pterygopalatine ganglion. The pharyngobasilar fascia is attached to the whole of the posterior margin of the medial plate, and the superior pharyngeal constrictor is attached to its lower end. The small pterygoid tubercle is found at the upper end of the plate, just below the posterior opening of the pterygoid canal. The processus tubarius, which supports the cartilaginous pharyngeal end of the pharyngotympanic tube, projects back near the midpoint of the margin of the medial pterygoid plate.

Though adjacent, the medial and lateral pterygoid plates have distinct roles. The lateral plate is the province of the infratemporal fossa and masticator space, forming part of the medial boundary of the infratemporal fossa and providing attachment for the lateral and medial pterygoids. The medial plate is functionally related to the pharynx, providing

attachment for the pharyngobasilar fascia, superior constrictor and pterygomandibular raphe.

Midface fractures Midface fractures at Le Fort I, II and III levels invariably involve the pterygoid plates at different levels; displacement of the outlines of these bones radiographically confirms the diagnosis. Midface fractures and current classification of these injuries are described and discussed in Chapter 36.

Sphenoidal conchae

The sphenoidal conchae are two thin, curved small plates, attached anteroinferiorly to the body of the sphenoid bone. The superior concave surface of each forms the anterior wall and part of the floor of a sphenoidal sinus. *In situ*, each has vertical quadrilateral anterior and horizontal triangular posterior parts. The anterior part consists of a superolateral depressed area that completes the posterior ethmoidal sinuses and joins below with the orbital process of a palatine bone, and a smooth and triangular inferomedial area that forms part of the nasal roof and is perforated above by a round opening connecting the sphenoidal sinus and spheno-ethmoidal recess.

Anterior parts of the two bones meet in the midline and protrude as the sphenoidal crest. The horizontal part appears in the nasal roof and completes the sphenopalatine foramen. Its medial edge articulates with the rostrum of the sphenoid and the ala of the vomer. Its apex, directed posteriorly, is superomedial to the vaginal process of the medial pterygoid plate and joins the posterior part of the ala. A small conchal part sometimes appears in the medial wall of the orbit, lying between the orbital plate of the ethmoid anteriorly, the orbital process of the palatine bone inferiorly and the frontal bone superiorly.

Ossification

Until postmenstrual weeks 25–32, the sphenoid body has a presphenoidal part, anterior to the tuberculum sellae and continuous with the lesser wings, and a postsphenoidal part, consisting of the sella turcica and dorsum sellae, that is integral with the greater wings and pterygoid processes. Much of the bone is preformed in cartilage. There are six ossification centres for the presphenoidal parts and eight centres for the postsphenoidal parts.

Presphenoidal part

At about postfertilization weeks 8–9 (postmenstrual week 10–11), a centre appears in each wing, lateral to the optic canal; two bilateral centres appear in the presphenoidal body a little later. Each sphenoidal concha has a centre that appears superoposteriorly in the nasal capsule during postmenstrual weeks 17–20. As it enlarges, it partly surrounds a posterosuperior expansion of the nasal cavity that becomes the sphenoidal sinus. The posterior conchal wall is absorbed and the sinus invades the presphenoidal component. The concha fuses with the ethmoidal labyrinth in the fourth year and with the sphenoid and palatine bones before puberty; its anterior deficiency persists as an opening for the sphenoidal sinus.

Postsphenoidal part

The first centres appear in the greater wings at about postmenstrual week 11, one in the basal cartilage of each wing below the foramen rotundum. These centres only contribute to the root of the greater wing (near the foramen rotundum and pterygoid canal). The remainder of the greater wing and the lateral pterygoid plate are ossified in mesenchyme. Two centres flanking the sella turcica appear between postmenstrual weeks 13 and 16 and soon fuse. The medial pterygoid plates are also ossified in 'membrane', a centre in each probably appearing in about postmenstrual weeks 9 or 10. The hamulus is chondrified during postmenstrual weeks 9–12 and begins to ossify at once. The medial and lateral pterygoid plates join at about postmenstrual weeks 21–24. A centre for each lingula appears during postmenstrual weeks 13–16 and soon joins the body. The neonatal optic canal is relatively large and has a keyhole or 'figure of eight' shape rather than the circular profile seen in the adult (Lang 2001).

Postnatal details

Presphenoidal and postsphenoidal parts fuse at about postmenstrual weeks 29–32; an unciform cartilage persists after birth in the lower parts of this junction. At birth, the bone is tripartite and consists of a central part (body and lesser wings) and two lateral parts that each consist of a greater wing and pterygoid process. During the first year, the greater wings and body unite around the pterygoid canals, and the lesser wings extend medially above the anterior part of the body, meeting to form the smooth, elevated jugum sphenoidale. By the twenty-fifth year, the sphenoid and occipital bones are completely fused. An occasional vascular foramen, often erroneously termed the craniopharyngeal canal, is occasionally seen in the anterior part of the hypophysial fossa.

Although the sphenoidal sinus can be identified between postmenstrual weeks 13 and 16 as an evagination of the posterior part of the nasal capsule, by full-term birth (notionally postmenstrual week 40) it represents an outgrowth of the spheno-ethmoidal recess. Pneumatization of the body of the sphenoid has been identified from 4 postnatal months and a distinct cell is visible by 2 years. Pneumatization spreads first into the presphenoid and later invades the postsphenoid part. The sinus reaches full size in adolescence, but often enlarges further by absorption of its walls as age advances.

Certain parts of the sphenoid are connected by ligaments that may occasionally ossify, e.g. the pterygospinous ligament between the sphenoidal spine and the upper part of the lateral pterygoid plate; the interclinoid ligament between the anterior and posterior clinoid processes; and the caroticoclinoid ligament between the anterior and middle clinoid processes.

Premature synostosis of the junction between pre- and postsphenoidal parts, or of the spheno-occipital suture, produces a characteristic appearance, obvious in profile, of an abnormal depression of the nasal bridge.

Stylohamular plane

Mandible

The mandible is the largest, strongest and lowest bone in the face. It has a horizontally curved body that is convex forwards, and two broad rami that ascend posteriorly (**Fig. 38.5**). The body of the mandible supports the mandibular teeth within the alveolar process. The rami bear the coronoid and condylar processes. Each condyle articulates with the adjacent temporal bone at the temporomandibular joint.

Body

The body has external and internal surfaces separated by upper and lower borders. Anteriorly, the upper external surface shows an inconstant faint median ridge indicating the site of the fused symphysis menti. Inferiorly, this ridge divides to enclose a triangular mental protuberance; its base is centrally depressed but raised on each side as a mental tubercle. The mental protuberance and mental tubercles constitute the chin. The mental foramen, from which the mental neurovascular bundle emerges, lies midway between the upper and lower borders of the body, below either the interval between the premolar teeth, or the second premolar tooth. The posterior border of the foramen is smooth and accommodates the nerve as it emerges posterolaterally. A faint external oblique line ascends backwards from each mental tubercle and sweeps below the mental foramen, becoming more marked as it continues into the anterior border of the ramus.

The lower border of the body, the base, extends posterolaterally from the mandibular symphysis into the lower border of the ramus behind the third molar tooth. The anterior belly of digastric is attached to a rough digastric fossa near the midline on each side. Behind the fossa, the base of the body is thick and rounded, with a slight anteroposterior convexity that changes to a gentle concavity as the ramus is approached, giving the base an overall sinuous profile.

The upper border, the alveolar part, contains 16 alveoli for the roots of the lower teeth. It consists of buccal and lingual plates of bone joined by interdental and inter-radicular septa. Near the second and third molar teeth, the external oblique line is superimposed on the buccal plate. As is the case in the maxilla, the form and depth of the mandibular tooth sockets is related to the morphology of the roots of the mandibular teeth. The sockets of the incisor, canine and premolar teeth usually contain a single root, while those for the three molar teeth each contain two or three roots. The third molar is variable in its position and root presentation: it may be impacted vertically, horizontally, mesially or distally, and its roots may be bulbous, hooked, divergent or convergent, and occasionally embrace the mandibular (inferior dental) canal. The internal surface of the mandible is divided by an oblique mylohyoid line that gives attachment to mylohyoid and, above its posterior end, to the superior pharyngeal constrictor, some retromolar fascicles of buccinator, and the pterygomandibular raphe behind the third molar. The mylohyoid line extends from a point approximately 1 cm from the upper border behind the third molar as far forwards as the mental symphysis; it is sharp and distinct near the molars but faint further forwards. The mylohyoid groove extends downwards and forwards from the ramus below the posterior part of the mylohyoid line and contains the mylohyoid neurovascular bundle. The area below the line is a slightly concave submandibular fossa and is related to the submandibular gland.

A plane exists between the pharyngeal side wall and the infratemporal fossa/masticator space. It is readily identified by palpating the tip of the styloid process and with gentle blunt finger dissection passing anteriorly and medially to the pterygoid hamulus at the lower border of the medial pterygoid plate. Termed the 'stylohamular plane' (Friedman et al 1981), it defines the medial and superior boundaries of the infratemporal fossa and is the medial boundary for tumours confined to the infratemporal fossa. With resections using the stylohamular plane as a guide, the internal carotid artery, internal jugular vein and the vagus nerve should not be at risk because they are deep to the styloid apparatus (**Fig. 38.4**).

The area above the line widens anteriorly into a triangular sublingual fossa and is related to the sublingual gland; the bone is covered by mucosa above the sublingual fossa as far back as the third molar. In an edentulous subject, it may be necessary to reduce any ridge-like prominence of the mylohyoid line so that dentures can fit without traumatizing the overlying oral mucosa.

Above the anterior ends of the mylohyoid lines, the posterior symphysial aspect bears a small elevation that is often divided into upper and lower parts, the mental spines (genial tubercles). The spines are sometimes fused to form a single eminence, or they may be absent, in which case their position is indicated merely by an irregularity of the surface. Genioglossus is attached to the upper part, and geniohyoid is attached to the lower part. Midline lingual (genial) foramina, above and/or below the genial tubercles, and lateral lingual foramina in the premolar region are present in most mandibles and are of importance in the vascular supply to the symphysis. A rounded elevation of compact bone, the torus mandibularis, sometimes develops above the mylohyoid line; it is most prominent in the premolar region, is usually bilateral and only of clinical significance if repeatedly traumatized.

Ramus

The mandibular ramus is quadrilateral. It has two surfaces (lateral and medial), four borders (superior, inferior, anterior and posterior) and two processes (coronoid and condylar). The lateral surface is relatively featureless and bears the (external) oblique ridge in its lower part. On the medial surface, the mandibular foramen lies midway between the anterior and posterior borders of the ramus, about level with the occlusal surfaces of the teeth. The inferior alveolar neurovascular bundle passes through the foramen to gain access to the mandibular canal. The foramen is overlapped anteromedially by a thin, sharp, triangular spine, the lingula, to which the sphenomandibular ligament is attached, and which is the landmark for an inferior alveolar local anaesthetic block injection. There is often a small prominence on the lateral surface of the ramus level with the lingula that forms a guide during surgical exposure of the lateral surface for osteotomies of the vertical ramus. Below and behind the foramen, the mylohyoid groove runs obliquely downwards and forwards.

The inferior border is continuous with the mandibular base and meets the posterior border at the angle, which is typically everted in males but frequently inverted in females. The thin superior border bounds the mandibular incisure (sigmoid or mandibular notch, incisura semilunaris), which is surmounted in front by the somewhat triangular, flat coronoid process and behind by the condylar process. The thick, rounded posterior border extends from the condyle to the angle, and is gently convex backwards above and concave below. The anterior border is thin above, where it is continuous with the edge of the coronoid process, and thicker below, where it is continuous with the external oblique line. The temporal crest is a ridge that descends on the medial side of the coronoid process from its tip to the bone just behind the third molar tooth. The triangular depression between the temporal crest and the anterior border of the ramus is the retromolar fossa (retromolar trigone).

The ramus and its processes provide attachment for the four primary muscles of mastication: masseter to the lateral surface; medial pterygoid to the medial surface; temporalis to the coronoid process and anterior ramus; the inferior head of lateral pterygoid to the condyle. The thickness of the ramus decreases markedly behind the external oblique line laterally, the temporal crest medially, and above the lingual, and there may be fusion of the lateral and medial cortical plates. This is of importance in mandibular ramus osteotomies and also influences the frequency of fractures of the mandibular angle.

Antilingula

Available with the *Gray's Anatomy* e-book

Mandibular canal

The mandibular foramen leads into the mandibular canal, which runs downwards and forwards within the ramus, gently curving inferiorly within the body under the roots of the molar teeth, with which it communicates by small openings, and ascending in the premolar region to the mental foramen. The canal is not always easy to define on plain X-rays, especially anterior to the mental foramen. Its walls may be formed either by a thin layer of cortical bone or, more frequently, by trabecular bone. Although the buccal–lingual and superior–inferior positions of the canal vary considerably between mandibles, in general, the mandibular canal is situated nearer the lingual cortical plate in the posterior two-thirds of the bone, and closer to the labial cortical plate in the anterior third. Bilateral symmetry (location of the canal in each half of the mandible) is reported to be common. Near the mental foramen, the inferior alveolar nerve branches into the mental nerve, which ultimately leaves the mandible via the mental foramen, and the incisive nerve, which remains within the bone and supplies the anterior teeth. The mental nerve may extend anteriorly for 2–3 mm within the mandible before curving back to the mental foramen (the 'anterior loop' of the mental nerve). Appreciation of the three-dimensional course of the mandibular canal during its passage through the mandible from the mandibular to the mental foramina is essential if damage to the inferior alveolar nerve is to be avoided in third molar surgery, mandibular osteotomies, dental implant surgery and harvesting of mandibular bone grafts.

Coronoid process

The coronoid process projects upwards and slightly forwards as a triangular plate of bone. Its posterior border bounds the mandibular incisure and its anterior border continues into that of the ramus.

Coronoid hyperplasia

Available with the *Gray's Anatomy* e-book

Condylar process

The mandibular condyle varies considerably in both size and shape. It consists of a core of cancellous bone covered by a thin outer layer of compact bone; the intra-articular aspect is covered by layers of fibrocartilage. When viewed from above, the condyle is roughly ovoid in outline, its anteroposterior dimension (approximately 1 cm) being roughly half its mediolateral dimension. The long axis of the condyle is at right-angles to that of the mandibular ramus but, as a result of the flare of the ramus, the lateral pole of the condyle is slightly anterior to the medial: if the long axes of the two condyles are extended, they meet at an obtuse angle, varying from 145° to 160°, at the anterior border of the foramen magnum. The slender neck of the condyle expands transversely upwards and joins the ramus to the articular head. The pterygoid fovea, a small depression on the anterior surface of the neck below the articular surface, receives part of the attachment of the inferior head of lateral pterygoid. The condyle is one of the most common sites for mandibular fractures.

Condylar hyper- and hypoplasia

Available with the *Gray's Anatomy* e-book

Accessory foramina

Accessory mandibular foramina are usually unnamed and infrequently described, and yet they are numerous. They may transmit auxiliary nerves to the teeth (from facial, mylohyoid, buccal, transverse cervical cutaneous, lingual and other nerves), and their occurrence is significant in dental anaesthetic blocking techniques. The innervation of the teeth is discussed in Chapter 37. The accessory lingual foramina in the mandibular symphysis are particularly relevant in dental implant surgery and osteotomies, e.g. genioplasty, at this site.

Ossification

The mandible forms in dense fibromembranous tissue lateral to the inferior alveolar nerve and its incisive branch, and also in the lower parts of Meckel's cartilage (first branchial arch). Each half is ossified from a centre that appears near the mental foramen between postfertilization days 42 and 50. From this site, ossification spreads medially and posterocranially to form the body and ramus, first below, and then around, the inferior alveolar nerve and its incisive branch. Ossification then spreads upwards, initially forming a trough, and later crypts, for the developing teeth. From postmenstrual week 10, Meckel's cartilage below the incisor rudiments is surrounded and invaded by bone. The mandibular condyle and coronoid process do not develop from the primary (Meckel's) cartilage but from secondary cartilages that appear later (Fig. 38.6). A conical mass, the condylar cartilage, extends from the mandibular head downwards and forwards in the ramus, and contributes to its growth in height. Although it is largely replaced by bone by midfetal life, its proximal end persists as proliferating cartilage under the fibrous articular lining until about the third decade. Another secondary cartilage, which soon ossifies, appears along the anterior coronoid border, and disappears before birth. One or two cartilaginous nodules also occur at the symphysis menti. These may ossify as variable mental ossicles in symphysial fibrous tissue between postmenstrual weeks 25 and 28; they unite with adjacent bone before the end of the first postnatal year.

Age changes in the mandible

At birth, the two halves of the mandible are united by a fibrous symphysis menti (Fig. 38.7B). The anterior ends of both rudiments are covered

The term 'antilingula' has been used to describe an inconstant bony prominence on the lateral aspect of the ramus. This localized bulge, initially thought to be the result of the entrance of the inferior alveolar neurovascular bundle into the medial ramus, has been used as a guide to the position of the mandibular foramen in mandibular osteotomies. However, there is little correlation between the position of the antilingula and the mandibular foramen. It has been suggested that the prominence (when present) on the lateral ramus could reflect the insertion of fibres of masseter (Lang 1995, Hogan and Ellis 2006, Park et al 2014).

The availability of computed tomography (CT), cone beam CT (CBCT) imaging and computer-assisted intraoperative navigation permits the assessment of the course of the mandibular canal throughout its length both prior to and during any surgical procedure that could place the inferior alveolar nerve and/or the mental nerve at risk (Aizenbud et al 2012, Wittwer et al 2012).

Elongation of the coronoid process may be found bilaterally or unilaterally, resulting in progressive, painless restriction of mandibular opening, as a result of the impingement of the coronoid process on the medial aspect of the zygomatic arch(es) or on the posterior maxilla. This rare condition is more common in patients with ankylosis (fusion) of the temporomandibular joint as a reactive response to attempted muscle function against resistance and more common in males. It usually presents in the middle of the third decade, although it has been reported in neonates. The aetiology is unknown. Treatment involves the resection of the coronoid process(es) (McLoughlin et al 1995, Satoh et al 2006, Mulder et al 2012).

Hyperplasia of the mandibular condyle is a rare unilateral condition that results in facial asymmetry and an altered occlusion (bite). The condition may present at any age; if it develops prior to puberty, growth may not cease at the end of the growth period. Reports vary as to male : female ratio. Although condylar hyperplasia is said to be self-limiting, removal of the growth site in the condyle may be necessary to arrest the condition. Correction of the asymmetry of the jaw is usually performed; however, self-correction of the asymmetry has been reported. A variety of classification systems have been suggested (Obwegeser and Make 1986, Nitzan et al 2008, Nitzan 2009, Wolford et al 2014).

Condylar hypoplasia is also uncommon. It is often associated with more extensive craniofacial anomalies, particularly hemifacial microsomia, where many of the first arch structures fail to develop fully and with failure of the development of the whole temporomandibular articulation. The condition has been subclassified by Pruzansky (1969) and a modified version by Kaban et al (1981): currently the OMENS classification is widely used to assess both bone and soft tissue defects (Vento et al 1991).

by cartilage, separated only by a symphysis. Until fusion occurs, new cells are added to each cartilage from symphysial fibrous tissue, and ossification on its mandibular side proceeds towards the midline. When the latter process overtakes the former and ossification extends into median fibrous tissue, the symphysis fuses. At this stage, the body is a mere shell, which encloses the imperfectly separated sockets of deciduous teeth. The mandibular canal is near the lower border, and the mental foramen opens below the first deciduous molar and is directed forwards. The condyle is almost in line with the occlusal plane of the mandible and the coronoid projects above the condyle. During the first three postnatal years, the two halves join at their symphysis from below upwards, although separation near the alveolar margin may persist into the second year. The body elongates, especially behind the mental foramen, providing space for three additional teeth. During the first and second years, as a chin develops, the mental foramen alters direction; it no longer faces forwards but now faces backwards, as in the adult mandible, and accommodates the changing direction of the emerging mental nerve.

In general terms, increase in height of the body of the mandible is achieved primarily by formation of alveolar bone associated with the developing and erupting teeth, although some bone is also deposited on the lower border. Increase in length of the mandible is accomplished by deposition of bone on the posterior surface of the ramus and concomitant compensatory resorption on the anterior surface (accompanied by deposition of bone on the posterior surface of the coronoid process and resorption on the anterior surface of the condylar process); a part of the ramus is therefore modelled into an addition to the mandibular body. Increase in width of the mandible is produced by deposition of bone on the outer surface of the mandible and resorption on the inner surface. An increase in the comparative size of the ramus compared with the body of the mandible occurs during postnatal growth and tooth eruption.

The role of the condylar cartilages in mandibular growth remains controversial. One view suggests that continued proliferation of this cartilage is primarily responsible for the increase in both the mandibular length and the height of the ramus. Alternatively, there is persuasive experimental evidence that proliferation of the condylar cartilage is an adaptive response to function, rather than being genetically determined. Condylar growth and remodelling have been shown to be influenced significantly by local factors – notably, movement and loading of the temporomandibular joint – and to be relatively immune to systemic influences such as vitamin C and D deficiency. Considering the changes that occur in the dentition throughout life, continuous adaptation of the temporomandibular articulation is required in order to maintain functional occlusal alignment between the upper and lower arches of teeth; this adaptation is thought to be largely the result of ongoing condylar remodelling.

In adults, alveolar and subalveolar regions are about equal in depth, and the mental foramen appears midway between the upper and lower borders. If teeth are lost, alveolar bone is resorbed, and both the mental foramen and the mandibular canal come to lie closer to the superior border (Fig. 38.7A). The mental foramen is placed higher than the mandibular canal posterior to it, and so resorption of the alveolus in edentulous patients exposes the nerve at the foramen, i.e. prior to the nerve in the mandibular canal (Cawood and Howell 1988, Lang 1995, Eufinger et al 1997).

Bone resorption in the mandible

Available with the *Gray's Anatomy* e-book

Blood supply of the mandible

The blood supply to the body of the mandible is derived from its principal nutrient artery, the inferior alveolar artery, and from the vessels supplying genioglossus, geniohyoid and the anterior belly of digastric (all muscles attached to the lingual aspect of the body of the mandible between the mental foramina). The blood supply to these muscles is from the sublingual branch of the lingual artery and the submental branch of the facial artery. Branches of these vessels may perforate the lingual cortical plate through lateral lingual foramina in the premolar region and genial foramina in the midline (when these foramina are present) (Fig. 38.10). Anastomoses are common. A branch of the submental artery may anastomose with the mental artery, permitting retrograde vascular supply to the body and symphysis (relevant in mandibular fractures). The vascular supply to the mandibular symphysis is of importance in dental implant surgery. The ramus, including the mandibular angle, is supplied by the inferior alveolar artery and from the vessels supplying masseter and medial pterygoid. Vessels supplying temporalis supply the coronoid process. The vascular supply to the

The pattern of bone resorption (atrophy) of the mandible following the loss of teeth is said to be in a centrifugal ('down and out') direction, compared to a centripetal direction in the maxilla. These differences produce a progressive increase in the incongruity of the alveolar processes of the jaws. Bone loss is not limited to the alveolar part; it can involve the base (basal bone) to varying degrees. Progressive remodelling of the mandible and maxilla accompany the bone loss; it is not limited to the body of the mandible but also involves the coronoid process and the mandibular condyle, and reduction in both the height and width of the ramus. This bone loss has implications in denture construction, dental implant surgery and mandibular fractures (**Figs 38.8–38.9**) (Cawood and Howell 1988, Eufinger et al 1997, Sutton et al 2004, Ellis and Price 2008, Aziz and Najjar 2009).

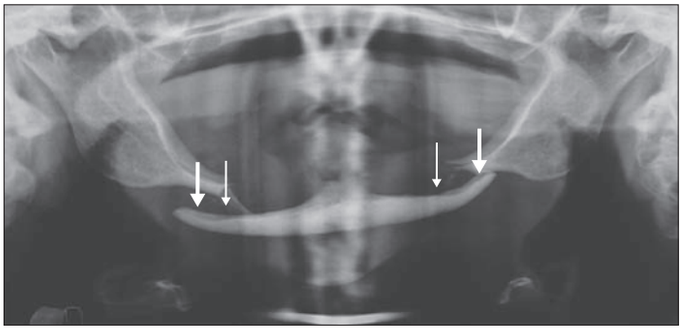

Fig. 38.9 Orthopantomogram showing a bilateral fracture of an edentulous atrophic mandible. There is complete loss of the alveolar process, extending into the underlying basal bone. The mental foramen (narrow arrows) and the mandibular canal (broad arrows) are at the superior border.

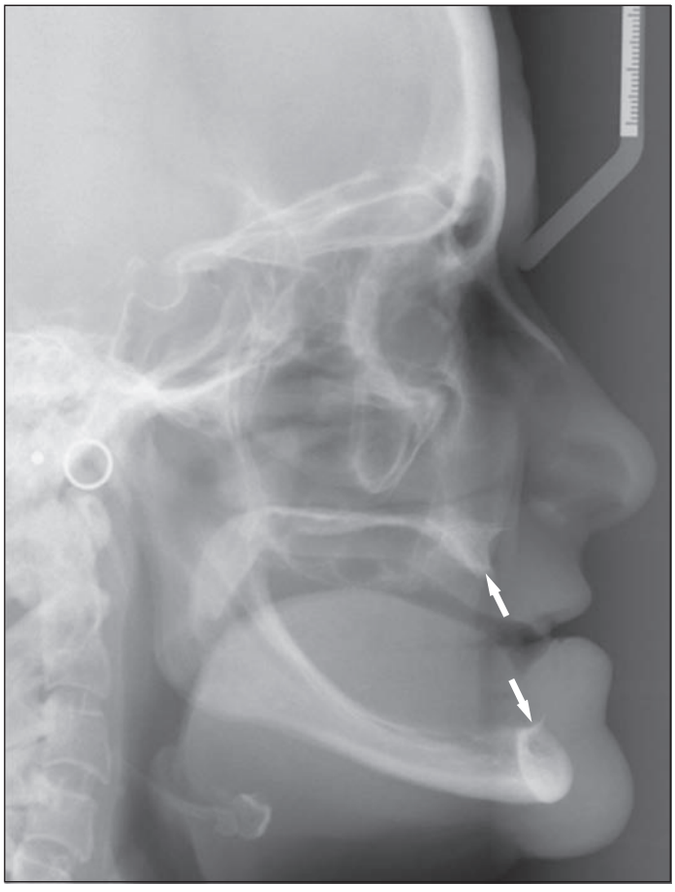

Fig. 38.8 Lateral skull radiograph showing the opposing direction (arrows) of resorption ('atrophy') of the mandible and maxilla, resulting in increasing incongruity between the jaws. The resorption involves the alveolus and the basal bone. (Courtesy of Dr Alf Nastri, Royal Melbourne Hospital.)

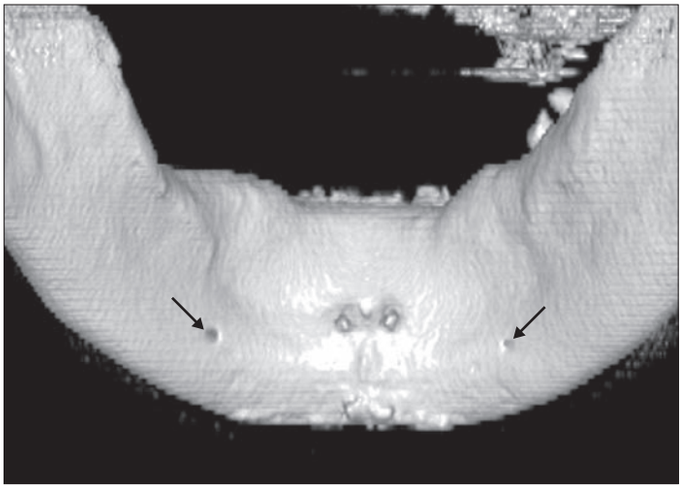

Fig. 38.10 A CT image showing the lateral lingual foramina (arrows). (Courtesy of Dr Koh Nakajima, with permission from Nakajima K, Tagaya A, Otonari-Yamamoto M et al 2014 Composition of the blood supply in the sublingual and submandibular spaces and its relationship to the lateral lingual foramen of the mandible. mandibular condyle, temporomandibular joint and the individual masticatory muscles is described below (McDonnel et al 1994, Janfanza et al 2001, Jacobs et al 2007, Romanos et al 2012, Nakajima et al 2014).

Endosseous blood supply to the mandible via lingual foramina

Available with the *Gray's Anatomy* e-book

Tissue spaces

The contents of the infratemporal fossa are contained within a well-defined space that is bounded by and incorporates the masticatory muscles and is termed the masticator space (Fernandes et al 2013). It contains temporalis, masseter, medial and lateral pterygoid, the ramus and coronoid process of the mandible, the mandibular nerve and otic ganglion, the maxillary artery and the pterygoid venous plexus, and part of the buccal fat pad anterolaterally. The masticator space is closed posteriorly by the attachment of the deep cervical fascia, medial pterygoid and masseter (pterygomasseteric sling), and anteriorly, lateral to the ramus, by the firm attachment of masseter (the submasseteric space is a 'potential' space). Above the level of the zygomatic arch, the temporal fascia provides both the superior and lateral limits, by its attachments to the superior temporal line and the zygomatic arch, respectively. Below the zygomatic arch, the investing layer of deep cervical fascia (superficial layer of deep cervical fascia) splits into two laminae to enclose masseter, the lower part of temporalis and medial pterygoid, further defining the boundaries of the masticator space. The superficial (lateral) lamina covers masseter and is attached to the zygomatic arch, and the deep (medial) lamina runs on the deep surface of medial pterygoid, attaching to the skull base medial to the foramen ovale (Guidera et al 2014). This fascial covering of the masticatory muscles is considered to be distinct from the parotid fascia (capsule). The superficial temporal space lies between the temporal fascia laterally and temporalis medially. The deep temporal space, like the submasseteric space, is a 'potential' space between temporalis laterally and the temporal fossa of the skull medially. Both spaces are in communication with the remainder of the masticator space inferiorly. There is a view that the upper limit of the masticator space should be at the level of the zygomatic arch, on the grounds that since both temporal spaces communicate with the remainder of the masticator space, a single masticator space incorporates the temporal fascia, muscles and temporal spaces. Medial to the ramus of the mandible, the pterygomandibular space (part of the masticator space) communicates freely with the pterygopalatine fossa, offering little resistance to the spread of infection or tumours. Posteriorly penetrating maxillary tumours directly involve the masticator space/infratemporal fossa and the pterygopalatine fossa. Resection of the masticator space has been termed a 'compartment' resection of the mandible (Blanchaert and Ord 1998, McMahon et al 2013) (**Fig. 38.12**).

TEMPOROMANDIBULAR JOINT

The temporomandibular joint (TMJ) is a synovial joint between the glenoid fossa (mandibular fossa) of the temporal bone and the mandibular condyle. It is unusual in that its articular surfaces are lined by fibrocartilage, rather than by hyaline cartilage: fibrocartilage is less susceptible to degeneration and has a greater repair capacity. The joint cavity is divided into upper and lower compartments ('spaces') by a fibrocartilaginous articular disc.

The anterior limit of the glenoid fossa is the articular eminence. This transverse ridge of dense bone, tilted down at an angle of approximately 25° to the occlusal plane, forms most of the articular surface of the mandibular fossa. It is strongly convex in the sagittal plane with a slight concavity in the coronal plane and extends out laterally to the zygomatic arch as the articular tubercle. The articular eminence may contain air cells from the mastoid in around 5% of cases on CT scan (Ladeira et al 2013), which may be clinically relevant when the eminence is surgically reduced or screws are placed for fixation. The roof of the glenoid fossa is thin and often translucent when held to the light, confirmation that this is not a major load-bearing area of the joint (Hylander 2006). The posterior wall is formed by the tympanic plate, which also forms the anterior wall of the external acoustic meatus.

The anterior articular area of the fossa (articular fossa) is formed entirely from the squamous portion of the temporal bone and lined by articular tissue that extends anteriorly beyond the articular summit on to the preglenoid plane. The squamotympanic fissure marks the junction with the posterior non-articular (tympanic) area. The tegmen tympani, a bony plate of the petrous temporal, intervenes in the medial aspect of the fissure, where the squamotympanic fissure becomes the petrotympanic fissure. The postglenoid tubercle at the root of the zygomatic arch, just anterior to the squamotympanic fissure, separates the squamotympanic fissure laterally from the tympanic plate.

The condylar head, tilted forwards on the neck at an angle of approximately 30° (physiological anteversion), articulates with the fossa on its anterior and superior surfaces. Like the eminence, both its slope and shape are variable and influenced by age, function and dentition. In the coronal plane, its shape varies from that of a gable (particularly marked in those whose diet is hard) to roughly horizontal (in the edentulous).

It is probably impossible to measure the pressure developed on the articular surfaces of the human jaw joint when biting: direct measurement of loads across the joint in animals has demonstrated significant intermittent loading during mastication. However, there is irrefutable theoretical evidence based on Newtonian mechanics that the jaw joint is a weight-bearing joint. With a vertical bite force of 500 N on the left first molar, the right condyle must support a load of well over 300 N (Osborn 1995). The non-working condyle is more loaded than the condyle on the working side, which may help explain why patients with a fractured condyle choose to bite on the side of the fracture.

Fibrous capsule

The lower part of the joint is surrounded by tight fibres that attach the condyle of the mandible to the disc (collateral ligament). The upper part of the joint is surrounded by loose fibres that attach the disc to the temporal bone (**Fig. 38.13**). Thus, the articular disc is attached separately to the temporal bone and to the mandibular condyle, forming what could be considered two joint capsules. These attachments stabilize the disc but allow rotation over the condyle. Longer fibres joining the condyle directly to the temporal bone may be regarded as reinforcing. The capsule is attached superiorly to the anterior edge of the preglenoid plane, posteriorly to the lips of the squamotympanic fissure, between these to the edges of the articular fossa, and inferiorly to the periphery of the neck of the mandible.

Ligaments

The ligaments of the temporomandibular joint are the temporomandibular (lateral), sphenomandibular and stylomandibular ligaments.

Temporomandibular (lateral) ligament

The broad temporomandibular ligament reinforces the joint capsule laterally and is attached superiorly to the articular tubercle on the root of the zygomatic process of the temporal bone (see Fig. 38.13). It extends downwards and backwards at an angle of approximately 45° to the horizontal, and is attached to the lateral surface and posterior border of the neck of the condyle, deep to the parotid gland. A short, almost horizontal band of collagen connects the articular tubercle anteriorly to the lateral pole of the condyle posteriorly and may function to prevent posterior displacement of the resting condyle and initiate translation of the condyle on mouth opening.

Sphenomandibular ligament

The sphenomandibular ligament is medial to, and normally separate from, the capsule (see Fig. 38.13). It is a flat, thin band that descends from the spine of the sphenoid. It widens as it reaches the lingula of the mandibular foramen, having an average width at its insertion into the mandible of about 12 mm. Some fibres traverse the medial end of the petrotympanic fissure and attach to the anterior malleolar process: they represent a vestige of the dorsal end of Meckel's cartilage.

With the jaw closed, there is approximately 5 mm slack within the ligament. It becomes taut when the jaw is about half open. Superiorly, lateral pterygoid, the auriculotemporal nerve and the maxillary artery and vein are lateral to the ligament, the nerve and vessels running between the ligament and the condylar neck. The chorda tympani nerve lies medially and occasionally grooves the spine of the sphenoid. Anteroinferiorly, the inferior alveolar nerve and vessels and a parotid lobule separate the ligament from the ramus of the mandible. The vessels and nerves to mylohyoid pierce the ligament adjacent to the lingula. Medial pterygoid is inferolateral. The sphenomandibular ligament is separated from the pharynx by fat and a pharyngeal vein.

The endosseous supply of the mandibular symphysis via the lingual foramina, and the rich vascular supply to the anterior floor of the mouth are of particular importance in dental implant surgery and osteotomies, e.g. genioplasty, at this site.

Foramina at the level of, or above, the genial tubercle (superior genial foramen) and below the genial tubercle (inferior genial foramen) are almost always found (McDonnel et al 1994, Jacobs et al 2007). Lateral lingual foramina are usually identified, with an average distance above the lower border of the mandible of 5 mm (Romanos et al 2012). The superior genial foramen may contain a branch of the lingual artery and nerve. The inferior foramen may contain a branch of the sublingual or submental arteries and a branch of the mylohyoid nerve. The lateral foramen may contain a branch of the submental artery (Jacobs et al 2007, Nakajima et al 2014). Although the relative contributions from the individual vessels vary, anastomoses between these perforating vessels and the inferior alveolar artery, within the mandible, are common. The soft tissues in the anterior floor of the mouth adjacent to the mandible are supplied by contributions from the sublingual, submental and mylohyoid arteries; there are considerable anastomoses between them (Flanagan 2003, Loukas et al 2008, Romanos et al 2012, Nakajima et al 2014). Brisk, potentially life-threatening haemorrhage has been reported with dental implant placement in the mandibular symphysis, usually associated with perforation of the lingual cortical plate of the mandible (Woo et al 2006, Loukas et al 2008, Dubois et al 2010, Romanos et al 2012) (**Fig. 38.11**) and death has resulted from genioplasty, secondary to haemorrhage in the anterior floor of the mouth (personal communication). The precise source of the haemorrhage can be difficult to detect and may arise from both within the mandible and the soft tissues in the floor of the mouth, from any of the above-named vessels. The anastomoses between the vessels may result in haemorrhage on both sides of mylohyoid and thus into the sublingual and the submental/submandibular spaces bilaterally. As the lateral and midline lingual foramina are closer to the lower border of the mandible, caution with longer implants has been recommended in this region.

Fig. 38.11 A three-dimensional reformatted CT image showing an implant perforating the lingual cortical plate (arrow), leading to haemorrhage in the anterior floor of the mouth. A tracheostomy was required to secure the airway. CHAPTER 38

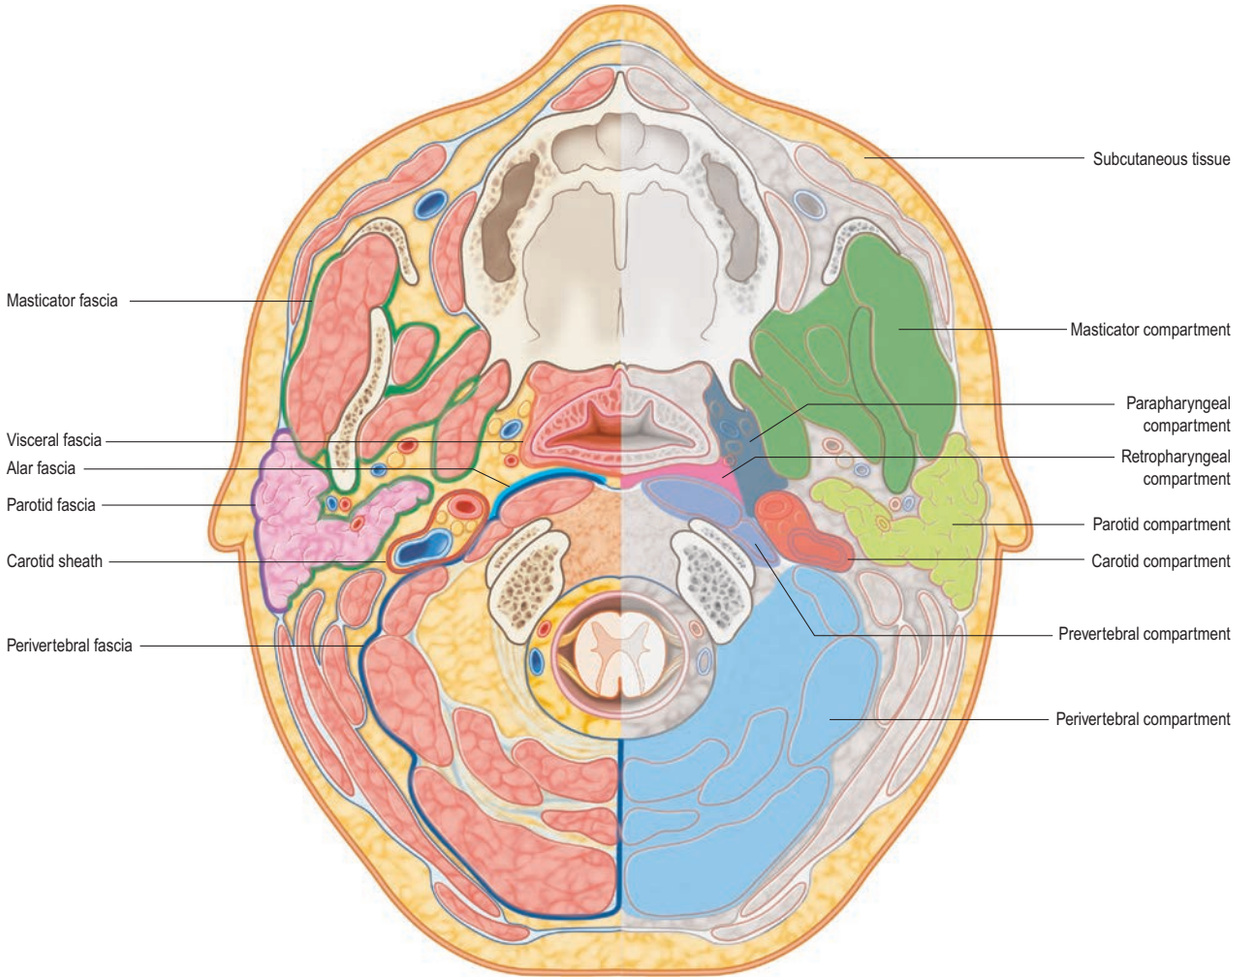

Fig. 38.12 A transverse section at the level of the hard palate demonstrating the cranial fascia (left) and associated compartments (right). (With permission from Guidera AK, Dawes PJD, Fong A et al 2014 Head and neck fascia and compartments: no space for spaces. Head Neck 36:1058–68.)

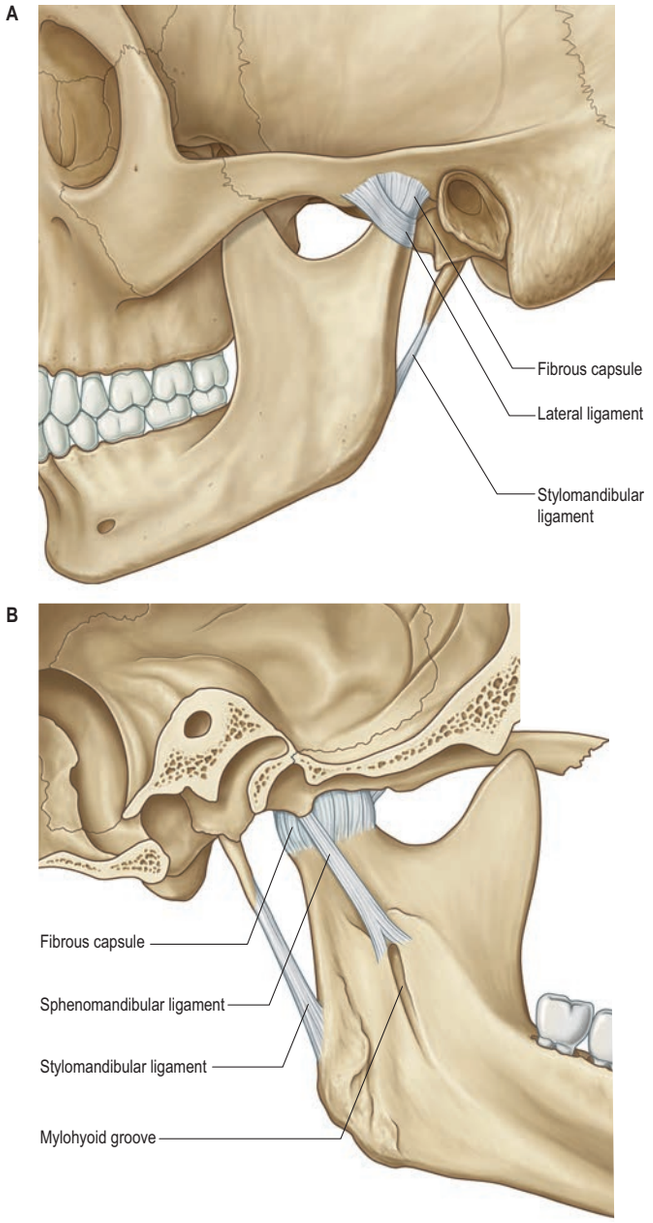

Fig. 38.13 The left temporomandibular joint. **A**, Lateral aspect. **B**, Medial aspect.

Stylomandibular ligament

The stylomandibular ligament is a thickened band of deep cervical fascia that stretches from the apex and adjacent anterior aspect of the styloid process to the angle and posterior border of the mandible (see Fig. 38.13). Its position and orientation indicate that it cannot mechanically constrain any normal movements of the mandible and does not seem to warrant the status of a ligament of the joint.

Synovial membrane

The synovial membrane lines the inside of the capsule of the joint but does not cover the disc or the articular surfaces (condyle, fossa or articular eminence). The synovium is most abundant in the bilaminar zone of the articular disc, forming loose folds posteriorly when the condyle is positioned in the glenoid fossa. These folds disappear when the condyle is protruded and the synovium is stretched.

Synovial fluid and joint lubrication

The coefficient of friction between the articulating surfaces of the temporomandibular joint is almost zero (Nickel et al 2006), reflecting the net result of a combination of adequate joint lubrication, the surface structure of the articulating surfaces and the articular disc. Joint lubrication depends on the synovial fluid, which also provides protection and nutrition to the articular surfaces and is the sole supplier of nutrients to the avascular disc. Surface active phospholipids (SAPLs) and hyaluronic acid are the key lubricants of the joint and act to protect the articular surfaces. Abnormalities of the joint lubrication system, e.g. changes resulting from uncontrolled oxidative stress, may play a role in the onset of some temporomandibular joint disorders such as anchored disc phenomenon (Nitzan 2001).

Articular surfaces

The anterior and superior surfaces of the mandibular condyle and the articular eminence and preglenoid plane of the squamous temporal bone are the principal articulating surfaces of the joint, as reflected in the thickness of the articular tissue covering these surfaces. The fibrocartilaginous covering of the condyle is composed of four distinct layers (De Bont et al 1984). The most superficial layer consists of densely packed fibres of type I collagen arranged mostly parallel to the articular surface and aligned in an anteroposterior direction (this can be seen as striation on arthroscopy – **Video 38.1**). This covers a thin cellular layer, the proliferative zone that is continuous with the cambial layer of the periosteum beyond the margins of the joint. The third layer, of hypertrophic cartilage, is rich in intercellular matrix and contains chondrocytes scattered throughout its depth and randomly orientated fibres of collagen type II. The fourth layer, immediately above the subchondral bone, is the zone of calcification. Although the number of chondrocytes within the hypertrophic zone decreases with age, undifferentiated mesenchymal cells have been identified in postmortem specimens of all ages (Hansson et al 1977), indicating a persistent capacity for proliferation and repair in condylar cartilage and may explain why condylar remodelling occurs throughout life (Toller 1974, Robinson 1993).

Articular disc

The articular disc divides the joint into a superior (discotemporal) space and an inferior (discomandibular) space, both filled with synovial fluid. The transversely oval disc is composed of avascular dense fibrous connective tissue with some chondrification in areas of maximum loading (**Fig. 38.14**). It has a thick margin forming a peripheral anulus and a central depression in its lower surface that accommodates the articular surface of the mandibular condyle. The depression probably develops as a mechanical response to pressure from the condyle as it rotates inside the anulus. The disc is stabilized on the condyle in three ways. Its edges are fused with the part of the capsular ligament that surrounds the lower joint compartment tightly and is attached around the neck of the condyle; well-defined bands in the capsular ligament attach the disc to the medial and lateral poles of the condyle (collateral ligaments); the thick anulus prevents the disc sliding off the condyle (self-centring capability), provided that the condyle and disc are firmly lodged against the articular fossa (as is normally the case).

In sagittal section, the disc has three distinct parts, namely an anterior band, a thinner intermediate zone and a posterior band. The posterior band is the thickest. Its upper surface is concavo-convex where it fits against the convex articular eminence and the concavity of the articular fossa. Posteriorly, the disc is attached to a richly vascularized and innervated region, the bilaminar zone (posterior attachment), that splits into two laminae: unlike the rest of the disc, its normal function is to provide attachment rather than intra-articular support. The upper lamina is composed of fibroelastic tissue and is attached to the squamotympanic fissure. A condensation of elastic fibres in the medial portion of the upper lamina is visible as the posterior oblique protuberance on arthroscopy (see Video 38.1). The lower lamina is composed of fibrous non-elastic tissue and is attached to the posterior aspect of the condyle. The intervening connective tissue between the upper and lower laminae contains a vascular plexus and is well innervated, but the central part of the disc itself is avascular and not innervated. With anterior movement of the disc–condyle complex, the volume of the posterior attachment increases as a result of the negative pressures generated, resulting in an influx of blood into the venous plexus: this pumping mechanism is important in the nutrition of the joint (Stegenga and de Bont 2006).

Upper and lower joint compartments

The upper joint space contains approximately 1.2 ml of synovial fluid and the lower approximately 0.9 ml. Both spaces may be considerably distended with fluid for diagnostic purposes in temporomandibular joint arthrography, for therapeutic purposes in arthrocentesis, and to improve access and visibility in arthroscopy. Both joint spaces

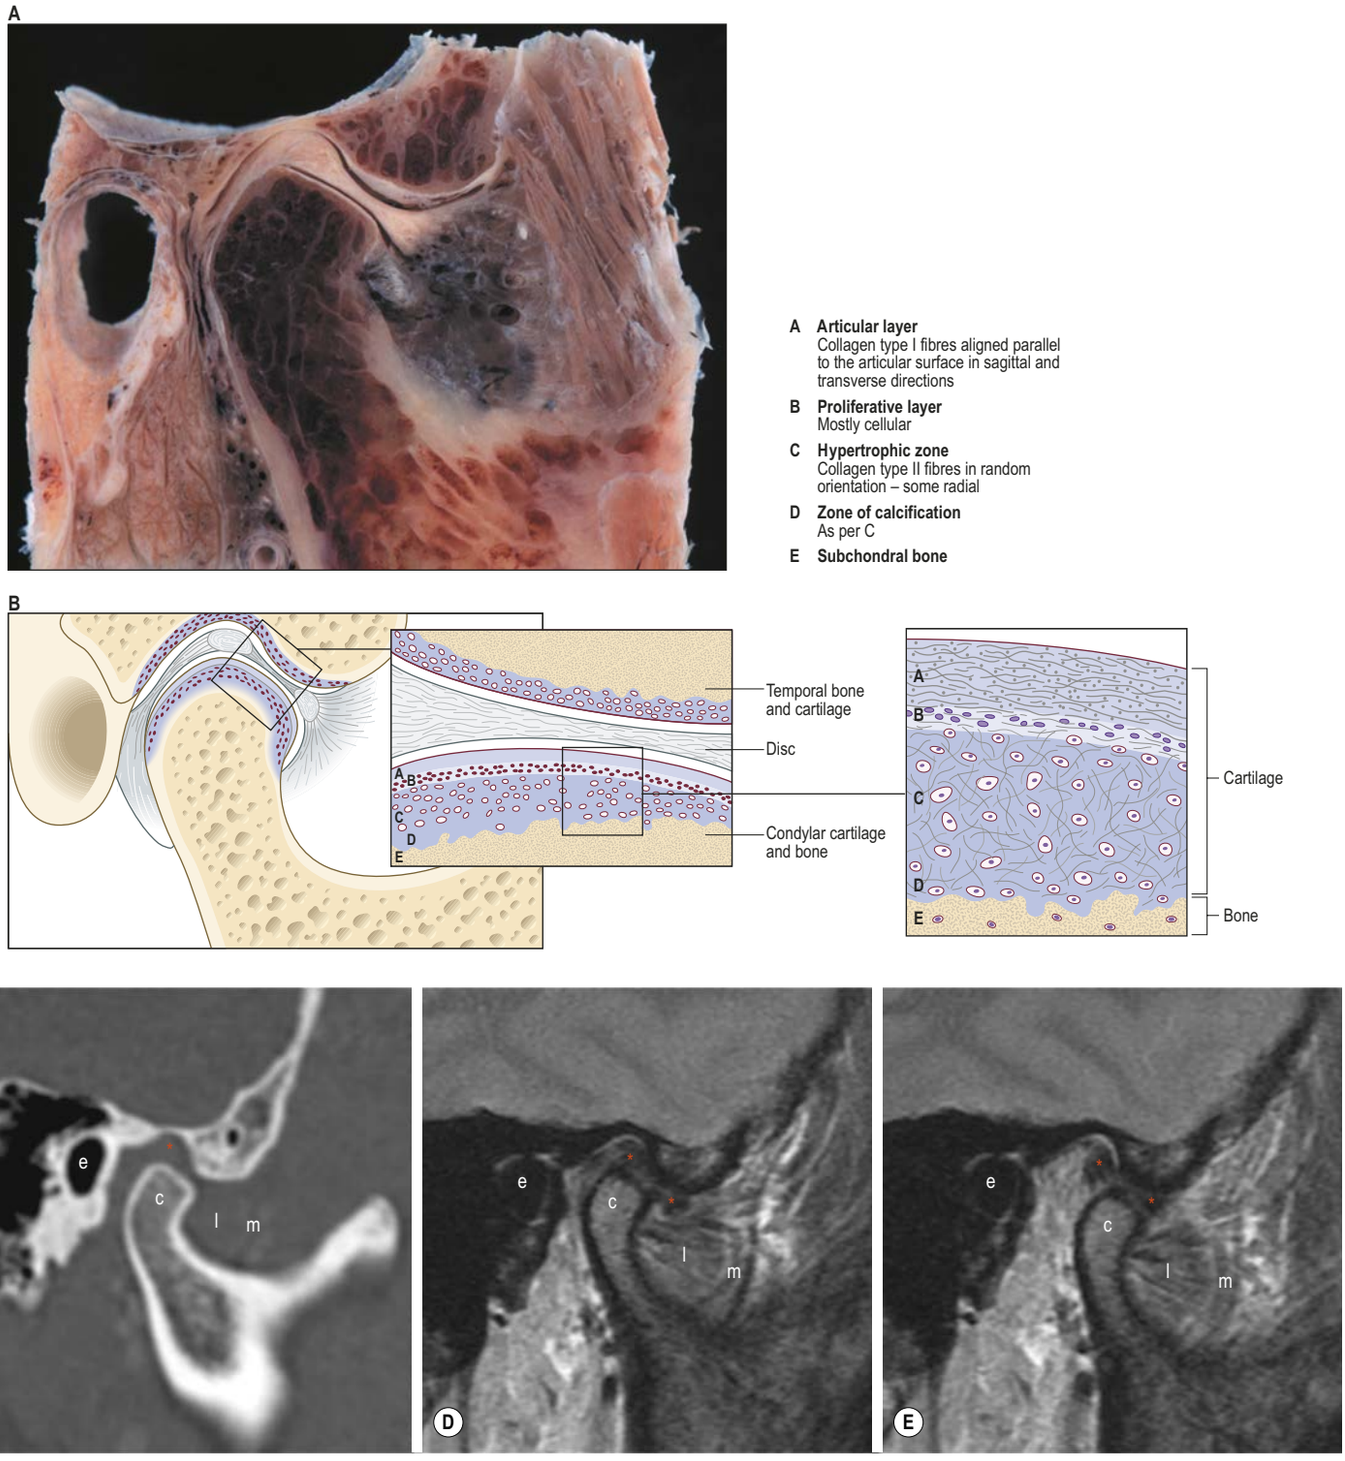

Fig. 38.14 Sagittal sections through the right temporomandibular joint. **A**, Note the relationship of the external acoustic meatus and articular disc to the mandibular condyle. **B**, The microstructure of condylar cartilage. **C**, Contrast enhanced CT (bone window setting) in the sagittal plane through the closed temporomandibular joint. **D**, Proton density sagittal MRI through the closed joint. **E**, Same MRI acquisition parameters as for **D**, but with the mouth open. Note the relationship of the external acoustic meatus (e) to the condylar process of the mandible (c) and the articular disc (*), which deforms on opening. Lateral pterygoid muscle fibres (l) are seen in close relationship to the maxillary vessels (m). have an anterior and posterior recess or pouch, and are lined by synovium, which has a grey hue when viewed through an arthroscope (see Video 38.1).

Functions of the articular disc

The articulating surfaces of the mandibular condyle and the articular fossa are highly incongruent. Wear of the articular surfaces may be reduced by the presence of a deformable articular disc, which not only distributes compressive joint loading over a larger contact area but also significantly reduces the frictional force on the condyle and the articular fossa by separating slide and rotation into different joint compartments.

The disc may aid joint lubrication by storing fluid squeezed out from loaded areas to create a weeping lubricant. Its flexibility, due to its high water content and viscoelastic properties, allows it to function almost like a fluid, further reducing friction within the joint and so aiding joint lubrication. The friction between the articulating surfaces in the absence of the disc is 2–3 times greater than with the disc *in situ*.

The role of the disc in relation to joint stability is controversial. One view is that a deformable and viscoelastic disc stabilizes the condyle within the joint by filling the changing and irregular joint space created during movement. The disc moves in an almost congruent manner relative to the condyle controlled by neuromuscular forces: the upper head of

The anterior portion of the disc is attached to part of the upper head of lateral pterygoid and this muscle may aid in anterior translation of the disc during joint function. Hyperactivity of lateral pterygoid is thought to contribute to anterior disc displacement and possibly dislocation of the condyle, and for this reason injection of botulinum toxin is found to be helpful in the management of both of these conditions.

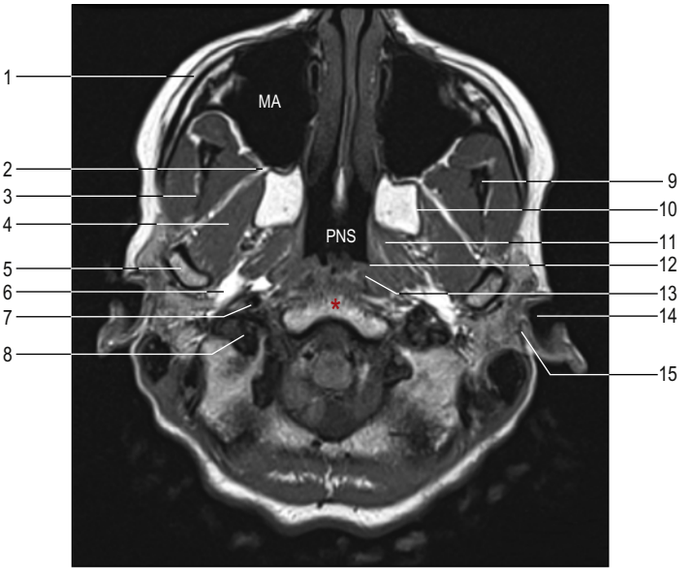

Fig. 38.15 An axial T1-weighted MRI at the level of the external acoustic meatus. Key: 1, body of zygoma; 2, pterygopalatine fossa; 3, temporalis; 4, lateral pterygoid; 5, condyle; 6, parapharyngeal fat stripe; 7, internal carotid artery; 8, jugular bulb/foramen; 9, coronoid process; 10, lateral pterygoid plate; 11, torus tubarius; 12, fossa of Rosenmüller; 13, longus colli; 14, external auditory meatus; 15, superficial lobe of parotid gland. lateral pterygoid anteriorly and the elastic tissue in the bilaminar region posteriorly together pull the disc forwards or backwards and the shape of the disc with its thick, 'self-seating' anulus helps to prevent it sliding off the condyle. An alternative view is that a slippery articular disc doubles the number of virtually friction-free sliding surfaces, and so destabilizes the condyle in the same way that stepping on a slippery object destabilizes the foot. These two roles are not mutually exclusive. A deformable disc stabilizes the condyle within the joint whilst, by doubling the friction-free surfaces, the disc–condyle assembly slides freely under compressive loading and so is 'destabilized'.

Relations

Superiorly, the roof of the glenoid fossa has a mean thickness of 0.9 mm (range 0.2–4 mm). It separates the upper joint space from the middle cranial fossa. This bony partition is occasionally fenestrated by inflammatory processes or inadvertently during surgery to the joint, particularly for release of ankylosis, and, rarely, by the condyle being driven superiorly by violent trauma to the mandible. The foramen of Hushke (a tympanic foramen found in some 4% of cadaveric dissections) may communicate directly with the middle cranial fossa or middle ear (Lacout et al 2005). The maxillary artery and its proximal branches, most notably the middle meningeal artery, lie medially, just beyond the joint capsule. The uppermost part of the parotid capsule enclosing the branches of the facial nerve that supply the muscles of the upper face, including orbicularis oculi, are lateral to the joint capsule, and the thread-like nerves are at risk during surgical approach to the joint. The upper part of the infratemporal fossa, which contains the two heads of lateral pterygoid, is anterior to the condyle (Fig. 38.15). This is the space, anterior to the articular eminence, into which the condyle is displaced in cases of dislocation of the temporomandibular joint, or fracture/dislocation of the condylar head due to the vector of pull from lateral pterygoid attached to the anterior condylar neck. Posteriorly, the tympanic plate and tegmen tympani separate the joint from the middle ear cavity. Perforation through this thin, bony wall into the middle ear is a recognized complication of temporomandibular joint arthroscopy.

Vascular supply and innervation

The joint derives its arterial supply from the superficial temporal artery laterally and the maxillary artery medially. Penetrating vessels that supply lateral pterygoid may also supply the condyle. Veins drain the anterior aspect of the joint and associated tissues into the plexus surrounding lateral pterygoid; posteriorly, they drain into the vascular region that separates the two laminae of the bilaminar region of the disc. Positive and negative pressure produced by forward and backward movement of the condyle shunts blood between these regions. Lymphatics drain deeply to the upper cervical lymph nodes surrounding the internal jugular vein.

The articular tissues and the dense part of the articular disc have no nerve supply. The nerve supply to the temporomandibular joint is from branches from the mandibular division of the trigeminal nerve, mostly through the auriculotemporal branch, and branches from the masseteric and deep temporal nerves. Postganglionic sympathetic nerves supply the tissues associated with the capsular ligament and the looser posterior bilaminar extension of the disc. The temporomandibular joint capsule, lateral ligament and retroarticular tissues all contain mechanoreceptors and nociceptors: the input from mechanoreceptors provides a source of proprioceptive sensation that helps control mandibular posture and movement.

Jaw movements

Movements of the condyle in the temporomandibular joint

The major function of the mandible is to exert, via the teeth, the force necessary to break down food into smaller particles and so facilitate digestion. Pure vertical movements of the lower teeth create a crushing force that is ineffective in breaking up tough fibrous food. Humans use a lateral movement of the lower jaw to create a shear force that enhances the effectiveness of the power stroke of mastication. Bodily lateral movement of the whole jaw, the Bennett shift, is insignificant. Extensive lateral movement is only possible when the jaw is rotated horizontally about one condyle while the other condyle slides backwards and forwards. The temporomandibular joint is structurally adapted to accommodate both sliding/translation and rotation/hinging in a sagittal plane. Sliding/translation occurs because the capsular ligament that surrounds the upper joint compartment is loose, whereas the capsular ligament that encloses the lower joint compartment is tight, and only allows the condyle to rotate over the depression inside the anulus of the articular disc. The normal range of maximum mouth opening measured between the upper and lower incisor tips is 35–50 mm, the first 15–25 mm of which is due to hinging of the condyle; the remainder is due to condylar translation. The adult range of movements is reached at around 10 years in females and 15 years in males. Lateral excursions of the chin (including protrusion) can normally achieve 8–12 mm of movement at the lower incisors. At the limit of normal opening, the condyle has translated on to the peak or just beyond the peak of the articular eminence. Translation beyond this results in subluxation (temporary) and dislocation (longer standing) of the joint, when the condyle lies anterior and superior to the peak of the articular eminence.

Symmetric opening

Symmetric jaw opening is associated with preparation for incising. At the start, each mandibular condyle rotates in the lower joint compartment inside the anulus of its disc. After a few degrees of opening, the condyle continues rotating inside its disc and, in addition, both slide forwards down the articular eminence of the upper joint compartment. Without this forward slide or translation, it becomes impossible to continue opening the jaw beyond a gape of approximately 25 mm.

Opinions differ as to why this forward slide should occur. A cadaveric condyle slides forwards when the jaw is rotated open, suggesting that this is not a neuromuscular response but rather the result of mechanical constraints. When the jaw is rotated open, the temporomandibular ligament rapidly becomes taut (Osborn 1995). The taut ligament acts as a constraint that allows the mandible only two rotary movements: it can swing about the upper attachment of the ligament and rotate about the lower attachment. The lower end of the taut ligament acts as a moving fulcrum that converts the downward and backward pull of the opening rotary force (created at the front by digastric and geniohyoid) into one that drives the condyle upwards and forwards into the concavity of the overlying articular disc. This now pushes the disc forward. Swing about the upper attachment creates space above for the disc to slide further forwards, which is possible because the upper part of the capsular ligament is loose. The two movements, rotation and swing, are inextricably linked by the taut ligament and, via the condyle, combine to keep the disc in firm contact with the articular eminence while the jaw is opened. The disc is stabilized by its tight attachment to the condyle (collateral ligament) and by the thickened margins of its anulus that prevent it sliding through the thinner compressed region between the centre of the condyle and the articular eminence.

The articular disc is designed to withstand compressive and shearing loads. It has viscoelastic properties that allow it to deform when loaded and to conform to the surfaces causing this deformation. Removal of the disc increases surface friction within the joint by 2–3 times compared to joints with an intact disc. Long-term follow-up of patients who have had the disc removed ('discectomy') demonstrates that the joint undergoes significant remodelling similar to that seen in osteoarthrosis. There is flattening, slight roughening and sclerosis of the condylar head and articular fossa. These changes, which are believed to be adaptive responses of the condyle and fossa to the absence of an intervening disc, collectively produce a broader contact, decreasing the load per unit area. A layer of fibrous tissue (scar) also forms between the surfaces and synovial tissue may reform over this area providing a 'neo-disc'.

The main purpose of collagen in tissue is to resist tensile forces. The orientation of the collagen fibres in the disc varies in the individual regions, reflecting the direction of the tensile forces imparted to the disc. In the intermediate zone, these fibres are predominantly orientated in an anteroposterior direction. Around the periphery, they form a ring-like structure with a three-dimensional framework of fibrils. In the posterior and anterior bands, their predominant orientation is lateral–medial and superior–inferior. Type 1 collagen, similar to that found in the superficial layers of the head of the condyle and the articular fossa, predominates in the disc.

Chondroitin sulphate and dermatan sulphate are the principal glycosaminoglycans (GAGs) in the intercellular matrix. GAGs are very hydrophilic and play an important role in the resistance and distribution of compressive load applied to the temporomandibular joint. Their concentration varies with the area of the disc and is highest in the superficial layer of the intermediate zone (Nickel and McLachlan 1994, Detamore and Athanasiou 2003, Paegle et al 2003, Obrez and Gallo 2006, Tanaka et al 2006, Miloro and Henrickson 2010).

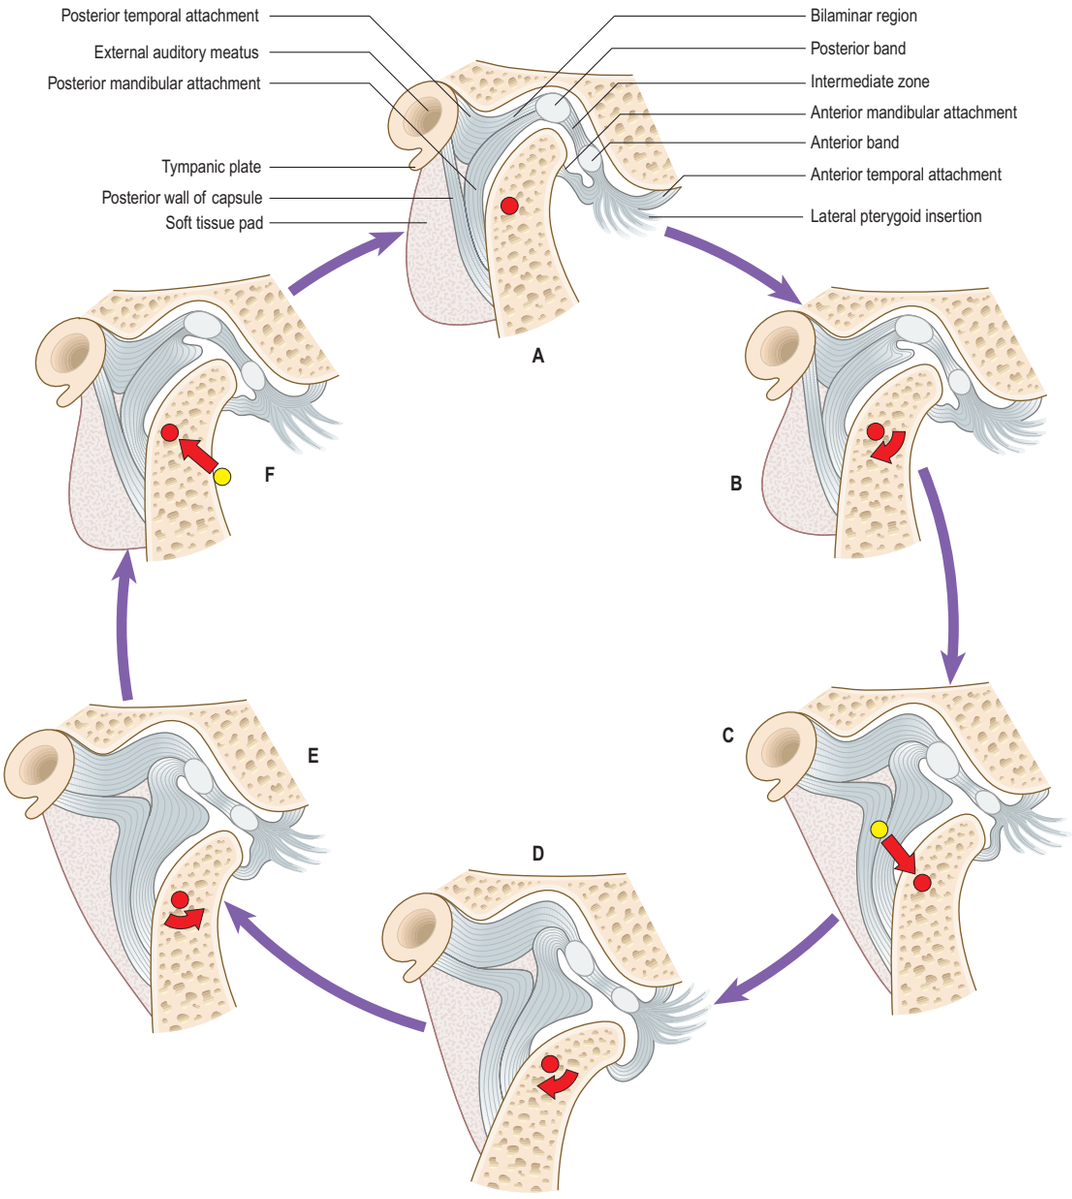

Fig. 38.16 Changing relationships of the condyle of the mandible, the articular disc and the articular surface of the temporal bone during one complete opening (A → D) and closing (D → A) cycle of the mouth.

As forward slide of the condyle continues, the controlling influence exerted by the temporomandibular ligament diminishes. The lingula of the mandible moves away from the spine of the sphenoid, tautening the originally slack sphenomandibular ligament, which now acts in the same way as the temporomandibular ligament, to maintain the condyle against the articular eminence. Symmetric opening thus appears to consist of at least three separate phases: an early phase controlled by the temporomandibular ligament and articular eminence; a short middle phase in which either both temporomandibular and sphenomandibular ligaments, or neither, act to constrain movements; and a late phase controlled by the sphenomandibular ligament and articular eminence.

Changes in disc position during movement

With the teeth in occlusion, the condyle is in the glenoid fossa and the intra-articular disc sits on the condylar head, with its posterior band at the 12 o'clock position from the centre of the condylar head in the sagittal plane (Fig. 38.16A). As mouth opening begins (Fig. 38.16B), the condyle rotates within the lower joint space and the disc remains stationary. At about mid-opening, the condyle and disc begin to move forwards together so that their relative position is maintained (Fig. 38.16C). At maximum gape (Fig. 38.16D), the condylar head slides further anteriorly than the disc and the disc is rotated backwards relative to the condyle by the pull of the elastic superior lamina of the posterior attachment, so that the anterior band of the articular disc is above the summit of the condyle. This differential movement results in the disc moving only about half the distance of the condyle. Mouth closure involves the disc moving back in tandem with the condyle under the influence of the elastic fibres in the upper lamina of the bilaminar area posterior to the disc itself (Fig. 38.16E), which also reverses its angular rotation (Fig. 38.16F) to resume the starting position of the cycle.

Eccentric jaw opening

Jaw movement during mastication can be divided into three parts: opening, closing and power strokes. Eccentric jaw opening is associated with preparing for the power stroke of mastication. The mandibular condyle on the non-working side slides back and forth during lateral movements associated with the power stroke on the working side. Although the jaw muscles now have the major control over mandibular movements, the temporomandibular and sphenomandibular ligaments keep the condyle firmly against its articular eminence during opening.

Eccentric and symmetric jaw closing

During closure of the jaw, the masticatory muscles act in combination to force the joint surfaces together. This compresses the joint tissues and potentially shortens the ligaments so that they no longer constrain jaw movements. Under these conditions, jaw movements and the positions of the condyles are controlled by neuromuscular processes, within the limits of constraints imposed by the articular eminence, the occluding surfaces of the teeth and the presence of food between them. The non-working condyle moves the furthest, and is the most heavily loaded, during the power stroke of mastication. The loads on each joint, balancing and working, drive each condyle more forcefully into its articular eminence.

The envelope of motion

The envelope of motion is the volume of space within which all movements of a point on the mandible have to occur because the limits are set by anatomical features: the shape or size of the upper and lower

Changes in disc position may become out of phase with the condyle, causing obstruction to smooth mandibular movement. The disc is typically pulled anteromedially by lateral pterygoid, preventing forward translation of the condyle. With the disc in this position, the posterior band of the disc is anterior to the condyle, obstructing forward translation of the condyle. As the force from the condyle on the disc increases, the elastic posterior attachments of the disc are stretched until the resistance to movement is overcome and the disc reduces into a normal relationship with the condyle, a movement that is associated with an audible click (audible to the patient and occasionally to others). Once the normal disc–condyle relation is re-established, the mouth is free to achieve maximum opening (see Fig. 38.16C,D). The disc may then snap back anterior to the condyle on mouth closure. This phenomenon is called reciprocal clicking or disc displacement with reduction. If the disc remains completely anterior to the condylar head and does not reduce into a normal relationship with the condyle during opening, the condyle may be prevented from further forward translation and mouth opening is restricted. This common clinical condition is known as disc displacement without reduction.

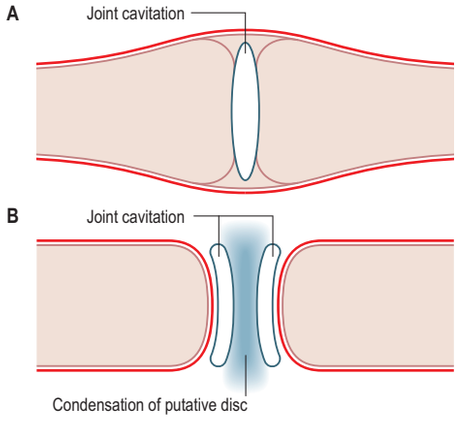

Fig. 38.17 A–B, Development of the temporomandibular joint; the temporal and condylar components of the joint develop from two separate condensations of neural crest mesenchyme.

jaws, tooth contacts, and the attachment of muscle and ligaments. The mandibular movements at these extremes are termed 'border movements'.

In consciously controlled movement of the jaw from the rest position to the fully opened position, the trajectory of the mandibular incisal edge is two-phased. The first phase is a hinge-like movement during which the condyles are retruded within the mandibular fossae. When the teeth are opened by approximately 25 mm, the second phase of opening occurs by anterior movement or protrusion of the condyles down the articular eminences with further rotation. If conscious effort is used, a closure path can then be followed in which the jaw is closed to an extreme protruded tooth contact position, after which it has to be retruded to the starting position. Similar considerations apply to lateral movements: mandibular rotation around a retruding condyle and the protraction of the opposite condyle are anatomically limiting factors that are rarely encountered in normal function.

Although all mandibular movement occurs within or along the border movements, knowledge of the extent of border movements provides little information on the nature of the movements during chewing or on the free ('empty'), habitual movements during both opening and closing, that have a more limited trajectory.

Disc position and internal derangement

Available with the *Gray's Anatomy* e-book

Development of the temporomandibular joint

Unlike the development of most synovial joints, where a single blastema cavitates to form a joint space and the articulating bones are derived from the same condensation of tissue, the temporomandibular joint develops from separate condensations of mesenchyme that coalesce to form the joint. It is first seen at the end of the embryonic period in postfertilization week 8, when condensations of neural crest mesenchyme for the mandibular condyle and the zygomatic process of the squamous part of the temporal bone appear. Chondrogenesis is seen in the mandibular condyle at the end of postfertilization week 9 (postmenstrual week 11), when the articular disc and inferior joint cavity appear. The superior joint cavity is seen from postmenstrual week 13 and endochondral ossification of the mandibular condylar cartilage is seen from postmenstrual week 17. The articular surfaces of the bones that form the joint are covered by a persisting layer of proliferative cells continuous with the periosteum that surrounds each bone (Fig. 38.17).

Muscles

The four principal muscles of mastication are medial and lateral pterygoid, temporalis and masseter: their actions produce movements of the mandible at the temporomandibular joints. The infratemporal fossa contains medial and lateral pterygoid and the tendon of temporalis. Masseter lies on the face, on the lateral surface of the ramus of the mandible, but will be considered here.

Masseter

Masseter (Fig. 38.18) is a quadrilateral multipennate muscle consisting of three layers that blend anteriorly. The superficial layer is the largest.

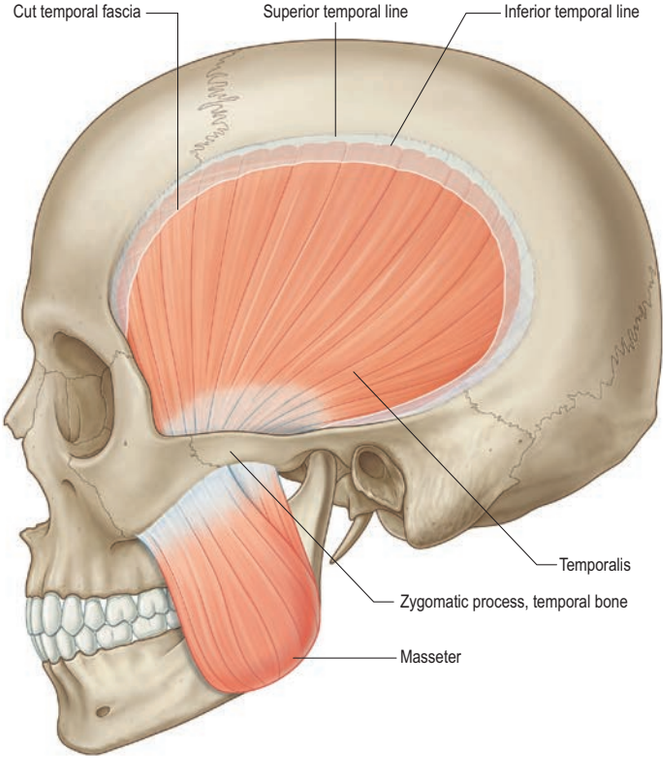

Fig. 38.18 Masseter and temporalis muscles. (Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

It arises by a thick aponeurosis from the maxillary process of the zygomatic bone and from the anterior two-thirds of the inferior border of the zygomatic arch. Its fibres pass downwards and backwards and are attached to the angle and lower posterior half of the lateral surface of the mandibular ramus. The superficial fibres are angled approximately 10° from the vertical, as is visible in lean individuals. In the coronal (frontal) plane, the muscle forms a 10° angle with the mandibular ramus. Intramuscular tendinous septa in this layer are responsible for the ridges on the surface of the ramus. The middle layer arises from the medial aspect of the anterior two-thirds of the zygomatic arch and from the lower border of the posterior third of this arch and is attached to the central part of the ramus of the mandible. The deep layer arises from the deep surface of the zygomatic arch and is attached to the upper part of the mandibular ramus and its coronoid process. The deep fibres run vertically and are evident just anterior to the temporomandibular joint, where they are not covered by the more superficial layers. There is still debate as to whether fibres of masseter are attached to the anterolateral part of the articular disc of the temporomandibular joint. Hypertrophy of the masseter may present either unilaterally or bilaterally. The aetiology is uncertain, but may be related to a clenching habit; there may be an associated prominence of the mandibular angle. Treatment can involve surgical reduction of the deep aspect of the muscle and contouring of the mandibular angle or, more commonly, injections of botulinum toxin to prevent function of the motor end plates with associated muscle atrophy.

Relations Skin, platysma, risorius, zygomaticus major, the parotid gland and duct, branches of the facial nerve and the transverse facial branches of the superficial temporal vessels are all superficial relations. Temporalis and the ramus of the mandible lie deep to masseter. The anterior margin of masseter is separated from buccinator and the buccal branch of the mandibular nerve by a buccal pad of fat and crossed by the facial vein. The posterior margin of the muscle is overlapped by the parotid gland. The masseteric nerve and artery reach the deep surface of masseter by passing over the mandibular incisure (mandibular notch).

Vascular supply Masseter is supplied by the masseteric branch of the maxillary artery, the facial artery and the transverse facial branch of the superficial temporal artery.

Innervation Masseter is supplied by the masseteric branch of the anterior trunk of the mandibular nerve.

Abnormalities of disc position (collectively known as internal derangements) can be a cause of joint noises (clicking), limitation of jaw movement and/or pain. The position of the disc is considered to be normal when, with the mandible at rest, the posterior band is positioned in the 12 o'clock position from the centre of the condyle in the sagittal plane. Displacement of the disc anteromedially is most common. MRI and arthrography have demonstrated that, although disc position and clinical symptoms are often linked, a significant proportion of subjects with apparently normal temporomandibular joint function have disc displacement on imaging and, conversely, patients with normally positioned discs may have severe restriction of mouth opening. Similarly, individuals with displaced discs who have undergone disc repositioning surgery often show functional improvement despite persistent displacement of their intra-articular disc and vice versa. Limited mouth opening is not always related to disc displacement or non-reducibility but may be the result of impaired joint lubrication, disc mobility and muscle spasm. In an otherwise asymptomatic jaw with normal movements, an anteriorly 'displaced' disc could be considered a normal variant (Stegenga and de Bont 2006) or, at the least, not an indication for treatment.

It would appear that the adaptive remodelling capacity of the joint (both the mandibular condyle and articular fossa) and adequate joint lubrication are important for maintaining function of the temporomandibular joint.

Actions Masseter elevates the mandible to occlude the teeth in mastication, and has a minor effect in side-to-side movements, protraction and retraction. Its electrical activity in the resting position of the mandible is minimal.

Submasseteric space infections

Available with the *Gray's Anatomy* e-book

Temporalis

Temporalis (see Figs 38.18, 38.20) arises from the whole of the temporal fossa up to the inferior temporal line, other than the part formed by the zygomatic bone, and from the deep surface of the temporal fascia. Its fibres converge and descend into a tendon that passes through the gap between the zygomatic arch and the side of the skull anterior and medial to the articular eminence. A plane exists beneath the temporal fascia attached to the superior surface of the zygomatic arch, and the muscle passing beneath the arch. An elevator introduced into this plane through an incision above the hairline may therefore be placed beneath a fractured zygomatic arch or bone in order to reduce the fracture (Gillies approach). Temporalis is attached to the medial surface, apex, anterior and posterior borders of the coronoid process and to the anterior border of the mandibular ramus almost up to the third molar tooth. Its anterior fibres are orientated vertically, the most posterior fibres almost horizontally, and the intervening fibres with intermediate degrees of obliquity, in the manner of a fan. Fibres of temporalis may occasionally gain attachment to the articular disc. Though less common than enlargement of masseter, hypertrophy of temporalis may develop unilaterally or bilaterally, producing prominence of the temporal fossa, which may be considered unsightly; botulinum toxin injections to prevent function of the motor end plates of the muscle fibres is the preferred treatment for this condition.

Relations Skin, auriculares anterior and superior, temporal fascia, superficial temporal vessels, the auriculotemporal nerve, temporal branches of the facial nerve, the zygomaticotemporal nerve, the epicranial aponeurosis, the zygomatic arch and masseter are all superficial relations. The posterior relations of temporalis are the temporal fossa above and the major components of the infratemporal fossa below. The masseteric vessels and nerve traverse the mandibular notch posterior to the tendon of temporalis. The anterior border of the muscle is separated from the zygomatic bone by an extension of the buccal fat pad.

Vascular supply

Temporalis is supplied by anterior and posterior deep temporal branches from the second part of the maxillary artery that enter its deep aspect, and middle temporal branches from the superficial temporal artery that enter its lateral aspect. There are significant vascular anastomoses within the muscle.

Innervation Temporalis is supplied by the anterior, middle and posterior deep temporal branches of the anterior trunk of the mandibular nerve.

Actions Temporalis elevates the mandible and so closes the mouth and approximates the teeth. This movement requires both the upward pull of the anterior fibres and the backward pull of the posterior fibres because the head of the mandibular condyle rests on the articular eminence when the mouth is open. The muscle also contributes to side-to-side grinding movements. The posterior fibres retract the mandible after it has been protruded. These fibres are almost horizontal and so are the only source of mandibular retrusion.

Lateral pterygoid

Lateral pterygoid is a short, thick muscle with two heads (**Fig. 38.20**). The upper (superior) head arises from the infratemporal surface and infratemporal crest of the greater wing of the sphenoid bone. The lower (inferior) head arises from the lateral surface of the lateral pterygoid plate. The fibres from the two heads converge and pass backwards and laterally, to be inserted into a depression, the pterygoid fovea, on the anterior aspect of the neck of the mandible. A part of the upper head may be attached to the capsule of the temporomandibular joint and to the anterior and medial borders of the articular disc. Unlike the other muscles of mastication, lateral pterygoid is not pennate, and few Golgi tendon organs are associated with its attachments.

Relations The mandibular ramus and masseter, the maxillary artery (which crosses either deep or superficial to lateral pterygoid), the superficial head of medial pterygoid and the tendon of temporalis are all superficial relations. The deep head of medial pterygoid, the sphenomandibular ligament, the middle meningeal artery and the mandibular nerve are all deep relations. The upper border is related to the temporal and masseteric branches of the mandibular nerve and the lower border is related to the lingual and inferior alveolar nerves. A deeply placed posterior superior alveolar nerve block has been known also to anaesthetize the lingual nerve. The buccal nerve and the maxillary artery pass

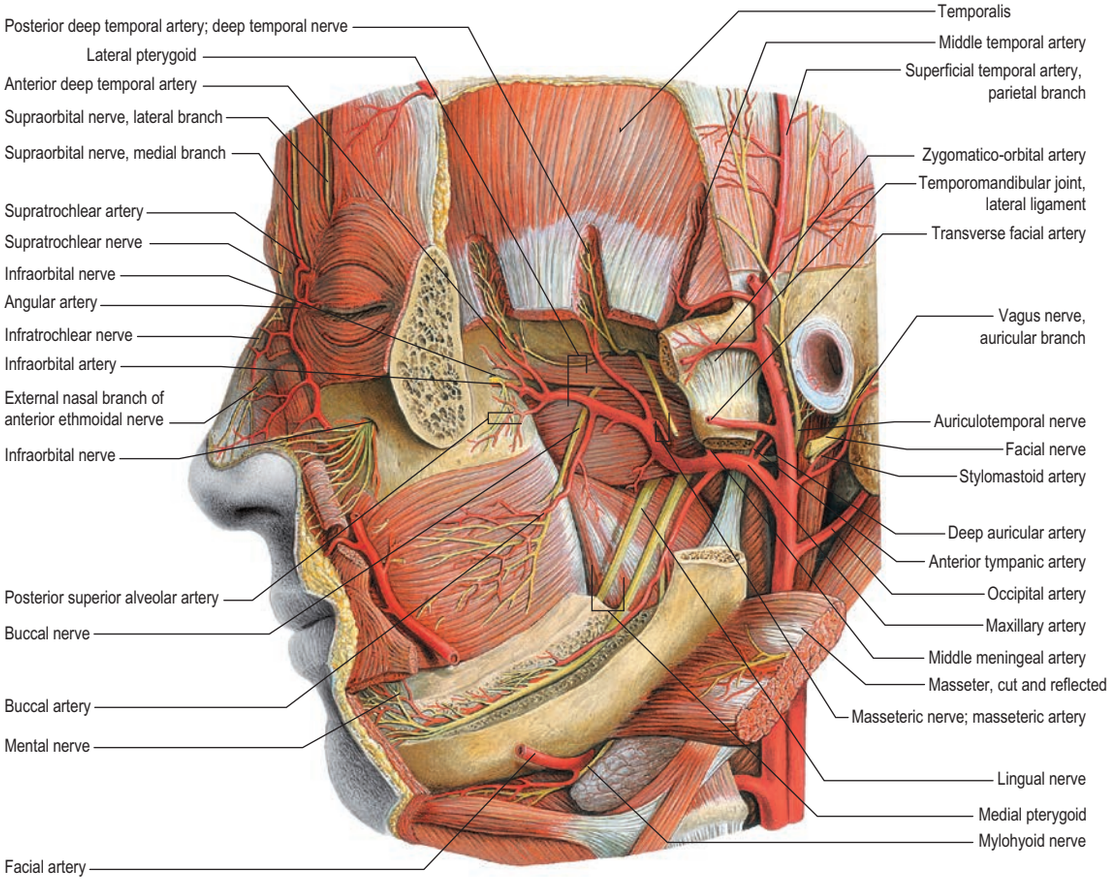

Fig. 38.20 Arteries and nerves of the head; deeper lateral regions. Most of the zygomatic arch and the ramus and body of the mandible have been removed; masseter has been cut and reflected laterally. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Infection around a mandibular third molar tooth sometimes tracks backwards, lateral to the mandibular ramus, and purulence localizes in the submasseteric tissue space deep to the attachment of masseter to the ramus of the mandible. An abscess lying deep to this thick muscle produces little visible swelling but is accompanied by profound muscle spasm and severe limitation of jaw opening (trismus).

The arterial supply is axial, i.e. the vessels run the entire length of the muscle. It is this vascular arrangement that permits the use of temporalis as an inferiorly based pedicled flap, either dynamic or static (increased length being obtained with division of the coronoid process), for the reconstruction of a variety of local facial and oral defects and in the treatment of facial paralysis. The temporalis fascia can be incorporated with the flap. The muscle may be split longitudinally (along its long axis), retaining its axial supply from individual arteries: the vessels are identified at operation with Doppler ultrasound if necessary. A further vascular advantage is that the arterial supply is disposed medially (deep temporal) and laterally (middle temporal), and there are few vessels in the mid-sagittal plane, which means that splitting the muscle flap in the sagittal plane is possible (**Fig. 38.19**) (Cheung 1996).

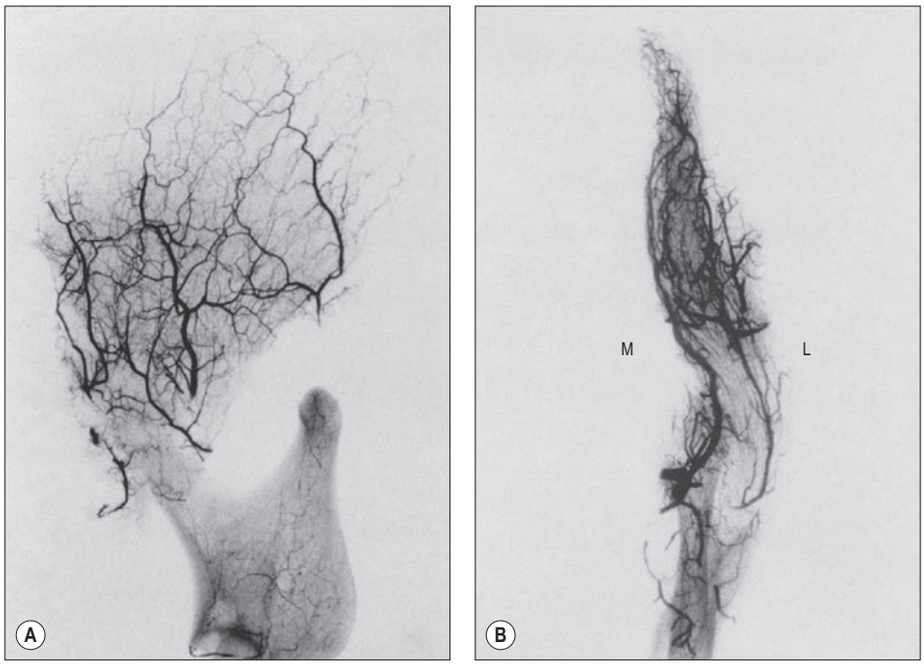

Fig. 38.19 The arterial network of the human temporalis. **A**, Lateral plane. **B**, Coronal plane. In the lateral plane, the muscle is supplied by the three primary arteries: the anterior deep temporal artery in the anterior portion, the posterior deep temporal artery in the mid-portion and the middle deep temporal artery in the posterior portion. In the coronal plane, the arterial distribution is concentrated mainly lateral (L) and medial (M) with less vascular density in the mid-sagittal region of the muscle. (With permission from Cheung LK 1996 The vascular anatomy of the human temporalis muscle: implications for surgical splitting techniques. Int J Oral Maxillofac Surg 25:414–421.)

between the two heads of lateral pterygoid. In temporomandibular joint dysfunction syndrome, spasm of lateral pterygoid can give rise to tenderness when palpating high in the buccal sulcus behind the maxillary tuberosity (the pterygoid sign).

Vascular supply Lateral pterygoid is supplied by the ascending palatine branch of the facial artery and by pterygoid branches of the maxillary artery given off as the artery crosses the muscle.

Innervation The nerves to lateral pterygoid (one for each head) arise from the anterior trunk of the mandibular nerve, deep to the muscle. The upper head and the lateral part of the lower head are innervated by a branch given off from the buccal nerve. The medial part of the lower head is innervated by a branch that arises directly from the anterior trunk of the mandibular nerve.

Actions Lateral pterygoid has assumed a specialized role in mandibular opening that is mediated by its horizontally orientated fibres. When left and right muscles contract together, the condyle is pulled forwards and slightly downwards. This protrusive movement alone has little or no function except to assist in opening the jaw. Digastric and geniohyoid are the main jaw opening muscles: unlike lateral pterygoid, when acting alone, they rotate the jaw open, provided other muscles attached to the hyoid prevent it from being pulled forwards. If only one lateral pterygoid contracts, the jaw rotates about a vertical axis passing roughly through the opposite condyle and is pulled medially towards the opposite side. This contraction, together with that of the adjacent medial pterygoid (both attached to the lateral pterygoid plate), provides most of the strong medially directed component of the force used when grinding food between teeth of the same side. It is arguably the most important function of the lower head of lateral pterygoid.

It is often stated that the upper head is used to pull the articular disc forwards when the jaw is opened. However, electromyographic studies (e.g. McNamara 1973, Juniper 1981) have demonstrated that the upper and lower heads are reciprocally innervated, so that the lower head contracts during mouth opening whilst the upper head relaxes, the situation reversing during closure. An explanation for this surprising activity is as follows (Osborn 1995). Most of the power of a clenching force is due to contractions of masseter and temporalis. The associated backward pull of temporalis is greater than the associated forward pull of (superficial) masseter, and so their combined jaw-closing action potentially pulls the condyle backwards. This is prevented by the simultaneous contraction of the upper head of lateral pterygoid, which stabilizes the condylar head against the articular eminence during closure, particularly during biting and mastication.

Medial pterygoid

Medial pterygoid is a thick, quadrilateral muscle with two heads (see Fig. 38.20). Mirroring masseter (which lies laterally), its fibres descend posteroinferiorly at an angle of about 10° to the vertical. In the coronal plane, the muscle forms a 30° angle with the ramus. The major component is the deep head which arises from the medial surface of the lateral pterygoid plate of the sphenoid bone and is therefore deep to the lower head of lateral pterygoid. The small, superficial head arises from the maxillary tuberosity and the pyramidal process of the palatine bone, and therefore lies on the lower head of lateral pterygoid. The fibres of medial pterygoid descend posterolaterally and are attached by a strong tendinous lamina to the posteroinferior part of the medial surface of the ramus and angle of the mandible, as high as the mandibular foramen and almost as far anteriorly as the mylohyoid groove. This area of attachment is often ridged. Inferior alveolar nerve block injection can occasionally cause haemorrhage into the muscle, which may give rise to painful trismus. Medial pterygoid and masseter act together to support the angle of the mandible as the pterygomasseteric sling: their strong muscle attachments resist lengthening of the mandibular ramus surgically.

Relations The lateral surface of medial pterygoid is related to the mandibular ramus, from which it is separated above its insertion by lateral pterygoid, the sphenomandibular ligament, the maxillary artery, the inferior alveolar vessels and nerve, the lingual nerve and a process of the parotid gland. The medial surface is related to tensor veli palatini and is separated from the superior pharyngeal constrictor by styloglossus and stylopharyngeus and by some areolar tissue.

Vascular supply Medial pterygoid derives its main arterial supply from the pterygoid branches of the maxillary artery.

Innervation Medial pterygoid is innervated by the medial pterygoid branch of the mandibular nerve.

Actions The medial pterygoids assist in elevating the mandible. Acting with the lateral pterygoids, they protrude it. When the medial and lateral pterygoids of one side act together, the corresponding side of the mandible is rotated both forwards and to the opposite side, with the opposite mandibular head as a vertical axis. Alternating activity in the left and right sets of muscles produces side-to-side movements, which are used to triturate food.

Pterygospinous ligament

The pterygospinous ligament, which is occasionally replaced by muscle fibres, stretches between the spine of the sphenoid bone and the posterior border of the lateral pterygoid plate near its upper end. It is sometimes ossified, and then completes a foramen that transmits the branches of the mandibular nerve to temporalis, masseter and lateral pterygoid.

Vascular supply and lymphatic drainage

Maxillary artery

The maxillary artery, the larger terminal branch of the external carotid artery, arises behind the neck of the mandible and is at first embedded in the parotid gland. It then crosses the infratemporal fossa to enter the pterygopalatine fossa through the pterygomaxillary fissure. The artery is widely distributed to the mandible, maxilla, teeth, muscles of mastication, palate, nasal cavity and cranial dura mater (see Fig. 38.20; **Fig. 38.21**). It will be described in three parts: mandibular, pterygoid and pterygopalatine.

The mandibular part runs horizontally by the medial surface of the ramus and passes between the neck of the mandible and the sphenomandibular ligament, parallel with and slightly below the auriculotemporal nerve. It next crosses the inferior alveolar nerve and skirts the lower border of lateral pterygoid. The pterygoid part ascends obliquely forwards medial to temporalis and is usually superficial to the lower head of lateral pterygoid. When it runs deep to lateral pterygoid, it lies between the muscle and branches of the mandibular nerve and may project as a lateral loop between the two parts of lateral pterygoid. Asymmetry in this pattern of distribution may occur between the right and left infratemporal fossae. Where the maxillary artery runs superficial to the lower head of lateral pterygoid, the most common pattern is that the artery passes lateral to the inferior alveolar, lingual and buccal nerves. Less frequently, only the buccal nerve crosses the artery laterally, and rarely the artery can pass deep to all the branches of the mandibular nerve. The pterygopalatine part passes between the two heads of lateral pterygoid to reach the pterygomaxillary fissure before it passes into the pterygopalatine fossa, where it terminates as the third part of the maxillary artery. The mandibular part of the maxillary artery has five branches that all enter bone. The branches are the deep auricular, anterior tympanic, middle meningeal, accessory meningeal and inferior alveolar arteries. The pterygoid part of the maxillary artery has five branches that do not enter bone but supply muscle, and include the deep temporal, pterygoid, masseteric and buccal arteries. The branches of the pterygopalatine part of the artery accompany similarly named branches of the maxillary nerve (including those associated with the pterygopalatine ganglion) and are described on pp. 682–683.

Deep auricular artery

The deep auricular artery pierces the osseous or cartilaginous wall of the external acoustic meatus and supplies the skin of the external acoustic meatus and part of the tympanic membrane. A small branch contributes to the arterial supply of the temporomandibular joint.

Anterior tympanic artery

The anterior tympanic artery passes through the petrotympanic fissure to supply part of the lining of the middle ear and accompanies the chorda tympani nerve.

Middle meningeal artery

The middle meningeal artery is the main source of blood to the calvaria (**Fig. 38.22**). It may arise either directly from the first part of the maxillary artery or from a common trunk with the inferior alveolar artery. When the maxillary artery lies superficial to lateral pterygoid, the middle meningeal artery is usually the first branch of the maxillary artery: this is not usually the case when the maxillary artery takes a deep course in relation to the muscle. The middle meningeal artery ascends between the sphenomandibular ligament and lateral pterygoid, passes between the two roots of the auriculotemporal nerve, and leaves the infratemporal fossa through the foramen spinosum to enter the cranial cavity medial

(Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

to the midpoint of the zygomatic bone. Its further course is described in Chapter 25.

Accessory meningeal artery

The accessory meningeal artery runs through the foramen ovale into the middle cranial fossa and may arise directly from the maxillary artery or as a branch of the middle meningeal artery itself. In its course in the infratemporal fossa, the accessory meningeal artery is closely related to tensor veli palatini and levator veli palatini and usually runs deep to the mandibular nerve. Although it runs intracranially, its main distribution is extracranial, principally to medial pterygoid, lateral pterygoid (upper head), tensor veli palatini, the greater wing and pterygoid processes of the sphenoid, branches of the mandibular nerve and the otic ganglion. The accessory meningeal artery is sometimes replaced by several separate small arteries.

Inferior alveolar artery

The inferior alveolar artery descends in the infratemporal fossa posterior to the inferior alveolar nerve, between the ramus laterally and the sphenopalatine ligament medially. It gives off two anterior branches before entering the mandibular foramen. The further course of the artery is described in Chapter 37.

Deep temporal arteries

The arterial supply to the temporalis in the coronal plane is concentrated mainly on its medial and lateral aspects. The anterior and posterior branches of the deep temporal arteries pass between temporalis and the pericranium, producing shallow grooves in the bone. They anastomose with the middle temporal branch of the superficial temporal artery situated laterally (Cheung 1996). The anterior deep temporal artery anastomoses with the lacrimal artery by small branches that perforate the zygomatic bone and greater wing of the sphenoid.

Masseteric artery

The masseteric artery is small and accompanies the masseteric nerve as it passes through the mandibular incisure (notch), posterior to the tendon of temporalis, to enter the deep surface of masseter (see Fig. 38.20). Its branches can also supply the temporomandibular joint. The masseteric artery anastomoses with the masseteric branches of the facial artery and with the transverse facial branch of the superficial temporal artery. This vessel is at risk and may cause considerable bleeding if damaged when the sigmoid notch is entered or split surgically.

Pterygoid arteries

The pterygoid arteries are irregular in number and origin, and are distributed to lateral and medial pterygoid.

Buccal artery

The buccal artery runs obliquely forwards between medial pterygoid and the attachment of temporalis, accompanying the lower part of the buccal branch of the mandibular nerve to supply the skin and mucosa over buccinators (see Fig. 38.21A). It anastomoses with branches of the facial and infraorbital arteries. A small lingual branch may be given off to accompany the lingual nerve and supply structures in the floor of the mouth.

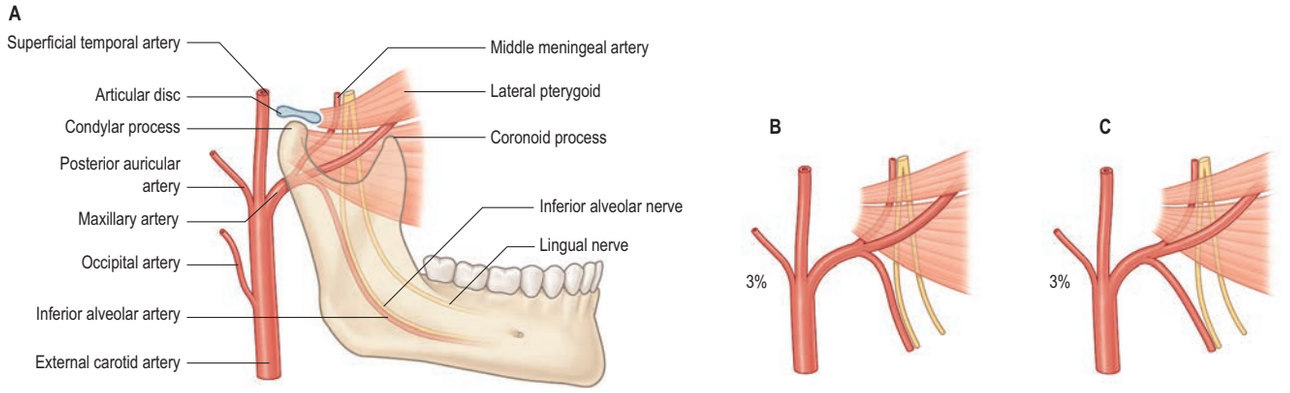

Fig. 38.22 Variations in the origin of the middle meningeal artery. **A**, The middle meningeal artery branches off proximal to the inferior alveolar artery. **B**, The artery branches off opposite the inferior alveolar artery. **C**, The artery branches off distal to the inferior alveolar artery. SECTION 4

Maxillary veins and the pterygoid venous plexus

Maxillary vein

The maxillary vein is a short trunk that accompanies the first part of the maxillary artery (see Fig. 38.21A). It is formed from the confluence of veins from the pterygoid plexus and passes back between the sphenomandibular ligament and the neck of the mandible to enter the parotid gland. It unites within the substance of the gland with the superficial temporal vein to form the retromandibular vein.

Pterygoid venous plexus

The pterygoid plexus of veins consists of copious large calibre veins that surround the pterygoid segment of the maxillary artery. It is found partly between temporalis and lateral pterygoid, and partly between the two pterygoid muscles. Sphenopalatine, deep temporal, pterygoid, masseteric, buccal, alveolar (dental), greater palatine and middle meningeal veins and a branch or branches from the inferior ophthalmic vein are all tributaries. The plexus is connected with the facial vein via the deep facial vein; with the cavernous sinus through veins that pass through the sphenoidal emissary foramen (of Vesalius), foramen ovale and foramen lacerum; and with the orbit via the inferior ophthalmic vein(s). Its deep temporal tributaries often connect with tributaries of the anterior diploic veins and thus with the middle meningeal veins.

Lymphatic drainage

Lymphatic drainage of the infratemporal fossa (and the temporal fossa) is to the superior deep cervical nodes.

Innervation

The infratemporal fossa contains the major subdivisions of the mandibular branch of the trigeminal nerve, together with the chorda tympani, which enters the fossa and joins the lingual nerve, and the otic ganglion, which is functionally related to the parotid gland. The main sensory branches of the mandibular nerve extend beyond the infratemporal fossa and their distribution to the face is described in Chapter 36.

Mandibular nerve

The mandibular nerve is the largest trigeminal division and is a mixed nerve. Its sensory branches supply the teeth and gingivae of the mandible, the skin in the temporal region, part of the auricle, including the external acoustic meatus and tympanic membrane, and the lower lip, the lower part of the face and the mucosa of the anterior two-thirds (presulcal part) of the tongue and the floor of the oral cavity (see Figs 38.20, 38.21A; **Fig. 38.23**). The motor branches innervate the muscles of mastication. The large sensory root emerges from the lateral part of the trigeminal ganglion and exits the cranial cavity through the foramen ovale. The small motor root passes under the ganglion and through the foramen ovale to unite with the sensory root just outside the skull. As it descends from the foramen ovale, the nerve is usually around 4 cm from the surface and a little anterior to the neck of the mandible. The mandibular nerve immediately passes between tensor veli palatini medially, and lateral pterygoid laterally, and gives off a meningeal branch and the nerve to medial pterygoid from its medial side. The nerve then divides into a small anterior and large posterior trunk. The anterior division gives off branches to the four main muscles of mastication and a buccal branch that is sensory to the cheek. The posterior division gives off three main sensory branches, the auriculotemporal, lingual and inferior alveolar nerves, and motor fibres that supply mylohyoid and the anterior belly of digastric.

As is the case with the extraocular muscles, the masticatory muscles function as a group; only when pathology intervenes do their individual actions, or lack of action, become apparent. Wasting of the masticatory muscles, most evident in the temporal fossa, happens when tumours affect the motor root of the mandibular nerve. The mandible deviates to the side of the pathology as a result of the unopposed action of the contralateral lateral and medial pterygoids.

Meningeal branch (nervus spinosus)

The meningeal branch re-enters the cranium through the foramen spinosum with the middle meningeal artery. It divides into anterior and posterior branches that accompany the main divisions of the middle meningeal artery and supply the dura mater in the middle cranial fossa and, to a lesser extent, in the anterior fossa and calvaria.

Nerve to medial pterygoid

The nerve to medial pterygoid is a slender ramus that enters the deep aspect of the muscle. It supplies one or two filaments that pass through the otic ganglion without interruption to supply tensor tympani and tensor veli palatini.

Anterior trunk of mandibular nerve

The anterior trunk of the mandibular nerve gives rise to the buccal nerve, which is sensory, and the masseteric, deep temporal and lateral pterygoid nerves, which are all motor.

Buccal nerve

The buccal nerve passes between the two heads of lateral pterygoid (see Fig. 38.23). It descends deep to the tendon of temporalis, passes laterally anterior to masseter, and anastomoses with the buccal branches of the facial nerve. It carries motor fibres to lateral pterygoid that are given off as the buccal nerve passes through the muscle. It may also give off the anterior deep temporal nerve. The buccal nerve supplies sensation to the skin over the anterior part of buccinator and the buccal mucous membrane, and the posterior part of the buccal gingivae adjacent to the second and third molar teeth.

Nerve to masseter

The nerve to masseter passes laterally above lateral pterygoid, on to the skull base, anterior to the temporomandibular joint and posterior to the tendon of temporalis. It crosses the posterior part of the mandibular notch with the masseteric artery, ramifying on and then entering the deep surface of masseter. Its articular branches innervate the temporomandibular joint.

Deep temporal nerves

There are usually two deep temporal nerves, anterior and posterior; there may be a middle branch. The nerves pass superior to lateral pterygoid to enter the deep surface of temporalis.

The anterior deep temporal nerve can arise from the buccal nerve, and the posterior deep temporal nerve can arise from the nerve to masseter. Branches from the buccal and masseteric nerves may supply the inferior aspect of the muscle independently from the deep temporal nerves. Discrete neuromuscular subunits based on the anterior, middle and posterior deep temporal nerves have been identified within the muscle, suggesting the possibility of individual dynamic muscle flaps, each with a different vector, in the treatment of facial palsy (Chang et al 2013) (**Fig. 38.24**).

Fig. 38.24 The foramen ovale, inferolateral view. Nerves supplying temporalis originate from the anterior trunk of the mandibular division of the trigeminal nerve V_3 (arrow). Key: 1, (long) buccal nerve; 2, anterior deep temporal nerve; 3, middle deep temporal nerve; 4, posterior deep temporal nerve; 5, nerve to masseter. J Oral Maxillofac Surg 71:1170–7.)

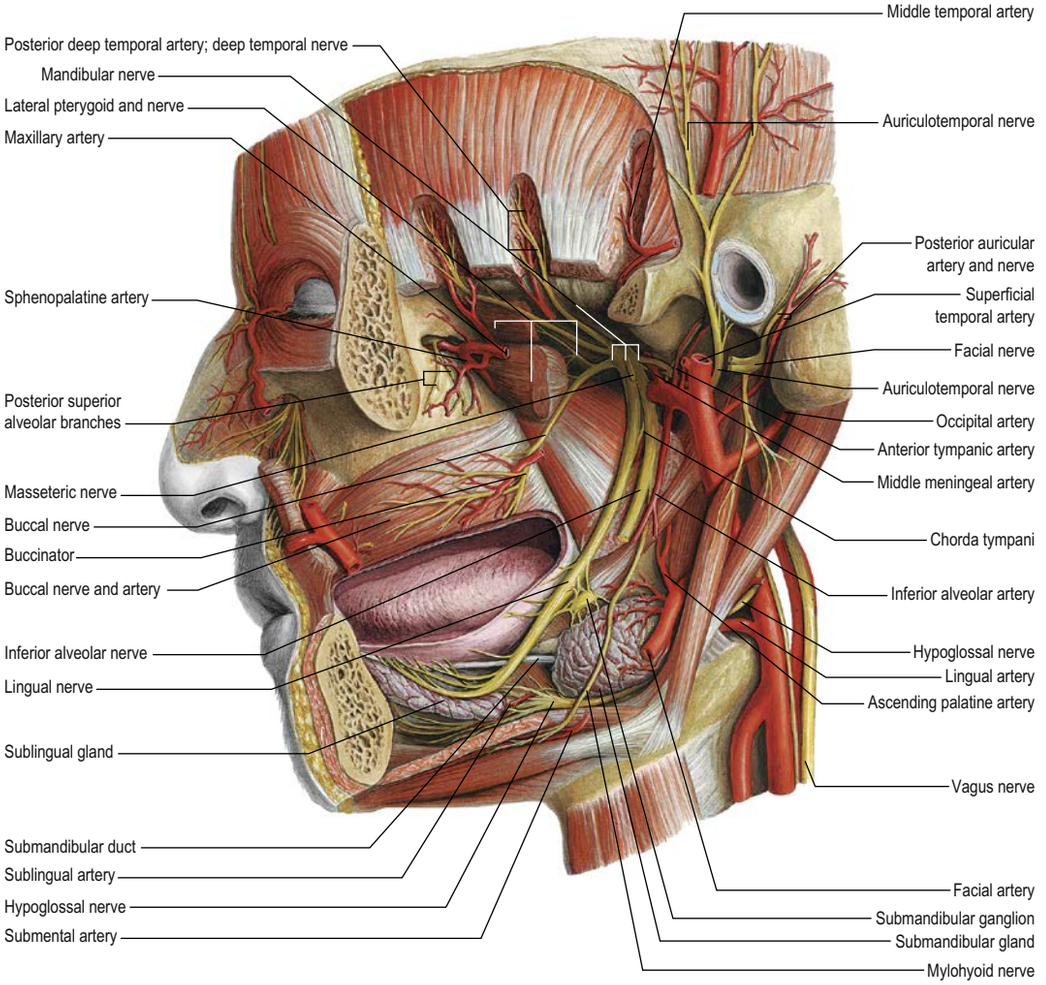

Fig. 38.23 Arteries and nerves of the head, deepest lateral regions. Compare with Figs 38.20 and 38.21A. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Nerve to lateral pterygoid

The nerve to lateral pterygoid enters the deep surface of the muscle and may arise separately from the anterior division of the mandibular nerve or from the buccal nerve.

Posterior trunk of mandibular nerve

The posterior trunk of the mandibular nerve is larger than the anterior and is mainly sensory, although it receives fibres from the motor root for the nerve to mylohyoid. It divides into auriculotemporal, lingual and inferior alveolar (dental) nerves (see Fig. 38.23).

Auriculotemporal nerve

The auriculotemporal nerve usually has two roots that encircle the middle meningeal artery. It runs back under lateral pterygoid on the surface of tensor veli palatini, passes between the sphenomandibular ligament and the neck of the mandible, and then runs laterally posterior to the temporomandibular joint related to the upper part of the parotid gland. Emerging from behind the joint, it ascends over the posterior root of the zygoma, posterior to the superficial temporal vessels, and divides into superficial temporal branches. It communicates with the facial nerve and otic ganglion. The rami to the facial nerve, usually two, pass anterolaterally behind the neck of the mandible to join the facial nerve at the posterior border of masseter. Filaments from the otic ganglion join the roots of the auriculotemporal nerve close to their origin. The sensory distribution of the auriculotemporal nerve on the face is described in Chapter 36.

Lingual nerve

The lingual nerve is sensory to the mucosa of the anterior two-thirds of the tongue, the floor of the mouth and the mandibular lingual gingivae. It arises from the posterior trunk of the mandibular nerve and at first runs beneath lateral pterygoid and superficial to tensor veli palatini, where it is joined by the chorda tympani branch of the facial nerve, and often by a branch of the inferior alveolar nerve. Emerging from under cover of lateral pterygoid, the lingual nerve then runs downwards and forwards on the surface of medial pterygoid (see Fig. 38.23), and is thus carried progressively closer to the medial surface of the mandibular ramus. It becomes intimately related to the bone a few millimetres below and behind the junction of the vertical ramus and horizontal body of the mandible. Here it lies anterior to, and slightly deeper than, the inferior alveolar nerve. It next passes below the mandibular attachment of the superior pharyngeal constrictor and pterygomandibular raphe, closely applied to the periosteum of the medial surface of the mandible, until it lies opposite the posterior root of the third molar tooth, where it is covered only by the gingival mucoperiosteum. At this point, it usually lies approximately 3 mm below the alveolar crest with a mean distance from the bone of 2 mm. In more than 25% of cases, the nerve may be in direct contact with the bone at this site, but sometimes it lies above the alveolar crest. It next passes medial to the mandibular origin of mylohyoid, which carries it progressively away from the mandible and separates it from the alveolar bone that covers the mesial root of the third molar tooth (Pogrel et al 1995). The rest of the nerve is described with the oral cavity in Chapter 37.

Inferior alveolar (dental) nerve

The inferior alveolar nerve descends behind lateral pterygoid. At the lower border of the muscle, the nerve passes between the sphenomandibular ligament and the mandibular ramus and enters the mandibular canal via the mandibular foramen (Barker and Davies 1972). Below lateral pterygoid, it is accompanied by the inferior alveolar artery (see Fig. 38.23), a branch of the first part of the maxillary artery that also enters the canal with associated veins. The subsequent course of the inferior alveolar nerve is described in Chapter 37.

Neural anastomoses with the mandibular nerve

Available with the *Gray's Anatomy* e-book

Otic ganglion

The otic ganglion is a small (major diameter 3–4 mm), oval, flat reddish-grey ganglion situated just below the foramen ovale. It is a peripheral

There are anastomoses between branches of the mandibular division of the trigeminal nerve and branches of the facial nerve. The connection between the lingual nerve and the chorda tympani (facial nerve) is the most familiar interconnection. Connections have also been demonstrated between the auriculotemporal nerve and branches of the facial nerve (**Fig. 38.25**); the buccal branch of the mandibular division of the trigeminal nerve and the buccal and zygomatic branches of the facial via the 'communicating buccal nerve'; and between the mental nerve and the buccal and marginal mandibular branch of the facial nerve. The functional significance of these neural connections is unclear, but may be related to the proprioceptive innervation of the facial musculature (Shoja et al 2014). A branch from the auriculotemporal nerve may join the inferior alveolar nerve within the infratemporal fossa with evident implications for referred pain.

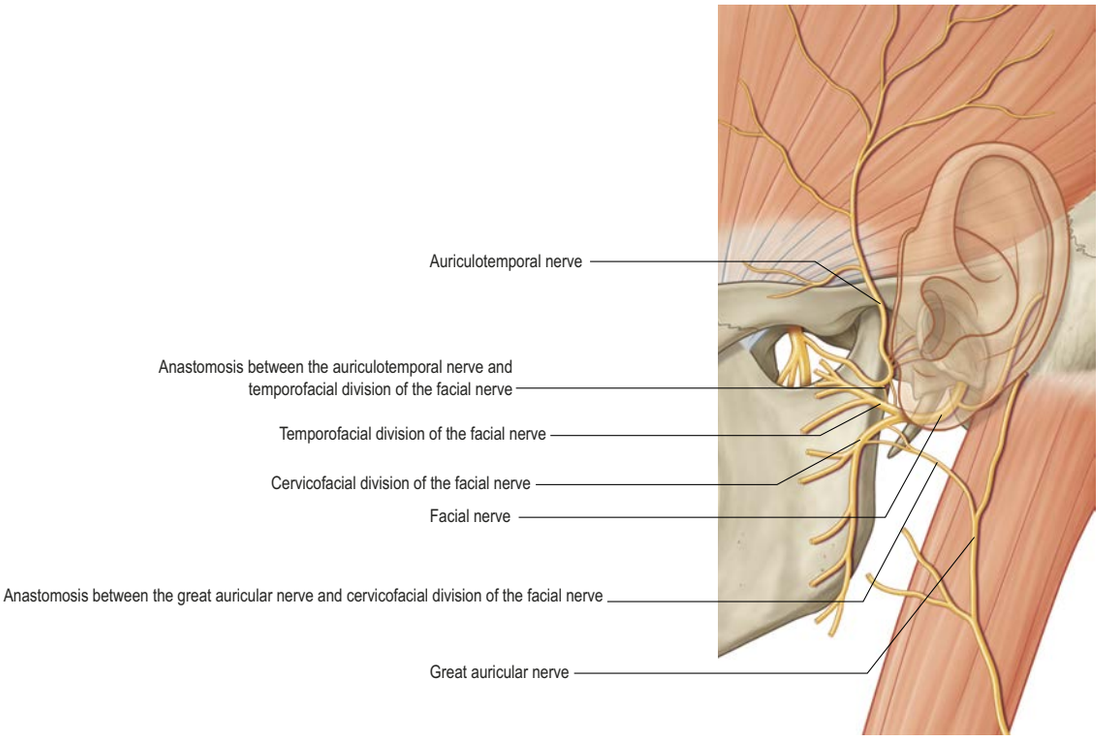

Fig. 38.25 Anastomoses of the auriculotemporal nerve with the temporofacial division of the facial nerve, and of the great auricular nerve with the cervicofacial division of the facial nerve in the parotid and periparotid regions. (With permission from Shoja MM, Oyesiku NM, Grissenauer CJ et al 2014 Anastomoses between lower cranial and upper cervical nerves: a comprehensive review with potential significance during skull base and neck operations, Part 1: Trigeminal, facial and vestibulocochlear nerves. Clin Anat 27:118–30.)

parasympathetic ganglion related topographically to the mandibular nerve but connected functionally with the glossopharyngeal nerve (see Fig. 42.11). Near its junction with the trigeminal motor root, the mandibular nerve lies lateral to the ganglion, tensor veli palatini lies medially, separating the ganglion from the cartilaginous part of the pharyngotympanic tube, and the middle meningeal artery is posterior to the ganglion. The otic ganglion usually surrounds the origin of the nerve to medial pterygoid. It has three roots, parasympathetic motor, sympathetic and sensory: only the parasympathetic fibres relay in the ganglion (see Fig. 33.7). The parasympathetic fibres arise from cell bodies in the inferior salivatory nucleus and travel in the lesser petrosal branch of the glossopharyngeal nerve. The lesser petrosal nerve runs intracranially in the middle cranial fossa on the anterior surface of the petrous temporal bone and passes through either the foramen ovale or the sphenopetrosal fissure or the innominate canal of Arnold (a canal in the greater wing of the sphenoid close to the foramen spinosum), to join the otic ganglion where it synapses. Postganglionic fibres pass by a communicating branch to the auriculotemporal nerve to reach the parotid gland. The sympathetic root arises from a plexus on the middle meningeal artery. It contains postganglionic vasomotor fibres from the superior cervical sympathetic ganglion that pass through the otic ganglion and join the parasympathetic fibres to travel via the auriculotemporal nerve to the parotid gland. Sensory fibres from the parotid gland are derived from the auriculotemporal nerve. Clinical observations suggest that in humans the parotid gland also receives secretomotor parasympathetic fibres through the chorda tympani.

Branches

The otic ganglion is connected by branches to the chorda tympani nerve and the nerve of the pterygoid canal. These branches may form an additional pathway by which gustatory fibres from the anterior two-thirds of the tongue reach the geniculate ganglion without passing through the middle ear: they do not synapse in the otic ganglion. Motor branches to tensor veli palatini and tensor tympani, derived from the nerve to medial pterygoid, pass through the ganglion without synapsing. (For further reading, see Senger et al (2014).)

Chorda tympani

The chorda tympani nerve enters the infratemporal fossa by passing through the medial end of the petrotympanic fissure posterior to the capsule of the temporomandibular joint. The nerve descends medial to the spine of the sphenoid bone, which it sometimes grooves, lying posterolateral to tensor veli palatini. It is crossed medially by the middle meningeal artery, the roots of the auriculotemporal nerve and the inferior alveolar nerve (see Fig. 38.23). It joins the posterior aspect of the lingual nerve at an acute angle. It carries taste fibres from the anterior two-thirds of the tongue and efferent preganglionic parasympathetic secretomotor fibres destined for the submandibular ganglion in the floor of the mouth.

Spread of infection from the infratemporal fossa

Infections from most teeth in the upper jaw or the anterior part of the lower jaw usually drain harmlessly into the oral cavity, either via the vestibule buccally, or via the palate or mouth lingually. In contrast, a pericoronitis that affects a mandibular third molar tooth that communicates with the oral cavity, or, less commonly, either a dental abscess associated with this tooth, or a postoperative infection, can spread along tissue planes. Spread may be buccal, submandibular, submental, parapharyngeal, sublingual, or less commonly, submasseteric and, rarely, infratemporal. The main symptom caused by infection of the pterygomandibular space is trismus (painful reflex muscle spasm) that usually affects medial pterygoid. There are few anatomical barriers to the spread of infection from this space. When the submandibular, sublingual and submental areas are affected either unilaterally or bilaterally (bilateral involvement is known as Ludwig's angina), there is a risk of airway obstruction. Infection may (potentially) spread further, usually to the parapharyngeal, and occasionally to the retropharyngeal spaces, with the possibility of spread into the mediastinum inferiorly. Superior spread can even reach the orbit via the inferior orbital fissure. Life-threatening cavernous sinus thrombosis is a remote possibility once infection has spread to the orbit, with further spread directly through the superior orbital fissure into the cranial cavity. Infection can also spread to the cavernous sinus from the pterygoid plexus and ophthalmic veins (Smyth 2007, Guidera et al 2014) (**Fig. 38.26**).

PTERYGOPALATINE FOSSA

The pterygopalatine fossa is a small pyramidal space below the apex of the orbit on the lateral side of the skull. Placed between the infratemporal fossa laterally and the nasopharynx medially, it functions as a neurovascular conduit. The body of the sphenoid forms the roof, the posterior boundary is the root of the pterygoid process and adjoining anterior surface of the greater wing of the sphenoid, and the anterior boundary is the superomedial part of the infratemporal surface (posterior wall) of the maxilla. The perpendicular plate of the palatine bone, with its orbital and sphenoidal processes, forms the medial boundary, and the pterygomaxillary fissure is the lateral boundary. There are two openings in the posterior wall of the pterygopalatine fossa: the foramen rotundum, which transmits the maxillary nerve, and the pterygoid canal (Vidian canal), which transmits the nerve of the pterygoid canal (Vidian nerve). When the anterior aspect of the pterygoid plate is examined in a disarticulated sphenoid, the foramen rotundum is seen to lie above and lateral to the pterygoid canal (see Figs 38.3A–B).

The fossa communicates with the nasal cavity via the sphenopalatine foramen; with the orbit via the medial end of the inferior orbital fissure; and with the infratemporal fossa via the pterygomaxillary fissure, which lies between the posterior aspect of the maxilla and the pterygoid process of the sphenoid and transmits the maxillary artery. It also communicates with the middle fossa via the foramen rotundum and the pterygoid canal, and with the oral cavity via the greater palatine canal, which opens in the posterolateral aspect of the hard palate. Its proximity to these adjacent areas permits the ready spread of both tumours and infection.

The main contents of the pterygopalatine fossa are the third part of the maxillary artery, the maxillary nerve and many of its branches, and the pterygopalatine ganglion.

Maxillary artery

The maxillary artery passes through the pterygomaxillary fissure from the infratemporal fossa into the pterygopalatine fossa, where it terminates as the third (pterygopalatine) part of the maxillary artery. The artery has a variable and tortuous course in its short passage through the pterygopalatine fossa, where it gives off numerous branches, including the posterior superior alveolar and infraorbital arteries and the artery of the pterygoid canal (Vidian artery), and terminates in the sphenopalatine and greater palatine arteries.

Posterior superior alveolar artery

The posterior superior alveolar artery arises from the maxillary artery within the pterygopalatine fossa and runs through the pterygomaxillary fissure on to the maxillary tuberosity. It gives off branches that penetrate the bone here to supply the maxillary molar and premolar teeth and the maxillary air sinus, and other branches that supply the buccal mucosa. Occasionally, the posterior superior alveolar artery arises from the infraorbital artery.

Infraorbital artery

The infraorbital artery enters the orbit through the inferior orbital fissure. It runs on the floor of the orbit in the infraorbital groove and infraorbital canal, and emerges onto the face at the infraorbital foramen to supply the lower eyelid, part of the cheek, the side of the external nose, and the upper lip. Within the infraorbital canal it gives off the anterior superior alveolar artery that runs downwards to supply the anterior teeth and the anterior part of the maxillary sinus. A middle superior alveolar artery is often described. When present, it branches from the infraorbital artery within the infraorbital canal and runs inferiorly along the lateral wall of the maxillary sinus towards the region of the canine and lateral incisor teeth, anastomosing with the anterior and posterior superior alveolar arteries.

Artery of the pterygoid canal

The artery of the pterygoid canal (Vidian artery) usually arises as a branch of the distal part of the maxillary artery or sometimes as a branch of the petrous segment of the internal carotid artery. It passes through the pterygoid canal and anastomoses with the pharyngeal, ethmoidal and sphenopalatine arteries in the pterygopalatine fossa and with the ascending pharyngeal, accessory meningeal, ascending palatine and descending palatine arteries in the oropharynx and around the pharyngotympanic tube. Through these complex anastomoses, the artery of the pterygoid canal contributes to the supply of part of the pharyngotympanic tube, the tympanic cavity and the upper part of the pharynx. It can also anastomose with the artery of the foramen rotundum and so

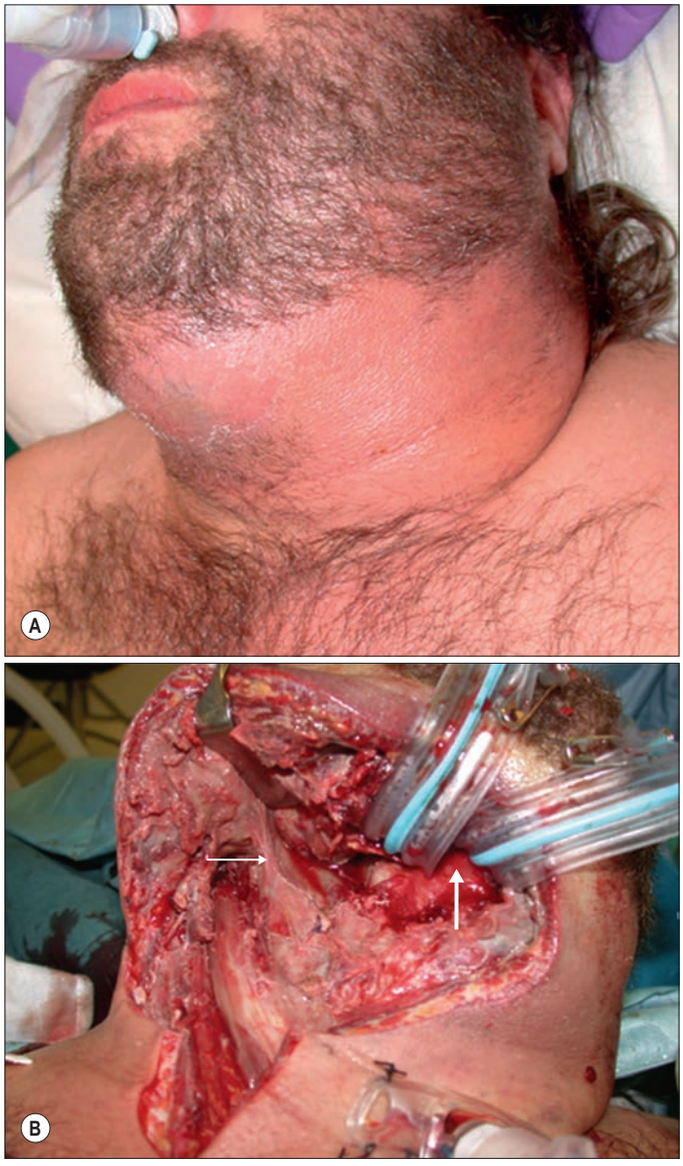

Fig. 38.26 A, Ludwig's angina: spread of infection from an infected lower left third molar to the pterygomandibular space and thence into the submandibular, sublingual and submental spaces bilaterally. The infection is life-threatening due to restricted mouth opening and a compromised airway. **B**, In this case, the airway was secured with awake fibreoptic intubation followed by tracheostomy. Aggressive through-and-through drainage was initiated (note the grey discoloration of the tissues). Prior to the availability of antibiotics, Ludwig's angina had a mortality rate of 75%. Aggressive early treatment with surgical drainage and intravenous antibiotics has reduced the mortality to approximately 5%. The narrow white arrow indicates the cut edge of mylohyoid. The broad white arrow indicates through-and-through corrugated drains. (With permission from Smyth AG 2007 Management of orofacial infections. In: Ward-Booth P, Schendel SA, Hausamen JE (eds) Maxillofacial Surgery, 2nd ed. Edinburgh: Churchill Livingstone.)

Some authors describe anterior and posterior 'compartments' of the pterygopalatine fossa, where the anterior compartment contains the third part of the maxillary artery and its branches, and the posterior compartment contains the maxillary division of the trigeminal nerve and the nerve of the pterygoid canal, together with the pterygopalatine ganglion and its branches (**Figs 38.27–38.28**) (Alfieri et al 2003, Cavallo et al 2005, Falcon et al 2010).

communicate with branches of the cavernous portion of the internal carotid artery.

Pharyngeal artery

The pharyngeal branch of the maxillary artery passes through the palatovaginal canal, accompanying the nerve of the same name, and is distributed to the mucosa of the nasal roof, nasopharynx, sphenoidal air sinus and pharyngotympanic tube.

Greater (descending) palatine artery

The greater palatine artery leaves the pterygopalatine fossa through the greater (anterior) palatine canal, within which it gives off two or three lesser palatine arteries. The greater palatine artery supplies the inferior meatus of the nasal cavity, then passes on to the roof of the hard palate at the greater (anterior) palatine foramen and runs forwards to supply the hard palate and the palatal gingivae of the maxillary teeth. It gives off a branch that runs up into the incisive canal to anastomose with the nasopalatine artery and so contribute to the arterial supply of the nasal septum. The lesser palatine arteries emerge on to the palate through the lesser (posterior) palatine foramen, or foramina, and supply the soft palate.

Sphenopalatine artery

The sphenopalatine artery and the greater palatine artery are the terminal branches of the maxillary artery. The sphenopalatine artery is the principal artery that supplies the mucosa of the nasal cavity. It passes through the sphenopalatine foramen posterior to the superior meatus. From here, its posterior lateral nasal branches ramify over the turbinates and meatuses and anastomose with the ethmoidal arteries and nasal branches of the greater palatine artery to supply the frontal, maxillary, ethmoidal and sphenoidal air sinuses. The sphenopalatine artery next crosses anteriorly on the inferior surface of the sphenoid and ends on the nasal septum in a series of posterior septal branches that anastomose with the ethmoidal arteries (see Fig. 39.9).

Spatial arrangement of the neurovascular contents in the pterygopalatine fossa

Available with the *Gray's Anatomy* e-book

Maxillary nerve

The maxillary division of the trigeminal nerve is wholly sensory (**Fig. 38.30**). It gives off many of its branches in the pterygopalatine fossa. These can be subdivided into those that come directly from the nerve, and those that are associated with the pterygopalatine parasympathetic ganglion. Named branches from the main trunk are meningeal, ganglionic, zygomatic, posterior, middle and anterior superior alveolar and infraorbital nerves. Named branches from the pterygopalatine ganglion are orbital, nasopalatine, posterior superior nasal, greater (anterior) palatine, lesser (posterior) palatine and pharyngeal.

The meningeal branch is given off in the middle fossa. The maxillary nerve leaves the skull via the foramen rotundum to enter the upper part of the pterygopalatine fossa. As it crosses the fossa, the nerve gives off two large ganglionic branches containing fibres destined for the nasal cavity, palate and pharynx, and that pass through the pterygopalatine ganglion without synapsing. It then inclines sharply laterally on the posterior surface of the orbital process of the palatine bone and on the upper part of the posterior surface of the maxilla in the inferior orbital fissure (which is continuous posteriorly with the pterygopalatine fossa): it lies outside the orbital periosteum and gives off its zygomatic and then posterior superior alveolar branches. About halfway between the orbital apex and the orbital rim, the maxillary nerve turns medially to enter the infraorbital canal as the infraorbital nerve. The subsequent course of the maxillary nerve is described in Chapter 36.

Meningeal nerve

The meningeal branch of the maxillary nerve arises within the middle cranial fossa and runs with the middle meningeal vessels. It contributes to the innervation of the dura mater.

Ganglionic branches

There are usually two ganglionic branches that connect the maxillary nerve to the pterygopalatine ganglion.

Zygomatic nerve

The zygomatic branch of the maxillary nerve leaves the pterygopalatine fossa through the inferior orbital fissure together with the maxillary nerve. Its subsequent course is described in Chapter 36 (p. 631).

Posterior superior alveolar nerve

The posterior superior alveolar nerve leaves the maxillary nerve in the pterygopalatine fossa. Its subsequent course and distribution are described in Chapter 37.

Infraorbital nerve

The infraorbital nerve can be regarded as the terminal branch of the maxillary nerve. It leaves the pterygopalatine fossa to enter the orbit at the inferior orbital fissure, and its subsequent course and distribution are described in Chapter 36 (p. 631).

Orbital branches

Fine orbital branches enter the orbit through the inferior orbital fissure and supply orbital periosteum. Some fibres also pass through the posterior ethmoidal foramen to supply the sphenoidal and ethmoidal sinuses. The orbital branches are believed to join branches of the internal carotid nerve to form a 'retro-orbital' plexus, from which orbital structures such as the lacrimal gland and orbitalis receive an autonomic innervation (Ruskell 2004).

Nasopalatine nerve

The nasopalatine nerve leaves the pterygopalatine fossa through the sphenopalatine foramen and enters the nasal cavity. It passes across the cavity to the posterior part of the nasal septum, runs downwards and forwards on the septum in a groove in the vomer, and then turns down through the incisive fossa in the anterior part of the hard palate to enter the roof of the mouth (see Fig. 39.13). When an anterior and a posterior incisive foramen exist in this fossa, the left nasopalatine nerve usually passes through the anterior foramen and the right nerve passes through the posterior foramen. The nasopalatine nerve supplies the lower part of the nasal septum and the anterior part of the hard palate, where it communicates with the greater palatine nerve. The nasopalatine artery, a branch of the maxillary artery, accompanies the nasopalatine nerve and ends in the incisive canal, where it anastomoses with the greater palatine artery and the septal branch of the superior labial artery.

Posterior superior nasal nerves (lateral and medial)

The posterior superior alveolar nerves enter the posterior nasal cavity through the sphenopalatine foramen. Lateral posterior superior nasal nerves (about six) innervate the mucosa lining the posterior parts of the superior and middle nasal turbinates and the posterior ethmoidal sinuses. Two or three medial posterior superior nasal nerves cross the nasal roof below the opening of the sphenoidal sinus to supply the mucosa of the posterior parts of the roof and nasal septum.

Palatine nerves (greater and lesser)

The greater and lesser palatine nerves pass downwards from the pterygopalatine ganglion through the greater palatine canal. The greater palatine nerve descends through the greater palatine canal, emerges on the hard palate from the greater palatine foramen and runs forwards in a groove on the inferior surface of the bony palate almost to the incisor teeth. It supplies the gingivae, mucosa and glands of the hard palate and communicates with the terminal filaments of the nasopalatine nerve. In the greater palatine canal, it gives off posterior inferior nasal branches that emerge through the perpendicular plate of the palatine bone and ramify over the inferior turbinate and walls of the middle and inferior meatuses. As it leaves the greater palatine canal, it gives off branches that are distributed to both surfaces of the adjacent part of the soft palate (see Fig. 37.3).

The lesser (middle and posterior) palatine nerves are much smaller than the greater palatine nerve. They descend through the greater palatine canal, from which they diverge low down to emerge through the lesser palatine foramina in the tubercle or pyramidal process of the palatine bone. They innervate the uvula, tonsil and soft palate.

Fibres conveying taste impulses from the palate probably travel via the palatine nerves to the pterygopalatine ganglion. They pass through the ganglion without synapsing and leave via the greater petrosal nerve. Their cell bodies are located in the geniculate ganglion and their central processes pass via the sensory root of the facial nerve (nervus intermedius) to the gustatory nucleus in the nucleus of the tractus solitarius.

Pharyngeal nerve

The pharyngeal branch of the maxillary nerve leaves the pterygopalatine ganglion posteriorly. It passes through the palatovaginal canal with the pharyngeal branch of the maxillary artery and supplies the mucosa of the nasopharynx posterior to the pharyngotympanic tube.

The communication between the internal and external carotid arteries via the artery of the pterygoid canal is one of a number of collateral vascular pathways that exist between the external carotid artery and branches of the petrous and intracavernous segments of the internal carotid artery. Albeit small and difficult to demonstrate angiographically, these vascular connections may nevertheless provide the arterial supply for arteriovenous malformations, dural-based fistulae and skull base tumours, and may also compensate for occlusion of the internal carotid artery. They also pose a risk of inadvertent embolization of the brain parenchyma during interventional angiography of the external carotid artery system.

There are extensive communications between the artery of the pterygoid canal and the highly vascular nasopharyngeal mucosa. Embolization of branches of the external carotid artery can result in incomplete obliteration of a vascular nasopharyngeal lesion when the artery of the pterygoid canal arises from the internal carotid artery. The collateral circulation provided by the artery of the pterygoid canal can help to maintain cerebral circulation if there is stenosis of the petrous internal carotid artery proximal to the point where the artery of the pterygoid canal joins it, because blood flow in the post-stenotic segment of the internal carotid artery will be supplemented from the external carotid artery via the artery of the pterygoid canal (**Fig. 38.29**) (Allen et al 2005, Takeuchi et al 2005, Tubbs et al 2007).

As the greater palatine artery runs the length of the hard palate, it permits axial mucoperiosteal flaps to be raised, if necessary bilaterally, for the reconstruction of local defects. It is also possible to pedicle the entire mucoperiosteum of the hard palate on a single greater palatine artery. The vascular supply to the denuded palatal bone is sufficient, presumably from its nasal surface, to permit regeneration of the palatal soft tissue. Contracture of the regenerated tissue does not occur because the defect lies over the palatal bone (Gullane and Arena 1977, Gullane and Arena 1985, Salins and Benjamin 2009).

Ligation of the sphenopalatine artery may be necessary in the control of refractory epistaxis. It is usually located endoscopically at the postero-inferior end of the middle turbinate. Multiple branches may be encountered. The sphenopalatine artery provides the axial blood supply to the nasal septal mucosal flap (nasoseptal flap) used in endoscopic skull-base repair, a reflection of its contribution to the vascular supply to the nasal cavity (Hadad et al 2006).

The maxillary artery and its branches are located in a plane anterior to the maxillary nerve, pterygopalatine ganglion and the nerve of the pterygoid canal. This spatial arrangement is particularly relevant in endoscopic approaches to the pterygopalatine fossa (**Video 38.2**). The veins accompanying the third (pterygopalatine) part of the maxillary artery, in common with those accompanying the second (pterygoid) part, are in the form of a venous plexus. Profuse haemorrhage may be encountered from this pterygopalatine venous plexus.

Neural anastomoses with the maxillary nerve

Available with the *Gray's Anatomy* e-book

Pterygopalatine ganglion

The pterygopalatine ganglion, known colloquially as the 'ganglion of hay fever', is the largest of the peripheral parasympathetic ganglia, and is well protected, deep in the pterygopalatine fossa. Immediately anterior to the pterygoid canal, the ganglion lies below and medial to the foramen rotundum and the maxillary nerve and lateral to the sphenopalatine foramen (see Fig. 38.30B). It is flattened and reddish-grey in colour and lies just below the maxillary nerve as it crosses the pterygopalatine fossa. The majority of the 'branches' of the ganglion are connected with it morphologically but not functionally, because they are primarily sensory branches of the maxillary nerve and so pass through the ganglion without synapsing to enter the ganglionic branches of the maxillary nerve.

Preganglionic parasympathetic fibres destined to synapse in the pterygopalatine ganglion run initially in the greater petrosal branch of the facial nerve, and then in the nerve of the pterygoid canal (Vidian nerve) after the greater petrosal unites with the deep petrosal nerve. The nerve of the pterygoid canal enters the ganglion posteriorly. Postganglionic parasympathetic fibres leave the ganglion: some may join the maxillary nerve via a ganglionic branch and then travel via its zygomatic and zygomaticotemporal branches to the lacrimal gland, but most are thought to travel by orbital branches to the gland. The parasympathetic supply to the pre-ocular part of the central artery of the retina is believed to be derived mainly from the pterygopalatine ganglion and is vasodilatory.

Connections between the zygomaticotemporal branch of the maxillary nerve and the temporal branches of the facial nerve, and the zygomaticofacial branch of the maxillary nerve and the zygomatic branches of the facial nerve have been demonstrated (Shoja et al 2014). It was once thought that the connection between the zygomaticotemporal and lacrimal nerves in the orbit provided parasympathetic secretomotor fibres to the lacrimal gland, but that is now less certain. It is more likely that the postganglionic orbital branches pass through the inferior orbital fissure and innervate the lacrimal gland directly (Ruskell 2004).

Preganglionic secretomotor fibres of uncertain origin also travel in the nerve of the pterygoid canal and synapse in the pterygopalatine ganglion: postganglionic fibres are distributed to palatine, pharyngeal and nasal mucous glands via palatine and nasal branches of the maxillary nerve.

Postganglionic sympathetic fibres pass through the ganglion without synapsing and supply blood vessels and orbitalis. They arise in the superior cervical ganglion and travel via the internal carotid plexus and deep petrosal nerve to enter the pterygopalatine ganglion within the nerve of the pterygoid canal.

General sensory fibres destined for distribution via orbital, nasopalatine, superior alveolar, palatine and pharyngeal branches of the maxillary division of the trigeminal nerve run through the ganglion without synapsing.

An electromyographic study in human subjects demonstrating that the superior and inferior heads of the lateral pterygoid have opposing (antagonistic) action. The superior head is active during closure – particularly the terminal closing phase and on clenching, stabilizing the condyle against the articular eminence.

CHAPTER
39 Nose, nasal cavity and paranasal sinuses

Box 39.1 and Table 39.1 set out the different anatomical and clinical terms that are applied to some of the structures described in this chapter.

Box 39.1 A note on terminology

'The advent of endoscopic sinus surgery led to a resurgence of interest in the detailed anatomy of the internal nose and paranasal sinuses. However, the official *Terminologia Anatomica* used by basic anatomists omits many of the structures of surgical importance. This led to numerous clinical anatomy papers and much discussion about the exact names and definitions for the structures of surgical relevance. The European position paper on the anatomical terminology of the internal nose and paranasal sinuses was conceived to re-evaluate the anatomical terms in common usage by endoscopic sinus surgeons and to compare this with the official *Terminologia Anatomica*' (Lund et al 2014).

Where appropriate, the terms used in this chapter are those commonly used in surgical practice as set out in the 'European position paper on the anatomical terminology of the internal nose and paranasal sinuses' (see Table 39.1). Conflicts inevitably arise but hopefully have been minimized. The terms 'concha' and 'turbinate' are often used interchangeably but anatomists rarely use the latter term, while clinicians rarely use the former; in this chapter, concha is used to describe the bony structure seen in dried skulls, while turbinate is used to describe the bony structures, together with their overlying soft tissue and mucosa, that are encountered during surgery. 'Ethmoturbinal' does not appear in *Terminologia Anatomica* but is the collective term for the superior and middle turbinates, occasionally supplemented by a supreme turbinate. With regard to the terms 'skull base' and 'cranial base', although they are frequently used as though synonymous (the term 'skull base' is favoured in the position paper), the anterior skull base includes the inferior surface of the facial skeleton and will therefore be distinguished from the anterior cranial base, which is delimited by the inner and outer surfaces of the anterior cranial fossa (Ch. 34).

NOSE

The nose is the first part of the upper respiratory tract and is responsible for warming, humidifying and, to some extent, filtering inspired air. It also houses the olfactory epithelium, which contains olfactory receptor neurones responsible for detecting airborne odorant molecules.

The nose may be subdivided into an external nose, which opens anteriorly on to the face through the nostrils or nares, and an internal chamber, divided sagittally by a septum into right and left cavities, which open posteriorly into the nasopharynx through the posterior nasal apertures or choanae. The nasal cavities are housed in a supporting framework composed of bone and fibroelastic cartilages. The larger bones in this framework contain air-filled spaces lined with respiratory epithelium, described collectively as the paranasal sinuses. The sinuses and the nasolacrimal ducts drain into the nasal cavity via openings in its lateral walls (Fig. 39.1).

EXTERNAL NOSE

The external nose is a pyramidal structure located in the midline of the midface and attached to the facial skeleton. Its upper angle or root is continuous with the forehead, and its free tip forms the apex, which projects anteriorly. The overall shape of the external nose is very variable. The lateral surfaces of the nose unite in the median plane to form the dorsum, which is narrowest at the medial canthus. The lobule is an area containing the tip of the nose. Its base contains two ellipsoidal apertures, the external nares or nostrils, which open on to its inferior surface, separated by the nasal septum and columella. The columella usually projects below the alar margin. The alar sulcus is a groove in the skin bounding the nasal alae above and joining the nasiolabial sulcus. Below, it curves towards the tip of the nose but does not reach it.

Facial and nasal proportions

Available with the *Gray's Anatomy* e-book

Skin and soft tissue

The skin and soft tissue covering the nose vary in thickness. They are usually thin over the dorsum in the mid third, especially at the osseocartilaginous junction, the rhinion, and loosely connected to the nasal aponeurosis and the muscle fibres that fan out within it. It is thicker over the nasofrontal angle, and at the tip, where it has numerous large sebaceous glands and is more adherent. These variations affect the final nasal contour and profile after rhinoplasty.

The skin of the nose is separated from the underlying osteocartilaginous framework by four layers. These are the superficial fatty panniculus; the fibromuscular layer, a continuation of the facial superficial musculo-aponeurotic system (SMAS) (Ch. 36); the deep fatty layer; and the periosteum or perichondrium.

Soft tissue areas of the nose

Four soft tissue areas of the nose lack cartilaginous support. They have been given numerous eponymous names and descriptions, but were reclassified by Huizing (2003).

Paraseptal soft tissue area

The supratip area contains the paired lateral cartilages, which gradually separate from the septum to a level just above the septal angle. The amount of flare varies, and encloses a small paraseptal soft tissue triangle on each side of the septum.

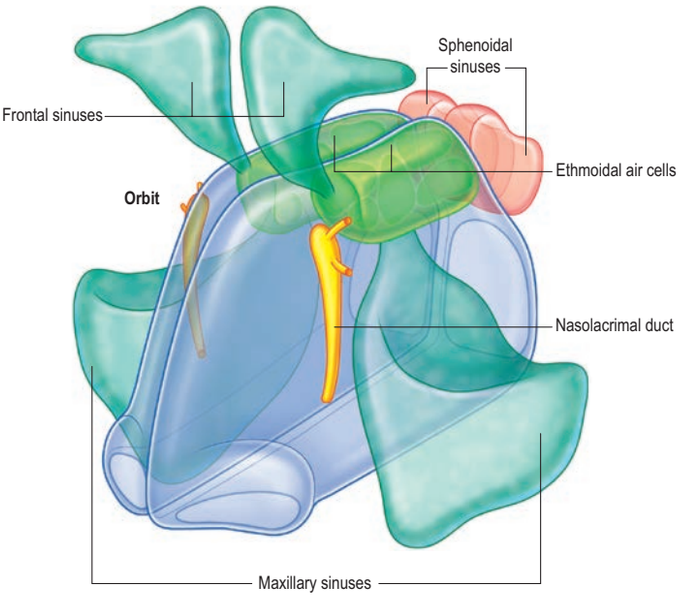

Fig. 39.1 An overview of the spatial relationships between the nasal cavity, paranasal sinuses and nasolacrimal ducts. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

*The frequency of specific variations in the anatomy varies considerably in the literature, which relates to the definitions used, the methodology utilized, i.e. anatomical dissection or imaging, whether the study included normal controls and/or patients with chronic rhinosinusitis (CRS), and the ethnicity of the subjects.

With permission from Lund VJ, Stammberger H, Fokkens WJ et al 2014 European position paper on the anatomical terminology of the internal nose and paranasal sinuses. Rhinology 50:Suppl 24:1–34.

The proportions of the nose and face, both from in front and from the side, are of enormous significance to the rhinoplastic surgeon. Aesthetic proportions of the nose vary depending on sex, age, ethnicity and facial characteristics; however, ranges of normality are described to assist in aesthetic assessment (Akguner et al 1998). The female nose is slightly smaller and narrower than the male nose; it is often slightly concave in profile view, with a slightly obtuse nasolabial angle (increased tip rotation). In terms of overall proportion, the face may be divided into horizontal thirds and vertical fifths, with the nose occupying the middle section of each. The width of the nose is roughly 70% of the length; the width of the alar base is usually equal to the intercanthal distance. The height of the nose is defined by tip projection, where the proportion of the length of a line from the tip to the alar groove to the length of a line from nasion to alar groove is in the range of 0.55–0.60. The nasolabial angle, reflecting upward rotation of the nose from the upper lip, normally lies within a range of 105–120° in females and 90–105° in males. On basal view, the nose is roughly shaped as an equilateral triangle. The nares usually measure 1.5–2 cm anteroposteriorly and 0.5–1 cm transversely, and are narrower in front; they occupy approximately two-thirds of the height of the base. The midline columella, containing the caudal end of the nasal septum and the medial crura of the lower lateral cartilages, usually extends 3–5 mm below the nares on lateral views (Fig. 39.2).

Fig. 39.2 The adult male nose. **A**, Basal view. **B**, Frontal view. The face can be divided into horizontal thirds and vertical fifths, with the nose filling the central segment in terms of both width and height. The basal view may also be divided into horizontal thirds, with the nostrils filling the lower two-thirds.

Lateral soft tissue area
The lateral margin of the lateral cartilage, the piriform aperture and the cranial margin of the lateral crus of the major alar cartilage enclose a triangle containing loose fibroareolar tissue, the transverse portion of nasalis, and one or more small sesamoid cartilages.

Caudal lobular notch
The domal segment of the intermediate crus of the major alar cartilage has a small indentation. The apex of the nostril is a soft tissue triangle with little soft tissue separating the internal and external skin. Incisions in this area may cause unsightly scarring and deformity.

Alar soft tissue area
The lateral crus fails to extend to the lateral limit of the lobule, forming the fourth soft tissue area.

Bones and cartilage

Bony skeleton of the external nose
The piriform aperture has sharp edges. It is bounded below and laterally by the maxilla and above by the nasal bones (Fig. 39.3). The lateral part of the inferior edge of the piriform aperture merges into its lateral wall, which is formed by the frontal process of the maxilla. It is bounded above by the nasal part of the frontal bone and superomedially by the lateral edge of the nasal bone.

The paired nasal bones vary in thickness and width, which is of significance in planning osteotomies. They are thickest and widest at the nasofrontal suture, narrow at the nasofrontal angle before they widen, and become thinner 9–12 mm below the nasofrontal angle. They average 25 mm in length but this can vary widely. The perpendicular plate of the ethmoid bone (part of the bony nasal septum) articulates with the undersurface of the nasal bones and provides support to the dorsum of the nose. A midline bony spine deep to the fused nasal bone projects inwards to articulate with the perpendicular plate of the ethmoid and fuses with the fibrous tissue connecting the lateral nasal cartilages and cartilaginous septum. This is known as the keystone area and provides essential support to the nasal dorsum (Simon et al 2013).

Fractures of the nasal bones The most common injury to the facial skeleton is a fracture of the nasal bones. In simple fractures, the break often occurs between the proximal thicker bone and the thinner bone distally. Displaced fractures require reduction to avoid cosmetic deformity. The terminal branch of the anterior ethmoidal nerve and its accompanying vessels are at risk when injuries involve the dorsum of the nose.

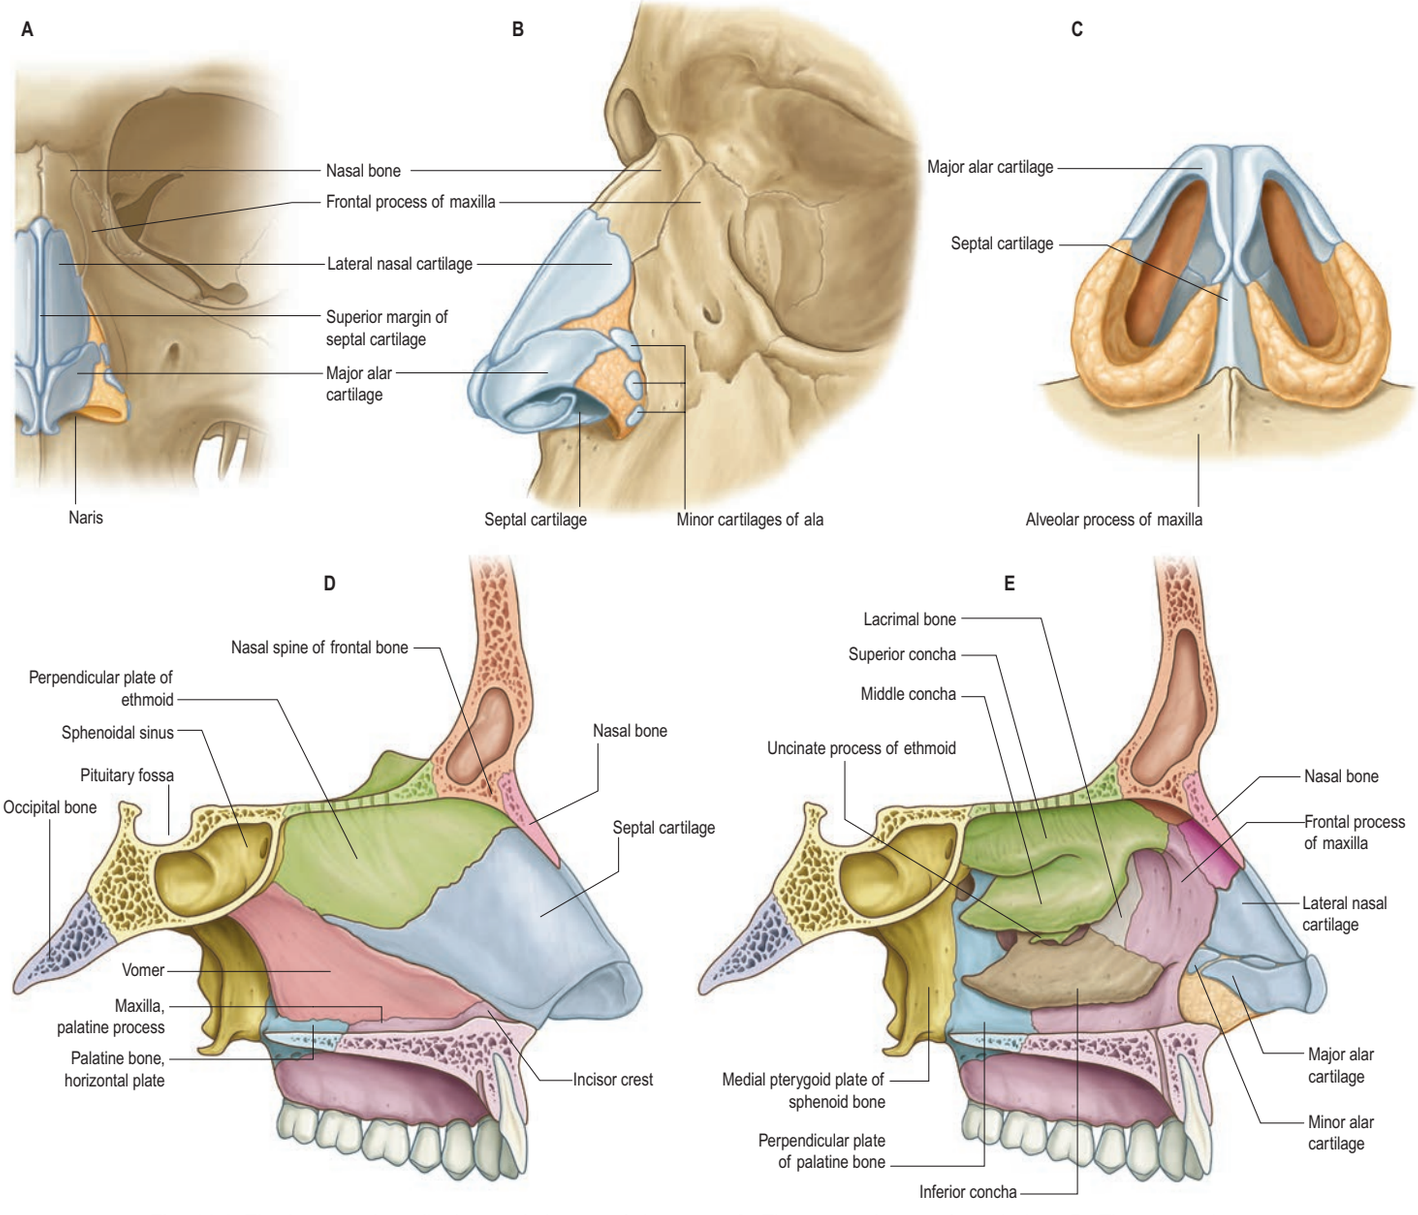

Fig. 39.3 The bony and cartilaginous skeletons of the nose. **A**, The external nose, frontal view. **B**, The external nose, lateral view. **C**, An inferior view of the cartilages. **D**, The nasal cavity, medial wall. **E**, The nasal cavity, lateral wall (left side).

The medial crus has two components, a footplate segment and a columellar segment, which angulate with each other in two planes; they diverge in the basal plane, and rotate upwards in the lateral plane. There is usually asymmetry in the pairs of medial crura.

The medial crus joins the intermediate crus at what is usually the most convex point of the columella, known as the columellar breakpoint.

The intermediate crus is also described in two components. The lobular segment is usually flared and forms the transition between the medial crus and the domal segment of the intermediate crus. The domal segment may be convex, producing an aesthetically pleasing tip; flat, giving a 'boxy' appearance; or convex, producing a 'double-dome'. The domal or tip-defining points are usually formed by the most anterior projection of the domal segment. The amount of divergence of the domes, and the thickness of the overlying soft tissue envelope, determine the relative position of the tip-defining points. The dome projects up to 8–10 mm caudal, and 3–6 mm anterior, to the anterior septal angle, the difference between the two creating the supratip break-point. Disruption of this relationship with rhinoplasty, with loss of projection of the tip, may produce a 'polybeak' deformity.

Classically, transverse connective tissue fibres have been described binding the medial and intermediate crura; interdomal, intercrural and septocrural ligaments have been described. Cadaveric studies by Zhai et al (1995) disputed the presence of transverse fibres, and found that all connective tissue fibres run parallel to the cartilages. These findings notwithstanding, the fibrous connections along the length of the medial and intermediate crura form a single functional unit in the tip.

The large lateral crus determines the shape of the alar lateral wall. Medially, it is a continuation of the intermediate crus, while laterally it connects with accessory cartilages. It runs at the caudal edge of the alar rim in the anterior half, then moves cephalically, leaving a soft tissue area in the rim laterally. Typically, the longitudinal axis of the lateral crus forms an angle of 45° with the septum. More vertical, or cephalic, positioning results in a 'parenthesis' tip deformity.

The lateral crus may take a highly variable position, being either convex or concave, or a combination of both, in medial and lateral portions; asymmetry from side to side has been reported in over half of anatomical specimens.

A chain of lateral accessory cartilages with dense fibrous attachments connect to the lateral crus and the piriform aperture, and to the anterior nasal spine through connection in the floor of the nose.

Tip support

The inherent strength and shape of the cartilaginous framework, and its attachments to surrounding structures, provide support to the tip of the nose. Typically, 'major' and 'minor' tip support mechanisms are described.

Major tip support mechanisms The major mechanisms supporting the tip are: the size, shape and strength of the major alar cartilages; the medial crural footplate attachment to the caudal part of the septum; the attachment of the caudal border of the lateral cartilages to the cephalic border of the major alar cartilages; and the cartilaginous dorsal septum.

Minor tip support mechanisms The minor mechanisms supporting the tip are: the ligamentous sling spanning the domes of the lower lateral cartilages (i.e. the interdomal ligament); the sesamoid complex of major alar cartilages; the attachment of the major alar cartilages to the overlying skin/soft tissue envelope; the nasal spine; and the membranous septum.

Rhinoplasty approaches, either through an intercartilaginous incision between the lateral and the major alar cartilages (closed rhinoplasty), or through an incision caudal to the major alar cartilages and degloving the entire cartilaginous framework (open rhinoplasty), disrupt the tip support mechanisms; the integrity of these mechanisms must be restored during the procedure to prevent loss of tip support and subsequent tip ptosis.

Cartilaginous skeleton of the external nose

The cartilaginous framework consists of the paired lateral and major cartilages and several minor alar nasal cartilages (see Fig. 39.3).

Lateral (superior/upper lateral) nasal cartilage

The lateral nasal cartilage is triangular, and its anterior margin is thicker than the posterior margin. The upper part fuses with the septal cartilage, but anteroinferiorly, it may be separated from it by a narrow fissure. The superior margin of the lateral nasal cartilage is attached to the nasal bone and frontal process of the maxilla, and the inferior margin is connected by fibrous tissue to the lateral crus of the major alar cartilage. Laterally, the cartilage is attached indirectly to the margins of the piriform aperture by loose fibroareolar connective tissue, which may also contain one or more small sesamoid cartilages. The angle formed between the caudal end of the lower lateral and the septum, the internal nasal valve, is usually between 10 and 15° and represents the narrowest cross-sectional area and the area of greatest airflow resistance. Structural abnormalities in this area are likely to produce symptomatic nasal obstruction.

Major alar (lower lateral) cartilage

The major alar cartilage is a highly complex, thin, flexible plate, which is integral to the nasal lobule. It lies below the upper lateral cartilage and curves acutely around the anterior part of its naris. The medial part, the narrow medial crus (septal process), is loosely connected by fibrous tissue to its contralateral counterpart and to the anteroinferior part of the septal cartilage. The intermediate crus forms the margin of the apex of the nostril. The domes give rise to the tip-defining points of the nose. The lateral crus lies lateral to the naris and runs superolaterally away from the margin of the nasal ala. The upper border of the lateral crus of the major alar cartilage is attached by fibrous tissue to the lower border of the lateral nasal cartilage. Its lateral border is connected to the frontal process of the maxilla by a tough fibrous membrane containing three or four minor alar cartilages. The junction between the lateral crura of the major alar and lateral cartilages is variable; the two edges may form a 'scroll', with an outcurving of the lateral cartilage meeting an incurving of the major alar cartilage, in which case the lateral crus is then the more lateral at the junction. The lateral crus is shorter than the lateral margin of the naris; the most lateral part of the margin of the ala nasi is fibroadipose tissue covered by skin. In front, the angulations or 'domes' between the medial and lateral crurae of the major alar cartilages are separated by a notch palpable at the tip of the nose.

Alar cartilage morphology

Muscles

The nasal muscle group includes procerus, nasalis, dilator naris anterior, depressor septi and levator labii superioris alaeque nasi (Fig. 39.4; see Figs 36.17, 36.18). These muscles are involved in respiration and facial expression. Any or all of these muscles may be absent in cleft lip deformities with corresponding functional and aesthetic consequences.

Procerus

Procerus is a small pyramidal muscle that lies close to, and is often partially blended with, the medial side of the frontal part of occipitofrontalis. It arises from a fascial aponeurosis attached to the periosteum covering the lower part of the nasal bone, the perichondrium covering the upper part of the lateral nasal cartilage, and the aponeurosis of the transverse part of nasalis. It is inserted into the glabellar skin over the lower part of the forehead between the eyebrows.

Vascular supply Procerus is supplied mainly by branches from the facial artery.

Innervation Procerus is supplied by temporal and lower zygomatic branches from the facial nerve (a supply from the buccal branch has been described).

Actions Procerus draws down the medial angle of the eyebrow and produces transverse wrinkles over the bridge of the nose. It is active in frowning and 'concentration', and helps to reduce the glare of bright sunlight. Not surprisingly, it is a common target in non-surgical facial rejuvenation techniques, using botulinum toxin.

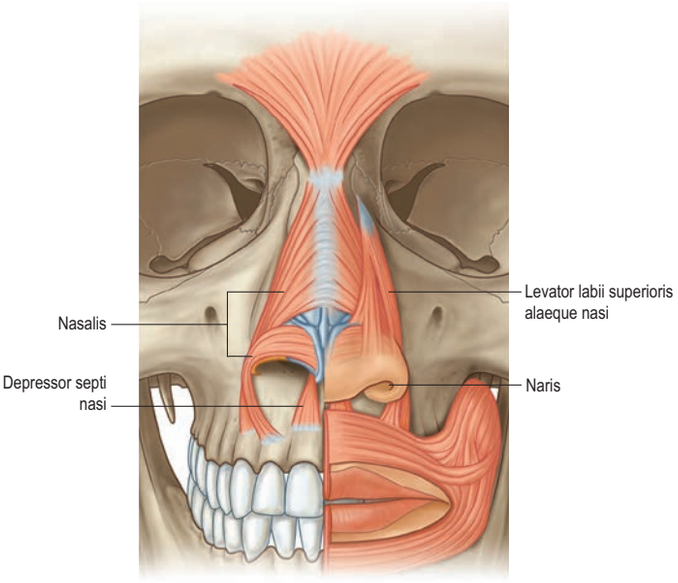

Fig. 39.4 The nasal musculature. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Nasalis

Nasalis consists of transverse and alar components. The transverse part (compressor naris) is attached to the maxilla above and lateral to the incisive fossa, and lateral to the alar part. Its fibres pass upwards and medially, and expand into a thin aponeurosis that merges with its counterpart across the bridge of the nose, with the aponeuroses of procerus, and with fibres from levator labii superioris alaeque nasi. Fibres from the transverse part may also blend with the skin of the nasolabial and alar folds. The alar part (pars alaris or dilator naris posterior) is attached to the maxilla above the lateral incisor and canine, lateral to the bony attachment of depressor septi, and medial to the transverse part, with which it partly merges. Its fibres pass upwards and anteriorly, and are attached to the skin of the ala above the lateral crus of the lower lateral cartilage, and to the posterior part of the mobile septum. The pars alaris helps to produce the upper ridge of the philtrum.

Dilator naris anterior (also known as apicis nasi or the small dilator muscle of the nose) is a very small muscle attached to the upper lateral cartilage, the alar part of nasalis, the caudal margin of the lateral crus and the lateral alar crus. It encircles the naris and acts as a primary dilator of the nostril.

Vascular supply Nasalis is supplied by branches from the facial artery and from the infraorbital branch of the maxillary artery.

Innervation Nasalis is supplied by the buccal branch of the facial nerve. It may also be supplied by the zygomatic branch of the facial nerve.

Actions The transverse part compresses the nasal aperture at the junction of the vestibule and the nasal cavity. The alar parts draw the alae and posterior part of the columella downwards and laterally, and so assist in widening the nares and in elongating the nose. They are active immediately before inspiration. Dilator naris anterior and the alar part of nasalis (dilator naris posterior) probably function to prevent collapse of the nasal valve during inspiration. Their electromyographic activity is directly proportional to ventilatory resistance and is modified by signals that travel from pulmonary mechano- and pressure receptors via afferent vagal pathways to the brainstem respiratory centre; the efferent limb of the reflex arc runs in the facial nerve.

Depressor septi

Depressor septi lies immediately deep to the mucous membrane of the upper lip. It is usually attached to the periosteum covering the maxilla above the central and lateral incisors and the anterior nasal spine, and to the fibres of orbicularis oris above the central incisor. Its fibres pass to the columella, the mobile part of the nasal septum and the base of the medial crus of the nasal cartilage. A few muscle slips may pass between the medial crura into the nasal tip. Depressor septi may be absent or rudimentary.

Vascular supply Depressor septi is supplied by the superior labial branch of the facial artery.

Innervation Depressor septi is innervated by the buccal branch, and sometimes by the zygomatic branch, of the facial nerve.

Actions Depressor septi pulls the columella, the tip of the nose and the nasal septum downwards. It tenses the nasal septum at the start of nasal inspiration and, with the alar part of nasalis, widens the nasal aperture, as well as causing the nose to 'dip' when some people smile.

Levator labii superioris alaeque nasi

Levator labii superioris alaeque nasi arises from the upper part of the frontal process of the maxilla and, passing obliquely downwards and laterally, divides into medial and lateral slips. The medial slip blends into the perichondrium of the lateral crus of the major alar cartilage of the nose and the skin over it. The lateral slip is prolonged into the lateral part of the upper lip, where it blends with levator labii superioris and orbicularis oris. Superficial fibres of the lateral slip curve laterally across the front of levator labii superioris and attach along the floor of the dermis at the upper part of the nasolabial furrow and ridge.

Vascular supply Levator labii superioris alaeque nasi is supplied by the facial artery and the infraorbital branch of the maxillary artery.

Innervation Levator labii superioris alaeque nasi is innervated by zygomatic and superior buccal branches of the facial nerve.

Actions The lateral slip raises and everts the upper lip and raises, deepens and increases the curvature of the top of the nasolabial furrow. The medial slip pulls the lateral crus superiorly, displaces the circumalar furrow laterally, and modifies its curvature; it is a dilator of the naris. Depressor septi and the medial slip of levator labii superioris alaeque nasi are sometimes described as secondary nasal dilators; there is little evidence that either of these muscles has any direct influence on the nasal valve.

Anomalous nasal muscles

Anomalous, inconstant, nasal muscles have been described. They include anomalous nasi, attached to the frontal process of the maxillae, transverse part of nasalis and the upper lateral cartilage (i.e. in a region normally devoid of muscle), and compressor narium minor, which passes between the anterior part of the lower lateral cartilage and the skin near the margins of the nares. The existence of a small levator septi nasi has been questioned.

Superficial musculo-aponeurotic system (SMAS)

Available with the *Gray's Anatomy* e-book

Cutaneous vascular supply and lymphatic drainage

Nasal skin receives its blood supply from branches of the facial, ophthalmic and infraorbital arteries. The alae and lower part of the nasal septum are supplied by lateral nasal and septal branches of the facial artery, and the lateral aspects and dorsum of the nose are supplied by the dorsal nasal branch of the ophthalmic artery and the infraorbital branch of the maxillary artery. The venous networks draining the external nose do not run parallel to the arteries but correspond to arteriovenous territories of the face. The frontomedian region of the face, including the nose, drains to the facial vein, and the orbitopalpebral area of the face, including the root of the nose, drains to the ophthalmic veins. The connections of the veins of the nose, upper lip and cheek (the 'danger triangle of the face') with the drainage area of the valveless ophthalmic veins, and hence to the cavernous sinus, are clinically significant because they can be a route for spreading infection that initiates thrombosis of the major intracranial sinuses. Lymph drainage is primarily to the submandibular group of nodes, although lymph draining from the root of the nose drains to superficial parotid nodes.

Cutaneous innervation

Nasal skin is innervated by the infratrochlear and external nasal branches of the nasociliary nerve (ophthalmic division, trigeminal nerve), and the nasal branch of the infraorbital nerve (maxillary division, trigeminal nerve).

NASAL CAVITY

The nasal cavity is an irregular space between the roof of the mouth and the cranial base. It is wider below than above, and widest and vertically deepest in its central region, where it is divided by a vertical, midline, osseocartilaginous septum. The bony part of the septum reaches the posterior limit of the cavity.

The nasal cavity communicates with the paranasal sinuses and opens into the nasopharynx through a pair of oval openings, the posterior nasal apertures or choanae. The latter are separated by the posterior border of the vomer, and each is limited above by the vaginal process of the medial pterygoid plates, laterally by the perpendicular plate of the palatine bone and the medial pterygoid plate, and below by the horizontal plate of the palatine bone (**Fig. 39.5**). The parameters of the intranasal spaces depend on age and gender: growth is usually completed by the age of 16 (Samoliński et al 2007). The adult choana typically measures 2.5 cm in vertical height and 1.3 cm transversely; size is not usually affected by deviations of the nasal septum. The vomerovaginal and palatovaginal canals are found in the roof of this region.

Each half of the nasal cavity has a vestibule, roof, floor, medial (septal) and lateral walls.

Nasal vestibule

The nasal vestibule lies just inside the naris. It is limited above and behind by a curved ridge, the limen nasi, raised where the greater ala of the lateral cartilaginous crus overlaps the lower edge of the lateral nasal cartilage on each side. On the septal side of the nasal cavity, the superior edge of the medial crus of the major alar cartilage (the medial intumescence) marks the boundary between the nasal vestibule and the nasal cavity. The medial wall of the vestibule is formed by a mobile septum consisting of the columella (which does not contain cartilage) and the underlying medial crura of the alar cartilages.

Roof

The roof is horizontal in its central part and slopes downwards in front and behind (**Fig. 39.3D–E**). The anterior slope is formed by the nasal spine of the frontal bones and by the nasal bones. The central region is formed by the cribriform plate of the ethmoid bone, which separates the nasal cavity from the floor of the anterior cranial fossa. It contains numerous small perforations that transmit the olfactory nerves and their ensheathing meningeal layers, and a separate anterior foramen that transmits the anterior ethmoidal nerve and vessels. The height of the cranial base is greatest anteriorly; hence, when dissecting along the cranial base during sinus surgery, it is safest to do so from back to front, addressing the lower-lying posterior region first to avoid inadvertent intracranial penetration. Posteriorly, the roof of the nasal cavity is formed by the anterior aspect of the body of the sphenoid, interrupted on each side by an opening of a sphenoidal sinus, and the sphenoidal conchae or superior conchae.

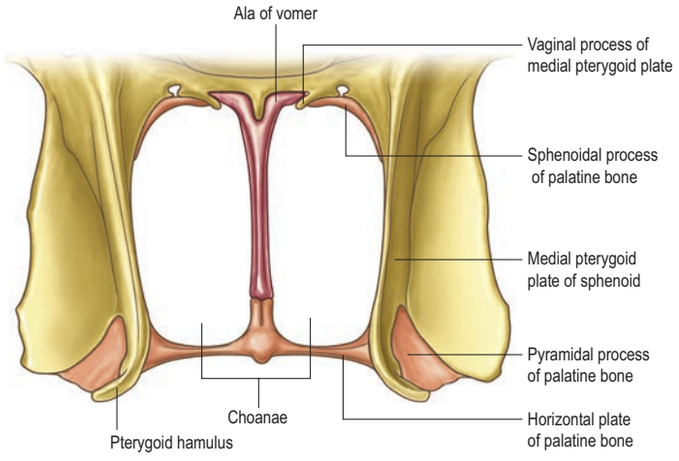

Fig. 39.5 A posterior view of the choanae.

Although each muscle is independent in terms of innervation and function, the mimetic muscles of the nose form a continuous layer with connections between all the muscular and ligamentous components (Saban et al 2008). Thus, the superficial musculo-aponeurotic system is continuous from the nasofrontal process to the nasal tip, splitting at the caudal end of the lateral cartilage into superficial and deep layers, each with medial and lateral components (Oneal et al 1999). Dissection in rhinoplasty is usually performed in a sub-superficial musculo-aponeurotic system plane. (For further information on the superficial musculo-aponeurotic system, see Ch. 36).

Floor

The floor of the nasal cavity is smooth and concave transversely, and slopes up from the anterior to the posterior apertures. The greater part is formed by the palatine processes of the maxillae, which articulate posteriorly with the horizontal plates of the palatine bones at the palatomaxillary suture (see Fig. 39.3D–E). Anteriorly, near the septum, a small infundibular opening in the bone of the nasal floor leads into the incisive canals that descend to the incisive fossa; this opening is marked by a slight depression in the overlying mucosa.

The floor of the nose may be deficient as a result of congenital clefting of the hard and/or soft palate.

Medial wall

The medial wall of each nasal cavity is the nasal septum, a thin sheet of bone (posteriorly) and cartilage (anteriorly) that lies between the roof and floor of the cavity (see Figs 36.4, 39.3D).

Bony septum

The septum is usually relatively featureless but sometimes exhibits ridges or bony spurs. The posterosuperior part of the septum and its posterior border are formed by the vomer, which extends from the body of the sphenoid to the nasal crest of the palatine bones and maxilla (see Fig. 36.4). The nasopalatine nerves and vessels groove its surface. (The nasopalatine artery, also known as the septal artery, is a branch of the maxillary artery; it leaves the pterygopalatine fossa through a canal inside the palatine bone, runs parallel to the nasopalatine nerve and ends in the incisive canal, where it anastomoses with the greater palatine artery.) The anterosuperior part of the septum is formed by the perpendicular plate of the ethmoid, which is continuous above with the cribriform plate and the frontal bone. Other bones that make minor contributions to the septum at the upper and lower limits of the medial wall are the nasal bones and the nasal spine of the frontal bones (anterosuperior), the rostrum and crest of the sphenoid (posterosuperior), and the nasal crests of the maxilla and palatine bones (inferior).

Cartilaginous septum

The septal cartilage is almost quadrilateral and may extend back (especially in children) for some distance between the vomer and the perpendicular plate of the ethmoid. Its anterosuperior margin is connected above to the posterior border of the internasal suture, and the distal end of its superior portion is continuous with the upper lateral cartilages. The anteroinferior border is connected by fibrous tissue on each side to the medial crurae of the major alar cartilage. Anteroinferiorly, the cartilaginous septum is attached to the anterior nasal spine, formed by anterior projections of each maxillary crest, and it has a strong, tongue-in-groove attachment with the premaxilla and vomer. The cartilaginous septum anterior to the spine is essential in tip support and should not be excised during septal surgery in order to prevent columellar retraction or loss of tip support. The posterosuperior border joins the perpendicular plate of the ethmoid, while the posteroinferior border is attached to the vomer and, anterior to that, to the nasal crest and anterior nasal spine of the maxilla. The anteroinferior part of the nasal septum between the nares is devoid of cartilage and is therefore called the membranous septum; it is continuous with the columella anteriorly.

Above the incisive canals, at the lower edge of the septal cartilage, a depression pointing downwards and forwards is all that remains of the nasopalatine canal, which connected the nasal and buccal cavities in early fetal life. Near this recess, a minute orifice leads back into a blind tubule, 2–6 mm long, that lies on each side of the septum and houses remnants of the vomeronasal organ (see below).

Lateral wall

The lateral wall of the nasal cavity is formed anteroinferiorly by the maxilla and its anterior and posterior fontanelles (bony deficiencies in the medial wall of the maxilla that are obliterated to varying degrees by fibrous tissue); posteriorly by the perpendicular plate of the palatine bone; and superiorly by the labyrinth of the ethmoid bone (**Fig. 39.6**; see Figs 39.3E, 36.5). It contains three projections of variable size: the inferior, middle and superior nasal conchae or turbinates. (A note on terminology. 'Concha' is the TA-compliant anatomical term; 'turbinate' is the preferred clinical term. In what follows, 'concha' refers to the bony structure seen in dried skulls, while 'turbinate' refers to that bony structure together with the overlying soft tissues and mucosa that are encountered during surgery).

The conchae curve inferomedially in general, each roofing a groove, or meatus, which is open to the nasal cavity. The middle concha may also curve inferolaterally; less commonly, it may often be expanded by an enclosed air cell to form a so-called 'concha bullosa', or occasionally may have a concave medial surface, known as a paradoxical turbinate. The main features of the lateral nasal wall are a rounded elevation, the bulla ethmoidalis, and a curved cleft, the hiatus semilunaris, formed by the posterior edge of the uncinate process and the anterior face of the ethmoidal bulla. This constitutes the medial limit of the ethmoidal infundibulum, a slit-like space that leads towards the maxillary ostium. The maxillary ostium is normally found lateral to the anteroinferior aspect of the uncinate process. The latter may have its predominant attachment to either the lateral nasal wall (>50%), the anterior cranial fossa, or the middle concha, or may have multiple sites of attachment (Netto et al 2015). Where the uncinate process is attached determines whether the frontal sinus drains lateral to the ethmoidal infundibulum or into it. If the uncinate process is attached to the lateral wall, the frontal sinus will drain into the middle meatus and not into the ethmoidal infundibulum, whereas with the other configurations, the sinus will drain into the infundibulum, and thus near or into the maxillary ostium. Agger nasi air cells are anterior ethmoidal air cells that lie anterior to the ethmoidal bulla (see Fig. 39.6). The posterior fontanelle lies posterior to the uncinate process where there is no bone in the medial wall of the maxillary sinus, inferoposterior to the hiatus, and frequently has an accessory opening (**Fig. 39.7**).

Inferior concha and inferior meatus

The inferior concha is a thin, curved, independent bone (for more details see Ch. 36). It articulates with the nasal surface of the maxilla and the perpendicular plate of the palatine bone. Its free lower border is gently curved and the subjacent inferior meatus reaches the nasal floor. The inferior meatus is the largest meatus, extending along almost all the lateral nasal wall. It is deepest at the junction of its anterior and middle thirds, where it admits the inferior opening of the nasolacrimal canal. The canal is formed by the articulations between the lacrimal groove of the maxilla, the descending process of the lacrimal bone and the lacrimal process of the inferior concha. During postnatal development, the ostium of the nasolacrimal duct moves upwards and is increasingly hidden under the over-arching inferior concha. Inconsistent epithelial folds (the valve of Hasner) may remain at its distal opening.

Middle concha and middle meatus

The middle concha is a medial process of the ethmoidal labyrinth and may be pneumatized (concha bullosa). Pneumatization that is restricted to the vertical lamella of the concha above the level of the ostiomeatal complex is termed an interlamellar cell of Grunwald (lamellar bulla, or conchal neck air cell). The middle concha extends back to articulate with the perpendicular plate of the palatine bone. The region beneath it is the middle meatus, which is deeper in front than behind, lies below and lateral to the middle concha, and continues anteriorly into a shallow fossa above the vestibule, termed the atrium of the middle meatus.

Sphenopalatine foramen

The sphenopalatine foramen, in reality a fissure, transmits the sphenopalatine artery and nasopalatine and superior nasal nerves from the pterygopalatine fossa. It is posterior to the middle meatus, and bounded above by the body and concha of the sphenoid, below by the superior border of the perpendicular plate of the palatine bone, and in front and behind by the orbital and sphenoidal processes of the palatine bone, respectively. The crista ethmoidalis, a small bony crest formed by the attachment of the basal lamella of the middle turbinate to the ascending palatine bone, is found anterior to the foramen, and is a reliable surgical landmark.

Ethmoturbinals

The ethmoturbinals are the superior and middle turbinates, occasionally supplemented by a supreme turbinate. They appear during weeks 9 and 10 of gestation as multiple folds on the developing lateral nasal wall and subsequently fuse into three or four ridges, each with an anterior (ascending) and a posterior (descending) ramus, separated by grooves. The first ridge develops into the agger nasi and the uncinate process. The second is thought to become the ethmoidal bulla and the fourth, if present, develops into the superior and supreme turbinates. The third is known as the basal lamella of the middle turbinate.

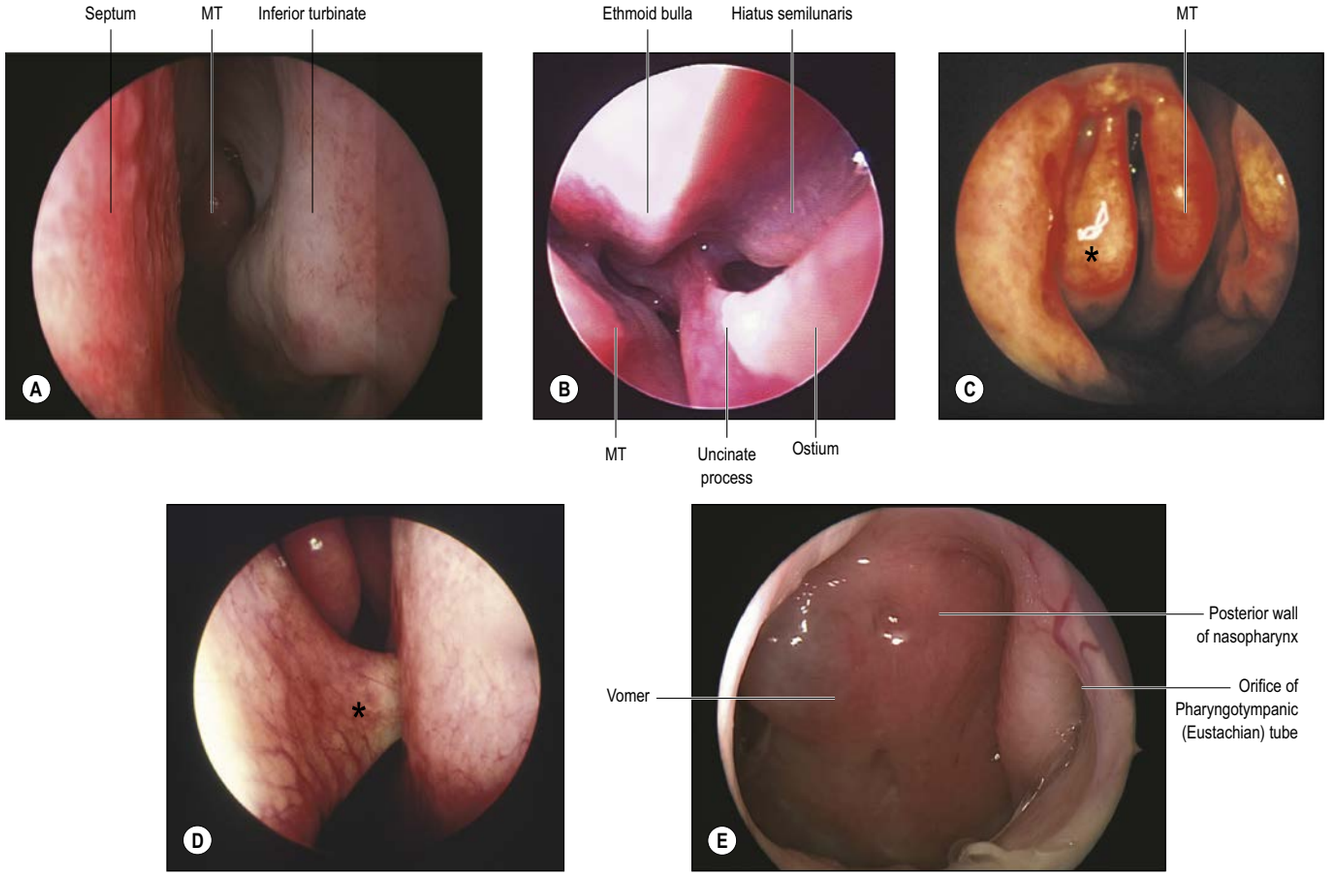

Fig. 39.7 A, An endoscopic view of the nasal cavity showing inferior and middle turbinates (MT). **B**, A view of the middle meatus and left lateral wall of the nose. **C**, An endoscopic view of the nose showing the middle turbinate and the pneumatized uncinate process in the middle meatus (asterisk). **D**, An endoscopic view of the nose demonstrating a deviated nasal septum (asterisk) making contact with the left inferior turbinate. **E**, An endoscopic view of the posterior nasal space.

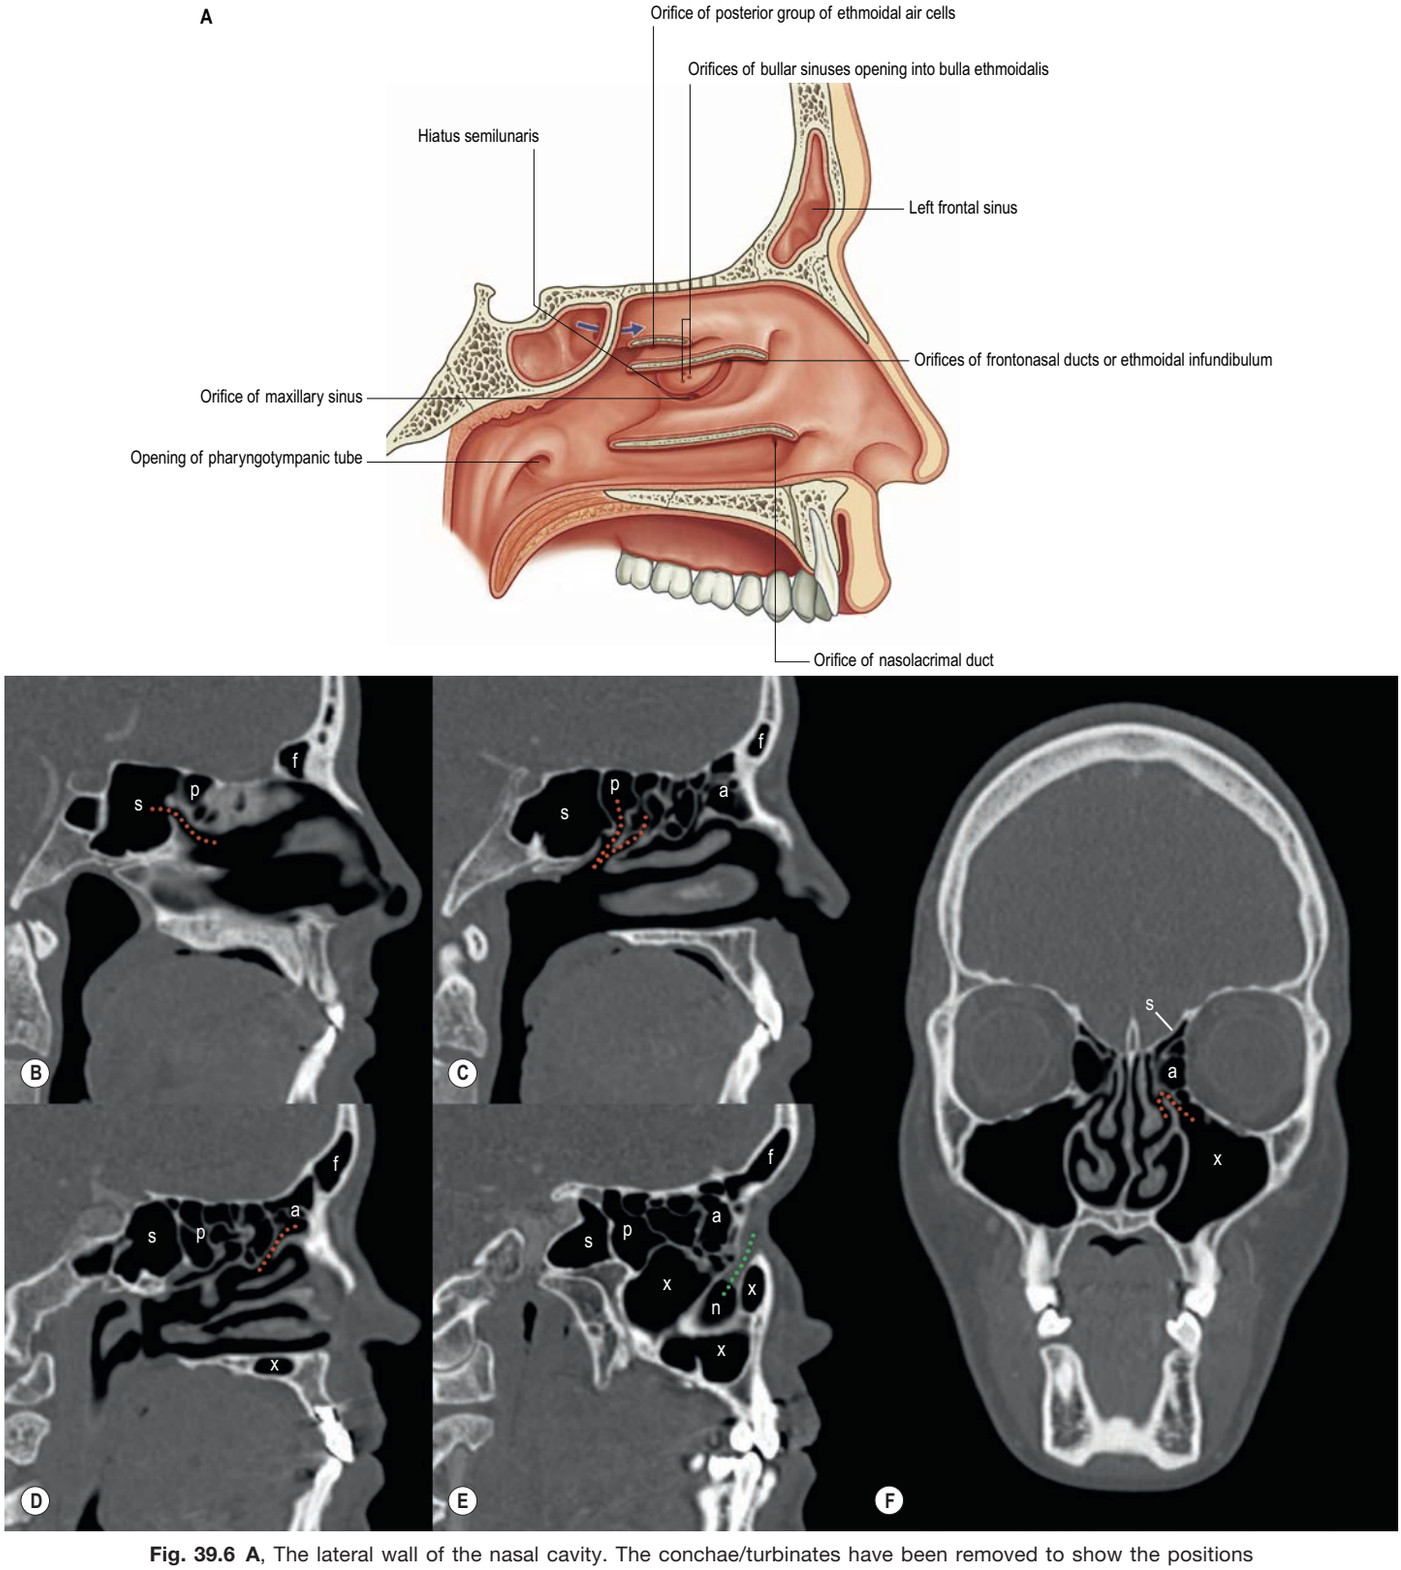

Fig. 39.6 A, The lateral wall of the nasal cavity. The conchae/turbinates have been removed to show the positions of the ostia of the paranasal sinuses and the nasolacrimal duct. The blue arrow passes through the orifice of the sphenoidal sinus into the sphenoethmoidal recess. **B–E**, Sagittal CT reconstructions through the left nasal cavity from medial to lateral. **F**, Coronal plane reconstruction through the maxillary air sinuses. The subject was given intravenous contrast medium and the images are viewed with bone window settings. Key: a, anterior ethmoidal air cells; f, frontal air sinus; n, nasal cavity; p, posterior ethmoidal air cells; s, sphenoidal air sinus; x, maxillary air sinus. The path from each air space to the nasal cavity is shown in dashed red and the path of the nasolacrimal duct is dashed green. (A, With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Attachments of the basal lamella of the middle turbinate

An understanding of the attachment of the middle turbinate to the roof and lateral wall of the nose is essential when undertaking sinus surgery. Anteriorly, it attaches to the crista ethmoidalis of the maxilla, and posteriorly it attaches to the crista ethmoidalis of the palatine bone, anterior to the sphenopalatine foramen. In between these points, the insertion lies in three different planes. The anterior third inserts vertically into the cranial base. The middle third turns laterally across the cranial base to the lamina papyracea, where it turns inferiorly; it may be indented by either anterior or posterior ethmoidal cells, but separates the two groups of cells. The posterior third runs horizontally, attaching to the lamina and the medial wall of the middle turbinate.

Superior concha and superior meatus

The superior concha is a medial process of the ethmoidal labyrinth and presents as a small curved lamina, posterosuperior to the middle concha. It roofs the superior meatus and is the shortest and shallowest of the three conchae. Above the superior concha, the sphenoidal sinus opens into the triangular sphenoethmoidal recess, which separates the superior concha and anterior aspect of the body of the sphenoid. The superior meatus is a short oblique passage extending about halfway along the upper border of the middle concha. The posterior ethmoidal sinuses open, via a variable number of apertures, into its anterior part.

Highest (supreme) nasal concha

Occasionally, a fourth concha, the highest or supreme nasal concha, appears on the lateral wall of the sphenoethmoidal recess. The passage immediately below it is called the supreme nasal meatus; it may contain an opening for the posterior ethmoidal sinus.

Functions of the nasal turbinates

In vivo, the conchae are covered with a thick, vascular, glandular soft tissue layer with pseudostratified columnar epithelium. They contain erectile tissue, modulated by trigeminal innervation detecting airflow and temperature; congestion and decongestion of the venous sinusoids regulate nasal resistance. The turbinates are essential for filtration, heating and humidification of inspired air. They direct airflow to the olfactory cleft, and some areas receive direct innervation from the olfactory bulb. Hypertrophy of the turbinates in allergy or environmental irritation results in nasal obstruction.

Nasal airflow and the nasal cycle

Nasal and olfactory mucosae

Nasal mucosa

The lining of the anterior part of the nasal cavity and vestibule is continuous with the skin, and consists of keratinized stratified squamous epithelium overlying a connective tissue lamina propria. Inferiorly, the skin bears coarse hairs (vibrissae), which curve towards the naris and help to arrest the passage of particles in inspired air. In males, after middle age, these hairs increase considerably in size. Further posteriorly, at the limen nasi, this changes into a mucosa, lined initially by non-keratinizing stratified squamous epithelium, and then by pseudostratified ciliated (respiratory) epithelium rich in goblet cells (see Fig. 2.2D). Respiratory epithelium forms most of the surface of the nasal cavity, i.e. it covers the conchae, meatuses, septum, floor and roof, except superiorly in the olfactory cleft, where the olfactory epithelium is present. It is adherent to the periosteum or perichondrium of the neighbouring skeletal structures. In some areas, cells of the respiratory epithelium may be low columnar or cuboidal, and the proportion of ciliated to non-ciliated cells is variable.

There are numerous seromucous glands within the lamina propria of the nasal mucosa. Their secretions make the surface sticky so that it traps particles in the inspired air. The mucous film is continually moved by ciliary action (the mucociliary escalator or rejection current) posteriorly into the nasopharynx at a rate of 6 mm per minute. Palatal movements transfer the mucus and its entrapped particles to the oropharynx for swallowing, but some also enters the nasal vestibule anteriorly. The secretions of the nasal mucosa contain the bacteriocides lysozyme, β-defensin and lactoferrin, and also secretory immunoglobulins (IgA). The mucosa is continuous with the nasopharyngeal mucosa through the posterior nasal apertures, the conjunctiva through the nasolacrimal duct and lacrimal canaliculi, and the mucosa of the sphenoidal, ethmoidal, frontal and maxillary sinuses through their openings into the meatuses.

The mucosa is thickest and most vascular over the conchae, especially at their extremities, and also on the anterior and posterior parts of the nasal septum and between the conchae. The mucosa is very thin in the meatuses, on the nasal floor and in the paranasal sinuses. Its thickness reduces the volume of the nasal cavity and its apertures significantly. The lamina propria contains cavernous vascular tissue with large venous sinusoids.

Olfactory mucosa

Olfactory mucosa (Fig. 39.8) covers approximately 5 cm^2 of the posterior upper parts of the lateral nasal wall, including the upper part of the vertical portion of the middle concha (where it is interspersed with respiratory epithelium in a chequerboard fashion) and the opposite part of the nasal septum, the superior concha, the sphenoethmoidal recess, the upper part of the perpendicular plate of the ethmoid and the portion of the roof of the nose that arches between the septum and lateral wall, including the underside of the cribriform plate (constituting the olfactory cleft or groove). It consists of a yellowish-brown pigmented pseudostratified epithelium, containing olfactory receptor neurones, sustentacular cells and two classes of basal cell, lying on a subepithelial lamina propria containing subepithelial olfactory glands (of Bowman) and bundles of axons derived from the olfactory receptor neurones that course through the mucosa on their way to the cribriform plate. The glands secrete a predominantly serous fluid through ducts that open on to the epithelial surface. These secretions form a thin fluid layer in which sensory cilia and the microvilli of the sustentacular cells are embedded.

Olfactory receptor neurones Olfactory receptor neurones are bipolar. Their cell bodies and nuclei are located in the middle zone of the olfactory epithelium. Each neurone has a single unbranched apical dendrite, 2 μm in diameter, which extends to the epithelial surface; and a basally directed unmyelinated axon, 0.2μm in diameter, which passes in the opposite direction, penetrates the basal lamina and enters the lamina propria. The tips of the dendrites project into the overlying secretory fluid and are expanded into characteristic endings (knobs) (Fig. 39.8B). Groups of up to 20 cilia radiate from the circumference of each ending and extend for long distances parallel to the epithelial surface. Internally, the short proximal part of each cilium has the '9 + 2' pattern of microtubules typical of motile cilia, while the longer distal trailing end contains only the central pair of microtubules. The olfactory cilia lack dynein arms and are thought to be non-motile; their primary purpose is to increase the surface area of sensory receptor membrane available for the efficient detection of odorant molecules transferred across the mucous layer by odorant-binding proteins. Mature olfactory neurones express olfactory marker protein (OMP), an abundant cytoplasmic protein involved in olfactory signal transduction (see Fig. 39.8D). Each olfactory receptor neurone expresses receptors for a single odorant molecule (or very few). In humans, over 1000 genes code for functional odorant receptors; the number of functional genes is much higher in macrosmotic animals (Buck and Axel 1991). Although neurones with the same receptor specificity are randomly distributed within anatomical zones of the epithelium, their axons all converge on the same glomerulus in the olfactory bulb. Specific odours activate a unique spectrum of receptor neurones, which in turn activate restricted groups of glomeruli and their second-order neurones.

The axons form small intraepithelial fascicles among the processes of sustentacular and basal cells. The fascicles penetrate the basal lamina and are immediately surrounded by olfactory ensheathing cells. Groups of up to 50 such fascicles join to form larger olfactory nerve rootlets that pass through the cribriform plate of the ethmoid bone, wrapped in meningeal sheaths. They immediately enter the overlying olfactory bulbs, where they synapse in glomeruli with mitral cells and, to a lesser extent, with smaller tufted cells (Ch. 32, p. 517).

Microvillar cells Microvillar cells occupy a superficial position in the olfactory epithelium. They are flask-shaped and electron-lucent, and the apical end of each cell gives rise to a tuft of microvilli that project into the mucus layer lining the nasal cavity (see Fig. 39.8B). Cell counts in longitudinal sections reveal that microvillar cells occur with a density that is approximately one-tenth of the density of ciliated olfactory neurones; their function and origin have yet to be determined.

Sustentacular cells Sustentacular, or supporting, cells are columnar cells that separate and partially ensheathe the olfactory receptor

The paired nasal valves are critical regulators of nasal airflow and resistance. Each is divided into external and internal portions, although often only the internal portion is regarded as the 'nasal valve' or flow-limiting segment. The external valve is made up of the ala, the skin of the vestibule, the nasal sill and the contour of the medial crus of the lower lateral cartilage. The external valve has a tendency to collapse at high flow rates, even in normal individuals.

The upper lateral cartilages are in continuity with the superior border of the nasal septum. A valve-like mechanism exists at its distal end that regulates nasal airflow. The nasal valve area and internal nasal valve are two entities that should not be confused. The nasal valve area is the narrowest portion of the nasal passage. It is bounded medially by the septum and the tuberculum of Zuckerkandl, and superiorly and laterally by the caudal margin of the upper lateral cartilage, its fibroadipose attachment to the piriform aperture and the anterior end of the inferior turbinate; inferiorly, it consists of the floor of the piriform aperture. The nasal valve, on the other hand, is the specific slit-like segment between the caudal margin of the upper lateral cartilage and the septum. It is measured in degrees and normally ranges between 10 and 15°. Dilator naris anterior and the alar part of nasalis support the nasal valves.

Airflow dynamics are recognized as playing a key role in conditioning (i.e. warming, humidifying and filtering) inspired air; however, these dynamics are still poorly understood (Churchill et al 2004, Boyce and Eccles 2006). It is generally agreed that airflow within the nose is both laminar and turbulent. Inspired air is forced to pass through the nasal valve and then expands as it passes further into the nasal cavity, which offers little airflow resistance. This sudden change in speed and pressure produces turbulence and eddies. These currents allow adequate contact of inspired air with respiratory epithelium and facilitate odorant transport to the olfactory area. Chewing also affects nasal airflow; pulses of aroma-laden air are pumped out of the mouth into the retronasal region with each chew.

The cross-sectional area of the nasal airway depends on the dimensions of the septal partition and inferior turbinates (which are modulated by changes in the dimensions of the erectile tissue that covers them), and on the stability of the lateral nasal walls during breathing. The nasal cycle is an alternating fluctuation of nasal engorgement and airflow through the nasal passages, with period lengths ranging from 1 to 5 hours. The mechanism involves changes in sympathetic tone to the venous erectile tissue of the nasal mucosa; increased sympathetic vasoconstriction causes resistance to fall. These alterations in the thickness and contours of the mucosal surfaces are visible as a swelling or shrinkage of the nasal lining, and may serve to protect the mucosae from desiccation. The pacemaker for the cycle is believed to lie within the suprachiasmatic nucleus. The rhythmicity of the cycle decreases with age.

Nasal obstruction

Disturbances of the normal airflow pattern, whether produced by mucocutaneous or skeletal changes within the nose, affect normal nasal breathing and are usually perceived as some form of nasal obstruction.

The septum may be displaced by injury or by disproportionate growth of the cartilage that may cause it to bend; sometimes, the deviation may cause unilateral nasal obstruction. Variations in the anatomy of the lateral nasal wall, usually associated with variations in the size and position of the anterior ethmoidal cells, may obstruct frontal or maxillary sinus drainage, e.g. frontal cells, supraorbital ethmoidal cells, and infraorbital or Haller's cells, which represent an extension of anterior ethmoidal pneumatization along the infraorbital margin, sometimes within the roof of the maxillary sinus (see below).

neurones. Their large nuclei form a layer superficial to the neuronal nuclei within the epithelium. The cells are capped by numerous long, irregular, microvilli, which lie in the secretory fluid layer that covers the surface of the epithelium, intermingled with the trailing ends of the cilia on the olfactory receptor endings. Their expanded bases contain numerous lamellated dense bodies, which are the remnants of secondary lysosomes, and which contribute significantly to the pigmentation of the olfactory area (see Fig. 39.8B,C). The granules gradually accumulate with age, and because these cells are long-lived, the intensity of pigmentation also increases with age. Neighbouring sustentacular cells are linked by desmosomes close to the epithelial surface, an arrangement that helps to stabilize the epithelium mechanically. Sustentacular cells and olfactory receptor neurones are linked by tight junctions at the level of the epithelial surface.

Basal cells There are horizontal and globose basal cells. Horizontal basal cells are flattened against the basal lamina. Their nuclei are condensed and their darkly staining cytoplasm contains numerous intermediate filaments of the cytokeratin family, inserted into desmosomes between the basal cells and surrounding sustentacular cells. Globose cells are rounded or elliptical in shape, and have pale, euchromatic nuclei and pale cytoplasm. They form a distinct zone that is slightly internal to the basal surface of the epithelium and characterized by mitotic figures; globose basal cells are the immediate source of new olfactory receptor neurones.

Olfactory ensheathing cells Olfactory ensheathing cells share properties with astrocytes and non-myelinating Schwann cells, but also possess distinctive features that indicate they are a separate class of glia. Developmentally, they are derived from the olfactory placode rather than the neural crest. They ensheathe olfactory axons in a unique manner throughout their entire course and accompany them into the olfactory bulb, where they contribute to the glia limitans. In recent years, olfactory ensheathing cells have been the focus of intense experimental scrutiny in the search for a source of transplantable glia capable of supporting neuronal regeneration within the central nervous system, possibly in the treatment of paraplegia.

Olfactory glands Olfactory (Bowman's) glands are branched tubuloalveolar structures that lie beneath the olfactory epithelium and secrete their products on to the epithelial surface through narrow, vertical ducts. Their secretions, which include defensive substances, lysozyme, lactoferrin, IgA and sulphated proteoglycans, together with odorant-binding proteins that increase the efficiency of odour detection, bathe the dendritic endings and cilia of the olfactory receptors. The fluid acts as a solvent for odorant molecules, allowing their diffusion to the sensory receptors.

Turnover of olfactory receptor neurones

Vascular supply and lymphatic drainage

Many of the vessels and nerves supplying the nasal cavities arise within the pterygopalatine fossa and these origins are described in Chapter 38.

Arteries

Branches of the ophthalmic, maxillary and facial arteries supply different territories within the walls, floor and roof of the nasal cavity (Fig. 39.9). They ramify to form anastomotic plexuses within and deep to the nasal mucosa. Anastomoses also occur between some larger arterial branches. The anterior and posterior ethmoidal branches of the ophthalmic artery supply the ethmoidal and frontal sinuses and the roof of the nose (including the septum). The anterior ethmoidal artery usually runs within the bone of the anterior skull base, unless this is well pneumatized with a supraorbital cell, in which case the artery is more likely to be positioned away from the skull base and to be more prone to surgical damage (Fig. 39.10). The anterior ethmoidal artery is usually exposed and ligated within the orbit through a medial canthal incision. That will arrest most bleeds high up in the nasal cavity. It can also be encountered unexpectedly in an anterior ethmoidal cell and cause brisk bleeding if ruptured or accidentally transected. Worse still, the transected proximal end of the artery may retract into the orbit continuing to bleed and causing an orbital haematoma that requires rapid exploration.

Olfactory receptor neurones are lost and replaced throughout life. Individual receptor cells have a variable lifespan, thought to average 1–3 months. Stem cells situated near the base of the epithelium undergo periodic mitotic division throughout life, giving rise to new olfactory receptor neurones, which then grow a dendrite to the olfactory surface and an axon to the olfactory bulb. The cell bodies of these new receptor neurones gradually move apically until they reach the region just below the supporting cell nuclei. When they degenerate, dead neurones either are shed from the epithelium or are phagocytosed by sustentacular cells. The rate of receptor cell loss and replacement increases after exposure to damaging stimuli but declines slowly with age, a phenomenon that presumably contributes to diminishing olfactory sensory function in old age. Biopsy specimens from normosmic adults have revealed that patchy replacement of olfactory with respiratory epithelium occurs even in young healthy adults (Paik et al 1992, Holbrook et al 2005).

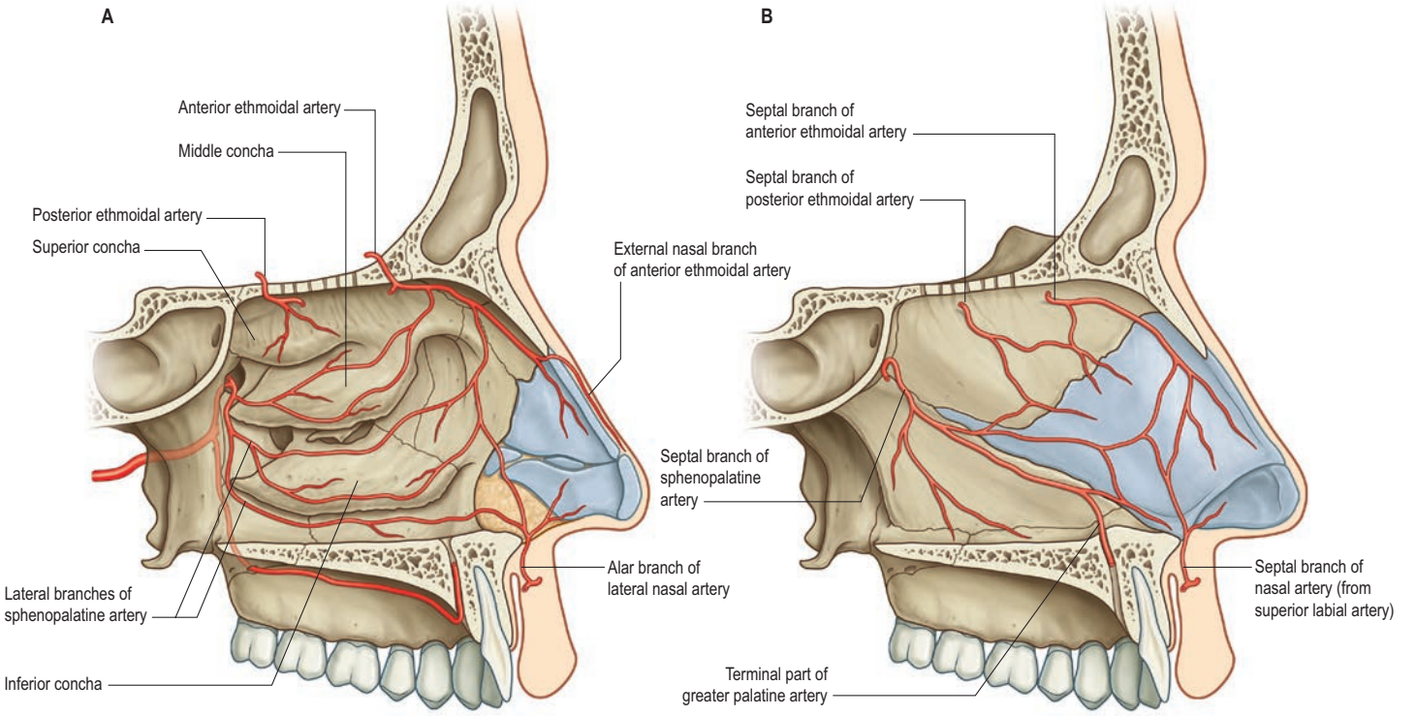

Fig. 39.9 The arterial supply of the nasal cavity. **A**, The lateral wall of the left nasal cavity. **B**, The medial wall of the left nasal cavity. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

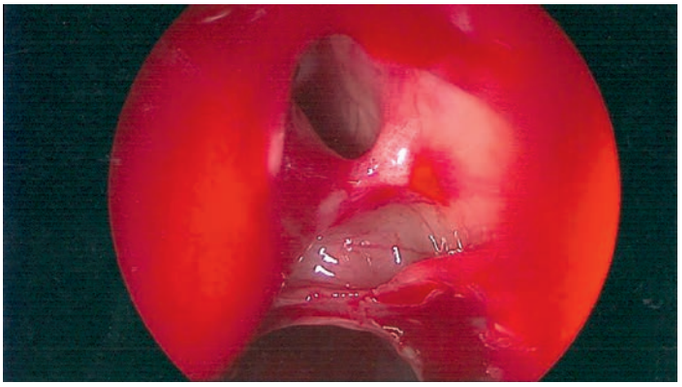

Fig. 39.10 *In vivo* demonstration of the anterior ethmoidal artery exposed in the anterior ethmoidal cells, after removing the anterior face of the ethmoid bulla. Inadvertent damage during sinus dissection may allow retraction of the stump into the orbit, with ongoing bleeding leading to development of an orbital haematoma

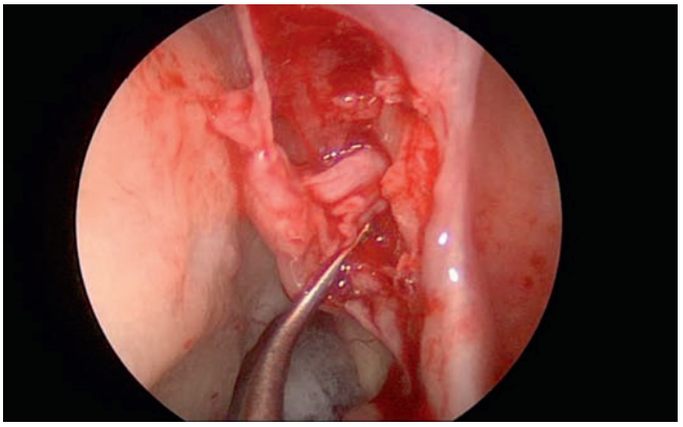

Fig. 39.11 *In vivo* demonstration of the sphenopalatine artery (main trunk, with smaller branch inferiorly demonstrated with the pointer) emerging from the sphenopalatine foramen, behind the crista ethmoidalis. The posterior wall of the maxillary sinus is visible through a large antrostomy, and a mucosal flap has been elevated to demonstrate the vessels.

A middle ethmoid artery may be identified in 20–30% of sinus cavities (Wang et al 2014). The sphenopalatine branch of the maxillary artery supplies the mucosa of the turbinates, meatuses and posteroinferior part of the nasal septum, i.e. it is the principal vessel supplying the nasal mucosa. The artery comes out of a fissure (erroneously termed a foramen), and normally divides before it enters the nasal cavity behind the crista ethmoidalis into posterior lateral nasal and posterior septal branches (Fig. 39.11). Sometimes, the artery may divide before it leaves the foramen. The number and distribution of its branches show great variation, with a median of three branches (Eordogh et al 2018). The greater palatine branch of the maxillary artery supplies the region of the inferior meatus. A branch crosses the sphenoidal rostrum, below its natural ostium, to supply the nasal septum. This is utilized to provide pedicled, vascularized nasoseptal flaps in skull-base reconstruction. Its terminal part ascends through the incisive canal to anastomose on the septum with branches of the sphenopalatine and anterior ethmoidal arteries, and with the septal branch of the superior labial artery. This septal region (Little's area or Kiesselbach's plexus) is a common site of bleeding from the nose. The infraorbital artery and the superior, anterior and posterior alveolar branches of the maxillary artery supply the mucosa of the maxillary sinus. The pharyngeal branch of the maxillary artery supplies the sphenoidal sinus.

Nose bleeds

Available with the *Gray's Anatomy* e-book

Veins

A rich submucosal cavernous plexus is especially dense in the posterior part of the septum and in the middle and inferior turbinates (Fig. 39.12). Numerous arteriovenous anastomoses are present in the deep layer of the mucosa and around the mucosal glands. The cavernous turbinate plexuses resemble those in erectile tissue; the nasal cavity is susceptible to blockage, should they become engorged. Veins from the posterior part of the nose generally pass to the sphenopalatine vein that runs back through the sphenopalatine foramen to drain into the pterygoid venous plexus. The anterior part of the nose is drained mainly through veins accompanying the anterior ethmoidal arteries, and these veins

subsequently pass into the ophthalmic or facial veins. Injection of vasoconstrictive agents or corticosteroids during surgery, particularly to the inferior turbinates, may permit access to the intracranial and ophthalmic circulations. Blindness has been reported in rare cases following such injections. A few veins pass through the cribriform plate to connect with those on the orbital surface of the frontal lobes of the brain. When the foramen caecum is patent, it transmits a vein from the nasal cavity to the superior sagittal sinus.

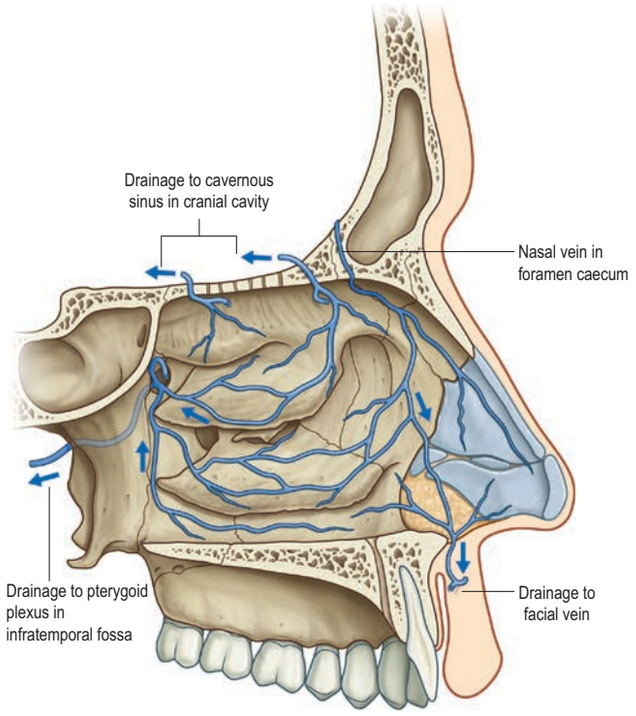

Fig. 39.12 The venous drainage of the nasal cavity: the lateral wall of the left nasal cavity. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Lymphatic drainage

Lymph vessels from the anterior region of the nasal cavity pass superficially to join those draining the external nasal skin and end in the submandibular nodes. The rest of the nasal cavity, paranasal sinuses, nasopharynx and pharyngeal end of the pharyngotympanic tube all drain to the upper deep cervical nodes, either directly or through the retropharyngeal nodes. The posterior nasal floor probably drains to the parotid nodes.

Innervation

Olfaction is mediated via the olfactory nerves. General sensation (touch, pain and temperature) from the nasal mucosa is carried by branches of the ophthalmic and maxillary divisions of the trigeminal nerves (Fig. 39.13). Trigeminal fibres close to, and within, the epithelial layer are sensitive to noxious chemicals, e.g. ammonia and sulphur dioxide. Autonomic fibres innervate mucous glands and control cyclical and reactive vasomotor activity.

Sensory (trigeminal) innervation

The anterior ethmoidal branch of the nasociliary nerve leaves the cranial cavity through a small slit near the crista galli and enters the roof of the nasal cavity, where it runs in a groove on the inner surface of the nasal bone, supplying the roof of the nasal cavity. It gives off a lateral internal branch to supply the anterior part of the lateral wall, and a medial internal branch to the anterior and upper parts of the septum, before emerging at the inferior margin of the nasal bone as the external nasal nerve to supply the skin of the external nose to the nasal tip; damage following nasal trauma may result in paraesthesia of the tip. The infraorbital nerve supplies the nasal vestibule. The anterior superior alveolar nerve supplies part of the septum, the floor near the anterior nasal spine and the anterior part of the lateral wall as high as the opening of the maxillary sinus; the lateral posterior superior nasal and the posterior inferior nasal branches of the greater palatine nerve together supply the posterior three-quarters of the lateral wall, roof and floor; the medial posterior superior nasal nerves and the nasopalatine nerve supply the inferior part of the nasal septum; and branches from the nerve of the pterygoid canal supply the upper and posterior part of the roof and septum.

Autonomic innervation

The deep petrosal nerve (postganglionic sympathetic fibres) and the greater petrosal nerve (preganglionic parasympathetic fibres) converge

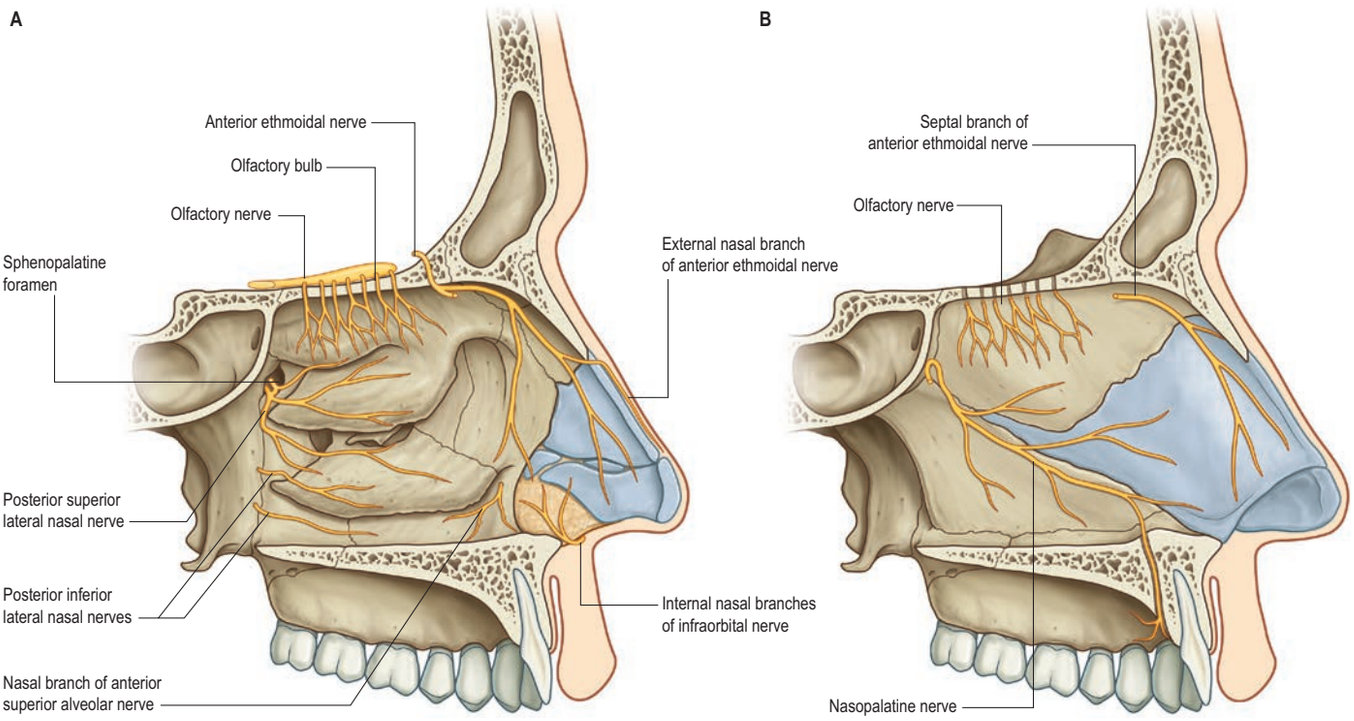

Fig. 39.13 The innervation of the nasal cavity. **A**, The lateral wall of the left nasal cavity. **B**, The medial wall of the left nasal cavity. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

The vast majority of nose bleeds, particularly in children, occur as a result of digital trauma to the anastomosis of arterioles and veins in Little's area, on the nasal septum just inside the nasal vestibule. This area is amenable to cautery when required. In older patients, brisker bleeding may occur as a result of the spontaneous rupture of arteries further back in the nose. These may be controlled by applying pressure with a nasal pack, but where this fails, knowledge of the pattern of arterial blood supply to the nasal cavity permits interruption of the appropriate blood supply by ligation or embolization of the feeding vessel. The sphenopalatine artery may be ligated under endoscopic visualization as it enters the nose through the sphenopalatine foramen. The ethmoidal arteries may be exposed within the orbit and ligated to arrest bleeding high up in the nasal cavity. The maxillary artery may be exposed surgically behind the posterior wall of the maxillary sinus and ligated, or alternatively it may be identified radiologically, using a radiopaque dye, so that it may be blocked by embolization (Simmen and Jones 2010).

to form the nerve of the pterygoid canal (Vidian nerve in the Vidian canal). The canal enters the pterygopalatine fossa, and the nerve joins the pterygopalatine ganglion, where the parasympathetic fibres synapse, but the sympathetic fibres pass through without synapsing (Ch. 38). The nerve of the pterygoid canal is an important landmark to the petrous portion of the internal carotid artery, and may also rarely be transected to treat intractable rhinorrhoea. Sympathetic postganglionic vasomotor fibres are distributed to the nasal blood vessels. Postganglionic parasympathetic fibres derived from the pterygopalatine ganglion provide the secretomotor supply to the nasal mucous glands, and are distributed via branches of the maxillary nerves.

Olfactory nerves

Olfactory nerves are bundles of very small axons derived from olfactory receptor neurones in the olfactory mucosa. The axons are unmyelinated, and in varying stages of maturity, reflecting the constant turnover of olfactory neurones that takes place in the olfactory epithelium. Bundles of axons surrounded by olfactory ensheathing cells form a plexiform network in the subepithelial lamina propria of the mucosa. The bundles unite into as many as 20 branches that cross the cribriform plate in lateral and medial groups, and enter the overlying olfactory bulb, where they end in glomeruli. Each branch is ensheathed by dura mater and pia arachnoid as it passes through the cribriform plate (**Fig. 39.14**). The dura subsequently becomes continuous with the nasal periosteum, and the pia arachnoid merges with the connective tissue sheaths surrounding the nerve bundles, an arrangement that may favour the spread of infection into the cranial cavity from the nasal cavity.

In severe injuries involving the anterior cranial fossa, the olfactory bulb may be separated from the olfactory nerves or the nerves may be torn, producing anosmia, i.e. loss of olfaction. Fractures may involve the meninges, so that cerebrospinal fluid may leak into the nose, resulting in cerebrospinal rhinorrhoea. Such injuries open up avenues for intracranial infection from the nasal cavity.

Vomeronasal organ

PARANASAL SINUSES

The paranasal sinuses are the frontal, ethmoidal, sphenoidal and maxillary sinuses, housed within the bones of the same name (**Fig. 39.15** , see Figs 39.1, 39.14–39.25). They all open into the lateral wall of the nasal cavity by small apertures that permit both the equilibration of air between the various air spaces and the clearance of mucus from the sinuses into the nose via a mucociliary escalator. The detailed position of these apertures, and the precise form and size of each of the sinuses, vary enormously between individuals (Lang 1989, Navarro 1997, Beale et al 2009). Respiratory epithelium extends through the apertures of the paranasal sinuses to line their cavities, a feature that unfortunately favours the spread of infections. Sinus mucosa is thinner and less vascular, and has fewer goblet cells, than nasal mucosa. Cilia are always present in the mucosa near the apertures but less evenly distributed elsewhere within the sinuses.

The functions of the paranasal sinuses remain speculative. They clearly add some resonance to the voice, and also allow the enlargement of local areas of the skull while minimizing a corresponding increase in bony mass. It is likely that such growth-related changes serve to strengthen particular regions, e.g. the alveolar processes of the maxillae when the secondary dentition erupts, but they may also function in contouring the head to provide visual signals indicating the individual's status in a social context (e.g. gender, sexual maturity and group identity).

Most sinuses are rudimentary or absent at birth, but enlarge appreciably during the eruption of the permanent teeth and after puberty, events that significantly alter the size and shape of the face.

Development of the paranasal sinuses and anatomical variations in childhood

At birth, both small ethmoidal and maxillary sinuses are present, but the frontal sinus is nothing more than an out-pouching from the nasal cavity, and there is no pneumatization of the sphenoid bone. Understanding the development of the sinuses at each stage of childhood is essential for interpreting pathology and planning surgery. Cadaveric and radiological studies have provided normative data for sinus development.

Elsevier, Saunders. Copyright 2013.)

In most amphibians, reptiles and mammals, the vomeronasal organ is the peripheral sensory organ of the accessory olfactory system. In these animals, paired vomeronasal organs are located either at the base of the nasal septum or in the roof of the mouth, and are involved in chemical communication that is often, but not exclusively, mediated via pheromones. In many macrosomatic animals, the vomeronasal organ consists of a vomeronasal duct that contains chemosensory cells, and a vomeronasal nerve that terminates centrally in the accessory olfactory bulb. The vomeronasal organ exists in the developing human fetus but its existence in the adult has long been controversial. A bilateral structure in the anteroinferior wall of the nasal septum just dorsal to the paraseptal cartilages, which is presumed to be analogous to the vomeronasal organ of other vertebrates, has been demonstrated in adult human tissue; while there is no evidence that this structure has any neuroreceptive function, it has been suggested that it might have an as yet unknown endocrine function (Wessels et al 2014).

Variations in sinus development

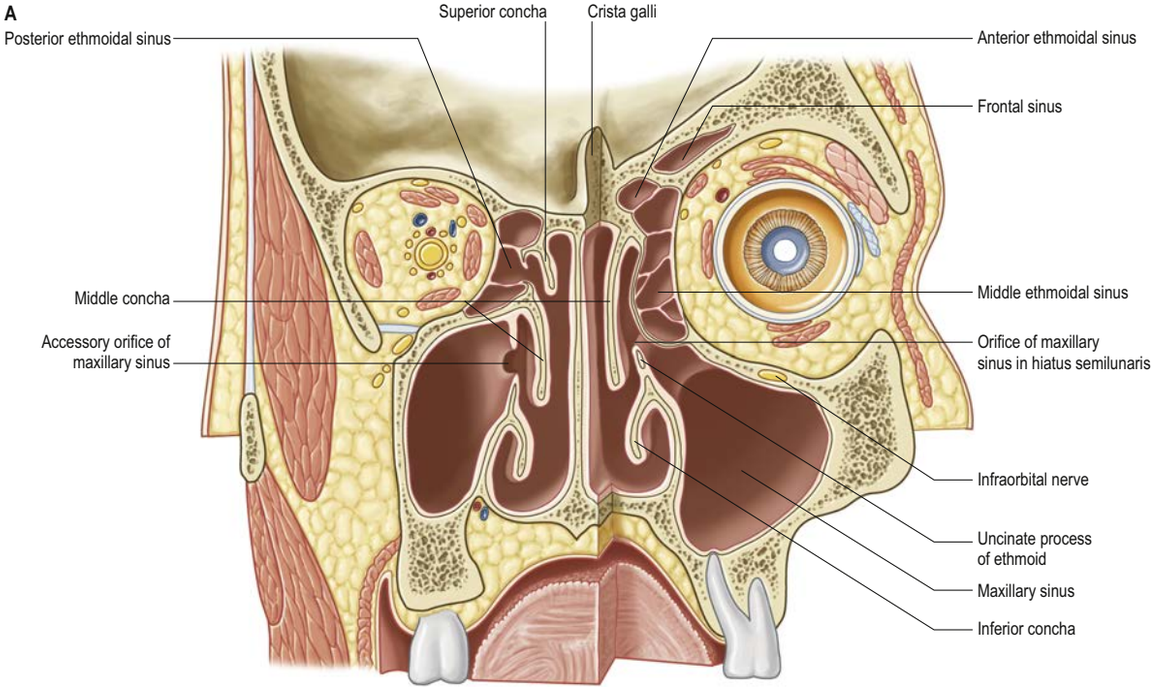
Available with the *Gray's Anatomy* e-book

Frontal sinus

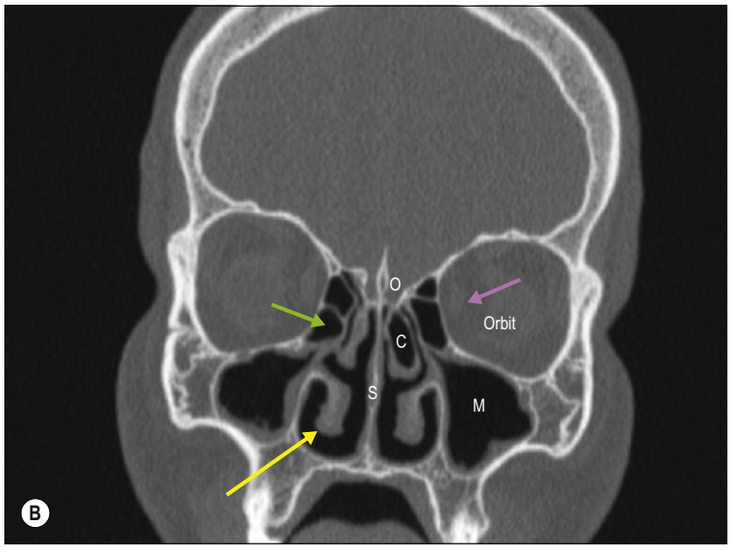
The paired frontal sinuses are posterior to the superciliary arches, between the outer and inner tables of the frontal bone (**Figs 39.16–39.17**). Each usually underlies a triangular area on the surface of the face, its angles formed by the nasion, a point 3 cm above the nasion and the junction of the medial third and lateral two-thirds of the supraorbital margin. The two sinuses are rarely symmetric, since the septum between them usually deviates from the median plane. Each sinus may be further divided into a number of communicating recesses by incomplete bony septa.

The average dimensions of an adult frontal sinus are: height 3.2 cm; breadth 2.6 cm; and depth 1.8 cm. Each usually has a frontal portion that extends upwards above the medial part of the eyebrow, and an orbital portion that extends back into the medial part of the roof of the orbit. One or both sinuses may rarely be hypoplastic or even absent; racial differences have been reported. The prominence of the superciliary arches is no indication of the presence or size of the frontal sinuses. They are more prominent in males, and lend the forehead an obliquity that contrasts with the vertical or convex profile typical of children and females.

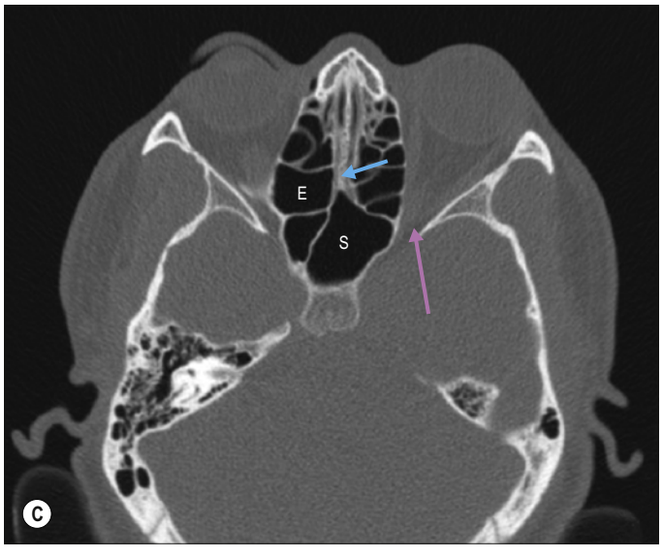
The aperture of each frontal sinus opens either into the anterior part of the corresponding middle meatus by the ethmoidal infundibulum as a frontonasal recess (rather than a duct), or medial to the hiatus semilunaris if the uncinate process is attached to the lateral nasal wall or an agger nasi cell (Kuhn 2002). The frontal recess is actually the most anterior part of the anterior ethmoidal complex but is described here because of its importance in the drainage of the frontal sinus. Its lateral wall is the lamina papyracea; the medial wall is formed by the middle turbinate; and posteriorly, the wall is made up of either the cranial base, in a suprabullar recess, or the insertion of the bulla, if this reaches the cranial base. Anteriorly, the wall extends from the frontal sinus proper to the anterior attachment of the middle turbinate. In its simplest form, it takes the shape of an inverted funnel, forming an hourglass shape with the floor of the frontal sinus. However, the frontal recess is often narrowed both from in front and from behind by anterior ethmoidal cells, such that it may be highly convoluted (see Fig. 39.17).



These frontoethmoidal cells may be classified with regard to their attachments to the inner walls of the frontal sinus and relationship to the frontal recess as anterior or posterior, medial or lateral (Lund et al 2014), or with regard to their relationship with the agger nasi cell or the ethmoid bulla (Wormald et al 2016) (**Table 39.2**).



Vascular supply, lymphatic drainage and innervation



The frontal sinuses receive their arterial supply from the supraorbital and anterior ethmoidal arteries. The veins drain into an anastomotic vein in the supraorbital notch that connects the supraorbital and superior ophthalmic veins. Lymphatic drainage is to the submandibular nodes. The sinuses are innervated by branches of the supraorbital nerves (general sensation) and the orbital branches of the pterygopalatine ganglia (parasympathetic secretomotor fibres).

Sphenoidal sinus

The sphenoidal sinuses are two large, irregular cavities within the body of the sphenoid and therefore lie posterior to the upper part of the nasal cavity (**Figs 39.18–39.19**). Each opens into the corresponding sphenoethmoidal recess via an aperture high on the anterior wall of the sinus. The sphenoid ostium is usually medial to the superior turbinate, although the height of the ostium is highly variable. The average dimensions of the adult sphenoid are: vertical height 2 cm; transverse breadth 1.8 cm; and anteroposterior depth 2.1 cm. The sinuses are usually separated by a septum that usually deviates from the midline, so that they are unequal in size and form. Their lumina may be further partially divided by bony laminae and accessory septa, especially in the region of former synchondroses, and these septa commonly insert on to the internal carotid artery. Occasionally, one sinus overlaps the other above and, rarely, they intercommunicate. Bony ridges, produced by the internal carotid artery, pterygoid canal, maxillary branch of trigeminal and sometimes the optic nerve, may project into the sinuses from their lateral walls. The sphenoidal sinuses are related above to the optic chiasma and hypophysis cerebri, and on each side to the internal carotid artery and cavernous sinus. One or both sinuses may partially encircle the

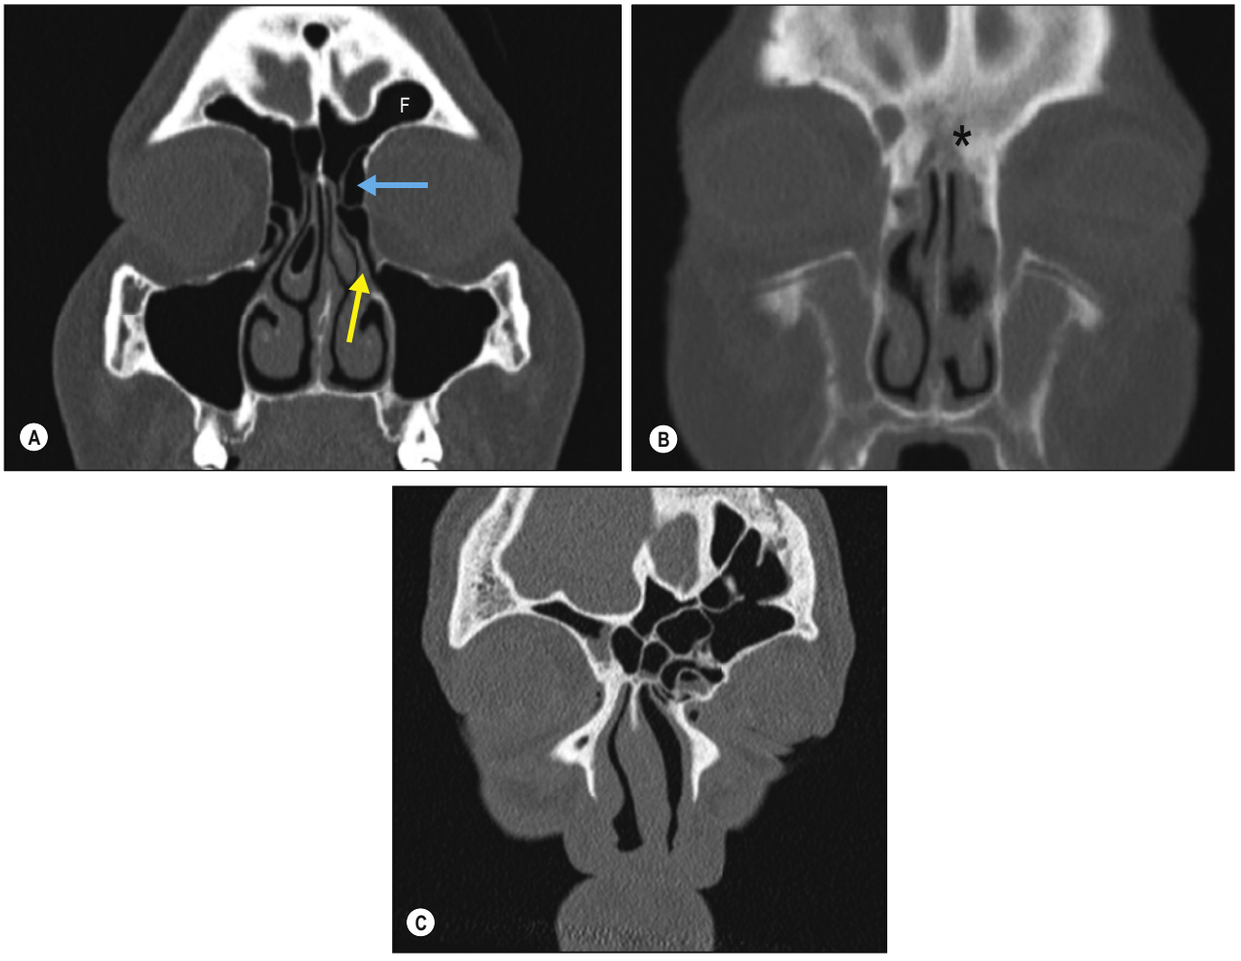

Fig. 39.17 **A**, A coronal CT demonstrating the frontal sinus (F), agger nasi cell (blue arrow) and uncinate process inserting into the middle turbinate (yellow arrow). **B**, An absent frontal sinus (asterisk). **C**, A coronal CT demonstrating variations in the frontal sinus with multiple cells within the frontal recess.

The turbinates at birth are usually bulky and the inferior and middle meatuses are underdeveloped. The uncinate, hiatus semilunaris and ethmoidal bulla are already well-defined, fixed landmarks, and both the anterior and posterior ethmoidal cells are already almost completely developed in terms of number but not size. The cells are separated by connective tissue, which becomes compressed with subsequent expansion of the cells. The ethmoid complex ranges from 8 to 12 mm in length, 1 to 3 mm in width and 1 to 5 mm in height; the complexes expand rapidly in size in the first few years of life. The maxillary sinus is roughly spherical, with a volume of 6–8 cm^3, and measures 10 mm in length, 4 mm in height and 3 mm in width. It lies initially medial to the orbit, but projects laterally under the orbit by the end of the first year of life. The sphenoid is devoid of air, although a blind mucosal sac may sometimes be identified. At birth, the sphenoid has two major ossification centres; failure of fusion between the two may give rise to anatomical variations such as a persistent 'craniopharyngeal canal'. The Eustachian tube is found within the nasal cavity, behind the posterior end of the inferior turbinate. The frontal sinus is no more than a small out-pouching that drains into the infundibulum.

The supreme turbinate has usually disappeared, while the remaining three turbinates reduce relatively in size. The inferior meatus develops and contributes to the nasal airway. The maxillary sinus enlarges rapidly up to the age of 4 years, reaching laterally as far as the infraorbital canal, and inferiorly to the attachment of the inferior turbinate; it ranges between 22 and 30 mm in length, 12 and 18 mm in height and 11 and 19 mm in width. The ethmoidal cells enlarge in all directions, starting anteriorly and then progressing posteriorly. By the age of 4, they are well developed; variants such as the agger nasi cell, infraorbital cell and concha bullosa are identifiable. Sphenoidal pneumatization commences around 7 months of age; a distinct cell is visible by the age of 2 years. By 4 years of age, it is roughly pea-sized, with a diameter of 4–8 mm. The frontal sinus is the last to develop and is imperceptible in infants less than 1 year old. It begins to pneumatize after the age of 2, gradually enlarging as an out-pouching from the anterior ethmoids. Early growth is slow; by 4 years, the vertical height reaches only half the height of the orbit (between 6 and 9 mm in height) (Wolf et al 1993).

TABLE 39.2 Comparison of classification of frontal sinus cells

Kuhn classification (Kuhn 2002)	European position paper (Lund et al 2014)	International Frontal Sinus Anatomy Classification (Wormald at al 2016)
Agger nasi – most anterior ethmoid, anterior to attachment of middle turbinate	Agger nasi cell	Agger nasi cell
Type 1 – single frontal cell above the agger	Anterior and lateral fronto-ethmoidal cell	Supra-agger cell (not extending into frontal sinus)
	Posterior fronto-ethmoidal cell	Supra-bulla cell (not extending into frontal sinus)
Type 2 – tier of cells above agger	Anterior fronto-ethmoidal cells	Supra-agger frontal cell (extending into frontal sinus)
	Posterior fronto-ethmoidal cells	Supra-bulla frontal cell (extending into frontal sinus)
Type 3 – single massive cell above agger extending into frontal sinus	Anterior fronto-ethmoidal cells	Supra-agger frontal cell (extending into frontal sinus)
Type 4 – single isolated cell within frontal sinus (artefact of coronal plane imaging)	Posterior fronto-ethmoidal cells	Supra-bulla frontal cell (extending into frontal sinus)
	Medial (and usually anterior) fronto-ethmoidal cell	Frontal septal cell
	Supraorbital recess – extension over orbit	Supraorbital ethmoid cell

The Kuhn nomenclature was developed based on coronal imaging alone, and has been rendered obsolete by new multi-planar imaging techniques. Both the European and International classifications, while using different terminology, highlight the relationship of frontoethmoidal cells to the drainage pathway of the frontal sinus, thereby facilitating anatomical understanding and surgical approaches.

By 8 years, the sinuses have expanded in all directions. The maxillary sinus has reached the maxillary bone laterally and the plane of the hard palate, becoming tetrahedral in shape. It ranges from 34 to 38 mm in length, 22 to 26 mm in height and 18 to 24 mm in width. The dental buds of unerupted teeth are closely related to the floor of the sinus. The ethmoidal cells continue to enlarge, but more slowly than before; the posterior cells become larger than the anterior cells.

Pneumatization into the vertical plate of the frontal bone does not usually begin until the fifth year, at which time the frontal sinus may be identified radiologically. The frontal sinus pneumatizes rapidly and begins to pneumatize into the vertical plate of the frontal bone; its height reaches the orbital roof at 8 years (Ruf and Pancherz 1996).

By 12 years, the sinuses have almost reached adult proportions. The maxillary sinus pneumatizes into the maxillary alveolus after eruption of the permanent dentition, so that the floor of the sinus now sits 4–5 mm below the level of the floor of the nasal cavity. The ethmoidal sinuses reach adult size, and the frontal sinuses extend into the frontal bone, continuing to enlarge until puberty. The sphenoidal sinus reaches its full size by the age of 14 years.

Asymmetry in the size and shape of the sinuses, hypoplasia and anatomical variants are common (Navarro 1997). Unilateral or bilateral maxillary hypoplasia occurs infrequently; the condition is rarely bilateral. Variation in the pneumatization of almost all the bony lamellae found in the nasal cavity and paranasal sinuses have been described. Pneumatization of an ethmoidal cell into the middle concha creates a concha bullosa, and inferolaterally creates an infraorbital cell. The degree of pneumatization of the sphenoid is highly variable but aplasia is very rare. In contrast, unilateral aplasia of the frontal sinus is present in 15% of adults, and present bilaterally in 5%.

optic canal. Dehiscences in the osseous walls may occasionally leave their mucosa in contact with the overlying dura mater, optic nerve or carotid artery.

The extent of pneumatization of surrounding bone is highly variable. Sometimes, a lateral recess may extend into the greater and lesser wings of the sphenoid or the pterygoid processes, separating the pterygoid (Vidian) canal and foramen rotundum, and may even invade the basilar part of the occipital bone almost to the foramen magnum. A posterior ethmoidal sinus may extend posterosuperior to the relatively smaller sphenoidal sinuses. In such cases, the sphenoid is medial and inferior to this sphenoethmoidal cell (Onodi cell), which itself will be closely related to the optic nerve and carotid artery. An attempt to approach the sphenoid through a sphenoethmoidal cell places these structures at risk of injury. Sphenoethmoidal cells are readily identified on computed tomographic (CT) imaging, where a horizontal bar can be seen in the coronal plane. The anterior clinoid process may be pneumatized in up to 15% of sphenoidal cells.

The shape and position of the sphenoidal sinus are of clinical importance in an endoscopic trans-sphenoidal surgical approach to the hypophysis cerebri. The sinuses may be classified into three main types: sellar, the most common type, in which the sinus extends for a variable distance beyond the tuberculum sellae; presellar, in which the sinus occasionally extends posteriorly towards, but not beyond, the tuberculum sellae; and conchal, the rarest type, in which a small sinus is separated from the sella turcica by approximately 10 mm of trabecular bone. The anterior midline septum often becomes deviated to one side posteriorly; identification of this septation is important prior to surgery (Fig. 39.20).

Vascular supply, lymphatic drainage and innervation

The sphenoidal sinuses receive their arterial supply from the posterior ethmoidal branches of the ophthalmic arteries and nasal branches of

the sphenopalatine arteries. Venous drainage is through the posterior ethmoidal veins draining into the superior ophthalmic veins. Lymph drainage is to the retropharyngeal nodes. The sinuses are innervated by the posterior ethmoidal branches of the ophthalmic nerves (general sensation) and the orbital branches of the pterygopalatine ganglia (parasympathetic secretomotor fibres).

Ethmoidal sinuses

The ethmoidal sinuses differ from the other paranasal sinuses in that they are formed of multiple thin-walled cavities in the ethmoidal labyrinth (see Figs 39.16, 39.17, 39.19). The number and size of the cavities vary, from 3 large to 18 small sinuses on each side. They lie between the upper part of the nasal cavity and the orbit, and are separated from the latter by the paper-thin lamina papyracea or orbital plate of the ethmoid (this presents a poor barrier to infection, which may therefore spread into the orbit). Pneumatization may extend into the middle concha, or into the body and wings of the sphenoid bone lateral to the sphenoidal sinus. (There is a view that the ethmoidal sinuses are aerated after birth, rather than pneumatized, as happens with the other paranasal sinuses (Jankowski 2013).)

The ethmoidal sinuses are divided clinically into anterior and posterior groups on each side, distinguished by their embryological development, sites of communication with the nasal cavity, their mucociliary drainage, and their relation to the basal lamella of the middle turbinate. (Cells wrongly designated previously as belonging to a middle group are now included with the anterior group (Stammberger and Kennedy 1995).) The anterior and posterior groups are separated from each other by the basal lamella; this may be indented by cells from either group and therefore it forms a rather tortuous barrier between them. Within each group, the sinuses are only partially separated by incomplete bony septa.

Anterior ethmoidal sinuses

Up to 11 anterior ethmoidal air cells drain into the ethmoidal infundibulum, a three-dimensional, funnel-shaped cleft between the uncinate and lateral wall of the nose, by one or more orifices. The most anterior group, developmental remnants of the first ethmoturbinals, are the agger nasi cells. These cells are almost always present. They are medial relations of the lacrimal sac and duct, and invaginate beneath the frontal sinus on the lateral wall of the nasal cavity anteriorly. Removal of the superior walls of the agger nasi, 'uncapping the egg', is a key part of surgery of the frontal recess. The ethmoidal bulla, arising from the second ethmoturbinal of the nose, consists of a group of the largest and least variable anterior ethmoidal cells. The cleft between the posterior edge of the uncinate bone and the face of the ethmoidal bulla is known as the hiatus semilunaris. When the bullar lamella reaches the cranial base, this forms the posterior wall of the frontal recess. In other cases, a suprabullar recess may be found. Infraorbital (Haller) cells may develop medially beneath the orbital floor (**Fig. 39.21**).

Posterior ethmoidal sinuses

Up to seven posterior ethmoidal air cells usually drain by a single orifice into the superior meatus; one may drain into the supreme meatus when present, and one or more into the sphenoidal sinus (**Fig. 39.22**). The posterior group lies very close to the optic canal and optic nerve; optic nerve injury is a devastating potential complication of endoscopic sinus surgery, particularly if a sphenoethmoidal cell (Onodi cell) is present. The reported incidence varies widely (3.5–51%). The sphenoethmoidal cell is usually regarded as the most posterior ethmoidal cell that pneumatizes lateral and superior to the sphenoidal sinus, and is intimately associated with the optic nerve; it may contain a tuberculum nervi optici, where the optic canal bulges into the wall of the cell. Pneumatization of the posterior ethmoid cells inferolaterally may create a retromaxillary cell (Herzallah et al 2016).

Roof of the ethmoid bone

The ethmoid bone is open superiorly; the roof is closed by the orbital plate of the frontal bone. Ethmoidal air cells indent this plate; each one is a 'fovea ethmoidalis'. The thin, lateral cribriform lamella (one of the thinnest parts of the cranial base) forms the medial wall of the roof, extending from the middle turbinate to the cribriform plate, and the lateral wall of the olfactory fossa or niche. The olfactory fossa varies in depth and is frequently asymmetrical; it is at risk during sinus surgery.

Uncinate process

The uncinate process is a thin, hook-shaped bone that articulates with the perpendicular plate of the palatine bone and the ethmoidal process of the inferior concha. Its posterosuperior margin is free, forming the hiatus semilunaris with the ethmoidal bulla. It may sometimes reflect medially into the middle meatus and usually overlies the ostium of the maxillary sinus. It is frequently removed during sinus surgery (Becker 1994).

Vascular supply and innervation

The ethmoidal sinuses receive their arterial supply from nasal branches of the sphenopalatine artery and the anterior and posterior ethmoidal branches of the ophthalmic artery. Venous drainage is by the corresponding veins. The lymphatics of the anterior group drain to the submandibular nodes, and those of the posterior group to the retropharyngeal nodes. The sinuses are innervated by the anterior and posterior ethmoidal branches of the ophthalmic nerves (general sensation) and the orbital branches of the pterygopalatine ganglia (parasympathetic secretomotor fibres).

Maxillary sinus

The maxillary sinus is the largest of the paranasal sinuses. It usually fills the body of the maxilla and is pyramidal in shape (see Figs 36.8B, 39.15; **Fig. 39.23**). The base is medial and forms much of the lateral wall of the nasal cavity. The floor, which often lies below the nasal floor, is formed by the alveolar process and part of the palatine process of the maxilla. It is related to the roots of the teeth, especially the second premolar and first molar, but may extend posteriorly to the third molar tooth and/or anteriorly to incorporate the first premolar, and sometimes the canine. Defects in the bone overlying the roots are not uncommon. The roof of the sinus forms the major part of the floor of the orbit. It contains the infraorbital canal, which may exhibit dehiscences. The lateral truncated apex of the pyramid extends into the zygomatic process of the maxilla, and may reach the zygomatic bone, in which case it forms the zygomatic recess, which throws a V-shaped shadow over the antrum on a lateral radiograph.

The facial surface of the maxilla forms its anterior wall, and is grooved internally by a delicate canal (canalis sinuosus) that houses the anterior superior alveolar nerve and vessels as they pass forwards from the infraorbital canal. The prelacrimal recess, the most anteromedial part of the maxillary sinus, may be accessed anterior to the nasolacrimal duct to provide surgical access to the anterior wall of the maxillary sinus (Zhou et al 2013). The posterior wall is formed by the infratemporal surface of the maxilla: it contains alveolar canals that may produce ridges in the sinus and that also conduct the posterior superior alveolar vessels and nerves to the molar teeth. The medial wall is deficient posterosuperiorly at the maxillary hiatus, a large opening that is partially closed in an articulated skull by portions of the perpendicular plate of the palatine bone, the uncinate process of the ethmoid bone, the inferior nasal concha, the lacrimal bone and the overlying nasal mucosa, to form an ostium and anterior and posterior fontanelles. The ostium usually opens into the inferior part of the ethmoidal infundibulum, and thence into the middle meatus, via the hiatus semilunaris (the hiatus forms the area above the superior edge of the uncinate process). The ostium is not normally visible on examination of the nose, without prior resection of the uncinate process. The fontanelles are covered only by periosteum and mucosa, and may contain accessory ostia that may be visible on nasendoscopy and CT. All of the openings are nearer the roof than the floor of the sinus, which means that the natural drainage of the maxillary sinus is reliant on an intact mucociliary escalator; the cilia of the sinus mucoperiosteum normally beat towards the ostium.

The maxillary sinus may be incompletely divided by septa; complete septa are very rare. The thinness of its walls is clinically significant in determining the spread of tumours from the maxillary sinus. A tumour may push up the orbital floor and displace the eyeball; project into the nasal cavity, causing nasal obstruction and bleeding; protrude on to the cheek, causing swelling and numbness if the infraorbital nerve is damaged; spread back into the infratemporal fossa, causing restriction of mouth opening due to pterygoid muscle damage and pain; or spread down into the mouth, loosening teeth and causing malocclusion. Extraction of molar teeth may damage the floor, and impact may fracture its walls. Rarely, hypoplasia of one maxillary antrum is present.

Ostiomeatal complex

The term ostiomeatal complex, or ostiomeatal unit, refers to the area that includes the maxillary sinus ostium, ethmoidal infundibulum and the hiatus semilunaris (**Fig. 39.24**); it is a functional complex rather than a clearly defined anatomical structure. The complex is the common pathway for drainage of secretions from the maxillary and anterior group of ethmoidal sinuses; where the uncinate process attaches to the lateral nasal wall, the complex also drains the frontal sinus.

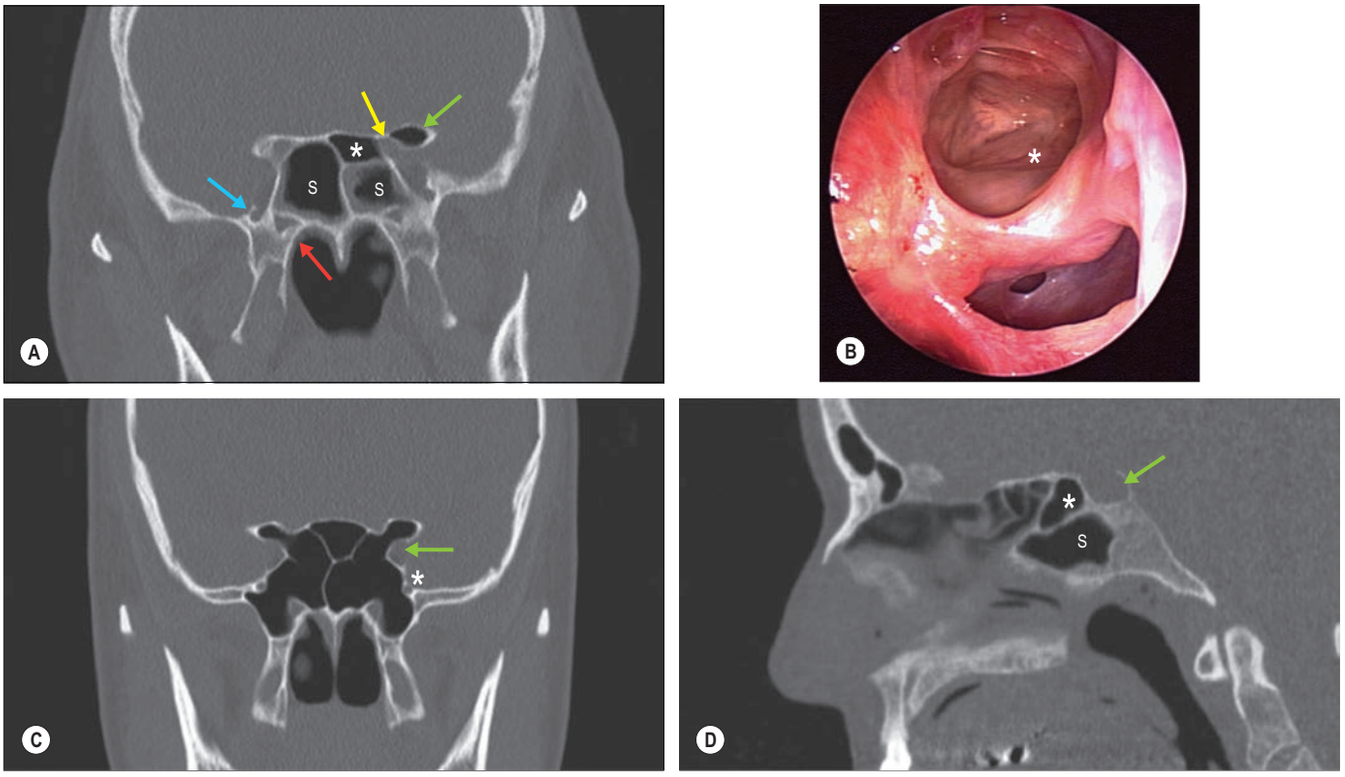

Fig. 39.20 **A**, A coronal CT demonstrating a normal right-sided sphenoidal sinus and a small left-sided sphenoidal sinus (S). The left sphenoethmoidal cell is also shown (asterisk). Pneumatization of the left anterior clinoid process (green arrow) means that the optic nerve (yellow arrow) lies exposed within the sphenoethmoidal cell. The foramen rotundum (blue arrow) and pterygoid (Vidian) canal (red arrow) can also be seen. **B**, An endoscopic view of a right Onodi cell; the optic nerve is visible in the posterolateral wall of the cell (asterisk). **C**, A coronal CT demonstrating well-pneumatized sphenoidal sinuses. The foramen rotundum (asterisk) and internal carotid artery (arrow) are also shown. **D**, A sagittal CT demonstrating the sphenoidal sinus (S), pituitary fossa (arrow) and posterior sphenoethmoidal cell (asterisk).

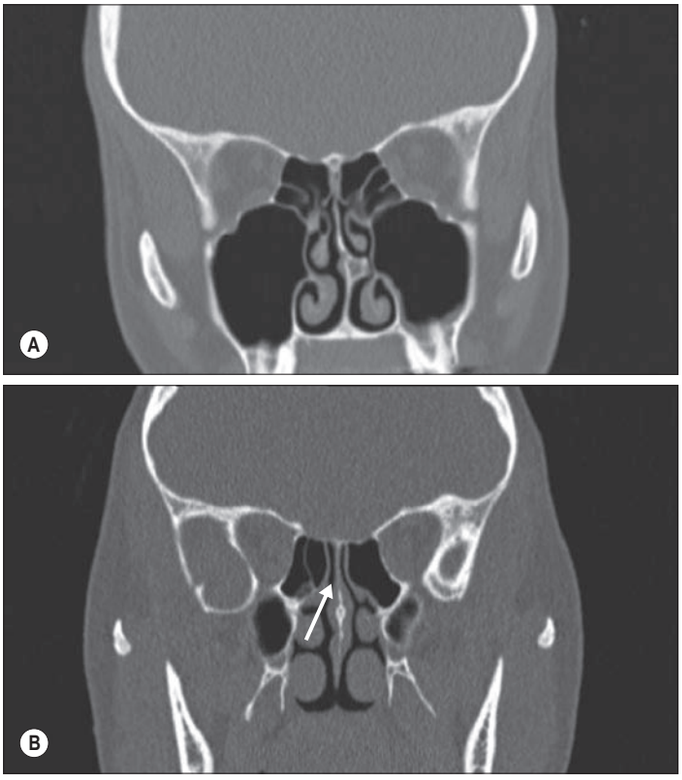

Fig. 39.22 **A**, A coronal CT demonstrating the posterior ethmoidal cells. A bony spur can be seen in the nasal septum. **B**, The posterior ethmoidal air cells and the sphenoethmoidal recess (arrow).

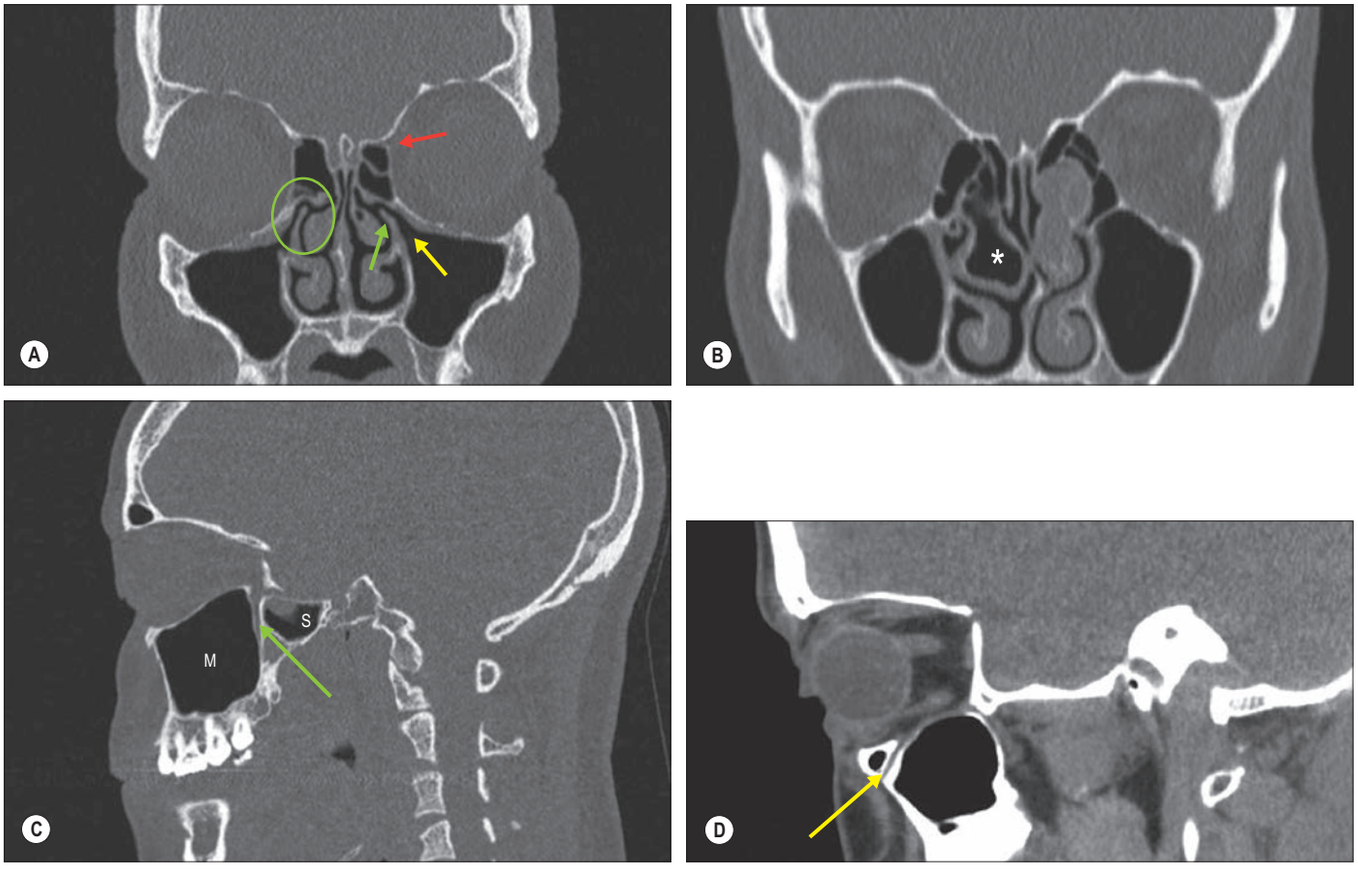

Fig. 39.23 **A**, A coronal section demonstrating the maxillary and anterior ethmoidal sinuses. The ostiomeatal complex (ringed) and infundibulum (yellow arrow) are shown. The anterior ethmoidal artery can be seen leaving the orbit (red arrow). The uncinate process is also visible (green arrow). **B**, A coronal CT demonstrating the maxillary sinuses and a right-sided, pneumatized middle concha (concha bullosa; asterisk). **C**, A sagittal CT demonstrating the relationship between the posterior wall of the maxillary sinus (M), the pterygopalatine fossa (arrow) and a lateral extension of the sphenoidal sinus (S). **D**, A sagittal CT showing the course of the infraorbital nerve through the maxillary sinus (arrow).

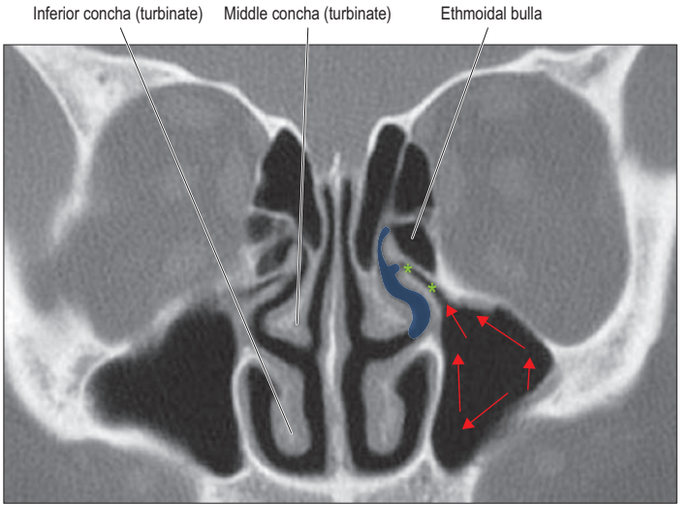

Fig. 39.24 A coronal CT scan through the ostiomeatal complex. Red arrows indicate the direction of mucociliary flow; The blue is quite hard to discern - suggest that it is brighter. This might mean that the green stars also have to be brighter in order to distinguish them from the blue. the middle meatus; and the green stars, the infundibulum.

Vascular supply, lymphatic drainage and innervation

The arterial supply of the maxilla is derived mainly from the maxillary arteries via the anterior, middle and posterior superior alveolar branches and from the infraorbital and greater palatine arteries. Branches of the posterior superior alveolar artery and the infraorbital artery form an anastomosis in the bony wall of the sinus, which also supplies the mucous membrane that lines the nasal chambers. An extraosseous anastomosis frequently exists between the posterior superior alveolar artery and the infraorbital artery. The intra- and extraosseous anastomoses form a double arterial arcade that supplies the lateral antral wall and, partly, the alveolar process. Veins corresponding to the arteries drain into the facial vein or pterygoid venous plexus on either side. Lymph drainage is to the submandibular nodes. The sinuses are innervated by the infraorbital and anterior, middle and posterior superior alveolar branches of the maxillary nerves (general sensation), and nasal branches of the pterygopalatine ganglia (parasympathetic secretomotor fibres).

Imaging of the paranasal sinuses

Standard radiological images are no longer recommended in the diagnosis of rhinosinusitis because of their poor specificity and sensitivity, although they may be used to confirm the presence of acute frontal or maxillary sinusitis that has failed to respond to medical treatment and requires urgent drainage. CT defines anatomical variations but should not be used in isolation for diagnosis because 1 in 3 asymptomatic individuals show incidental mucosal changes (Fig. 39.25). Spiral CT provides good-quality axial, coronal and sagittal images that facilitate an appreciation of the size and relationship of the paranasal sinuses (see Fig. 39.15B–D). Multiplanar and 3D reconstruction techniques have allowed enhanced understanding of the sinus anatomy and suggest that the concept of discrete sinus cells may be an artefact of planar imaging and dissection; in reality, the sinus air cells are likely to be more interconnected than currently described (Vaid and Vaid 2015).

Spread of infection from the sinuses

Uncontrolled paranasal sinus infection can cause very significant morbidity. In the pre-antibiotic era, it was often associated with mortality from meningitis and brain abscess. Paranasal sinus infection has the potential to spread to the orbit, cavernous sinuses, meninges and brain. The ability to overcome infection at this site depends on the virulence of the infecting organism, the speed with which appropriate treatment is delivered, innate immunity and individual anatomical aspects of the sinuses that may predispose to spread of infection. Normal mucociliary clearance of the nasal and paranasal mucosa becomes impaired very quickly with the onset of infection and the patency of drainage pathways become paramount. The middle meatus forms the common drainage pathway for the anterior ethmoidal, frontal and maxillary sinuses. The posterior ethmoidal and sphenoidal sinuses drain into the superior meatus and sphenoethmoidal recess. Endoscopic examination will usually show infected mucus draining from these areas in this situation (Simmen and Jones 2005).

The bony walls of the sinuses are paper-thin in places and dehiscences of them, particularly of the lamina papyracea and cribriform plate of the ethmoids, the lateral wall of the sphenoid, and the orbital and posterior walls of the frontal sinus, bring infected sinus mucosa into direct contact with orbital periosteum, the dura of the anterior cranial fossa and the cavernous sinus. Septic thrombophlebitis then develops and infection spreads rapidly by this route. Sequelae can include blindness, intra- and extradural collections, cavernous sinus thrombosis, meningitis, frontal lobe abscess and osteomyelitis of the cranial vault if diploic veins are involved.

CHAPTER
40

Pharynx

The pharynx is a 12–14 cm long musculomembranous tube shaped like an inverted cone. It extends from the cranial base to the lower border of the cricoid cartilage (the level of the sixth or seventh cervical vertebrae), where it becomes continuous with the oesophagus. The width of the pharynx varies constantly because it is dependent on muscle tone, especially of the constrictors. At rest, the pharyngo-oesophageal junction is closed as a result of tonic closure of the upper oesophageal sphincter; during sleep, muscle tone is low and the dimensions of the pharynx are markedly decreased (which may give rise to snoring and sleep apnoea). The pharynx is limited above by the posterior part of the body of the sphenoid and the basilar part of the occipital bone, and it is continuous with the oesophagus below. Behind, it is separated from the cervical part of the vertebral column and the prevertebral fascia covering longus colli and longus capitis, by loose connective tissue in the retropharyngeal space above and the retrovisceral space below.

The muscles of the pharynx are three circular constrictors and three longitudinal elevators. The constrictors resemble three overlapping cones that arise from structures at the sides of the head and neck and pass posteriorly to insert into a midline fibrous band, the pharyngeal raphe. The arterial supply to the pharynx is derived from branches of the external carotid artery, particularly the ascending pharyngeal artery, but also from the ascending palatine and tonsillar branches of the facial artery, the maxillary artery (greater palatine and pharyngeal arteries and the artery of the pterygoid canal), and dorsal lingual branches of the lingual artery. The pharyngeal veins begin in a plexus external to the pharynx, receive meningeal veins and a vein from the pterygoid canal, and usually end in the internal jugular vein. Lymphatic vessels from the pharynx and cervical oesophagus pass to the deep cervical nodes, either directly or via the retropharyngeal or paratracheal nodes. The motor and sensory innervation is principally via branches of the pharyngeal plexus.

The pharynx lies behind, and communicates with, the nasal, oral and laryngeal cavities via the nasopharynx, oropharynx and laryngopharynx, respectively (**Figs 40.1–40.2**). Its lining mucosa is continuous with that lining the pharyngotympanic tubes, nasal cavity, mouth and larynx. The retropharyngeal and parapharyngeal spaces surround the pharynx. The retropharyngeal space lies anterior to the prevertebral and alar fascia and thus to the alar space (so-called danger space) that lies between them (Scali et al 2015). For further reading, including reviews of some of the more important historical literature, see Wood-Jones (1940), Hollinshead (1982), Graney et al (1998), Flint et al (2010).

NASOPHARYNX

Boundaries

The nasopharynx lies above the soft palate and behind the posterior nares, which allow free respiratory passage between the nasal cavities and the nasopharynx (see Figs 40.1–40.2). The nasal septum separates the two posterior nares, each of which measures approximately 25 mm vertically and 12 mm transversely. Just within these openings lie the posterior ends of the inferior and middle nasal turbinates (Ch. 39). The nasopharynx has a roof, a posterior wall, two lateral walls and a floor. All are rigid boundaries except the floor, which can be raised or lowered by the soft palate: the cavity of the nasopharynx is therefore never obliterated by muscle action, unlike the cavities of the oro- and laryngopharynx. The nasal and oral parts of the pharynx communicate through the pharyngeal isthmus, which lies between the posterior border of the soft palate and the posterior pharyngeal wall. Elevation of the soft palate and constriction of the palatopharyngeal sphincter close the isthmus during swallowing.

The roof and posterior wall form a continuous concave slope that leads down from the nasal septum to the oropharynx. It is bounded above by mucosa overlying the posterior part of the body of the sphenoid, and further back by the basilar part of the occipital bone as far as the pharyngeal tubercle. Further down, the mucosa overlies the pharyngobasilar fascia and the upper fibres of the superior constrictor, and behind these, the anterior arch of the atlas. A lymphoid mass, the pharyngeal tonsil (adenoid, nasopharyngeal tonsil), lies in the mucosa of the upper part of the roof and posterior wall in the midline.

The lateral walls of the nasopharynx display a number of important surface features. On either side, each receives the opening of the pharyngotympanic tube (auditory or Eustachian tube), situated 10–12 mm behind and a little below the level of the posterior end of the inferior nasal concha (see Figs 40.1, 40.2). The tubal aperture is approximately triangular in shape and is bounded above and behind by the tubal elevation that consists of mucosa overlying the protruding pharyngeal end of the cartilage of the pharyngotympanic tube. A vertical mucosal fold, the salpingopharyngeal fold, descends from the tubal elevation behind the aperture (see Fig. 40.2) and covers salpingopharyngeus in the wall of the pharynx (**Fig. 40.3**); a smaller salpingopalatine fold extends from the anterosuperior angle of the tubal elevation to the soft palate in front of the aperture. As levator veli palatini enters the soft palate, it produces an elevation of the mucosa immediately around the tubal opening (see Fig. 40.3). A small variable mass of lymphoid tissue, the tubal tonsil, lies in the mucosa immediately behind the opening of the pharyngotympanic tube. Further behind the tubal elevation there is a variable depression in the lateral wall, the lateral pharyngeal recess (fossa of Rosenmüller), located between the posterior wall of the nasopharynx and the salpingopharyngeal fold. The floor of the nasopharynx is formed by the nasal, upper surface of the soft palate.

The relations of the nasopharynx are important in understanding the spread of nasopharyngeal carcinoma (Chong and Ong 2008, Hyare et al 2010). The mucosa of the nasopharynx is separated from the parapharyngeal space by the buccopharyngeal and pharyngobasilar fasciae. The carotid space, enclosed by the carotid sheath, lies posterior and lateral to the parapharyngeal space. The glossopharyngeal, vagus, accessory and hypoglossal nerves lie within the upper part of the carotid space and come to lie within the superior part of the parapharyngeal space together with the sympathetic chain. The carotid sheath is partially deficient at this level, becoming confluent with the retrostyloid compartment of the parapharyngeal space (Warshafsky et al 2012).The foramen lacerum lies superolateral to the fossa of Rosenmüller. The foramen ovale lies still further laterally and transmits the mandibular division of the trigeminal nerve, which passes through the parapharyngeal space and then the masticator space to innervate the muscles of mastication. The retropharyngeal space is posterior to the nasopharynx. The cartilagenous pharyngotympanic tube and levator veli palatine pass through a deficiency in the pharyngobasilar fascia around the sinus of Morgagni. Nasopharyngeal carcinoma typically spreads along the pharyngotympanic tube, causing secretory otitis media. It breaches the pharyngobasilar fascia anteriorly to infiltrate the pterygoid muscles and invades intracranial space through the foramen ovale by perineural spread along the mandibular nerve (Hyare et al 2010).

Microstructure of non-tonsillar nasopharynx The nasopharyngeal epithelium anteriorly is ciliated, pseudostratified respiratory in type with goblet cells (see Fig. 2.2D). The ducts of mucosal and submucosal seromucous glands open onto its surface. Posteriorly, the respiratory epithelium changes to non-keratinized stratified squamous epithelium which continues into the oropharynx and laryngopharynx. The transitional zone between the two types of epithelium consists of columnar epithelium with short microvilli instead of cilia. Superiorly, this zone meets the nasal septum; laterally, it crosses the orifice of the pharyngotympanic tube; and it passes posteriorly at the union of the soft palate and the lateral wall. Numerous mucous glands surround the tubal orifices.

Innervation Much of the mucosa of the nasopharynx behind the pharyngotympanic tube is supplied by the pharyngeal branch of the pterygopalatine ganglion, which traverses the palatovaginal canal with a pharyngeal branch of the maxillary artery.

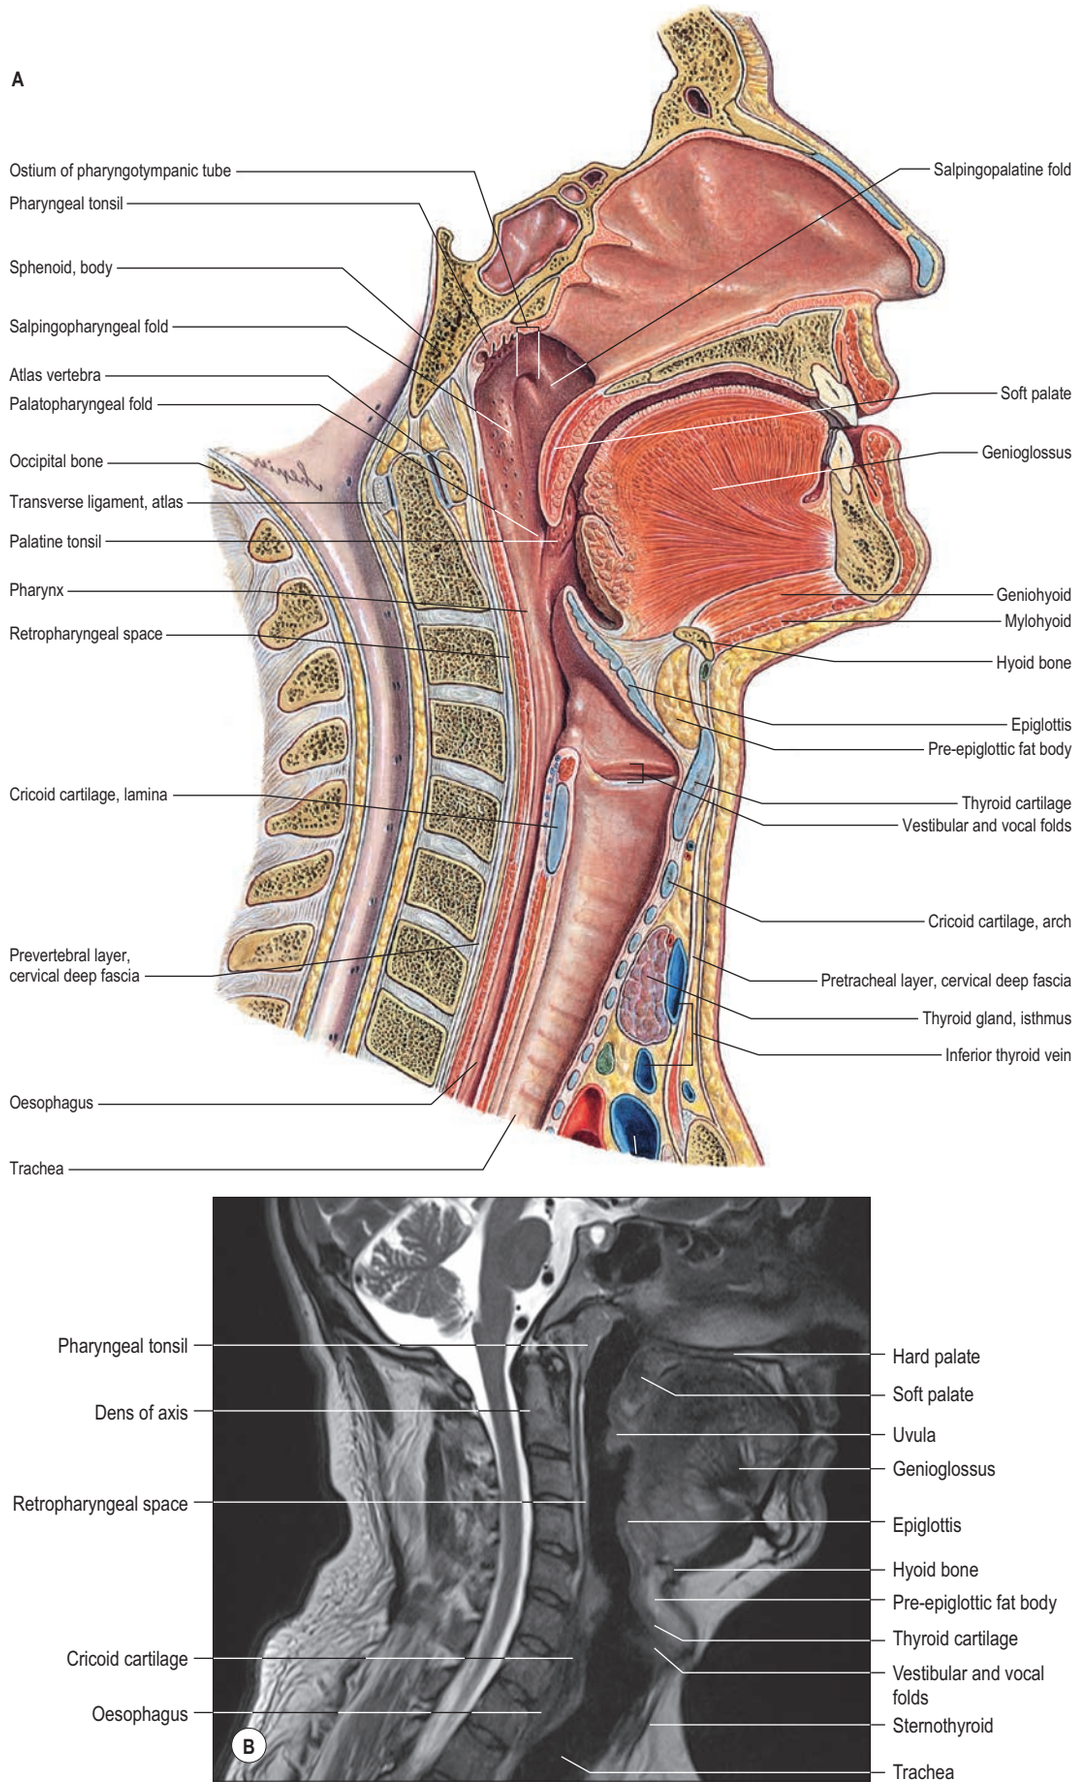

Fig. 40.2 **A**, Sagittal section through the head and neck, including the nasal and oral cavities but excluding the intracranial region. **B**, Corresponding sagittal T2-weighted magnetic resonance image (MRI) through the neck that includes the posterior cranial fossa, cerebellum and cervical spinal cord. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

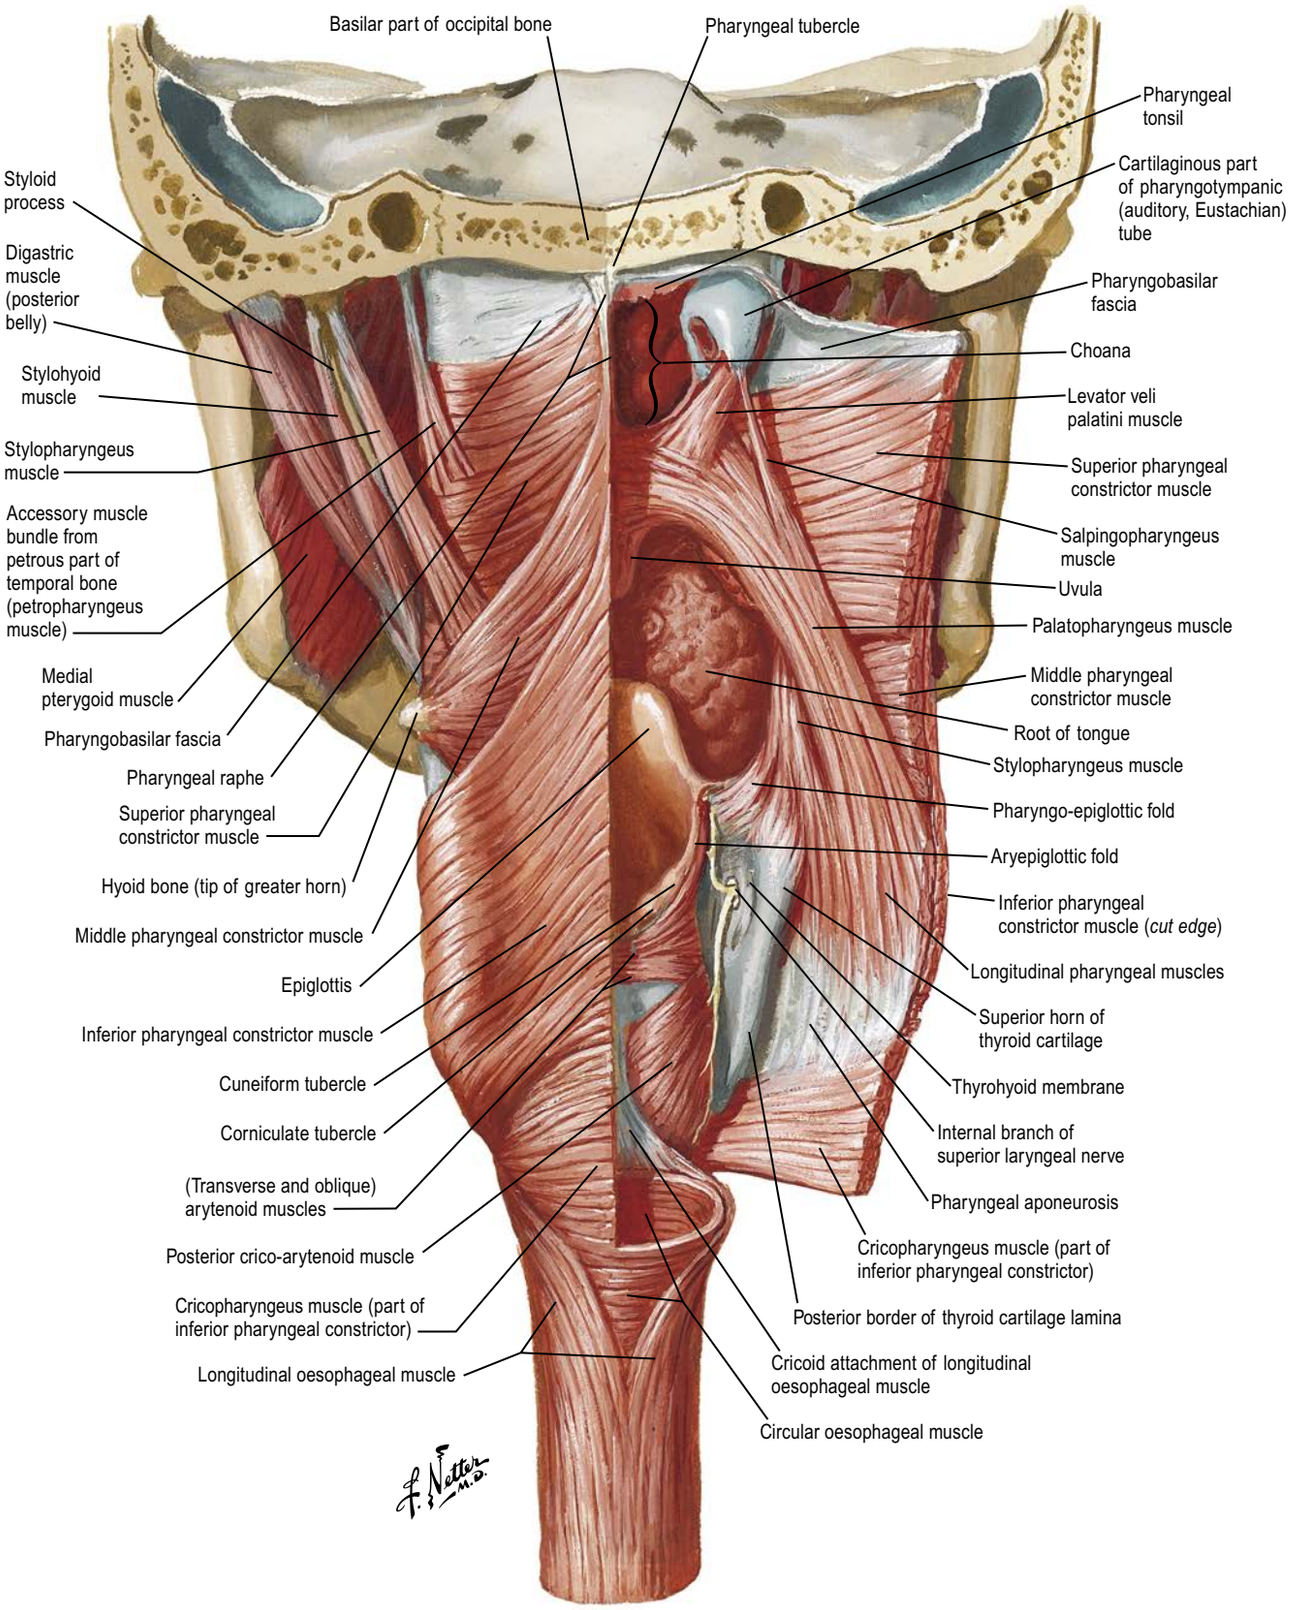

Fig. 40.1 The nasopharynx, oropharynx and laryngopharynx, exposed by cutting the median pharyngeal raphe and reflecting the constrictor muscles laterally on either side, posterior view. (With permission from Netter FH, Atlas of Human Anatomy, 7th ed. Elsevier. Copyright 2019.)

Pharyngeal tonsil

The pharyngeal tonsil (adenoid, nasopharyngeal tonsil) is a median mass of mucosa-associated lymphoid tissue (MALT; see Ch. 4, 'Lymphoid tissues') situated in the roof and posterior wall of the nasopharynx (Fig. 40.4). At its maximal size (during the early years of life), it is shaped like a truncated pyramid, often with a vertically orientated median cleft, so that its apex points towards the nasal septum and its base to the junction of the roof and posterior wall of the nasopharynx (Papaioannou et al 2013).

The free surface of the pharyngeal tonsil is marked by folds that radiate forwards and laterally from a median blind recess, the pharyngeal bursa (bursa of Luschka) that extends backwards and up. The recess marks the rostral end of the embryological notochord: it is present in

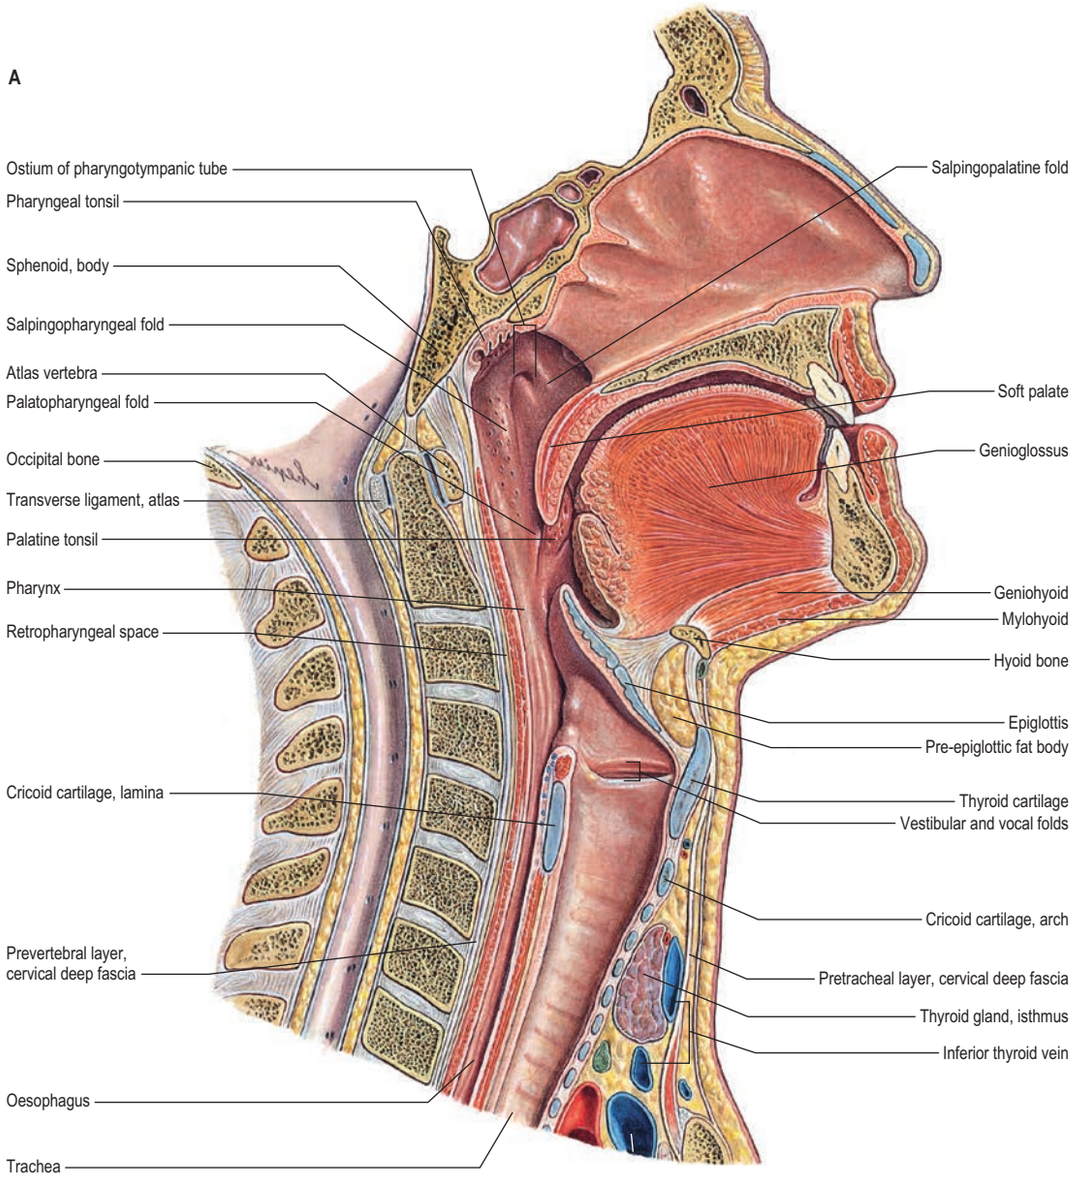

Fig. 40.2 A, Sagittal section through the head and neck, including the nasal and oral cavities but excluding the intracranial region. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.) (B, *continued online*)

the fetus and the young but only occasionally present in the adult. The number and position of the folds and of the deep fissures that separate them vary. A median fold may pass forwards from the pharyngeal bursa towards the nasal septum, or a fissure may extend forwards from the bursa, dividing the nasopharyngeal tonsil into two distinct halves that reflect its paired developmental origins (see Fig. 40.4).

The prenatal origins of the pharyngeal tonsil are described in Chapter 17. After birth, it initially grows rapidly, but usually undergoes a degree of involution and atrophy from the age of 8–10 years: hypoplasia may still be present in adults up to the seventh decade (and still cause problems because of its volume). Relative to the volume of the nasopharynx, the tonsil is largest at 5 years, which may account for the frequency of nasal obstruction in preschool children, and could be an indication for adenoidectomy in this age group.

Vascular supply and lymphatic drainage The arterial supply of the pharyngeal tonsil is derived from the ascending pharyngeal and ascending palatine arteries, the tonsillar branches of the facial artery, the pharyngeal branch of the maxillary artery and the artery of the pterygoid canal (see Fig. 40.7). In addition, a nutrient or emissary vessel to the neighbouring bone, the basisphenoidal artery, which is a branch of the inferior hypophysial arteries, supplies the bed of the pharyngeal tonsil and is a possible cause of persistent post-adenoidectomy haemorrhage in some patients.

Numerous communicating veins drain the pharyngeal tonsil into the internal submucous and external pharyngeal venous plexuses. They emerge from the deep lateral surface of the tonsil and join the external palatine (paratonsillar) veins to pierce the superior constrictor, either to join the pharyngeal venous plexus or unite to form a single vessel that enters the facial or internal jugular vein. They may also connect with the pterygoid venous plexus.

Microstructure The pharyngeal tonsil is covered laterally and inferiorly mainly by ciliated respiratory epithelium that contains scattered small patches of non-keratinized stratified squamous epithelium. Its superior surface is separated from the periosteum of the sphenoid and occipital bones by a connective tissue hemicapsule. The fibrous framework of the tonsil, consisting of a mesh of collagen type III (reticular) fibres supporting a lymphoid parenchyma similar to that in the palatine tonsil, is anchored to the hemicapsule. The nasopharyngeal epithelium lines a series of mucosal folds around which the lymphoid parenchyma is organized into follicles and extrafollicular areas. Internally, the tonsil is subdivided into 4–6 lobes by connective tissue septa, which arise from the hemicapsule and penetrate the lymphoid parenchyma. Seromucous glands lie within the connective tissue, and their ducts extend through the parenchyma to reach the nasopharyngeal surface.

Functions The pharyngeal tonsil forms part of the circumpharyngeal lymphoid ring (Waldeyer's ring) and therefore presumably contributes to the defence of the upper respiratory tract. The territories served by its lymphocytes are uncertain but may include the nasal cavities, nasopharynx, pharyngotympanic tubes and the middle and inner ears.

Thornwaldt's cyst is an embryonic remnant of the persisting cranial end of the notochord that sometimes develops if the pharyngeal bursa is occluded (Fig. 40.5). Usually benign and asymptomatic, these cysts can become infected; symptoms include halitosis, occipital headache and postnasal drip (Yuca and Varsak 2012).

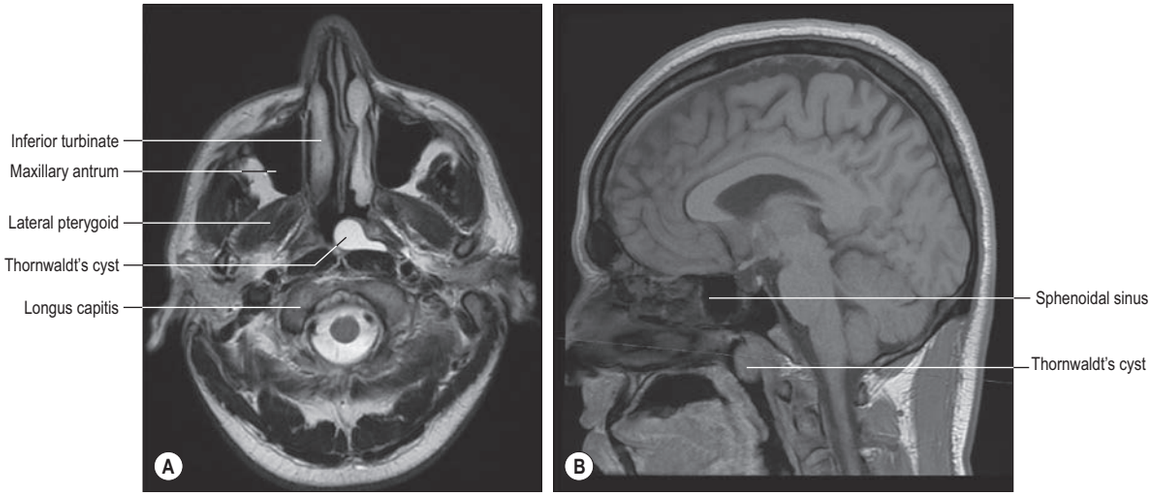

Fig. 40.5 Thornwaldt's cyst. Magnetic resonance images: **A**, axial view; **B**, sagittal view.

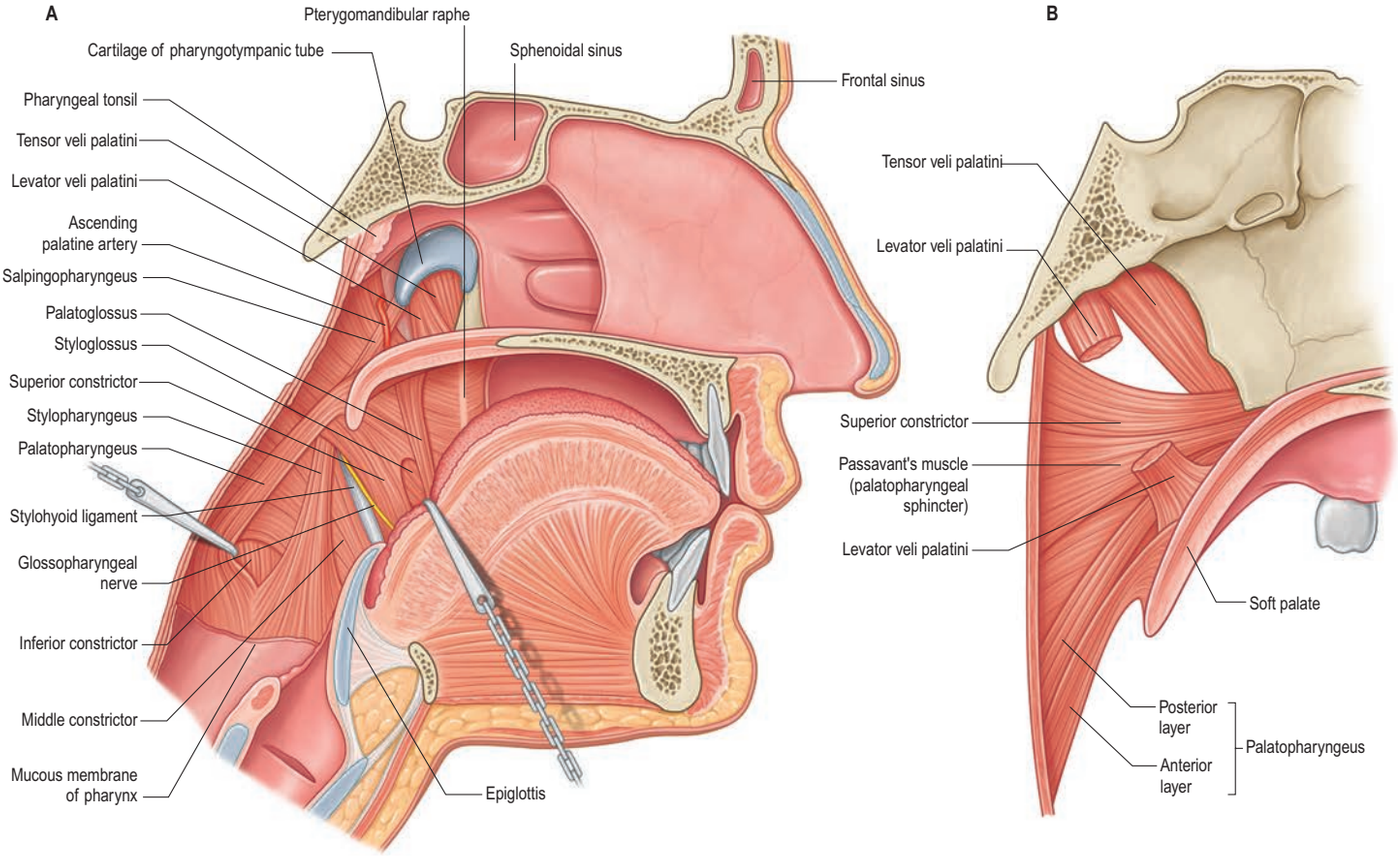

Fig. 40.3 **A**, The interior of the pharynx, exposed by removal of the mucous membrane, sagittal section. The bodies of the cervical vertebrae have been removed, the cut posterior wall of the pharynx retracted dorsolaterally and palatopharyngeus reflected dorsally to show the cranial fibres of the inferior constrictor. The dorsum of the tongue has been pulled ventrally to display a part of styloglossus in the angular interval between the mandibular and the lingual fibres of origin of the superior constrictor. **B**, Muscles of the left half of the soft palate and adjoining part of the pharyngeal wall, sagittal section.

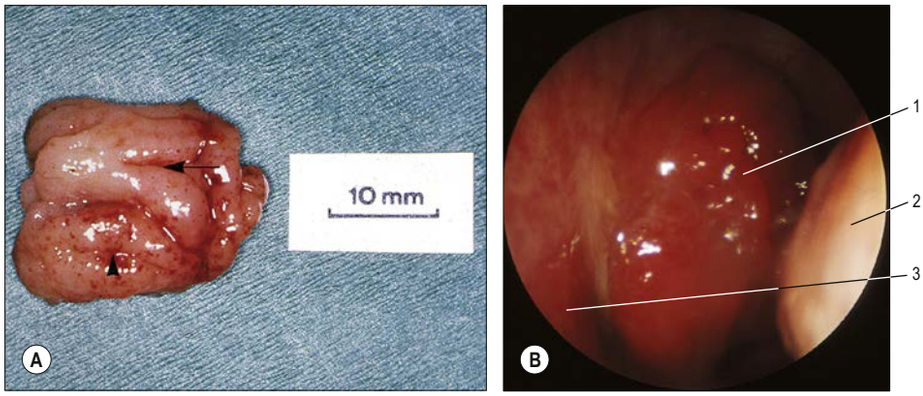

Fig. 40.4 **A**, A pharyngeal tonsil following adenoidectomy by curettage. The rostral surface is to the left; surface folds radiate forwards from a median recess (arrow). In this example, the impression left by contact with the left Eustachian cushion is evident laterally (arrowhead). **B**, A transnasal endoscopic view of a pharyngeal tonsil. Key: 1, pharyngeal tonsil (in posterior naris); 2, inferior concha (posterior view); 3, posterior end of nasal septum. Adenoidectomy

Available with the *Gray's Anatomy* e-book

Pharyngotympanic tube

The pharyngotympanic tube (see Figs 40.9A–B, 42.6) connects the tympanic cavity to the nasopharynx. It has several functions related to maintaining the health of the middle ear, including pressure equalization on both aspects of the tympanic membrane, mucociliary clearance and 'drainage', and protection from the influences of the nasopharyngeal environment and loud sounds. Approximately 36 mm long, it descends anteromedially from the tympanic cavity to the nasopharynx at an angle of approximately 45° with the sagittal plane and 30° with the horizontal (these angles increase with age and elongation of the cranial base). It is formed partly by cartilage and fibrous tissue, and partly by bone.

The cartilaginous part, which is approximately 24 mm long, is formed by a triangular plate of cartilage, the greater part of which is in the posteromedial wall of the tube. Its apex is attached by fibrous tissue to the circumference of the jagged rim of the bony part of the tube, and its base is directly under the mucosa of the lateral nasopharyngeal wall, forming a tubal elevation (torus tubarius; Eustachian cushion) behind the pharyngeal orifice of the tube (see Fig. 37.1). The upper part of the cartilage is bent laterally and downwards, producing a broad medial lamina and narrow lateral lamina. In transverse section, it is hook-like and incomplete below and laterally, where the canal is composed of fibrous tissue. The cartilage is fixed to the cranial base in the groove between the petrous part of the temporal bone and the greater wing of

Surgical removal of the pharyngeal tonsil (adenoid) is commonly performed to clear nasopharyngeal obstruction and as part of the treatment of chronic secretory otitis media. A variety of methods are employed, including suction micro-debridement and diathermy with per-nasal endoscopic control. Blind curettage is becoming less common. The newer endoscopic techniques avoid many of the complications previously seen with blind curettage and caused by hyperextension of the cervical spine, such as damage to the prevertebral fascia, anterior spinal ligaments and tubal orifice. Direct vision and diathermy also facilitate haemostasis. Removal of the pharyngeal tonsil in children with submucosal clefts can result in velopharyngeal insufficiency and cause excessive nasality of speech and nasal regurgitation: submucosal clefts are usually visible by careful clinical examination including palpation before surgery. Previous repair of a cleft palate is also a contraindication for adenoidectomy (Gray and Pinborough-Zimmerman 1998, Raol and Hartnick 2015).

the sphenoid and ends near the root of the medial pterygoid plate. In adults, the cartilaginous and bony parts of the tube are not in the same plane, the former descending a little more steeply than the latter. The diameter of the tube is greatest at the pharyngeal orifice and least at the junction of the two parts (the isthmus), increasing again towards the tympanic cavity. At birth, the pharyngotympanic tube is about half its adult length, more horizontal and its bony part is relatively shorter and much wider.

The bony part, approximately 12 mm long, is oblong in transverse section, with its greater dimension in the horizontal plane. It starts from the anterior tympanic wall and gradually narrows to end at the junction of the squamous and petrous parts of the temporal bone, where it has a jagged margin for the attachment of the cartilaginous part. The carotid canal lies medially.

The mucosa of the pharyngotympanic tube is continuous with the nasopharyngeal and tympanic mucosae. The bony canal is lined by a prolongation of the low cuboidal, ciliated mucosa that lines the middle ear. The histology changes to pseudostratified, ciliated, columnar epithelium typical of the upper respiratory tract after the bony/cartilaginous junction. Within the cartilaginous tube, the floor contains numerous mucus-producing goblet cells and is heavily rugated, whereas the walls in the upper half of the tube contain fewer goblet cells and are generally smooth. Mucosal folding is a feature of the childhood tube; the increased surface area and concomitant increased numbers of ciliated cells are presumed to facilitate improved clearance of the mucociliary blanket. Folds decrease with age up to the age of 20 years, when adult characteristics are reached. Mucous glands predominate in neonates; mucous, serous and mixed glands are present in equal amounts in young children; and serous glands predominate in later life (Orita et al 2002). (For further reading see Sade (1989), Bluestone (1998), O'Reilly and Sando (2010).)

Relations Salpingopharyngeus is attached to the inferior part of the cartilaginous tube near its pharyngeal opening. The petrous part of the temporal bone and levator veli palatini, which arises partly from the medial lamina of the tube, are posteromedial. Anterolaterally, tensor veli palatini separates the tube from the otic ganglion, the mandibular nerve and its branches, the chorda tympani nerve and the middle meningeal artery.

Vascular supply The osseous part of the pharyngotympanic tube is supplied by the tubal artery (a branch of the accessory meningeal artery) and the caroticotympanic branches of the internal carotid artery. The cartilaginous part of the tube is supplied by the deep auricular and pharyngeal branches of the maxillary artery, the ascending palatine artery (usually a branch of the facial artery but sometimes branching directly from the external carotid artery) and the ascending pharyngeal branch of the external carotid artery. The veins of the pharyngotympanic tube usually drain to the pterygoid venous plexus.

Innervation The pharyngotympanic tube is innervated by filaments from the tympanic plexus and from the pharyngeal branch of the pterygopalatine ganglion. The tympanic plexus ramifies on the promontory in the middle ear cavity and is formed by the tympanic branch of the glossopharyngeal nerve and caroticotympanic nerves of sympathetic origin (see Fig. 42.11).

Equalization of pressure At rest, the cartilaginous part of the pharyngotympanic tube is closed at the nasopharyngeal orifice. In normal individuals, the tube opens in order to equalize middle ear pressure to ambient pressure. Analysis of slow-motion video-endoscopy reveals four stages in tubal opening. Initially, the soft palate is elevated, the lateral pharyngeal wall moves medially and the medial lamina of the pharyngotympanic tube rotates medially (levator veli palatini is thought to open the distal part of the tube). The lateral wall of the pharyngotympanic tube moves laterally, so that the orifice is dilated both laterally and vertically. Tubal dilation propagates from distal to proximal by the action of dilator tubae. Finally, the proximal cartilaginous tube adjacent to the junctional region opens. Opening usually lasts for 0.3–0.5 sec but is prolonged during yawning. Closure depends on adhesion of the intraluminal mucous blanket, elastic forces of the supporting tissues, and the hydrostatic pressure of venous blood.

Pharyngotympanic tube dysfunction is a very common pathology. Young children, having an immature tube and a prominent adenoid, often present with persistent serous fluid in the middle ear or recurrent middle ear infections. Older children and adults also present with pharyngotympanic tube dysfunction, often caused by a respiratory tract infection, associated oedema and hypersecretion of the mucosal glands. The presenting symptoms are hearing loss, aural fullness, autophony and tinnitus. Nasal decongestants usually help but sometimes the insertion of ventilation tubes (grommets) is required temporarily.

OROPHARYNX

Boundaries

The oropharynx extends from below the soft palate to the upper border of the epiglottis (see Figs 40.1–40.2). It opens into the mouth through the oropharyngeal isthmus, demarcated by the palatoglossal arch, and faces the pharyngeal aspect of the tongue. Its lateral wall consists of the palatopharyngeal arch and palatine tonsil (see Fig. 37.3). Posteriorly, it is level with the bodies of the second, and upper part of the third, cervical vertebrae (see Fig. 40.2).

Soft palate

The soft palate is a mobile flap suspended from the posterior border of the hard palate, sloping down and back between the oral and nasal parts of the pharynx (see Figs 40.2–40.3). The boundary between the hard and soft palate is readily palpable and may be distinguished by a change in colour, the soft palate being a darker red with a yellowish tint. The soft palate is a thick fold of mucosa enclosing an aponeurosis, muscular tissue, vessels, nerves, lymphoid tissue and mucous glands; almost half its thickness is represented by numerous mucous glands that lie between the muscles and the oral surface of the soft palate. The latter is covered by a stratified squamous epithelium, while the nasal surface is covered with a ciliated columnar epithelium. Taste buds are found on the oral aspect of the soft palate.

In most individuals, two small pits, the fovea palatini, may be seen, one on each side of the midline; they represent the orifices of ducts from some of the minor mucous glands of the palate. In its usual relaxed and pendant position, the anterior (oral) surface of the soft palate is concave and has a median raphe. The posterior aspect is convex and continuous with the nasal floor, the anterosuperior border is attached to the posterior margin of the hard palate, and the sides blend with the pharyngeal wall. The inferior border is free and hangs between the mouth and pharynx. A median conical process, the uvula, projects downwards from its posterior border (see Fig. 37.3). It may be congenitally bifid and associated with submucous cleft palate, hypoplastic orifice of the pharyngotympanic tube and absence of the salpingopharyngeal folds.

The anterior third of the soft palate contains little muscle and consists mainly of the palatine aponeurosis. This region is less mobile and more horizontal than the rest of the soft palate and is the chief area acted on by tensor veli palatini.

A small bony prominence, produced by the pterygoid hamulus, can be felt just behind and medial to each upper alveolar process, in the lateral part of the anterior region of the soft palate. The pterygomandibular raphe (a tendinous band between buccinator and the superior constrictor) passes downwards and outwards from the hamulus to the posterior end of the mylohyoid line (see Fig. 40.8). When the mouth is opened wide, this raphe raises a fold of mucosa that indicates the internal, posterior boundary of the cheek; it is an important landmark for an inferior alveolar nerve block (Ch. 37). (For further reading, see Wood-Jones (1940).)

Palatine aponeurosis. A thin, fibrous, palatine aponeurosis, composed of the expanded tendons of the tensor veli palatini muscles, strengthens the soft palate. It is attached to the posterior border and inferior surface of the hard palate behind any palatine crests and extends medially from behind the greater palatine foramina. It is thick in the anterior two-thirds of the soft palate but very thin further back. Near the midline, it encloses the musculus uvulae. All the other palatine muscles are attached to the aponeurosis.

Palatoglossal and palatopharyngeal arches. The lateral wall of the oropharynx presents two prominent folds, the palatoglossal and palatopharyngeal folds (anterior and posterior pillars of the fauces, respectively) (see Figs 37.3, 40.6A). The palatoglossal arch, the anterior fold, runs from the soft palate to the side of the tongue and contains palatoglossus. The palatopharyngeal arch, the posterior fold, projects more medially and passes from the soft palate to merge with the lateral wall of the pharynx; it contains palatopharyngeus. A triangular tonsillar fossa (tonsillar sinus) lies on each side of the oropharynx between the diverging palatopharyngeal and palatoglossal arches and contains the palatine tonsil.

Vascular supply The arterial supply of the soft palate is usually derived from the ascending palatine branch of the facial artery. Sometimes, this is replaced or supplemented by a branch of the ascending pharyngeal artery, which descends forwards between the superior border of the superior constrictor and levator veli palatini and accompanies the latter to the soft palate. The veins of the soft palate usually drain to the pterygoid venous plexus.

Innervation General sensation from most of the soft palate is carried by branches of the lesser palatine nerve (a branch of the maxillary nerve) and from the posterior part of the palate by pharyngeal branches from the glossopharyngeal nerve and from the plexus around the tonsil (formed by tonsillar branches of the glossopharyngeal and lesser palatine nerves). The special sensation of taste from taste buds in the oral surface of the soft palate is carried in the lesser palatine nerve; the taste fibres initially travel in the greater petrosal nerve (a branch of the facial nerve) and pass through the pterygopalatine ganglion without synapsing. The lesser palatine nerve also carries the secretomotor supply to most of the mucosa of the soft palate, via postganglionic branches from the pterygopalatine ganglion. Postganglionic secretomotor parasympathetic fibres may pass to the posterior parts of the soft palate from the otic ganglion (which receives preganglionic fibres via the lesser petrosal branch of the glossopharyngeal nerve). Postganglionic sympathetic fibres run from the carotid plexus along arterial branches supplying the palate.

Obstructive sleep apnoea and snoring

Palatine tonsil

The palatine tonsils form part of the circumpharyngeal lymphoid ring. Each tonsil is an ovoid mass of lymphoid tissue situated in the lateral wall of the oropharynx (Fig. 40.6; see Figs 37.3, 37.5). Size varies according to age, individual anatomy and pathological status (tonsils may be hypertrophied and/or inflamed), and it is therefore difficult to define the 'normal' appearance of the palatine tonsil. For the first 5 or 6 years of life, the tonsils increase rapidly in size, usually reaching a maximum at puberty, when they average 20–25 mm in vertical, and 10–15 mm in transverse, diameters, and project conspicuously into the oropharynx. Between the ages of 1 and 11 years, the palatine tonsils and the adenoid grow proportionally to the lower facial skeleton (Arens et al 2002). Tonsillar involution begins at puberty, when the reactive lymphoid tissue begins to atrophy and by old age only a little tonsillar lymphoid tissue remains.

The long axis of the tonsil is directed from above, downwards and backwards. Its medial, free, surface usually presents a pitted appearance. The pits, 10–20 in number, lead into a system of blind-ending, often highly branching, crypts that extend through the whole thickness of the tonsil and almost reach the connective tissue hemicapsule. In a healthy tonsil, the openings of the crypts are fissure-like and the walls of the crypt lumina are collapsed so that they are in contact with each other. The human tonsil is polycryptic: the branching crypt system reaches its maximum size and complexity during childhood. The mouth of a deep tonsillar cleft (intratonsillar cleft, recessus palatinus) opens in the upper part of the medial surface of the tonsil. Often erroneously called the supratonsillar fossa, it is not yet situated above the tonsil but within its substance. The mouth of the cleft is semilunar, curving parallel to the convex dorsum of the tongue in the sagittal plane. The upper wall of the recess contains lymphoid tissue that extends into the soft palate as the pars palatina of the palatine tonsil. After the age of 5 years, this embedded part of the tonsil diminishes in size. There is a tendency for the whole tonsil to involute from the age of 14 years and for the tonsillar bed to flatten out. During young adult life, a mucosal fold, the plica triangularis, stretches back from the palatoglossal arch down to the tongue. It is infiltrated by lymphoid tissue and frequently represents the most prominent (anteroinferior) portion of the tonsil. It rarely persists into middle age.

The lateral or deep surface of the tonsil spreads downwards, upwards and forwards. Inferiorly, it invades the dorsum of the tongue; superiorly, it invades the soft palate; and, anteriorly, it may extend for some distance under the palatoglossal arch. This deep, lateral aspect is covered by a layer of fibrous tissue, the tonsillar hemicapsule. This is separable with ease for most of its extent from the underlying muscular wall of the pharynx, formed here by the superior constrictor and sometimes by the anterior fibres of palatopharyngeus, with styloglossus on its lateral side.

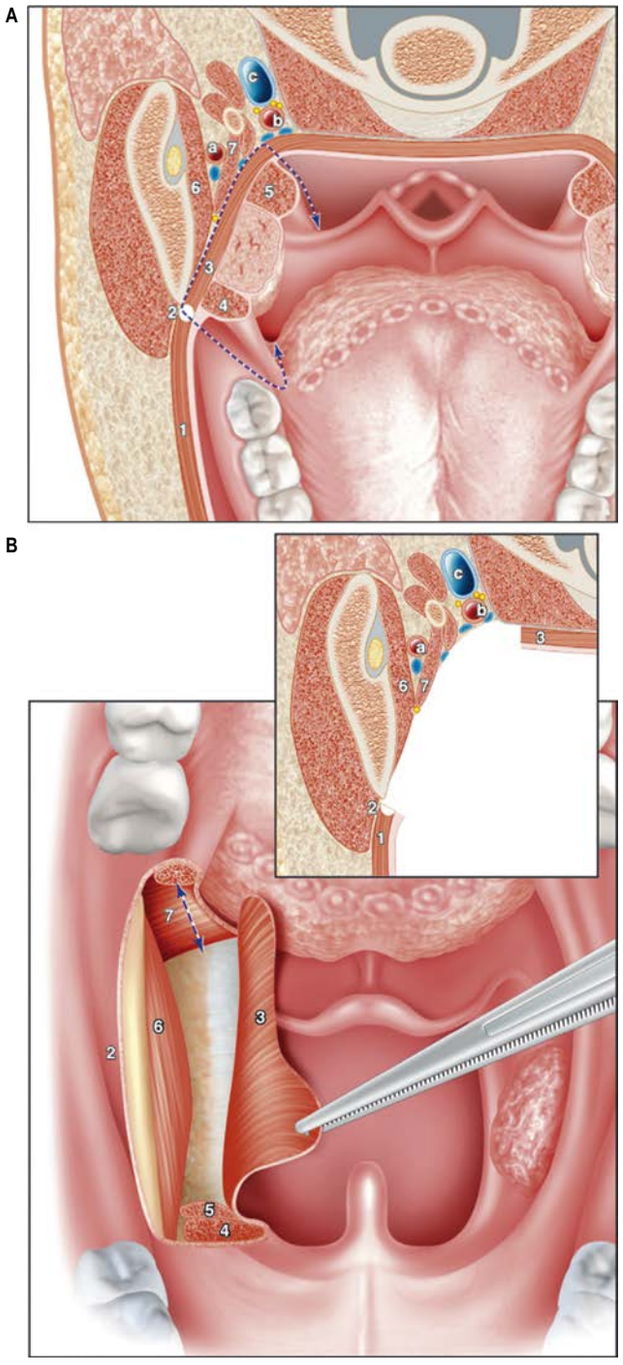

Fig. 40.6 **A**, Anatomical cross-section of the surgical approach in transoral lateral oropharyngectomy. **B**, Velar section and visualization of styloglossus. Key: 1, buccinator; 2, pterygomandibular raphe; 3, pharyngeal constrictor; 4, palatoglossus; 5, palatopharyngeus; 6, medial pterygoid; 7, styloglossus; a, external carotid artery; b, internal carotid artery; c, internal jugular vein. Blue dotted line indicates further transection of styloglossus. Yellow dots indicate cranial nerves IX, X, XI and XII. (Adapted from Rubin F, Laccourreye O, Weinstein GS et al 2017 Transoral lateral oropharyngectomy. Eur Ann Otorhinolaryngol Head Neck Dis 134:419–22.)

Anteroinferiorly, the hemicapsule adheres to the side of the tongue and to palatoglossus and palatopharyngeus. In this region, the tonsillar artery, a branch of the facial artery, pierces the superior constrictor to enter the tonsil, accompanied by venae comitantes. An important and sometimes large vein, the external palatine or paratonsillar vein, descends from the soft palate lateral to the tonsillar hemicapsule before piercing the pharyngeal wall. Haemorrhage from this vessel from the upper angle of the tonsillar fossa may complicate tonsillectomy. The muscular wall of the tonsillar fossa separates the tonsil from the ascending palatine artery, and occasionally from the tortuous facial artery, which may lie near the pharyngeal wall at the lower tonsillar level. The glossopharyngeal

The pharyngeal airway is kept patent in awake individuals by the combined dilating action of genioglossus, tensor veli palatini, geniohyoid and stylohyoid, which act to counter the negative pressure generated in the lumen of the pharynx during inspiration. The tone in the muscles is reduced during sleep, and is also affected by alcohol and other sedatives, hypothyroidism and a variety of neurological disorders. If the dilator muscle tone is insufficient, the walls of the pharynx may become apposed. Intermittent pharyngeal obstruction may cause snoring, and complete obstruction results in apnoea, hypoxia and hypercarbia leading to arousal and sleep disturbance. Obstructive sleep apnoea (OSA) is a serious syndrome affecting up to 4% of middle-aged people. It has potentially life-threatening consequences. The pathophysiological causes of OSA include an anatomically small upper airway, in which augmented pharyngeal dilator muscle activation can maintain airway patency when the individual is awake but not when asleep, coupled with instability in the respiratory control system. Individuals with OSA may demonstrate some or all of the following anatomical features: an increase in soft palate length and thickness; a retrusive or short mandible; lowered hyoid bone position; increased amount of fat in the soft palate and parapharyngeal tissues. While these studies differ in their assessment of the relative incidence and significance of these factors, they all confirm thatthe anatomical changes in OSA have the combined effect of both narrowing and shortening the airway. At the same time, physiological mechanisms that exist to ensure that the airways remain dilated and patent seem to suffer a sleep-induced fall in activity in OSA sufferers. The muscles primarily responsible for maintaining a dilated airway under normal conditions are the muscles that control the position of the hyoid bone, the infrahyoid and suprahyoid muscles, the muscles of the tongue, especially genioglossus, and the muscles that move the soft palate. (For further reading, see Ison et al (1997), Malhotra and White (2002), Fogel et al (2004), Johal et al (2007).)

The gold standard for very severe, life-threatening obstructive sleep apnoea is tracheostomy. Moderately severe OSA may respond to continuous positive airway pressure (CPAP) via a closely fitting facemask that inflates the pharynx and counters its tendency to collapse. Mild sleep apnoea is best managed at least initially by weight loss and a mandibular repositioning device that opens the mouth slightly and brings the mandible forwards, thus preventing the tongue base from falling backwards. An alternative surgical approach involves reduction in the length of the soft palate, removal of the tonsils and plication of the tonsillar pillars by uvulopalatopharyngoplasty (UPPP).

nerve lies immediately lateral to the muscular wall of the tonsillar fossa (see Figs 40.3A, 40.6A); it is at risk if the wall is pierced and is commonly temporarily affected by oedema following tonsillectomy, resulting in a disturbance of taste (Ohtsuka et al 2002). The internal carotid artery lies approximately 25 mm behind and lateral to the tonsil. In some individuals, the styloid process may be elongated and deviate towards the tonsillar bed where it can be felt.

Microstructure Each tonsil is a mass of lymphoid tissue associated with the oropharyngeal mucosa and fixed in its position, unlike most other examples of mucosa-associated lymphoid tissue. It is covered on its oropharyngeal aspect by non-keratinized stratified squamous epithelium. The whole of the tonsil is supported internally by a delicate meshwork of fine collagen type III (reticulin) fibres which are condensed in places to form more robust connective tissue septa that also contain elastin. These septa partition the tonsillar parenchyma, and merge at their ends with the dense irregular fibrous hemicapsule on the deep aspect of the tonsil and with the lamina propria on the pharyngeal surface. Blood vessels, lymphatics and nerves branch or join within the connective tissue condensations. The hemicapsule forms its lateral boundary with the oropharyngeal wall, and with the mucosa that covers its highly invaginated free surface.

The 10–20 crypts formed by invagination of the free surface mucosa are narrow tubular epithelial diverticula that often branch within the tonsil and frequently are packed with plugs of desquamated epithelial cells, lymphocytes and bacteria, that may calcify. The epithelium lining the crypts is mostly similar to that of the oropharyngeal surface, i.e. stratified squamous, but there are also patches of reticulated epithelium, which is much thinner and has a complex structure that is of great importance in the immunological function of the tonsil.

Reticulated epithelium Reticulated epithelium lacks the orderly laminar structure of stratified squamous epithelium. Its base is deeply invaginated in a complex manner so that the epithelial cells, with their slender branched cytoplasmic processes, provide a coarse mesh to accommodate the infiltrating lymphocytes and macrophages. The basal lamina of this epithelium is discontinuous. Although the oropharyngeal surface is unbroken, the epithelium may become exceedingly thin in places, so that only a tenuous cytoplasmic layer separates the pharyngeal lumen from the underlying lymphocytes. Epithelial cells are held together by small desmosomes, anchored into bundles of keratin filaments. Interdigitating dendritic cells (antigen-presenting cells, APCs) are also present. The intimate association of epithelial cells and lymphocytes facilitates the direct transport of antigen from the external environment to the tonsillar lymphoid cells, i.e. reticulated epithelial cells are functionally like the microfold (M) cells of the gut. The total surface area of the reticulated epithelium has been estimated at 295 cm^2 for an average palatine tonsil, reflecting the complex branched nature of the tonsillar crypts.

Tonsillar lymphoid tissue There are four lymphoid compartments in the palatine tonsils. Lymphoid follicles, many with germinal centres, are arranged in rows roughly parallel to neighbouring connective tissue septa. Their size and cellular content varies in proportion to the immunological activity of the tonsil. The mantle zones of the follicles, each with closely packed small lymphocytes, form a dense cap, always situated on the side of the follicle nearest to the mucosal surface. These cells are the products of B-lymphocyte proliferation within the germinal centres. Extrafollicular, or T-lymphocyte, areas contain a specialized microvasculature including high endothelial venules (HEVs), through which circulating lymphocytes enter the tonsillar parenchyma. The lymphoid tissue of the reticulated crypt epithelium contains predominantly IgG- and IgA-producing B lymphocytes (including some mature plasma cells), T lymphocytes and antigen-presenting cells. There are numerous capillary loops in this subsurface region.

Vascular supply and lymphatic drainage The arterial blood supply to the palatine tonsil is derived from branches of the external carotid artery (see Fig. 40.6; **Fig. 40.7**). Three arteries enter the tonsil at its lower pole. The largest is the tonsillar artery, a branch of the facial artery, or sometimes of the ascending palatine artery. It ascends between medial pterygoid and styloglossus, perforates the superior constrictor at the upper border of styloglossus, and ramifies in the tonsil and posterior lingual musculature. The other arteries found at the lower pole are the dorsal lingual branches of the lingual artery which enter anteriorly, and a branch from the ascending palatine artery which enters posteriorly to supply the lower part of the palatine tonsil. The upper pole of the tonsil also receives branches from the ascending pharyngeal artery which enter the tonsil posteriorly, and from the descending palatine artery and its branches, the greater and lesser palatine arteries. All of these arteries enter the deep surface of the tonsil, branch within the connective tissue septa, narrow to become arterioles and then give off capillary loops into the follicles, interfollicular areas and the cavities within the base of the reticulated epithelium. The capillaries rejoin to form venules, many with high endothelia, and the veins return within the septal tissues to the hemicapsule as tributaries of the pharyngeal drainage. The tonsillar artery and its venae comitantes often lie within the palatoglossal fold and may haemorrhage if this fold is damaged during surgery.

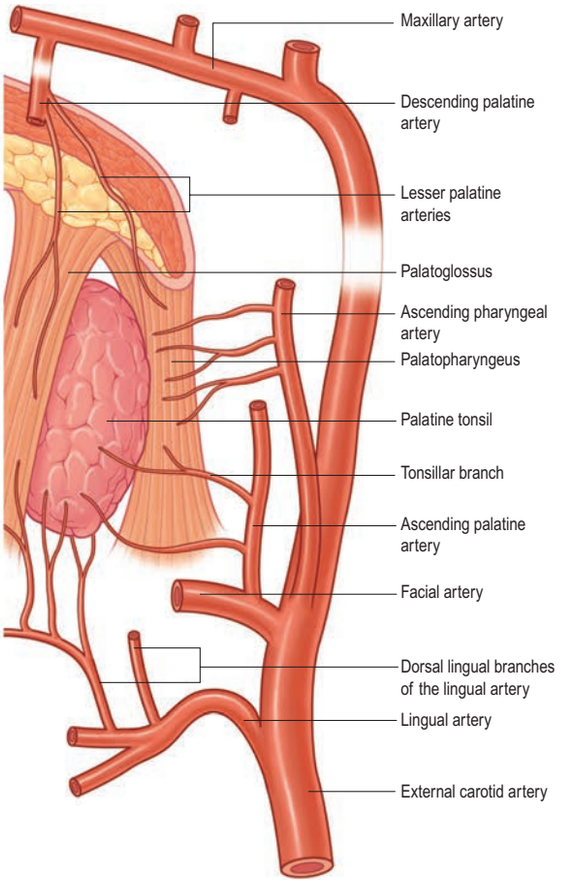

Fig. 40.7 The arterial supply to the palatine tonsil.

Unlike lymph nodes, the palatine tonsils do not possess afferent lymphatics or lymph sinuses. Instead, dense plexuses of fine lymphatic vessels surround each follicle and form efferent lymphatics that pass towards the hemicapsule, pierce the superior constrictor, and drain to the upper deep cervical lymph nodes directly (especially the jugulodigastric nodes) or indirectly through the retropharyngeal lymph nodes. The jugulodigastric nodes are typically enlarged in tonsillitis, when they project beyond the anterior border of sternocleidomastoid and are palpable superficially 1–2 cm below the angle of the mandible; when enlarged, they represent the most common swelling in the neck.

Innervation The tonsillar region is innervated by tonsillar branches of the maxillary and glossopharyngeal nerves. The fibres from the maxillary nerve pass through, but do not synapse in, the pterygopalatine ganglion; they are distributed through the lesser palatine nerves and form a plexus (the circulus tonsillaris) around the tonsil together with the tonsillar branches of the glossopharyngeal nerve. Nerve fibres from this plexus are also distributed to the soft palate and the region of the oropharyngeal isthmus. The tympanic branch of the glossopharyngeal nerve supplies the mucous membrane lining the tympanic cavity. Infection, malignancy and postoperative inflammation of the tonsil and tonsillar fossa may therefore be accompanied by pain referred to the ear.

Tonsillectomy

Available with the *Gray's Anatomy* e-book

Waldeyer's ring

Waldeyer's ring is a circumpharyngeal ring of mucosa-associated lymphoid tissue that surrounds the openings into the digestive and respiratory tracts. It is made up anteroinferiorly by the lingual tonsil, laterally by

Surgical removal of the palatine tonsils is most commonly undertaken for children who suffer from excessive episodes of acute tonsillitis. Other indications include airway obstruction caused by extremely large or infected palatine tonsils and a recurrent peritonsillar abscess. Tonsils are also removed in an older age group when malignancy is suspected. Tonsillectomy using a guillotine is no longer practised because it was associated with an unacceptable incidence of postoperative haemorrhage. Most tonsils are now removed by dissection in the plane of the fibrous hemicapsule, followed by ligation or electrocautery to the vessels that are divided during the procedure. The nerve supply to the tonsil is so diffuse that tonsillectomy under local anaesthesia can be performed successfully by local infiltration rather than by blocking the main nerves. Surgical access to the glossopharyngeal nerve and/or the styloid process may be achieved by separating the fibres of superior constrictor.

the palatine and tubal tonsils, and posterosuperiorly by the pharyngeal tonsil (adenoid) and smaller collections of lymphoid tissue in the intertonsillar intervals.

LARYNGOPHARYNX

Boundaries

The laryngopharynx is situated behind the entire length of the larynx (known clinically as the hypopharynx) and extends from the superior border of the epiglottis, where it is delineated from the oropharynx by the lateral glossoepiglottic folds, to the inferior border of the cricoid cartilage, where it becomes continuous with the oesophagus (see Figs 40.1–40.2). The laryngeal inlet lies in the upper part of its incomplete anterior wall, and the posterior surfaces of the arytenoid and cricoid cartilages lie below this opening.

Piriform fossa A small piriform fossa lies on each side of the laryngeal inlet, bounded medially by the aryepiglottic fold and laterally by the thyroid cartilage and thyrohyoid membrane. Branches of the internal laryngeal nerve lie beneath its mucous membrane. At rest, the laryngopharynx extends posteriorly from the lower part of the body of the third cervical vertebra to the upper part of the body of the sixth cervical vertebra. During deglutition, the laryngopharynx may be elevated considerably by the hyoid elevators.

Inlet of larynx The obliquely sloping inlet of the larynx lies in the anterior part of the laryngopharynx and is bounded above by the epiglottis, below by the arytenoid cartilages of the larynx, and laterally by the aryepiglottic folds (see Fig. 40.1). Below the inlet, the anterior wall of the laryngopharynx is formed by the posterior surface of the cricoid cartilage.

PHARYNGEAL FASCIA

The two named layers of fascia in the pharynx are the pharyngobasilar and buccopharyngeal fasciae. The fibrous layer that supports the pharyngeal mucosa is thickened above the superior constrictor to form the pharyngobasilar fascia (see Fig. 40.10). It is attached to the basilar part of the occipital bone and the petrous part of the temporal bone medial to the pharyngotympanic tube, and to the posterior border of the medial pterygoid plate and the pterygomandibular raphe. Inferiorly, it diminishes in thickness but is strengthened posteriorly by a fibrous band, the median pharyngeal raphe of the constrictors. The buccopharyngeal fascia covers the superior constrictor and passes forwards over the pterygomandibular raphe to cover buccinator.

PHARYNGEAL TISSUE SPACES

Pharyngeal tissue spaces can be subdivided into peripharyngeal and intrapharyngeal spaces: the terms 'deep neck' space, subdivided into supra- and infra-hyoid spaces, are commonly used clinically. The peripharyngeal suprahyoid neck spaces include the submandibular and submental spaces anteriorly, the retropharyngeal space posteriorly and the parapharyngeal spaces laterally. The retropharyngeal space is an area of loose connective tissue that lies behind the pharynx and anterior to the prevertebral fascia, extending upwards to the base of the skull and downwards to the retrovisceral space in the infrahyoid part of the neck. Each parapharyngeal space passes laterally around the pharynx and is continuous with the retropharyngeal space. However, unlike the retropharyngeal space, it is a space that is restricted to the suprahyoid region. It is bounded medially by the pharynx, laterally by the pterygoid muscles (where it is part of the infratemporal fossa) and by the sheath of the parotid gland, superiorly by the base of the skull, and inferiorly by suprahyoid structures, particularly the sheath of the submandibular gland. It may be helpful to think of the retropharyngeal space as shaped like an inverted pyramid extending from the base of the skull to the greater cornu of the hyoid bone. The parapharyngeal space can be subdivided into an anterior, prestyloid, compartment and a posterior, retrostyloid, compartment (Maran et al 1984). The prestyloid compartment contains the retromandibular portion of the parotid gland and minor or ectopic salivary glandular tissue, branches of the mandibular division of the mandibular nerve, maxillary artery, ascending pharyngeal artery and a pharyngeal venous plexus, fat and lymph nodes (Shin et al 2001). The retrostyloid compartment contains the internal carotid artery, the internal jugular vein, the glossopharyngeal, vagus, accessory and hypoglossal nerves, the sympathetic chain, fat and lymph nodes. The fascia surrounding the carotid is incomplete at the level above the mandibular angle (hence the term carotid space). Any of these structures may be damaged by penetrating injuries directed posterolaterally in the region; more lateral injuries may result in penetration of the parotid gland.

An intrapharyngeal space potentially exists between the inner surface of the constrictor muscles and the pharyngeal mucosa. Infections in this space are either restricted locally or spread through the pharynx into the retropharyngeal or parapharyngeal spaces. The peritonsillar space is an area of loose connective tissue between the palatine tonsil and superior constrictor that lies around the palatine tonsil between the pillars of the fauces. Infections in the intratonsillar space usually spread up or down the intrapharyngeal space, or through the pharynx into the parapharyngeal space. The pharyngeal mucosal space contains the mucosa of the nasopharynx, oropharynx and hypopharynx as well as the lymphoid tissue of Waldeyer's ring, adenoid, palatine tonsils, minor salivary glands, the torus tubarius, pharyngobasilar fascia and the cartilage of the pharyngotympanic tubes.

Tissue spaces between the layers of cervical fascia are described in Chapter 35 on pages 578 and 579; tissue spaces around the larynx are described in Chapter 41 on page 726.

Spread of infection

MUSCLES OF THE SOFT PALATE AND PHARYNX

The muscles of the soft palate and pharynx are levator veli palatini, tensor veli palatini, palatoglossus, palatopharyngeus, musculus uvulae, salpingopharyngeus, stylopharyngeus, and the superior, middle and inferior constrictors.

Levator veli palatini

Levator veli palatini arises by a small tendon from a quadrilateral roughened area on the medial end of the inferior surface of the petrous part of the temporal bone, in front of the lower opening of the carotid canal (see Fig. 40.3; **Figs 40.8–40.10**). Additional fibres arise from the inferior aspect of the cartilaginous part of the pharyngotympanic tube and from the vaginal process of the sphenoid bone. At its origin, the muscle is inferior rather than medial to the pharyngotympanic tube and only crosses medial to it at the level of the medial pterygoid plate. It passes medial to the upper margin of the superior constrictor and anterior to salpingopharyngeus. Its fibres spread in the medial third of the soft palate between the two strands of palatopharyngeus to attach to the upper surface of the palatine aponeurosis as far as the midline, where they interlace with those of the contralateral muscle. Thus, the two levator muscles form a sling above and just behind the palatine aponeurosis.

Vascular supply The blood supply of levator veli palatini is derived from the ascending palatine branch of the facial artery and the greater palatine branch of the maxillary artery (Freelander 1992).

Innervation Levator veli palatini is innervated via the pharyngeal plexus.

Actions The primary role of the two levator veli palatini muscles is to elevate the almost vertical posterior part of the soft palate and pull it slightly backwards; during swallowing, the soft palate is elevated so that it touches the posterior wall of the pharynx, separating the nasopharynx from the oropharynx. By additionally pulling on the lateral walls of the nasopharynx posteriorly and medially, the levator veli palatini muscles also narrow that space. They have little or no effect on the pharyngotympanic tube.

Tensor veli palatini

Tensor veli palatini arises from the scaphoid fossa of the pterygoid process and posteriorly from the medial aspect of the spine of the sphenoid bone (see Figs 38.3, 40.3, 40.8–40.10). Between these two sites, it is attached to the anterolateral membranous wall of the pharyngotympanic tube (including its narrow isthmus where the cartilaginous medial two-thirds meets the bony lateral third). Some fibres may be continuous with those of tensor tympani. Inferiorly, the fibres converge on a delicate tendon that turns medially around the pterygoid hamulus to pass through the attachment of buccinator to the palatine aponeurosis and

Infection that spreads into the parapharyngeal space causes pain and trismus. There may be swelling in the oropharynx that extends up to the uvula, displacing it to the contralateral side, and dysphagia. Posterior spread from the parapharyngeal space into the retropharyngeal space will produce bulging of the posterior pharyngeal wall, dyspnoea and nuchal rigidity. Involvement of the carotid sheath may cause thrombosis of the internal jugular vein and nerve palsies of the glossopharyngeal, vagus, accessory and hypoglossal nerves. If the infection continues to spread unchecked, mediastinitis can ensue. A virulent infection in the retropharyngeal space may spread through the alar fascia into the underlying danger space. Infection in this tissue space may also descend into the thorax and even below the respiratory diaphragm, giving rise to chest and shoulder pain, severe dyspnoea and retrosternal discomfort.

Pharyngeal infection from mucosa-associated lymph tissues such as the palatine tonsil, or as a result of a penetrating injury (e.g. from an ingested foreign body), can result in the spread of infection into the tissue spaces of the neck adjacent to the pharynx. This is an extremely serious and life-threatening situation, not only because of the rapidity with which it can involve the superior mediastinum but also because of associated critical airways obstruction.

Primary tumours of the parapharyngeal space are rare. More commonly tumours from adjacent spaces displace the easily identifiable parapharyngeal space on imaging, helping the radiologist to determine the origin of the tumour (Warshafsky et al 2012). Tumours that develop within the prestyloid compartment of the parapharyngeal space most often develop from either ectopic minor salivary tissue, the deep lobe of the parotid gland or in lymph nodes. Those in the post-styloid compartment of the parapharyngeal space are derived from lower cranial nerves in the carotid sheath or vascular tumours arising from the carotid body or the inferior vagal ganglion (Gupta et al 2012). All these tumours, with the exception of those arising in lymph nodes, present late because they grow slowly, produce few symptoms and tend to expand internally rather than externally. Internal expansion and compression of the pharynx often gives rise to a 'plummy' quality of the voice and snoring. Those that cause nerve palsies tend to develop slowly, which means that there is time for local accommodation to take place, but also that symptoms can be very subtle initially and overlooked by the patient. Voice change, dysphagia and aspiration becomes more obvious in later stages of the disease.

Several surgical approaches have been described for the management of parapharyngeal space tumours, including transcervical, transparotid, combined transcervical–transparotid and transoral approaches. Submandibulectomy and mandibulotomy are occasionally necessary (Mydlarz and Agrawal 2014, Sheahan 2014, Paderno et al 2015). Transoral robotic surgery (TORS) can be used for parapharyngeal tumour resection but is mainly, and much more frequently, employed in oropharyngeal tumour resection (see Fig. 40.6) (Baskin et al 2018). As has happened in other areas of surgery where minimally invasive approaches have either become or are becoming the norm, an appreciation of 'inside-out' anatomy, in this case the complex transoral (medial to lateral) anatomy of the oropharynx and parapharyngeal spaces, is increasingly important for the surgeon (Dallan et al 2011, Moore et al 2012, Lim et al 2013, Prades et al 2014,Wang et al 2014, Gun and Ozer 2015, Yarlagadda and Grillone 2015, Gun et al 2016). Very large tumours with significant superior extension may require a lateral skull base approach for safe resection.

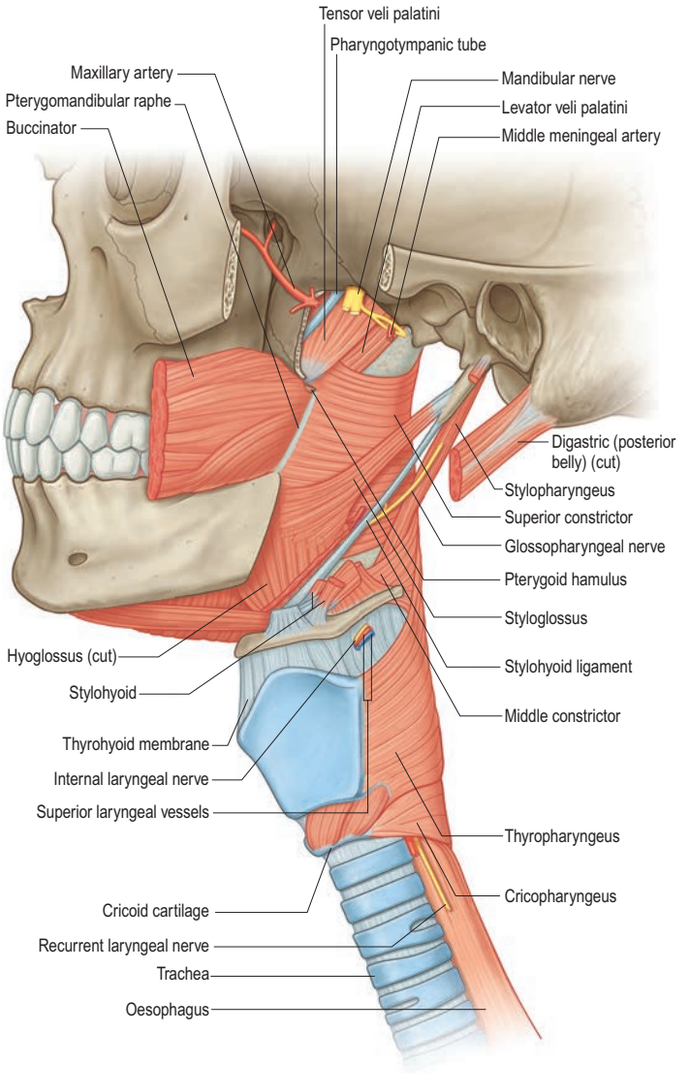

Fig. 40.8 Muscles of the pharynx, lateral view.

the osseous surface behind the palatine crest on the horizontal plate of the palatine bone. There is a small bursa between the tendon and the pterygoid hamulus.

The muscle is thin and triangular, and lies lateral to the medial pterygoid plate, pharyngotympanic tube and levator veli palatini. Its lateral surface contacts the upper and anterior part of medial pterygoid, the mandibular, auriculotemporal and chorda tympani nerves, the otic ganglion and the middle meningeal artery. Tensor veli palatini is connected with the styloid process through the tensor vascular styloid fascia, dividing the parapharyngeal space into pre- and retro-styloid portions (Gupta et al 2012).

Dilator tubae Some fibres of tensor veli palatini that arise from the hamulus of the medial pterygoid plate are attached to the short lateral lamina of the cartilage of the pharyngotympanic, to a condensation of connective tissue lateral to the tubal wall and to a portion of Ostmann's fat pad; these fibres are sometimes referred to as dilator tubae.

Vascular supply The blood supply of tensor veli palatini is derived from the ascending palatine branch of the facial artery and the greater palatine branch of the maxillary artery (Freelander 1992).

Innervation The motor innervation of tensor veli palatini is derived from the mandibular nerve via the nerve to medial pterygoid and reflects the development of the muscle from the first branchial arch.

Actions Tensor veli palatini is said to have three anchoring points on which it isometrically contracts: the pterygoid hamulus, Ostmann's fat pad and medial pterygoid (O'Reilly and Sando 2010). Acting together, the two tensor veli palatini muscles tauten the soft palate, principally its anterior part, and depress it by flattening its arch. Acting unilaterally, the muscle pulls the soft palate to one side. Although contraction of both muscles will slightly depress the anterior part of the soft palate, it is often assumed that the increased rigidity aids palatopharyngeal closure. A primary role of the tensor is to open the pharyngotympanic tube, e.g. during deglutition and yawning, via its dilator tubae component, and so aid equalization of air pressure between the middle ear and nasopharynx.

Palatoglossus

Palatoglossus is narrower at its middle than at its ends (see Figs 40.3, 40.6). Together with its overlying mucosa, it forms the palatoglossal arch or fold (see Fig. 37.3). It arises from the oral surface of the palatine aponeurosis, where it is continuous with its contralateral fellow. It extends forwards, downwards and laterally in front of the palatine tonsil to the side of the tongue. Some of its fibres spread over the dorsum of the tongue, while others pass deeply into its substance to intermingle with fibres of the intrinsic transverse muscle.

Vascular supply Palatoglossus receives its blood supply from the ascending palatine branch of the facial artery and from the ascending pharyngeal artery.

Innervation Palatoglossus is innervated via the pharyngeal plexus and is therefore unlike all the other muscles of the tongue, which are supplied by the hypoglossal nerve.

Actions Palatoglossus elevates the root of the tongue and approximates the palatoglossal arch to its contralateral fellow, thus shutting off the oral cavity from the oropharynx.

Palatopharyngeus

Palatopharyngeus and its overlying mucosa form the palatopharyngeal arch (see Fig. 37.3). Within the soft palate, palatopharyngeus is composed of two fasciculi that are attached to the upper surface of the palatine aponeurosis; they lie in the same plane but are separated from each other by levator veli palatini (see Figs 40.3, 40.9). The thicker, anterior fasciculus arises from the posterior border of the hard palate as well as the palatine aponeurosis, where some fibres interdigitate across the midline. The posterior fasciculus is in contact with the mucosa of the pharyngeal aspect of the palate and joins the posterior band of the contralateral muscle in the midline. The two layers unite at the posterolateral border of the soft palate and are joined by fibres of salpingopharyngeus. Passing laterally and downwards behind the tonsil, palatopharyngeus descends posteromedial to and in close contact with stylopharyngeus, to be attached with it to the posterior border of the thyroid cartilage. Some fibres end on the side of the pharynx, attached to pharyngeal fibrous tissue, and others cross the midline posteriorly, decussating with those of the contralateral muscle. Palatopharyngeus thus forms an incomplete internal longitudinal muscular layer in the wall of the pharynx.

Passavant's muscle (palatopharyngeal sphincter) The existence of a Passavant's muscle remains controversial (Cho et al 2013). It has been described as a part of the superior constrictor and palatopharyngeus muscles (see Fig. 40.3B). An alternative view holds that it is a distinct palatine muscle that arises from the anterior and lateral parts of the upper surface of the palatine aponeurosis, lies lateral to levator veli palatini, blends internally with the upper border of the superior constrictor, and encircles the pharynx as a sphincter-like muscle. Whatever its origin, when it contracts, it forms a ridge (Passavant's ridge) when the soft palate is elevated. Ciliated, 'respiratory' epithelium covers the superior surface in continuity with the superior aspect of the soft palate and changes to stratified, squamous epithelium inferiorly along the line of attachment of the palatopharyngeal sphincter to the palate. The muscle is hypertrophied in cases of complete cleft palate.

Vascular supply Palatopharyngeus receives its arterial supply from the ascending palatine branch of the facial artery, the greater palatine branch of the maxillary artery and the pharyngeal branch of the ascending pharyngeal artery.

Innervation Palatopharyngeus is innervated via the pharyngeal plexus.

Actions Acting together, the palatopharyngei pull the pharynx up, forwards and medially, and thus shorten it during swallowing. They also approximate the palatopharyngeal arches and draw them forwards.

Musculus uvulae

Musculus uvulae arises from the posterior nasal spine of the palatine bone and the superior surface of the palatine aponeurosis and lies between

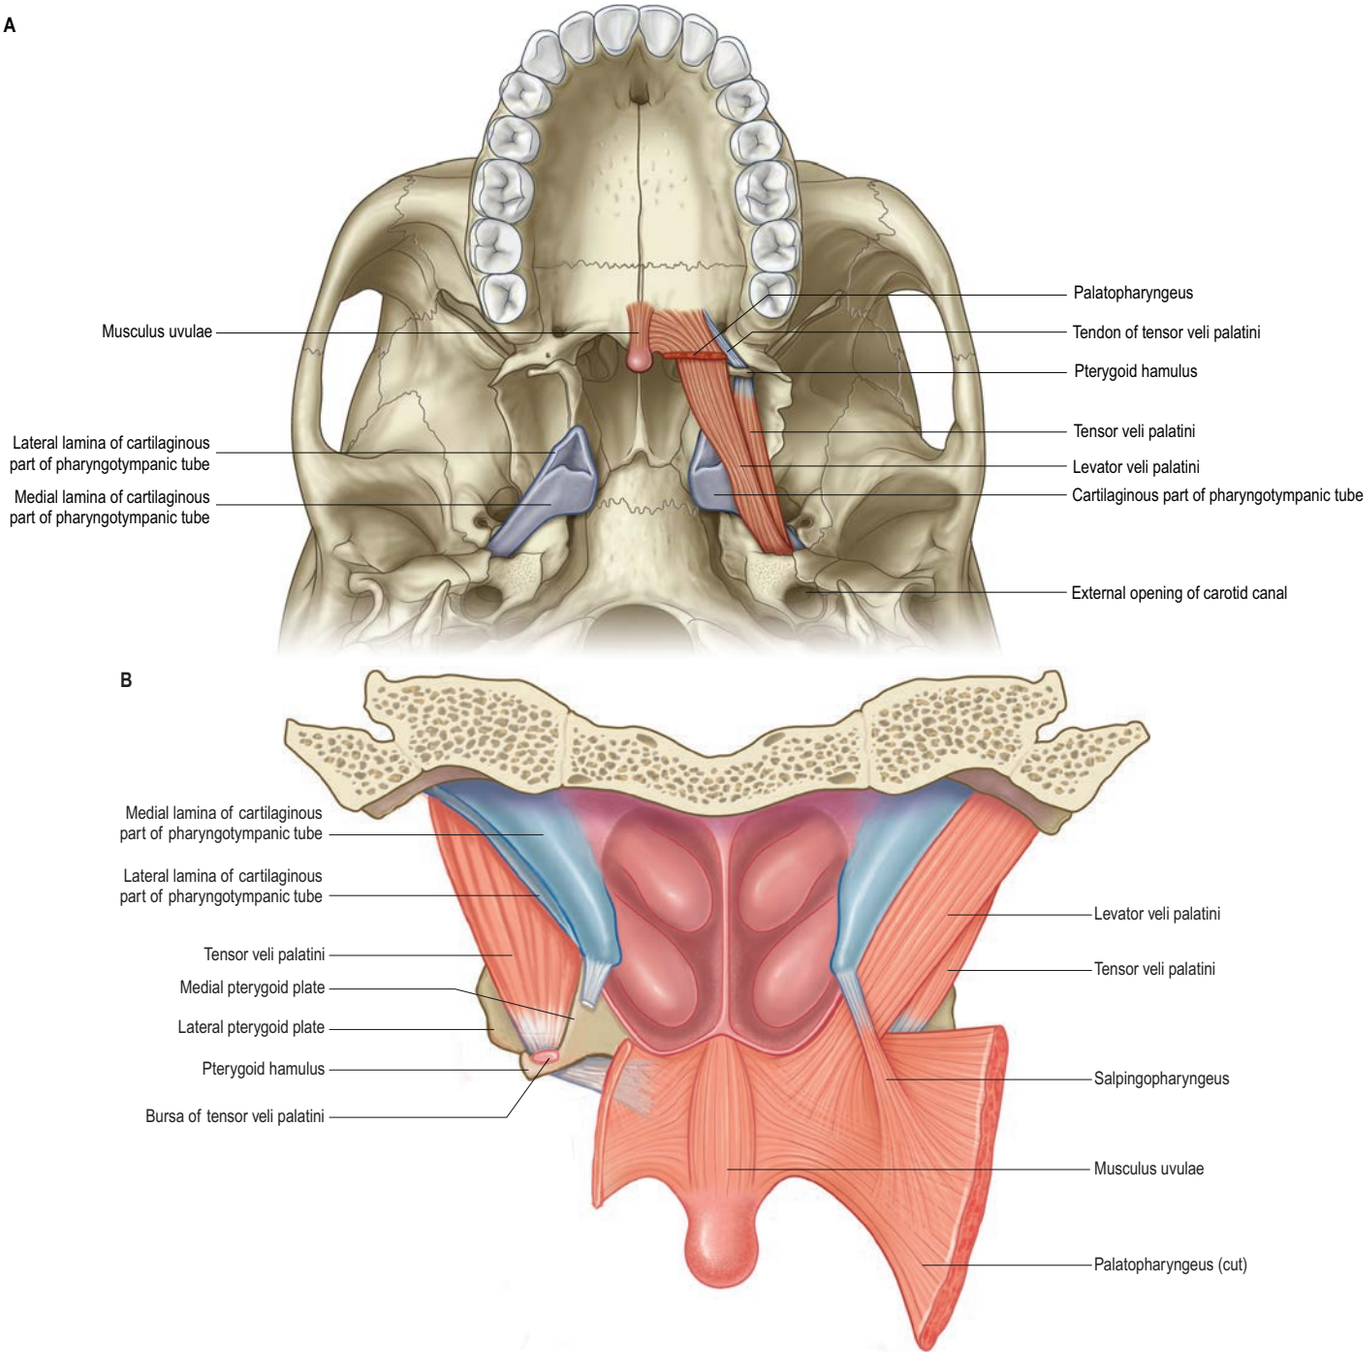

Fig. 40.9 Muscles of the soft palate. **A**, Inferior view. **B**, Superior view.

the two laminae of the aponeurosis (see Figs 40.1, 40.9). It runs posteriorly above the sling formed by levator veli palatini and inserts beneath the mucosa of the uvula. The two sides of the muscle are united along most of its length.

Vascular supply The blood supply of musculus uvulae is derived from the ascending palatine branch of the facial artery and the descending palatine branch of the maxillary artery.

Innervation The nerve supply to musculus uvulae is innervated via the pharyngeal plexus.

Actions By retracting the uvular mass and thickening the middle third of the soft palate, musculus uvulae aids levator veli palatini in palatopharyngeal closure. The two muscles run at right-angles to each other and their contraction raises a 'levator eminence' that helps seal off the nasopharynx.

Salpingopharyngeus

Salpingopharyngeus arises from the inferior part of the cartilage of the pharyngotympanic tube near its pharyngeal opening and passes downwards within the salpingopharyngeal fold to blend with palatopharyngeus (see Figs 40.1, 40.3A, 40.9).

Vascular supply Salpingopharyngeus receives its arterial supply from the ascending palatine branch of the facial artery, the greater palatine branch of the maxillary artery and the pharyngeal branch of the ascending pharyngeal artery.

Innervation Salpingopharyngeus is innervated via the pharyngeal plexus.

Actions Salpingopharyngeus elevates the pharynx and may also assist tensor veli palatini to open the cartilaginous end of the pharyngotympanic tube during swallowing.

Stylopharyngeus

Stylopharyngeus is a long slender muscle, cylindrical above and flat below. It arises from the medial side of the base of the styloid process, descends along the side of the pharynx, and passes between the superior and middle constrictors to spread out beneath the mucous membrane (see Figs 37.9, 40.3, 40.8, 40.10). Some fibres merge into the constrictors and the lateral glossoepiglottic fold, while others join fibres of

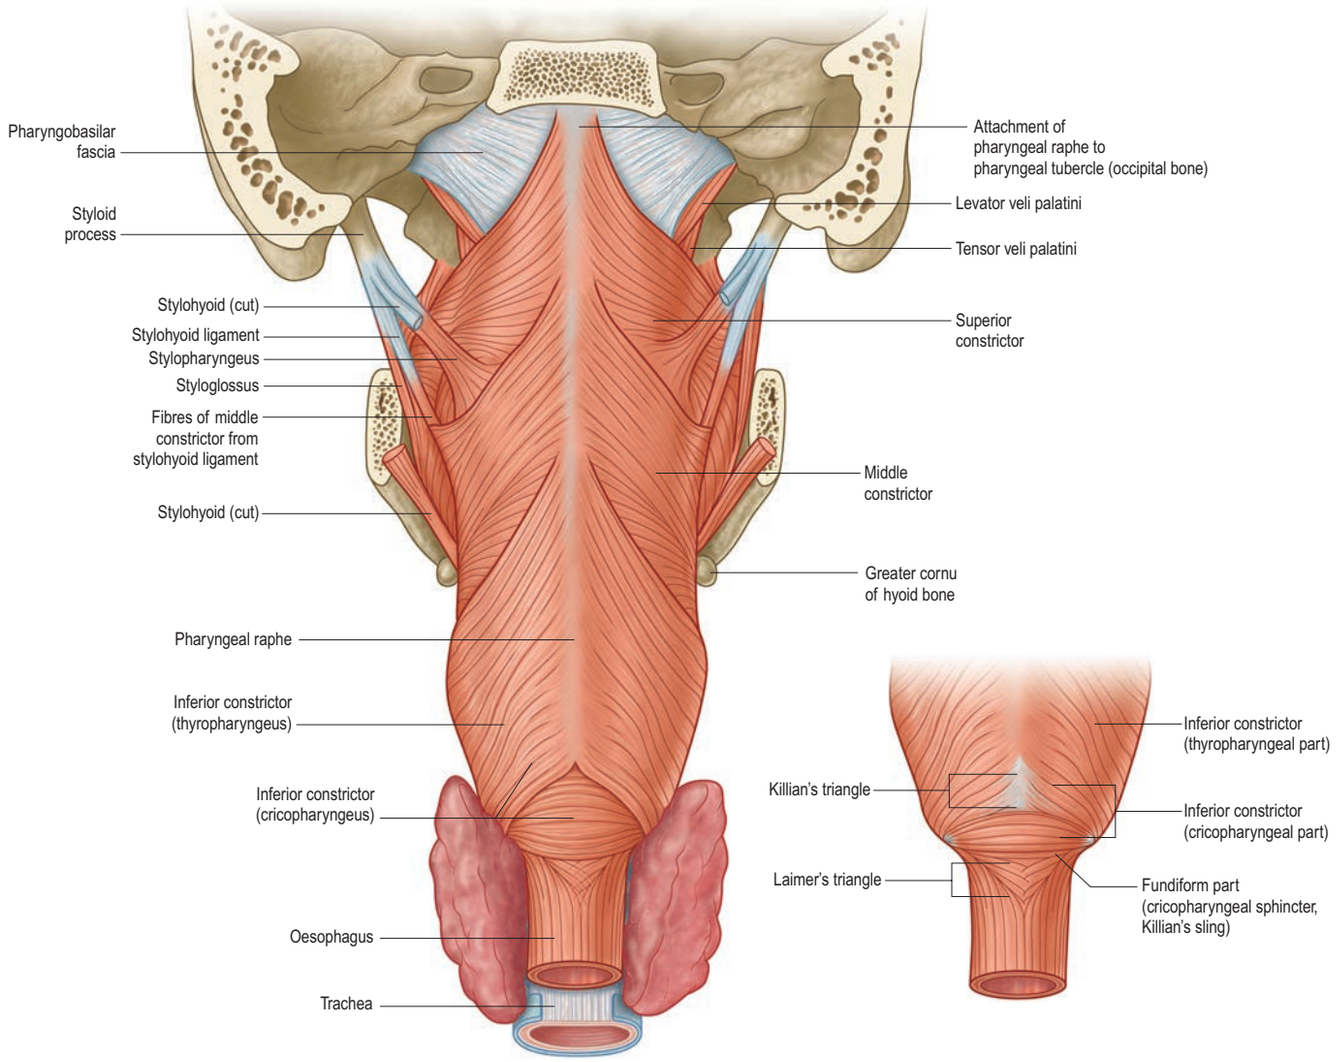

Fig. 40.10 Muscles of the pharynx and the pharyngobasilar fascia, posterior view.

palatopharyngeus and are attached to the posterior border of the thyroid cartilage. The glossopharyngeal nerve curves round the posterior border and the lateral side of stylopharyngeus and passes between the superior and middle constrictors to reach the tongue in most patients.

Vascular supply Stylopharyngeus receives its arterial supply from the pharyngeal branch of the ascending pharyngeal artery.

Innervation Stylopharyngeus is innervated by the glossopharyngeal nerve.

Actions Stylopharyngeus elevates the pharynx and larynx.

Superior constrictor

The superior constrictor is a quadrilateral sheet of muscle and is thinner than the other two constrictors. It is attached anteriorly to the pterygoid hamulus (and sometimes to the adjoining posterior margin of the medial pterygoid plate), the posterior border of the pterygomandibular raphe, the posterior end of the mylohyoid line of the mandible and, by a few fibres, to the side of the tongue (see Figs 40.1, 40.3, 40.8). The fibres curve back into a median pharyngeal raphe that is attached superiorly to the pharyngeal tubercle on the basilar part of the occipital bone.

Relations The upper border of the superior constrictor is separated from the cranial base by a crescentic interval that contains levator veli palatini, the pharyngotympanic tube and an upward projection of pharyngobasilar fascia. The lower border is separated from the middle constrictor by stylopharyngeus and the glossopharyngeal nerve (see Fig. 40.8). Anteriorly, the pterygomandibular raphe separates the superior constrictor from buccinator, and, posteriorly, the superior constrictor lies on the prevertebral muscles and fascia, from which it is separated by the retropharyngeal space. The buccopharyngeal fascia, ascending pharyngeal artery, pharyngeal venous plexus, glossopharyngeal and lingual nerves, middle constrictor, medial pterygoid, stylopharyngeus, styloglossus and the stylohyoid ligament all lie laterally. Palatopharyngeus and the tonsillar capsule lie medially.

Vascular supply The arterial supply of the superior constrictor is derived mainly from the pharyngeal branch of the ascending pharyngeal artery and the tonsillar branch of the facial artery.

Innervation The superior constrictor is innervated via the pharyngeal plexus.

Actions The superior constrictor constricts the upper part of the pharynx.

Middle constrictor

The middle constrictor is a fan-shaped sheet attached anteriorly to the lesser cornu of the hyoid and the lower part of the stylohyoid ligament (the chondropharyngeal part of the muscle), and to the whole of the upper border of the greater cornu of the hyoid (the ceratopharyngeal part) (see Figs 40.8, 40.10). The lower fibres descend deep to the inferior constrictor to reach the lower end of the pharynx; the middle fibres pass transversely, and the superior fibres ascend and overlap the superior constrictor. All fibres insert posteriorly into the median pharyngeal raphe (Sakamoto 2014).

Relations The glossopharyngeal nerve and stylopharyngeus pass through a small gap between the middle and superior constrictors, and the internal laryngeal nerve and the laryngeal branch of the superior thyroid artery pass between the middle and inferior constrictors. The prevertebral fascia and longus colli and longus capitis are posterior; the superior constrictor,

stylopharyngeus and palatopharyngeus are internal; and the carotid vessels, pharyngeal plexus of nerves and some lymph nodes are lateral. Near its hyoid attachment, the middle constrictor lies deep to hyoglossus, from which it is separated by the lingual artery.

Vascular supply The arterial supply of the middle constrictor is derived mainly from the pharyngeal branch of the ascending pharyngeal artery and the tonsillar branch of the facial artery.

Innervation The middle constrictor is innervated via the pharyngeal plexus.

Actions The middle constrictor constricts the middle part of the pharynx during swallowing.

Inferior constrictor

The inferior constrictor is the thickest of the three constrictor muscles and is usually described in two parts: thyropharyngeus and cricopharyngeus (see Figs 40.8, 40.10). Thyropharyngeus arises from the oblique line of the thyroid lamina, a strip of the lamina behind this, and by a small slip from the inferior cornu. Some additional fibres arise from a tendinous cord that loops over cricothyroid. Cricopharyngeus arises from the side of the cricoid cartilage between the attachment of cricothyroid and the articular facet for the inferior thyroid cornu. Some authors have described cricopharyngeus as consisting of a superficial upper oblique portion – the pars oblique – and a lower, deeper, transverse portion – the pars fundiformis. The upper part attaches to the median raphe while the lower part forms a circular band that lacks a median raphe. The area demarcated by the pars oblique and pars fundiformis of cricopharyngeus is termed Killian's dehiscence (or Killian's triangle). A second triangular area, Laimer's triangle, can be identified beneath cricopharyngeus between the longitudinal fibres of the oesophagus as they pass laterally on either side to attach to the cricoid cartilage; only the circular muscle of the oesophagus forms the wall here. Both triangles are postulated to be sites of weakness in the wall of the pharynx and oesophagus and are therefore areas where diverticula could potentially form. Both cricopharyngeus and thyropharyngeus spread posteromedially to join the contralateral muscle. Thyropharyngeus is inserted into the median pharyngeal raphe, and its upper fibres ascend obliquely to overlap the middle constrictor; however, cricopharyngeus blends with the circular oesophageal fibres around the narrowest part of the pharynx.

Relations The buccopharyngeal fascia is external; the prevertebral fascia and muscles are posterior; the thyroid gland, common carotid artery and sternothyroid are lateral; and the middle constrictor, stylopharyngeus, palatopharyngeus and the fibrous lamina are internal. The internal laryngeal nerve and laryngeal branch of the superior thyroid artery reach the thyrohyoid membrane by passing between the inferior and middle constrictors. The external laryngeal nerve descends on the superficial surface of the muscle, just behind its thyroid attachment, and pierces its lower part. The recurrent laryngeal nerve and the laryngeal branch of the inferior thyroid artery ascend deep to its lower border to enter the larynx.

Vascular supply The arterial supply of the inferior constrictor is derived mainly from the pharyngeal branch of the ascending pharyngeal artery and the muscular branches of the inferior thyroid artery.

Innervation Both parts of the inferior constrictor are usually innervated via the pharyngeal plexus. Although controversial, available evidence in humans suggests that cricopharyngeus is also supplied by the recurrent laryngeal nerve and the external branch of the superior laryngeal nerve (Sakamoto 2013).

Actions Thyropharyngeus constricts the lower part of the pharynx. Cricopharyngeus is the main component of the upper oesophageal sphincter, or pharyngo-oesophageal high-pressure zone, the other parts being thyropharyngeus and the proximal cervical oesophagus. (The extent to which the lower fibres of thyropharyngeus and the upper fibres of the oesophageal musculature are involved in closing the upper end of the oesophagus appears to depend on the physiological state, whereas cricopharyngeus always participates in closure.) The upper oesophageal sphincter is defined manometrically as a region of elevated intraluminal pressure, 2–4 cm long, located at the junction of the hypopharynx and cervical oesophagus.

Cricopharyngeus contains about 40% of endomysial connective tissue, much of which is elastic, but it lacks muscle spindles (Bonnington et al 1988, Brownlow et al 1989). It contains both slow-twitch type I and fast-twitch type II fibres, a structural arrangement that underpins the various functions of the upper oesophageal sphincter, i.e. maintaining constant basal tone, yet being able to relax and contract rapidly during swallowing, belching and vomiting. The tonic activity of cricopharyngeus between swallows prevents influx of air during inspiration and tracheobronchial aspiration and pharyngeal reflux of oesophageal contents during oesophageal peristalsis. For further reading, see Lang and Shaker (2000).

Hypopharyngeal diverticula

Available with the *Gray's Anatomy* e-book

PHARYNGEAL PLEXUS

Almost all of the nerve supply to the pharynx, whether motor or sensory, is derived from the pharyngeal plexus, which is formed by the pharyngeal branches of the glossopharyngeal and vagus nerves with contributions from the superior cervical sympathetic ganglion. The plexus lies on the external surface of the pharynx, especially on the middle constrictor. Filaments from the plexus ascend or descend external to the superior and inferior constrictors before branching within the muscular layer and mucosa of the pharynx.

The pharyngeal branch of the vagus supplies all the muscles of the soft palate (excluding tensor veli palatini, which is supplied by the mandibular division of the trigeminal via the nerve to medial pterygoid) and all the muscles of the pharynx (excluding stylopharyngeus, which is supplied by the glossopharyngeal nerve). It emerges from the upper part of the inferior vagal ganglion and consists of axons arising from neuronal cell bodies in the nucleus ambiguus. The nerve passes between the external and internal carotid arteries to reach the upper border of the middle pharyngeal constrictor and subsequently divides into numerous filaments that contribute to the pharyngeal plexus. It also gives off a minute filament, the ramus lingualis vagi, which joins the hypoglossal nerve as it curves round the occipital artery.

Whether a 'cranial root' of the accessory nerve serves as the conduit for the major motor drive to the pharyngeal plexus, albeit via the vagus nerve, is a matter of debate. The plexiform connections that may be demonstrated between the accessory nerve and the vagus nerve within the posterior cranial fossa are too variable and insubstantial to support this function.

ANATOMY OF SWALLOWING (DEGLUTITION)

Swallowing involves a series of activities that take place within a matter of seconds. Traditionally described as a reflex, the process is more properly regarded as programmed motor behaviour. Swallowing is initiated when food or liquid stimulates sensory nerves in the oropharynx. In a 24-hour period, an average person swallows between 600 and 1000 times but, of these, only some 150 will relate to feeding; the remainder clear saliva and are less frequent at night (Sato and Nakashima 2006, 2007).

Eating and drinking are basic human pleasures and problems associated with swallowing can impact dramatically on the quality of life. Swallowing disorders are usually symptoms of other complex diseases; an inability to swallow may adversely affect nutritional status and therefore indirectly exacerbate the underlying disease. Aside from the risk of asphyxiation through choking, swallowing disorders can also be a direct cause of morbidity and mortality as a result of aspiration of food, liquid or possibly refluxed gastric acid contents, causing bacterial infection or tissue damage.

Swallowing in the adult human has usually been studied in relation to swallowing solid or liquid food carried out on command. For descriptive purposes, the process has been traditionally divided into four phases: oral preparatory, oral transit/transfer, pharyngeal and oesophageal (in this traditional view some have only recognized three phases, combining the two oral phases of preparation and transit into a single oral phase). While this sequence of events may still be appropriate for describing the swallowing of liquids, it is not sufficiently detailed to represent the way in which solid food is prepared for swallowing, where suitably processed food is passed in stages to the oropharynx and valleculae until a swallow is initiated. Oral and pharyngeal stages overlap when swallowing solid food, but perhaps less so when swallowing saliva or other liquids. It is more appropriate to speak of an oral preparatory and an oral transit phase when describing the swallowing of liquids, but inappropriate when considering the swallowing of solid food. (For further reading, see Hiiemae and Palmer 1999, 2003, Matsuo and Palmer 2008, Mioche et al 2002, Palmer et al 2007.)

Hypopharyngeal diverticula arise in the lower portion of the pharynx through areas of weakness in the pharyngeal wall. The pharyngeal mucosa that lies between cricopharyngeus and thyropharyngeus is relatively unsupported by pharyngeal muscles (the dehiscence of Killian). A delay in the relaxation of cricopharyngeus, which can happen when the swallowing mechanism becomes discoordinated, generates a zone of elevated pressure adjacent to the mucosa in the dehiscence. The result is the development of a pulsion diverticulum (a pouch of prolapsing mucosa), also known as Zenker's diverticulum, which breaches the thin muscle wall adjacent to the sixth cervical vertebra and expands, usually a little to the left side, into the parapharyngeal potential space. This may trap portions (or all) of the passing food bolus, resulting in regurgitation of old food, aspiration pneumonia, halitosis and weight loss. Treatment may involve open excision or inversion of the pouch to prevent it filling, coupled with division of the circular fibres of cricopharyngeus, to prevent the build-up of pressure in the region and recurrence of the pouch. Endoscopic stapling, or laser-assisted diverticulotomy has become popular, first-line, treatment and avoids open surgery for most patients.

The majority of hypopharyngeal diverticula arise either between the two parts of cricopharyngeus (where the upper oblique and lower transverse fibres diverge) or below cricopharyngeus (where the longitudinal fibres of the oesophagus diverge in Laimer's triangle). Some arise between cricopharyngeus and thyropharyngeus. Diverticula are usually midline but may arise laterally below cricopharyngeus.

Oral preparatory phase

In the oral preparatory phase, liquids are taken into the mouth and held there either on the floor of the mouth or against the hard palate by the upward movement of the tongue. During swallowing, the muscles that dilate the pharyngotympanic tube are activated during a pause in the expiratory phase of respiration. Throughout this first phase, the soft palate is fully lowered by contraction of palatoglossus and palatopharyngeus, and the posterior part of the tongue is simultaneously elevated; the apposed soft palate and tongue form a tight seal that helps to prevent premature leakage of the bolus into the oropharynx before the airways are fully protected. Slight leakage of fluid does sometimes happen; the tendency for there to be leakage because of imperfect sealing increases with age.

Oral transit/transfer phase

In the oral transit/transfer phase, the liquid in the oral cavity is transported through the palatoglossal and palatopharyngeal arches into the oropharynx. Genioglossus raises both the tongue tip and the part of the tongue immediately behind the tip so that they come into contact with the alveolar ridge. Orbicularis oris and buccinator remain contracted, keeping the lips and cheeks taut and the liquid central in the oral cavity. The liquid is accommodated in a shallow midline gutter that forms along the dorsum of the tongue, probably as a result of the co-contraction of the styloglossi and the genioglossi, aided by the superior longitudinal and transverse fibres of the intrinsic muscles. The mandible is elevated and the mouth is closed. The floor of the mouth and the anterior and middle portions of the tongue are elevated by co-contraction of the suprahyoid group of muscles (mylohyoid, digastric, geniohyoid and stylohyoid); the effectiveness of the suprahyoid muscles is increased as they contract against a fixed mandible (the mouth does not have to be closed to swallow, but it is much harder to swallow if it is open). Contraction of stylohyoid elevates the more posterior parts of the tongue and empties the longitudinal gutter. At the same time, the tongue flattens, probably as a result of the contraction of hyoglossus and some of the intrinsic lingual muscles, especially the vertical fibres. The elevated, flattened tongue pushes the liquid against the hard palate, and the sides of the tongue seal against the maxillary alveolar processes, helping to move the liquid further posteriorly. Contraction of styloglossus and mylohyoid completes the elevation of the posterior part of the tongue. At the same time, the posterior oral seal relaxes and the posterior tongue moves forwards; the overall effect is of a cam-like action of the tongue, sweeping or squeezing the liquid towards the pillars of the fauces, finally delivering it to the oropharynx and initiating the pharyngeal stage of swallowing, where the pharyngeal aperture is initially increased and then closed.

Oral phases when swallowing solids

When solid food is swallowed, the process is slightly different from that just described for swallowing liquids. Food is mixed with saliva and reduced to smaller pieces by the processes of chewing. When it has been converted to a suitable consistency to be swallowed, it is transferred to the oropharynx and valleculae, where it can be retained for a few seconds prior to swallowing. During this time, chewing may continue; the bolus is progressively augmented in one or more stages until a swallow is initiated and the pharyngeal phase begins. In this part of the 'oral phase for solid food', the essential action is chewing; the mandible is moved by the action of the jaw elevators and depressors, and the food is reduced by the grinding action of the teeth and simultaneously mixed with saliva. The lips are maintained as a tight labial seal by the contraction of orbicularis oris; buccinator performs a similar function for the cheeks. In this way, the sulci are closed, the vestibule normally remains empty, and any food that enters the vestibule is returned to the oral cavity proper. Buccinator keeps the cheeks taut, ensuring that they are kept clear of the occlusal surfaces and that the food remains in place under the occlusal surfaces of the molar teeth. Loss of the nerve supply to buccinator as a result of damage to the facial nerve results in painful and repeated lacerations of the cheeks. It was thought that the soft palate was depressed throughout this phase. It is now recognized that the posterior seal is not tight, and that the oral cavity and oropharynx remain in communication, permitting addition of material to the bolus while chewing continues. Spillage may happen because the soft palate is not in continuous contact with the posterior part of the tongue, as was once thought (Hiiemae and Palmer 1999). Bolus formation appears to involve several cycles of transporting food from the anterior to the posterior part of the tongue through the palatoglossal and palatopharyngeal arches until a bolus accumulates on the oropharyngeal surface of the tongue (retrolingual loading), the valleculae and within the oropharynx. Throughout this phase, the lateral and rotatory tongue movements that deliver the food to the teeth for grinding and reduction are crucial for normal bolus formation because they ensure that the food is positioned under the occlusal surfaces of the teeth. If effective tongue movements are not achieved, chewing will be compromised. Movements of the tongue are also cyclical in phase with the movements of the jaw and hyoid bone. As the jaw is depressed, the tongue is also depressed and moves anteriorly. As the jaw is elevated, the tongue is retracted so that it no longer lies under the anterior teeth as they as are brought together by jaw elevation. These coordinated actions help to ensure that the tongue is not bitten during chewing.

Chewing continues until all the food has been moved posteriorly, a process that can last from less than 1 second to as much as 10 seconds. The oral preparatory, oral transport and pharyngeal phases of swallowing therefore overlap when solid food is being swallowed. As pieces of food are prepared in the mouth, they are moved to the posterior part of the tongue or on into the oropharynx in a similar manner to that used to transport liquids. The end of this phase of swallowing is marked by the tongue propelling the prepared bolus of food to the posterior part of the oral cavity and then on into the oropharynx to initiate the swallow. Contact with either the posterior wall of the oropharynx or the mucosa overlying the palatoglossal and palatopharyngeal arches was once thought to be necessary to initiate a swallow; it is now known that there is a great degree of variability in the position of the bolus at the time at which a swallow is initiated.

Pharyngeal phase

The delivery of the bolus to the oropharynx triggers the pharyngeal phase of the swallow. This phase, which is involuntary and is the most critical stage of swallowing, involves the pharynx changing from being an air channel (between the posterior nares and laryngeal inlet) to a food channel (from the fauces to the upper end of the oesophagus). The airway is protected from aspiration during swallowing by hyolaryngeal elevation, and by resetting respiratory rhythm so that airflow ceases briefly as the bolus passes through the hypopharynx; the total time that elapses from the bolus triggering the pharyngeal phase to the re-establishment of the airway is barely 1 second. Thus, there are two aspects of the process to be examined: the transport of the food down the pharynx and through the upper oesophageal sphincter, and the absolute need to protect the airways throughout this time.

The nasopharynx is sealed off from the oropharynx by activation of the superior pharyngeal constrictor and contraction of a subset of palatopharyngeal fibres to form a variable, ridge-like structure (Passavant's ridge; Cho et al 2013), against which the soft palate is elevated. From an evolutionary perspective, this ridge represents the remnant of a sphincter that encircled a more highly placed larynx; a high laryngeal position is the norm in other mammals and in the human infant (see below), but not in the human adult. Interestingly, the pharyngeal ridge becomes hypertrophic in an infant with a cleft palate, presumably in an attempt to produce a seal to the nasal airway. Ineffective velopharyngeal closure may result in nasal regurgitation of food.

The airway is sealed at the laryngeal inlet by closure of the glottis. The epiglottis is retroflexed over the laryngeal aditus as a result of passive pressure from the base of the tongue and active contraction of the aryepiglottic muscles. The conventional view that laryngeal closure during swallowing takes place from inferior to superior, i.e. the vocal folds adduct first and the epiglottis covers the arytenoids and glottis last, has been challenged by studies using simultaneous electromyography and fibreoptic endoscopic evaluation of swallowing (FEES). These studies have reported that the aryepiglottic folds close before vocal fold adduction during a swallow. The sequence of events that close the glottis may alter according to the type of swallow and consistency of the bolus (Steele and Miller 2010). To prevent aspiration of material, irrespective of its consistency, the hyoid bone and larynx are raised and pulled anteriorly with precise timing by the suprahyoid muscles and the longitudinal muscles of the pharynx (Kendall et al 2001). In this way, the laryngeal inlet is brought forwards under the bulge of the posterior tongue, i.e. out of the path of the bolus. This action helps expand the hypopharyngeal space and relax the upper oesophageal sphincter, which is also raised by several centimetres. The bolus passes over the reflected anterior surface of the epiglottis and is swept through the laryngopharynx to the upper oesophageal sphincter.

Breathing is suspended briefly during swallowing; the larynx is closed and the soft palate is elevated while there is active neural inhibition of ventilation. Swallowing is normally initiated during an expiration, which is then inhibited during the swallow (typically for a period of 0.5–1.5

seconds). Resumption of expiration provides a degree of protection against any residues of solid food that might remain uncleared within the pharynx following the swallow being inhaled into the airway. The bolus is moved by sequential contraction of the pharyngeal constrictor muscles superiorly behind the bolus. At the same time, the pharynx is shortened and elevated as palatoglossus and palatopharyngeus contract against the raised and fixed soft palate. The sequential contraction of the constrictor muscles is often assumed to be the driving force that propels the bolus towards the oesophagus. Evidence that the head of the bolus moves faster than the wave of pharyngeal contraction suggests that, at least in some situations, the kinetic energy imparted to the bolus as it is expelled from the mouth into the oropharynx may be sufficient to carry it through the pharynx. This energy is generated by pressure gradients created within the pharynx by the tongue's driving force, the hypopharyngeal suction pump, and the 'stripping action' of the pharyngeal constrictors (Nishino et al 1985).

The tongue driving force (tongue thrust pressure force) is a positive pressure that squeezes the bolus towards the laryngopharynx. It is generated by the upward movement of the tongue pressing the bolus against the contracting pharyngeal wall and requires a tight nasopharyngeal seal (created by elevation of the soft palate). There is a view that the tongue driving force is the most important factor responsible for moving the bolus down the pharynx. The hypopharyngeal suction pump is caused by the elevation and anterior movement of the hyoid and larynx. This creates a negative pressure in the laryngopharynx, drawing the bolus towards the oesophagus, aided by a more negative pressure inside the oesophagus. The pharyngeal constrictors generate a positive pressure wave behind the bolus. Their sequential contraction may facilitate clearance ('stripping') of the pharyngeal walls and piriform sinuses. Residues that remain in the valleculae reflect inadequate tongue force generation at the end of the oral phase of swallowing.

At the end of this phase, the bolus is propelled towards the upper oesophageal sphincter. At rest, this sphincter is closed by active contraction. Cricopharyngeus relaxes prior to the bolus arriving and the sphincter is then opened actively by the combined action of the suprahyoid muscles in moving the larynx anteriorly and superiorly, and passively by pressure from the arriving bolus. The upper oesophageal sphincter thus differs in its action from that of other sphincters where opening is generally passive and a consequence of pressures generated by the movements towards them of fluids or solids.

Gag reflex

Traditionally, the stimulus for triggering a swallow has been regarded as contact with the posterior wall of the pharynx, since this is usually where the gag reflex is triggered (see page 450.e1). However, many regions of the oropharynx, when appropriately stimulated by the presence of food or liquid, are capable of triggering a swallow, although some regions are more sensitive than others, e.g. the area over the palatoglossal arches. Moreover, there appears to be little relationship between a functioning gag reflex and the ability to swallow normally because individuals with a reduced or absent gag reflex can swallow safely. Conversely, the presence of a brisk and clear gag reflex is not always associated with the ability to swallow safely.

Oesophageal phase

The third, or oesophageal, stage begins after the relaxation of the upper oesophageal sphincter has allowed the bolus to enter the oesophagus. This is a true peristaltic movement, in that a muscular relaxation in front of the bolus and subsequent constriction behind the bolus move it towards the stomach. Sequential waves of contractions of the oesophageal musculature now propel the bolus down to the lower oesophageal sphincter, which opens momentarily to admit the bolus to the stomach. The oesophageal phase of swallowing is much more variable than the other phases and lasts between 8 and 20 seconds.

Swallowing pattern generator

The patterning and timing of striated muscle contraction during swallowing are generated at a brainstem level in a network of neural circuits that collectively form a central swallowing pattern generator. Experimental neurophysiological and tracer studies in animals have shown that the swallowing pattern generator includes several brainstem motor nuclei and two groups of interneurones in the dorsal and ventral medulla: a dorsal swallowing group and a ventral swallowing group. The dorsal swallowing group is located in the nucleus of the solitary tract and possibly in the adjacent reticular formation, and contains neurones that generate the swallowing pattern, probably triggered by convergent information from both cortical and peripheral inputs. The afferent feedback from the branches of the superior laryngeal nerve that innervate the valleculae, epiglottis and supraglottic part of the larynx, and which relay through the nucleus of the solitary tract, facilitates laryngeal closure during swallowing (Jafari et al 2003). The ventral swallowing group is in the ventrolateral medulla above the nucleus ambiguus and contains neurones that act as 'switches', distributing the swallowing drive to motoneurone pools in the trigeminal, facial and hypoglossal nuclei and in the nucleus ambiguus.

The patterns of activation in the smooth muscle of the lower part of the oesophagus are generated locally in intramural plexuses driven by vagal autonomics.

Supramedullary influence on swallowing

Techniques including transcranial magnetic stimulation, cortical evoked potentials, positron emission tomography and functional magnetic resonance imaging (fMRI) have all been exploited in the study of volitional swallowing in humans (Thexton 1998, Thexton and Crompton 1998, Harris et al 2005). Thus far, these studies have shown that numerous cortical and subcortical regions (primary motor and sensory cortices, operculum, supplementary motor area and cingulate cortex, insula, parietal cortical areas, basal regions and cerebellum) are recruited in swallowing, although, as yet, the functional contributions made by each region have not been established, and it is not known how they influence the swallowing pattern generator. The most consistent cortical activation occurs in the primary motor and somatosensory cortices. Perhaps not surprisingly, the greatest area of fMRI activation in the primary motor cortex occurs over the portion of the precentral gyrus where the face, tongue and pharynx are represented; there is evidence for functional asymmetry between the right and left oral sensorimotor cortices (Martin et al 2004). The activity of the swallowing pattern generator is coordinated with other medullary reflexes, e.g. it is difficult to elicit a swallow when the cortical masticatory centres are stimulated. (For further reading on the motor control of oropharyngeal swallowing, see Humbert and German (2013), and on the role of sensory feedback from the oropharynx in swallowing, see Michou and Hamdy (2009).)

Swallowing in the neonate

In the adult, the tip of the epiglottis is significantly lower than the inferior edge of the soft palate. In the neonate, the larynx is high in the neck and the epiglottis may extend above the soft palate so that the laryngeal airway is in direct continuity with the posterior nares (**Figs 40.11–40.12**); a potential space is therefore formed between the soft palate above, the epiglottis behind and the tongue anteroinferiorly. In other mammals with an oropharyngeal anatomy similar to that of the human infant, up to 14 cycles of tongue movement or oral phases cause the accumulation of food in this space. Subsequent emptying of the space is a single event followed by movement of the bolus down the oesophagus. The ratio of accumulation cycles to swallow events in the human neonate is approximately 1.5 : 1, which is lower than in other mammals but still implies some temporary accumulation. In the case of a liquid bolus, accumulated material may be passed laterally to the epiglottis through the piriform fossae rather than over the flexed epiglottis, although it is not known whether this happens in the human infant. (For further reading, see Delaney and Arvedson (2008).)

Swallow safety is critical at all ages. In the neonate, where coordination of suckling, swallowing and breathing is not fully developed, the potential risk of airway obstruction and/or aspiration of ingested milk or other material during swallowing is reduced because the intranarial larynx prevents the bolus from entering the larynx before and after a swallow. (Neonates born at term demonstrate an increase in suck and swallow rates over the course of the first 4weeks; efficiency of feeding, measured as volume of nutrient per suck and per swallow, doubles over the course of the neonatal period (Qureshi et al 2002).)

The change towards adult anatomy and coordination of the phases of swallowing starts a few months after birth (Kelly et al 2007). Differential growth in length of the human pharynx causes the larynx to take up its low adult position and the epiglottis to lose contact with the soft palate; the larynx reaches its final position around the time of puberty. The adult anatomy does not allow any significant accumulation of food immediately anterior to the epiglottis, which means that the transport of food through the fauces has to bear a 1 : 1 relationship to pharyngeal and oesophageal transit. Moreover, the lowered larynx compromises the previously protected airway; the hyoid and larynx are therefore raised and pulled forwards during a swallow in order to minimize the risk of deglutitive aspiration.

Fig. 40.11 A sagittal section of the head of a neonate. Note the relatively high position of the larynx, the opening being at the level of the soft palate (A). Other abbreviations: B, epiglottis. (With permission from Berkovitz BKB, Holland GR, Moxham BJ 2002 Oral Anatomy, Embryology and Histology, 3rd edn. Edinburgh: Mosby.)

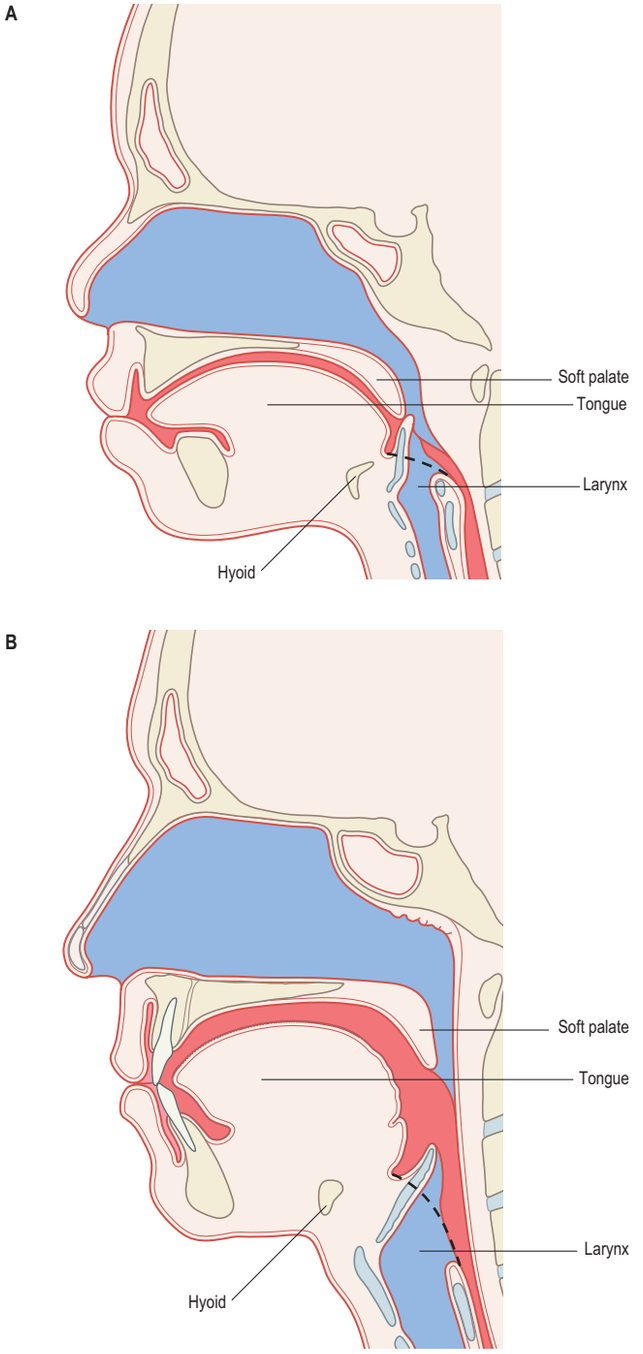

Fig. 40.12 A sagittal section of the head and neck in an infant (**A**) and adult (**B**) human. The food way and the airway are shaded in red and blue, respectively. **A**, In the infant human, the oral cavity is small and the tongue and palate are flatter. **B**, In the adult human, the larynx is lower in the neck, and the food way and airway cross in the pharynx. (Adapted with permission from Matsuo K, Palmer JB 2008 Anatomy and physiology of feeding and swallowing – normal and abnormal. Phys Med Rehabil Clin North Am 19:691–707.)

Dysphagia

Dysphagia is a symptom of many diseases and can arise from anatomical or functional deficits anywhere along the path from the oral cavity to the stomach or from a failure of neural control resulting from congenital malformations, trauma, stroke or neurodegenerative diseases within the central nervous system. Loss of muscle strength affecting tongue propulsion or pharyngeal contraction will impair the initiation of the swallow and/or bolus transport. This will result in retention of residues within the pharynx following a swallow. Residues may also accumulate in the valleculae and piriform sinuses. Failure to protect the airways adequately may result in the penetration of swallowed material food or liquid into the vestibule of the larynx. Aspiration will result if the material then passes through the vocal folds, which may result in airway obstruction or aspiration pneumonia. Penetration may sometimes occur in normal individuals.

Pharyngostomy

Loss of control of the pharyngeal phase of swallowing, e.g. due to neurological disease or ablative head and neck surgery, may result in aspiration of food, especially fluids, leading to pneumonia. This problem may be addressed surgically by pharyngostomy: more recently, percutaneous gastrostomy is favoured and more comfortable for the patient.

In cervical pharyngostomy, a tube may be passed through the cervical skin, fascia and platysma directly into the piriform fossa (Patil et al 2006). This is achieved by passing a curved forcep into the piriform fossa and pushing it laterally, displacing the contents of the carotid sheath and tenting up the platysma and cervical skin from the inside. By cutting down onto the forcep, it is possible to grasp the feeding tube and pull it into the piriform fossa prior to feeding it on into the oesophagus. The tract formed by such a puncture epithelializes and may be used for long-term alimentation.

CHAPTER
41

Larynx

The larynx is an air passage, a sphincter and an organ of phonation, and extends from the tongue to the trachea. It projects ventrally between the great vessels of the neck and is covered anteriorly by skin, fasciae and the infrahyoid strap muscles that lower the hyoid bone and the larynx. Above, it opens into the laryngopharynx and forms its anterior wall; below, it continues into the trachea (see Fig. 40.2). It is mobile on deglutition. At rest, the larynx lies opposite the third to sixth cervical vertebrae in adult males; it is somewhat higher in children and adult females. In infants between 6 and 12 months, the tip of the epiglottis (the highest part of the larynx) lies a little above the junction of the dens and body of the axis vertebra (Mijallili et al 2012). Until puberty, male and female larynges are similar in size. After puberty, the male larynx enlarges considerably in comparison with that of the female; all the cartilages increase in both size and weight, the thyroid cartilage projects in the anterior midline of the neck, and its sagittal diameter nearly doubles. The male thyroid cartilage continues to increase in size until 40 years of age, after which no further growth occurs.

For further reading, including an introduction to the more important historical literature, see Berkovitz et al (2000), Blitzer et al (2009), Dickson and Maue-Dickson (1982), Kaplan (1971), Hollinshead (1982), Tucker (1993).

SKELETON OF THE LARYNX

The skeletal framework of the larynx is formed by a series of cartilages interconnected by ligaments and fibrous membranes and moved by a number of muscles (**Figs 41.1–41.3**). The hyoid bone is attached to the larynx; it is usually regarded as a separate structure with distinctive functional roles and is described in the chapter on the neck (Ch. 35). The laryngeal cartilages are the midline, single thyroid, cricoid and epiglottic cartilages, and the paired arytenoid, cuneiform, corniculate and tritiate cartilages.

The thyroid, cricoid and the greater part of the arytenoid cartilages consist of hyaline cartilage and may undergo mottled calcification as age advances, starting about the twenty-fifth year in the thyroid cartilage and somewhat later in the cricoid and arytenoids. By the sixty-fifth year, these cartilages commonly appear patchily dense in radiographs. The corniculate, cuneiform, tritiate and epiglottic cartilages and the apices of the arytenoid are composed of elastic fibrocartilage, with little tendency to calcify (Munir Turk 1993).

The surface anatomy of the laryngeal cartilages is described on pages 554 and 555.

Epiglottis

The epiglottis is a thin, leaf-like plate of elastic cartilage that projects obliquely upwards behind the tongue and hyoid body, and in front of the laryngeal inlet (see Figs 41.2–41.3, 41.5). Its free end, which is broad and round, and occasionally notched in the midline, is directed upwards. Its attached part, or stalk (petiole, petiolus), is long and narrow and is connected by the elastic thyroepiglottic ligament to the back of the laryngeal prominence of the thyroid cartilage just below the thyroid notch. Its sides are attached to the arytenoid cartilages by aryepiglottic folds (which contain the aryepiglottic muscle) (see Fig. 41.6). Its free upper anterior, or lingual, surface is covered by mucosa (the epithelium is non-keratinized stratified squamous), which is reflected on to the pharyngeal aspect of the tongue and the lateral pharyngeal walls as a median glossoepiglottic, and two lateral glossoepiglottic, folds. This arrangement produces a depression, the vallecula, on each side between the median and lateral folds (see Fig. 41.5B). The lower part of its anterior surface, behind the hyoid bone and thyrohyoid membrane, is connected to the upper border of the hyoid by an elastic hyoepiglottic ligament, and separated from the thyrohyoid membrane by adipose tissue, which constitutes the clinically important pre-epiglottic space (see Fig. 41.5). The smooth posterior, or laryngeal, surface is transversely concave and vertically concavo-convex, and is covered by ciliated respiratory mucosa; its lower projecting part is called the tubercle. This surface forms the oblique anterior wall of the laryngeal vestibule. The cartilage is posteriorly pitted by small mucous glands (**Fig. 41.3D**) and is perforated

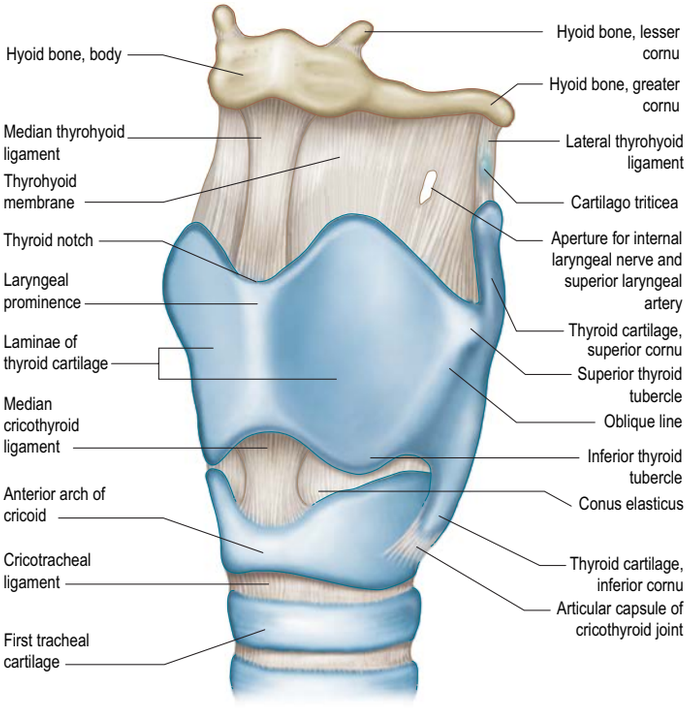

Fig. 41.1 Anterolateral view of the laryngeal cartilages and ligaments.

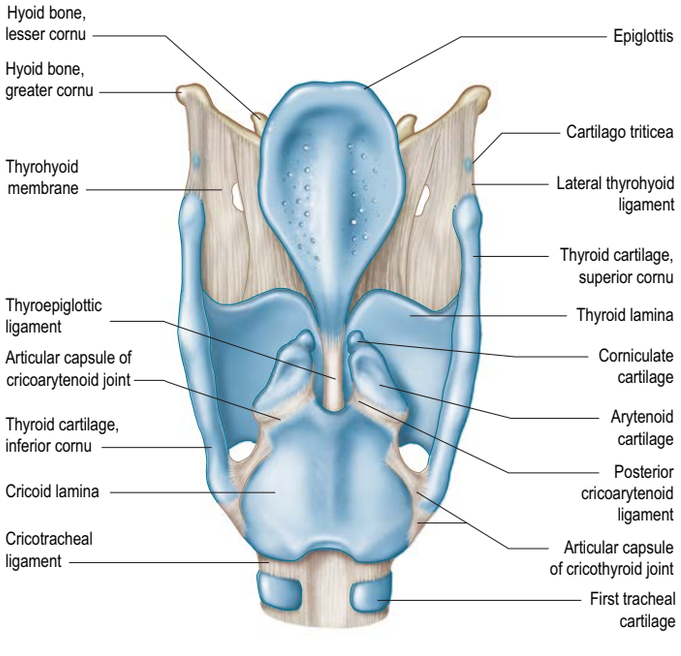

Fig. 41.2 Posterior view of the laryngeal cartilages and ligaments.v

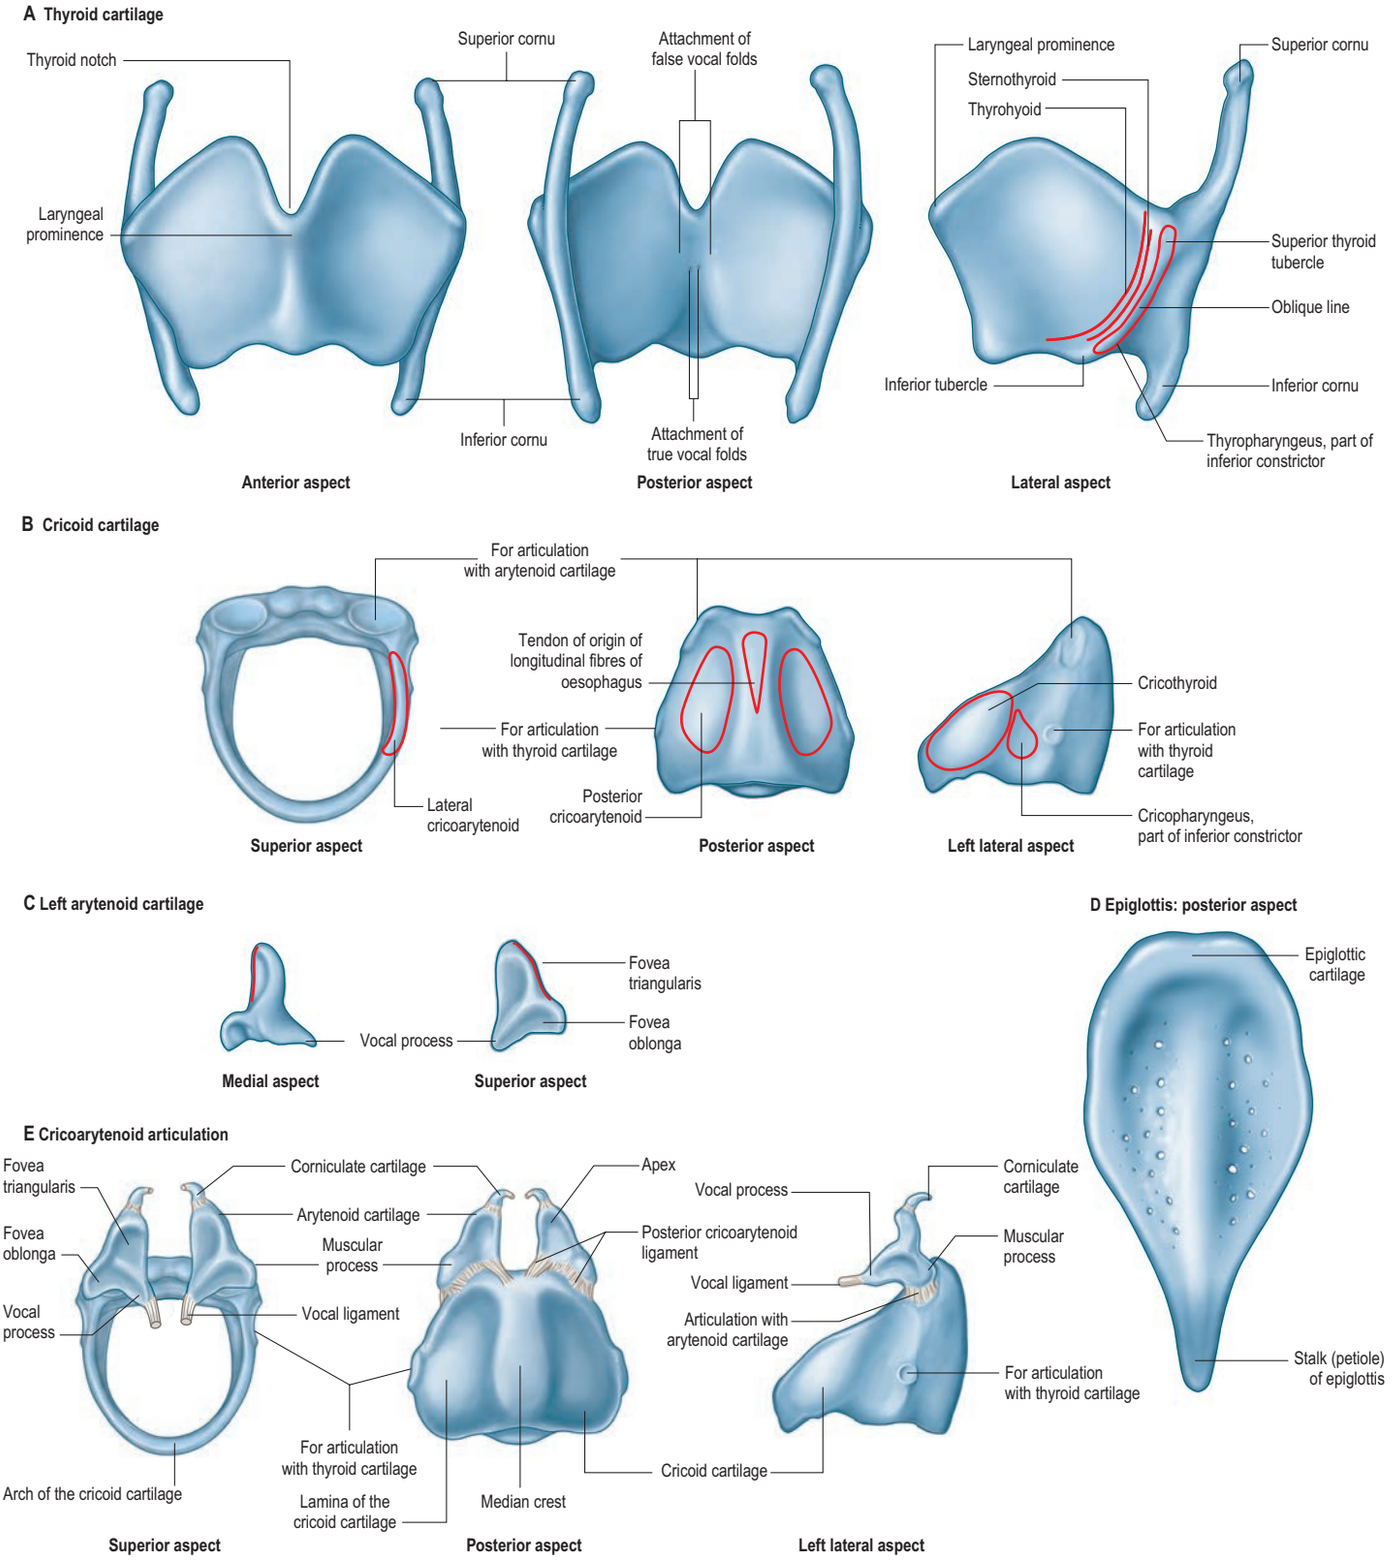

Fig. 41.3 Cartilages of the larynx: thyroid (**A**), cricoid (**B**), arytenoid (**C**), epiglottis (**D**), cricoarytenoid joint (**E**). The attachments of the false vocal folds (vestibular ligaments; above) and the true vocal folds (vocal ligaments; below) are shown in **A**, posterior aspect. Note the pitted surface of the epiglottis (**D**).

by branches of the internal laryngeal nerve and fibrous tissue, which means that the posterior surface of the epiglottis is in continuity through these perforations with the pre-epiglottic space.

Functions of the epiglottis

During swallowing, the hyoid bone moves upwards and forwards, and the epiglottis is bent posteriorly as a result of passive pressure from the base of the tongue and active contraction of the aryepiglottic muscles. Normally, the epiglottis diverts food and liquids away from the laryngeal inlet and into the lateral food channels. It is not essential for respiration or phonation.

Whether downward movement of the epiglottis is a passive process, produced by a combination of the weight of food or liquid on its lingual surface and forces originating elsewhere in the hyoid and larynx, or whether it is an active process brought about by active muscular control, remains the subject of debate. Neither scheme seems to explain epiglottic movement satisfactorily. It is likely that a combination of processes is taking place, in which passive forces originating in the tongue, hyoid and larynx are transmitted to the epiglottis by the hyoepiglottic ligaments while the base of the epiglottis is actively moved by thyroarytenoid and muscles of the laryngeal inlet (Logemann et al 1992, Vandaele et al 1994). Safe swallowing is still possible without an epiglottis, as after a supraglottic laryngectomy, but great care and training is necessary.

Thyroid cartilage

The thyroid cartilage is the largest of the laryngeal cartilages (see Figs 41.1–41.3). It consists of two quadrilateral laminae with anterior borders that fuse along their inferior two-thirds at a median angle to form the subcutaneous laryngeal prominence ('Adam's apple'). This projection is most distinct at its upper end and is well marked in men but less visible in women. Above, the laminae are separated by a V-shaped superior thyroid notch or incisure. Posteriorly, the laminae diverge, and their posterior borders are prolonged as slender horns: the superior and inferior cornua. A shallow ridge, the oblique line, curves downwards and forwards on the external surface of each lamina; it runs from the superior thyroid tubercle, lying a little anterior to the root of the superior cornu, to the inferior thyroid tubercle on the inferior border of the lamina. Often, the oblique line is barely visible or is just a faint line and only the tubercles are prominent. Sternothyroid, thyrohyoid and thyropharyngeus (part of the inferior pharyngeal constrictor) are attached to the oblique line, usually as little more than a tendon (**Fig. 41.3A**).

The internal surface of the lamina is smooth. Above and behind, it is slightly concave and covered by mucosa. The thyroepiglottic ligament, the paired vestibular and vocal ligaments, the thyroarytenoid, thyroepiglottic and vocalis muscles, and the stalk of the epiglottis are all attached to the inner surface of the cartilage, in the angle between the laminae. The true vocal folds lie 6–9 mm below the median thyroid notch. The superior border of each lamina is concave posteriorly and convex anteriorly, dropping sharply to form the thyroid notch; the thyrohyoid membrane is attached along the superior border (see Figs 41.1–41.2). The inferior border of each lamina is concave posteriorly and nearly straight anteriorly; the two parts are separated by the inferior thyroid tubercle. Anteriorly, the thyroid cartilage is connected to the cricoid cartilage by the median (anterior) cricothyroid ligament, which is the thickened medial portion of the conus elasticus.

The anterior border of each thyroid lamina fuses with its partner at an angle of approximately 90° in men and approximately 120° in women. The shallower angle in men is associated with the larger laryngeal prominence, the greater length of the vocal folds, and the resultant deeper pitch of the voice. The posterior border is thick and rounded and receives fibres of stylopharyngeus and palatopharyngeus. The superior cornu, which is long and narrow, curves upwards, backwards and medially, and ends in a conical apex to which the lateral thyrohyoid ligament is attached. The inferior cornu is short and thick, and curves down and slightly anteromedially. On the anteromedial surface of its lower end there is a small oval facet for articulation with the side of the cricoid cartilage; this facet is variable and is only sometimes well defined.

Cricoid cartilage

The cricoid cartilage is attached below to the trachea and articulates with the thyroid cartilage and the two arytenoid cartilages by synovial joints. It forms a complete ring around the airway, the only laryngeal cartilage to do so (**Fig. 41.3B**). It is smaller, but thicker and stronger, than the thyroid cartilage, and has a narrow curved anterior arch and a broad, flatter posterior lamina.

Cricoid arch

The cricoid arch is vertically narrow in front (5–7 mm in height) and widens posteriorly towards the lamina. Cricothyroid is attached to the external aspect of its front and sides, and cricopharyngeus (part of the inferior pharyngeal constrictor) is attached behind cricothyroid. The arch is palpable below the laryngeal prominence, from which it is separated by a depression containing the conus elasticus. The inferior border of the cartilage is nearly horizontal and is circular in outline, whereas the upper border is more elliptical.

Cricoid lamina

The cricoid lamina is approximately quadrilateral in outline, and 2–3 cm in vertical dimension. It bears a posterior median vertical ridge that creates posterior concavities on either side. The two bundles of the longitudinal layer of oesophageal muscle fibres (muscularis externa) are attached by a tendon to the upper part of the ridge. Posterior cricoarytenoid attaches to a shallow depression on either side of the ridge.

A discernible circular synovial facet, facing posterolaterally, sometimes marks the junction of the lamina and arch; it indicates the site where the cricoid articulates with the inferior thyroid cornu. The inferior border of the cricoid is horizontal and joined to the first tracheal cartilage by the cricotracheal ligament (see Fig. 41.1). The superior border runs obliquely up and back and gives attachment anteriorly to the thick median cricothyroid ligament, and laterally to the conus elasticus (see Fig. 41.1) and lateral cricoarytenoid. The posterosuperior aspect of the lamina presents a shallow median notch, on each side of which is a smooth, oval, convex facet, directed upwards and laterally, for articulation with the base of an arytenoid cartilage.

The internal surface of the cricoid cartilage is smooth and lined by mucosa.

Subglottic stenosis

Available with the *Gray's Anatomy* e-book

Arytenoid cartilage

The paired arytenoid cartilages articulate with the lateral parts of the superior border of the cricoid lamina (see Fig. 41.2; **Figs 41.3C,E**). Each is pyramidal and has three surfaces, two processes, a base and an apex. The posterior surface, which is triangular, smooth and concave, is covered by the transverse arytenoid muscle. The anterolateral surface is convex and rough. Near the apex of the cartilage there is an elevation from which a crest curves back, down and then forwards to the vocal process. The lower part of this arcuate crest separates two depressions (foveae). The upper is triangular (fovea triangularis), and the vestibular ligament is attached to it. The lower is oblong (fovea oblonga). Vocalis and thyroarytenoid are attached to it. The medial surface is narrow, smooth and flat, and is covered by mucosa; its lower edge forms the lateral boundary of the intercartilaginous part of the rima glottidis. The base is concave, with a smooth surface for articulation with the lateral part of the upper border of the cricoid lamina. Its round, prominent lateral angle, or muscular process, projects backwards and laterally; it gives attachment to posterior cricoarytenoid behind and lateral cricoarytenoid in front. The vocal ligament is attached to its pointed anterior angle (vocal process), which projects horizontally forwards. The apex curves backwards and medially to articulate with the corniculate cartilage.

Corniculate cartilages

The corniculate cartilages are two conical nodules of elastic cartilage that articulate with the apices of the arytenoid cartilages, elongating them posteromedially (see Figs 41.2, 41.3E). They lie in the posterior parts of the aryepiglottic mucosal folds and are sometimes fused with the arytenoid cartilages.

Cuneiform cartilages

The cuneiform cartilages are two small, elongated, club-like nodules of elastic cartilage, one in each aryepiglottic fold anterosuperior to the corniculate cartilages, and are visible as whitish elevations through the mucosa.

Tritiate cartilages (cartilago triticea)

The tritiate cartilages are two small nodules of elastic cartilage, situated one on either side above the larynx within the posterior free edge of the thyrohyoid membrane, about halfway between the superior cornu of the thyroid cartilage and the tip of the greater cornu of the hyoid bone (see Figs 41.1–41.2). Their functions are unknown, although they may serve to strengthen this connection.

Other inconstant or supernumerary cartilages can be present in the larynx. They are the small, paired sesamoid cartilages, found at the lateral edges of the arytenoid cartilages, and a single inter-arytenoid cartilage, enclosed by the cricopharyngeal ligament.

Calcification of laryngeal cartilages

The thyroid, cricoid and most of the arytenoid cartilages consist of hyaline cartilage and may therefore become calcified. This process normally starts at about 18 years of age. Initially, it involves the lower and posterior part of the thyroid cartilage, and subsequently spreads to involve the remaining cartilages, calcification of the arytenoid cartilage starting at its base. The degree and frequency of calcification of the thyroid and cricoid cartilages appear to be less in females.

Subglottic stenosis is usually acquired by damage to the cricoid ring by prolonged intubation in premature babies (Walner et al 2009). In contrast, congenital subglottic stenosis is uncommon. It is usually seen in children sporadically. Familial cases are rare but have been reported and born to consanguineous parents, suggesting a strong genetic link (Manickavasagam et al 2014). When congenital, it is caused by a small and narrow cricoid ring and may present with stridor and sometimes with just prolonged episodes of croup. Tracheostomy is necessary for nearly 50% of children and a 2% mortality has been reported in a very large series (Holinger et al 1976). Some children may be managed by regular dilatation and a few grow out of the disorder.

The tip and upper portion of the vocal process of the arytenoid cartilage consists of non-calcifying, elastic cartilage. This may have considerable functional significance: the vocal process may bend at the elastic cartilage during adduction and abduction, and the two arytenoid cartilages will contact mainly at their 'elastic' superior portions during adduction.

JOINTS

Cricothyroid joint

The joints between the inferior cornua of the thyroid cartilage and the sides of the cricoid cartilage are synovial. Each is enveloped by a capsular ligament strengthened posteriorly by fibrous bands (see Figs 41.1–41.2; **Fig. 41.4**). Both capsule and ligaments are rich in elastin fibres. The primary movement at the joint is rotation around a transverse axis that passes transversely through both cricothyroid joints. There is some controversy as to whether the cricoid or thyroid cartilage rotates more. The effect of this rotation is to move the cricoid and thyroid cartilages relative to one another in such a way as to bring together or approximate the lamina of the thyroid cartilage and the arch of the cricoid cartilage ('closing the visor'). When the joint is in a neutral position, the ligaments are slack and the cricoid can glide, to a limited extent, in horizontal and vertical directions on the thyroid cornua. The effect of these movements is to lengthen the vocal folds, provided the arytenoid cartilages are stabilized at the cricoarytenoid joint. This may also increase vocal fold tension. For further reading, see Vilkman et al (1987), Hammer et al (2010).

There is a significant amount of variation in the shape of the cricothyroid facet, which can vary from a well-defined facet to a nearly flat surface with just a slight protuberance or to no obvious definable facet. The shape of the facet determines the degree of horizontal and vertical gliding possible at the joint. The degree of elongation of the vocal folds has been shown to vary between 3% and 12%. It has been suggested that this variation might be one factor in determining the success of cricothyroid approximation surgery to raise the pitch of the voice in male to female transsexuals (Hammer et al 2010, Windisch et al 2010, Storck et al 2011, Chen et al 2012).

Cricoarytenoid joint

The cricoarytenoid joints are a pair of synovial joints between the facets on the lateral parts of the upper border of the lamina of the cricoid cartilage and the bases of the arytenoids (see Figs 41.2, 41.3E, 41.4). Each joint is enclosed by a capsular ligament and strengthened by a ligament that, although traditionally called the posterior cricoarytenoid ligament, is largely medial in position.

The cricoid facets are elliptical, convex and obliquely directed laterally, anteriorly and downwards. The long axes of the two facets intersect posteriorly at an angle of about 50°. Two movements take place at this joint. The first is rotation of the arytenoid cartilages at right-angles to the long axis of the cricoid facet (dorso-medio-cranial to ventro-latero-caudal). This causes each vocal process to swing laterally or medially to increase or decrease the width of the rima glottidis. This movement is sometimes referred to as a rocking movement of the arytenoid cartilages. There is also a gliding movement, by which the arytenoids approach or recede from one another, the direction and slope of their articular surfaces imposing a forward and downward movement on lateral gliding. The movements of gliding and rotation are associated. Hence medial gliding happens with medial rotation and lateral gliding with lateral rotation. This results in adduction or abduction of the vocal folds respectively. When viewed from above, foreshortening can give the illusion that the arytenoid cartilages are rotating about their vertical axes, but the shape of the facets prevents such movement happening (Selbie et al 1998). Some authors maintain that rotatory movement about a vertical axis can take place (Liu et al 2013). The posterior cricoarytenoid ligaments limit forward movements of the arytenoid cartilages on the cricoid cartilage. It has been suggested that the 'rest' position of the cricoarytenoid ligament is a major determinant of the position of a denervated vocal fold (England et al 1996).

Arytenocorniculate joints

Synovial or cartilaginous joints link the arytenoid and corniculate cartilages.

Innervation of the cricothyroid, cricoarytenoid and arytenocorniculate joints

The cricothyroid, cricoarytenoid and arytenocorniculate joints are innervated by branches of the recurrent laryngeal nerves that arise either independently or from branches of the nerve to the laryngeal muscles. The capsules of the laryngeal joints contain numerous lamellated (Pacinian) corpuscles, Ruffini corpuscles and free nerve endings (Bradley 2000).

SOFT TISSUES

The skeletal framework of the larynx is joined to surrounding structures by extrinsic membranes. It is also interconnected by intrinsic ligaments and fibroelastic membranes, of which the thyrohyoid and quadrangular membranes, together with the conus elasticus, are the most significant. The thyrohyoid membrane is external to the larynx, whereas the paired quadrangular membranes and conus elasticus are internal. The named ligaments are the median (anterior) cricothyroid ligament, the hyoepiglottic, thyroepiglottic and the cricotracheal ligaments.

Extrinsic ligaments and membranes

Thyrohyoid membrane

The thyrohyoid membrane is a broad, fibroelastic layer attached below to the superior border of the thyroid cartilage lamina and the front of

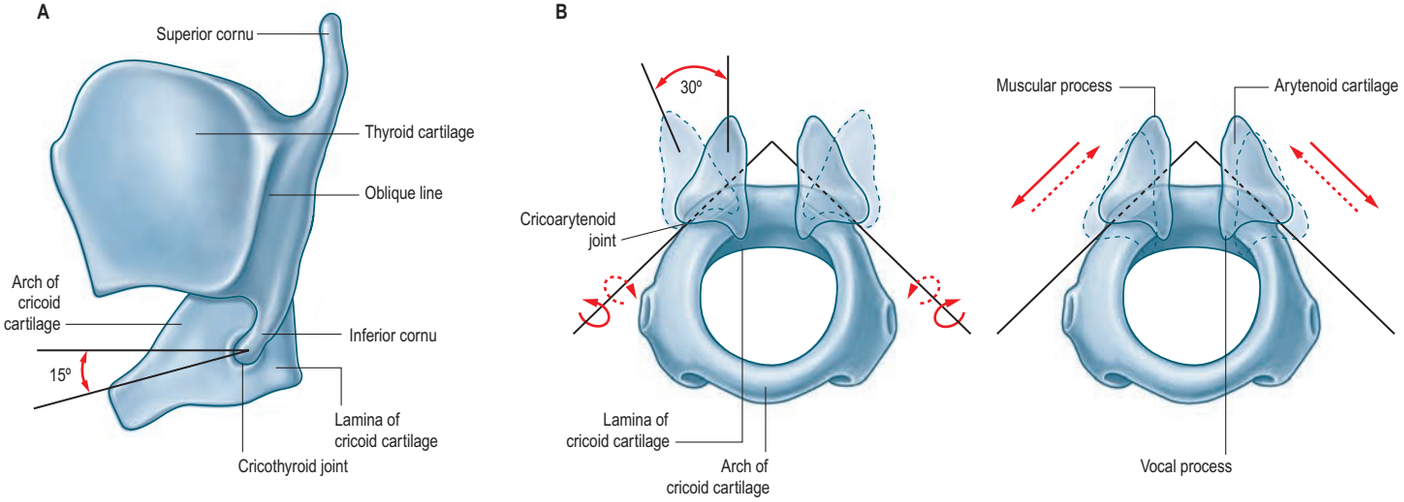

Fig. 41.4 **A**, Lateral view of the cricothyroid joint. **B**, An anterosuperior view of the cricoarytenoid joint.

its superior cornua and above to the superior margin of the body and greater cornua of the hyoid (see Figs 41.1–41.2; **Fig. 41.5C**). It thus ascends behind the concave posterior surface of the hyoid, separated from its body by a bursa that facilitates the ascent of the larynx during swallowing. Its medial portion is thickened, forming the median thyrohyoid ligament. The more lateral, thinner, parts are pierced by the superior laryngeal vessels and internal laryngeal nerves (see Fig. 41.1). Externally, it is in contact with thyrohyoid and omohyoid, and with the body of the hyoid bone. Its inner surface is related to the lingual surface of the epiglottis and the piriform fossae of the pharynx. The round, fold-like, elastic lateral thyrohyoid ligaments form the posterior borders of the thyrohyoid membrane and connect the tips of the superior thyroid cornua to the posterior ends of the greater hyoid cornua. For further reading, see Bosma and Bartner (1993).

Hyo- and thyroepiglottic ligaments

The epiglottis is attached to the hyoid bone and thyroid cartilage by the extrinsic hyoepiglottic and intrinsic thyroepiglottic ligaments, respectively (**Fig. 41.5A**).

Cricotracheal ligament

The cricotracheal ligament unites the lower border of the cricoid to the first tracheal cartilage and is continuous with the perichondrium of the trachea (see Fig. 41.1).

Intrinsic ligaments and membranes

The fibroelastic structures of the larynx lie within the cartilaginous skeleton of the larynx, beneath the laryngeal mucosa (**Fig. 41.5**). They form a discontinuous sheet, separated on both sides of the larynx by a horizontal cleft between the vestibular and vocal ligaments. Its upper part, the quadrangular membrane, lies within the walls of the upper part of the laryngeal cavity, the laryngeal vestibule, and extends between the arytenoid cartilages and the sides of the epiglottis. Its lower part, the conus elasticus, lies within the walls of the lower part of the laryngeal cavity, the infra-glottic cavity and connects the thyroid, cricoid and arytenoid cartilages.

Quadrangular membrane

Each quadrangular membrane passes from the lateral margin of the epiglottis to the apex and fovea triangularis of the ipsilateral arytenoid cartilage. It is often poorly defined, especially in its upper portion. The upper and lower borders of the membrane are free. The upper border slopes posteriorly to form the aryepiglottic ligament, which constitutes the central component of the aryepiglottic fold. Posteriorly, it passes through the fascial plane of the oesophageal suspensory ligament, and helps to form the median corniculopharyngeal ligament, which extends into the submucosa adjacent to the cricoid cartilage. This ligament may exert vertical traction on the tissues of the laryngopharynx. The cuneiform cartilages lie within the aryepiglottic folds. The lower border of the quadrangular membrane forms the vestibular ligament within the vestibular fold.

Cricothyroid membrane and conus elasticus

The conus elasticus is that part of the fibroelastic membrane found in the lower part of the cavity of the larynx. The terminology used to describe this structure is confusing, as different terms may be used to describe apparently similar structures. Two synonyms for the conus elasticus that are commonly found in the literature are the cricovocal membrane and the cricothyroid membrane. The conus elasticus consists of three distinct parts: right and left lateral parts and a thickened median portion. The term conus elasticus is frequently applied to the lateral parts, while the median part is often called either the median or the anterior cricothyroid ligament.

Median (anterior) cricothyroid ligament The median or anterior cricothyroid ligament is the thickened central portion of the conus elasticus. Inferiorly, it is attached to the upper border of the midline region of the cricoid arch and it extends upwards to attach to the inferior border of the thyroid cartilage, passing on to the inner surface of the thyroid angle as far superiorly as the attachment of thyroarytenoid.

Conus elasticus The lateral parts of the conus elasticus are thinner than the median cricothyroid ligament. Inferiorly, the conus elasticus

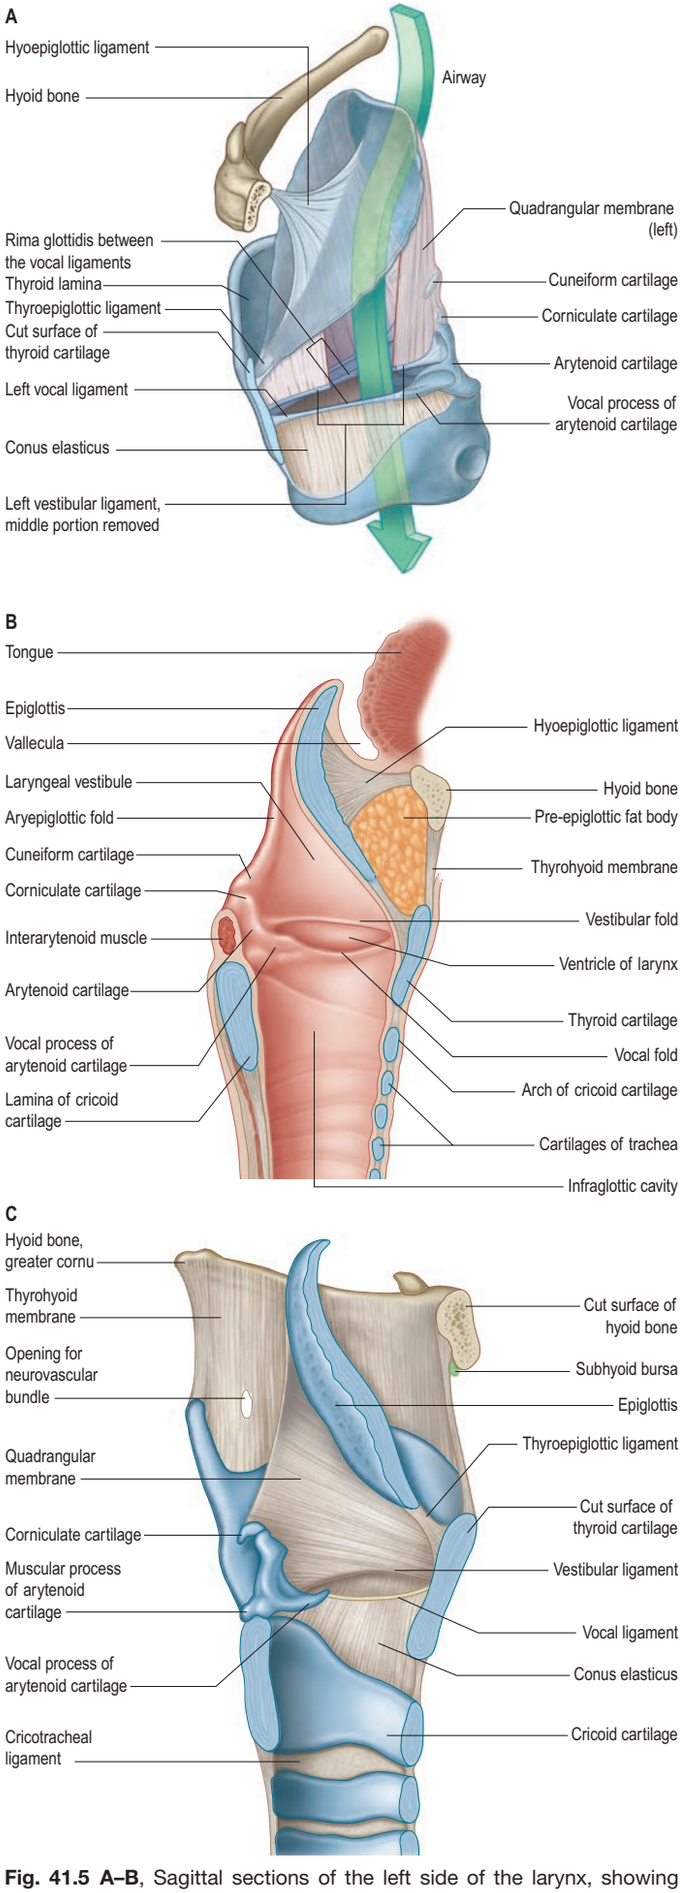

Fig. 41.5 A–B, Sagittal sections of the left side of the larynx, showing the laryngeal membranes (**A**) and the interior aspect (**B**) of the left half of the larynx. **C**, The quadrangular membrane viewed from the left side. (A, With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

attaches to the superior cricoid arch and the cricoid lamina. Superiorly, it extends upwards within the thyroid lamina to attach anteriorly to the inner surface of the thyroid cartilage (just below its midpoint) and posteriorly to the tip and upper surface of the vocal process and fovea oblonga of the arytenoid cartilage. Between these anterior and posterior attachments, the upper edges of the conus elasticus are free, thickened and aligned horizontally, forming the vocal ligaments. Each vocal ligament lies within a mucosa-covered vocal fold, covered on its internal surface by the mucosal lining of the larynx, and externally by the lateral cricoarytenoid and thyroarytenoid muscles (Reidenbach 1995).

The conus elasticus derives its name from the cone or funnel shape produced by the superior and medial curving of its walls between its inferior and superior attachments that is thought to maximize the efficient flow of air towards the rima glottidis during phonation (Lenneberg 1967).

LARYNGEAL CAVITY

The laryngeal cavity extends from the laryngeal inlet opening into the pharynx down to the lower border of the cricoid cartilage, where it continues into the trachea (see Fig. 41.5; **Fig. 41.6**). The walls of the cavity are formed of the fibroelastic membranes described above and lined with mucous membrane that folds over the free edges of these membranes within the larynx. On either side, the continuity of the fibroelastic membrane is interrupted between the upper vestibular and lower true vocal folds.

The folds project into the lumen of the cavity and divide it into upper and lower parts, separated by a middle portion between the two sets of folds that lead into the laryngeal ventricle. The upper folds are the vestibular (ventricular or false vocal) folds; the median aperture between them is the rima vestibuli. The lower pair are the (true) vocal folds (or vocal folds), and the aperture between them is the rima glottidis. The true vocal folds are the primary source of phonation, whereas the vestibular folds normally do not contribute directly to sound production. The supraglottis is a clinical term sometimes used in tumour staging; it refers to all those parts of the larynx that lie above the glottis and comprises the laryngeal inlet (formed of the laryngeal surface of the epiglottis and arytenoid cartilages, and the laryngeal aspects of the aryepiglottic folds), the laryngeal vestibule and the vestibular folds. Other terms that are used clinically in tumour staging are the glottis, defined as the anterior and inferior surfaces of the true vocal folds and the anterior and posterior commissures. The subglottis is defined as the region below the glottis that extends to the inferior border of the cricoid cartilage.

Microstructure of the larynx

The laryngeal mucosa is continuous with that of the pharynx above and the trachea below. It lines the entire inner surface of the larynx, including the ventricle and saccule. The mucosa is thickened over the vestibular folds, where it is the chief component, and is thinner over the vocal folds, where it overlies the vocal ligaments. It is loosely adherent to the anterior surface of the epiglottis but firmly attached to the floor of the valleculae. On the aryepiglottic folds, it is reinforced by a considerable amount of fibrous connective tissue and it adheres closely to the laryngeal surfaces of the cuneiform and arytenoid cartilages.

The laryngeal epithelium is mainly a ciliated, pseudostratified respiratory epithelium (see Fig. 2.2D) where it covers the inner aspects of the larynx, including the lower part of the posterior, laryngeal surface of the epiglottis. It provides a mucociliary clearance mechanism shared with most of the respiratory tract. The vocal folds are covered by non-keratinized, stratified squamous epithelium where they contact each other. This important variation protects the tissue from the effects of the considerable mechanical stresses that act on the surfaces of the vocal folds. Certain parts of the larynx are subject to the abrasive effects of swallowed food and are also covered by non-keratinized, stratified squamous epithelium. These are the 'exterior' surfaces of the larynx, which merge with the laryngopharynx and oropharynx (including the anterior, lingual and upper, posterior surfaces of the epiglottis and the upper parts of the aryepiglottic folds) (Sato 2018).

The laryngeal mucosa has numerous mucous glands, especially over the epiglottis, where the cartilage is pitted, and along the margins of the aryepiglottic folds anterior to the arytenoid cartilages, where they are known as the arytenoid glands. Many large glands in the saccules of the larynx secrete periodically over the vocal folds during phonation. Seromucinous tubule-alveolar glands in the saccule, posterior surface of the epiglottis and the aryepiglottic folds, and goblet cells all secrete mucus in the respiratory epithelium. The free edges of the vocal folds are devoid of glands, and their stratified epithelium is vulnerable to drying and requires the secretions of neighbouring glands. The epithelial surfaces of the vocal folds are lined by microvilli that may retain the lubricating secretions and help to ensure an even distribution of mucus. Poorly lubricated folds would appear to increase resistance to airflow, which means that higher subglottal pressures are needed to initiate and sustain phonation. Taste buds, like those in the tongue, are present on the posterior epiglottic surface and aryepiglottic folds, and less often in other laryngeal regions. Laryngeal stretch-, touch- and pressure-sensitive mechanoreceptors provide perceptual and proprioceptive afferent information for a variety of essential functions, including airway protection, breathing, deglutition, speech and voice (Hammer and Krueger 2014).

Upper part

The upper part of the laryngeal cavity consists of the laryngeal inlet (aditus), the aryepiglottic fold and the laryngeal vestibule.

Laryngeal inlet (aditus)

The upper part of the laryngeal cavity is entered by the laryngeal inlet (aditus laryngis), an approximately triangular aperture between the larynx and pharynx. This faces backwards and somewhat upwards because the anterior wall of the larynx is much longer than the posterior. It slopes downwards and forwards in its upper part because of the oblique inclination of the epiglottis. The inlet is bounded anteriorly by the upper edge of the epiglottis, posteriorly by the transverse mucosal fold between the two arytenoids (posterior commissure), and on each side by the edge of a mucosal ridge, the aryepiglottic fold, that runs between the side of the epiglottis and the apex of the arytenoid cartilage. The midline groove between the two corniculate tubercles is termed the interarytenoid notch.

Aryepiglottic fold

The aryepiglottic fold contains ligamentous and muscular fibres. The ligamentous fibres represent the free upper border of the quadrangular membrane (see Fig. 41.5). The muscle fibres are continuations of the oblique arytenoids (see Fig. 41.10D). The posterior part of the aryepiglottic fold contains two oval swellings, one above and in front, the other behind and below, that mark the positions of the underlying cuneiform and corniculate cartilages, respectively. They are separated by a shallow vertical furrow that is continuous below with the opening of the laryngeal ventricle.

Laryngeal vestibule

The laryngeal vestibule is the region between the laryngeal inlet and vestibular folds. It is wide above, narrow below, and higher anteriorly than posteriorly. The anterior wall is formed by the posterior surface of the epiglottis, the lower part of which (epiglottic tubercle) bulges backwards a little. The lateral walls, higher in front and shallow behind, are formed by the medial surfaces of the aryepiglottic folds. The posterior wall consists of the interarytenoid mucosa above the vestibular folds.

Middle part

The middle part of the laryngeal cavity is the smallest and extends from the rima vestibuli above to the rima glottidis below. On each side it contains the vestibular folds, the ventricle and the saccule of the larynx.

Vestibular folds and ligaments

The narrow vestibular ligament represents the thickened lower border of the quadrangular membrane (see Fig. 41.5C). It is fixed in front to the thyroid angle below the epiglottic cartilage and behind to the anterolateral surface of the arytenoid cartilage above its vocal process. With its covering of mucosa, it is termed the vestibular (ventricular or false vocal) fold (see Figs 41.5B, 41.6). The presence of a loose vascular

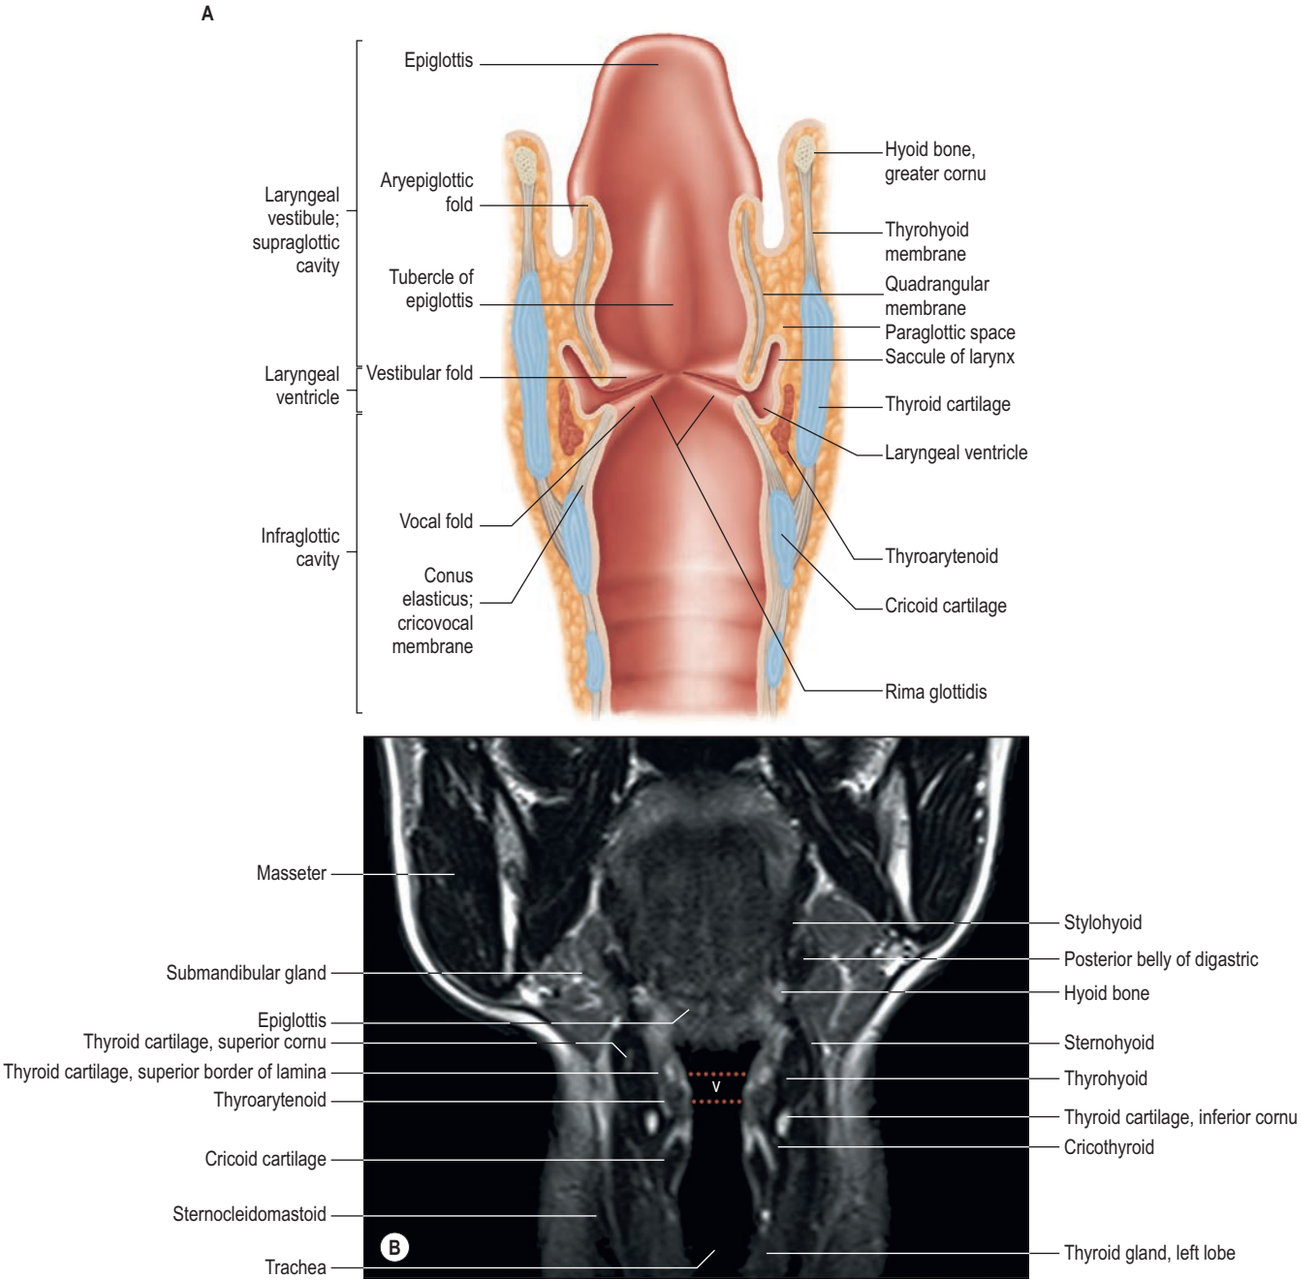

Fig. 41.6 A–C, Coronal sections through the larynx and proximal trachea. **A**, Posterior aspect. **B**, T2-weighted MRI. The limits of the laryngeal vestibule (V) are set by the dotted red lines; the supraglottic cavity is above and the infraglottic cavity is below. (*C, continued online*)

mucosa lends the vestibular folds a pink appearance *in vivo*, as they lie above and lateral to the vocal folds. Muscle fibres of thyroarytenoid can be observed within the vestibular folds, though they are variable in extent between individuals. Their function is disputed, with some authors suggesting that they cause adduction and downward movement on the vestibular folds (Reidenbach 1991, Moon and Alipour 2013). The vestibular (ventricular) folds are not the primary sound source in phonation, but they can be used to produce a rough quality of voice known as 'false fold phonation' or 'dysphonia plicae ventricularis'.

Ventricle of the larynx

The laryngeal ventricle (also known as the laryngeal sinus) is a slit between the vestibular folds above and the true vocal folds below (see Figs 41.5–41.6). On each side, it extends from a narrow opening in the wall of the middle part of the laryngeal cavity into a fusiform recess that extends upwards into the laryngeal wall, lateral to the vestibular fold, and opens anteriorly into the saccule.

Saccule of the larynx

The saccule is a conical pouch of variable size. It curves slightly backwards and ascends forwards from the anterior end of the ventricle, between the vestibular fold and thyroid cartilage (see Fig. 41.6), occasionally reaching the upper border of the cartilage or even beyond, when it protrudes through the thyrohyoid membrane. The orifice of the saccule is guarded by a delicate fold of mucosa, the ventriculosaccular fold.

The saccule has a fibrous capsule that is continuous below with the vestibular ligament. It is covered medially by a few muscular fasciculi from the apex of the arytenoid cartilage that pass forwards between the saccule and vestibular mucosa into the aryepiglottic fold. Laterally, it is separated from the thyroid cartilage by the thyroepiglottic muscle, which compresses the saccule, so that its secretions are expressed onto the vocal folds (which lack glands), to lubricate and protect them against desiccation and infection. The saccule has a greater density of mucous glands in the submucosa than elsewhere in the larynx. The glands open onto its luminal surface.

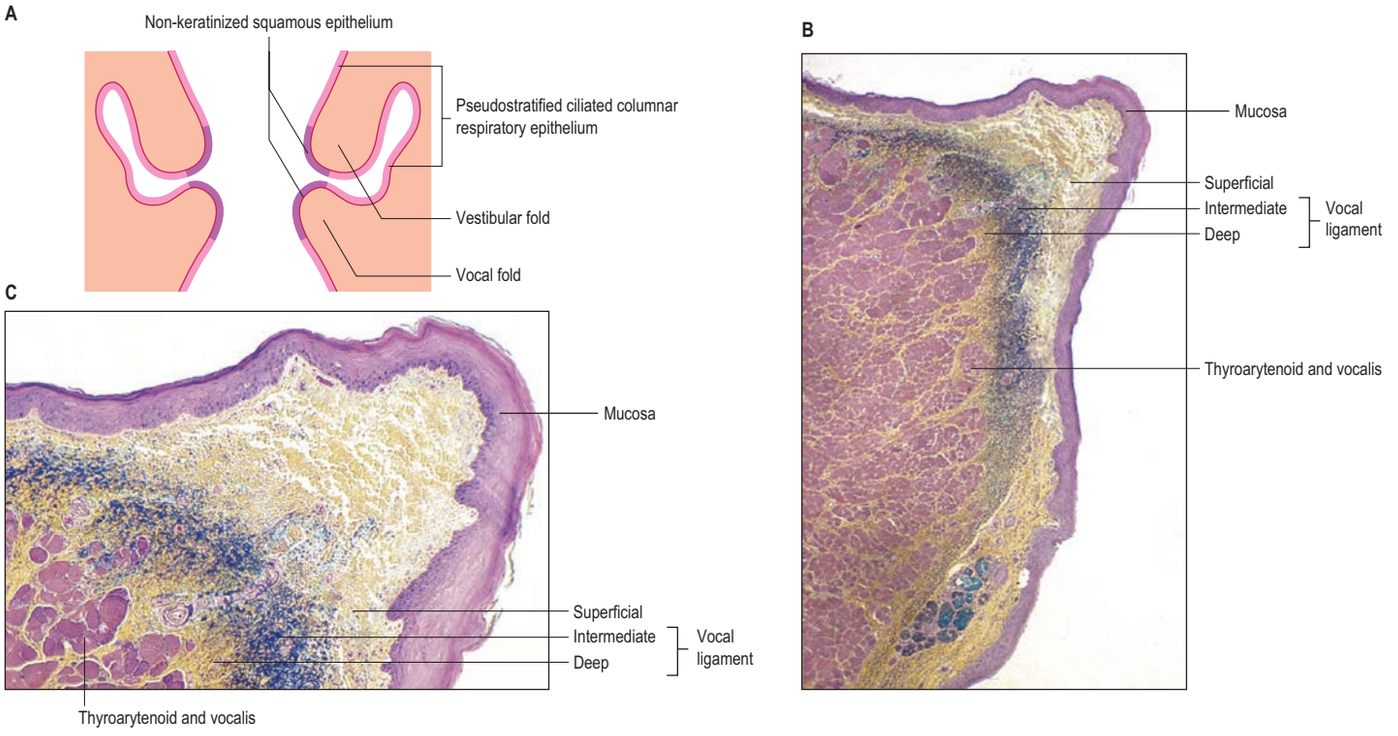

Fig. 41.7 A, Coronal view of the laryngeal cavity, showing the distribution of the mucous membrane in the laryngeal cavity. **B**, Structure of the true vocal folds at low power, ×40, stained with Movat's pentachrome stain. **C**, True vocal folds at high power, ×100; Movat's pentachrome stain. The non-keratinized squamous epithelium is shown forming a mucosal layer over the superficial part of the lamina propria, along with the three layers of the lamina propria, with thyroarytenoid and vocalis lying deep to the deep layer of the lamina propria. At higher magnification, the deeper yellow staining of the collagen in the deep layer of the lamina propria compared to the superficial layer indicates a greater degree of cross-linking. Vocal folds and ligaments

The vocal folds serve several functions. They protect the airway by closing during swallowing; they are responsible for generation of a cough by closing firmly and then moving rapidly apart during exhalation; they facilitate the Valsalva manoeuvre by closing the glottis and raising intrathoracic pressure, hence also increasing intra-abdominal pressure, such as during defaecation, parturition, or lifting heavy weights; and they are concerned with sound production. The free thickened upper edge of the conus elasticus forms the vocal ligament (see Fig. 41.5C). It stretches back on either side from the midlevel of the thyroid angle to the vocal processes and fovea oblonga of the arytenoids. When covered by mucosa, it is termed the vocal fold or vocal cord (vocal fold is the preferred clinical term) (see Figs 41.5B, 41.6). The vocal folds lie on either side of an aperture, the rima glottidis, and form the anterolateral three-fifths of its edges. The posterior two-fifths of the edges of the rima glottidis are formed by the medial surfaces of the arytenoid cartilages including the vocal processes of the arytenoid cartilages.

Each vocal fold consists of five layers: mucosal epithelium, lamina propria (which has three layers) and a muscular layer (fibres of thyroarytenoid and vocalis) (**Fig. 41.7**). The mucosa overlying the vocal ligament is thin and the epithelial cell layer is attached to the underlying superficial lamina propria by a basement membrane. It lies on the ligament, and so the vocal fold appears pearly white *in vivo*. At birth, the lamina propria consists of a single layer of cells. It becomes a bilaminar structure by 2 months of age and trilaminar (as defined by distinct regions of differential cell populations and cell density) by 7 years of age (Hartnick et al 2005). The most superficial layer (also known as Reinke's space) is hypocellular and consists mainly of loose fine collagen (reticular fibres) and elastic fibres. It is only loosely attached to the underlying vocal ligament that extends along the length of the free margin of the vocal ligament and a little way onto the superior surface of the fold; oedema readily collects here in disease. The middle layer consists predominantly of elastic fibres and the deep layer consists predominantly of collagen fibres; these two layers collectively form the vocal ligament (Sato 2018). The orientation of the collagen and elastin fibres in the middle and deep layers is parallel to that of the fibres of vocalis (Hartnick et al 2005). Thyroarytenoid and vocalis form the fifth layer of the vocal folds. These muscles shorten, relax and aid adduction of the vocal folds.

There are alternative descriptions of the soft tissues of the vocal folds. Some authors describe only two layers: the body (the deep layer of the lamina propria and muscle) and the cover (the mucosa and superficial and intermediate layers of the lamina propria). Others divide the soft tissues of the vocal folds into three layers: the mucosal layer (the mucosa and the superficial layer of the lamina propria), the vocal ligament (the intermediate and deep layers of the lamina propria) and the muscle layer (Titze 1994).

The site where the vocal folds meet anteriorly, the anterior commissure, is the region where fibres of the vocal ligament pass through the thyroid cartilage to blend with the overlying perichondrium. The point at which the vocal ligaments are attached to the thyroid cartilage is known as Broyles' ligament: it can be an anatomical escape pathway for primary tumours arising on the vocal fold.

The maculae flavae are located at the anterior and posterior end of each vocal ligament and can form mucosal bulges that are sometimes visible on endoscopic examination of the larynx through the mucosa as whitish-yellow masses. The vocal folds are connected to the thyroid cartilage anteriorly via the anterior maculae flavae and the anterior commissure tendon, and posteriorly via the posterior maculae flavae. The maculae flavae themselves are described as being formed of dense masses of stellate cells with a morphology markedly different from that of fibroblasts, surrounded by a dense extracellular matrix. The function of the maculae flavae remains unclear but it has been suggested that they play a critical role in the metabolism of the extracellular matrix of the vocal folds (Awd Allah et al 2009, Fayoux et al 2004, Sato et al 2010a, 2010b, Sato 2018).

Laryngeal carcinoma

Available with the *Gray's Anatomy* e-book

Laryngoceles and saccular cysts are air- or fluid-filled enlargements, respectively, of the saccule. A laryngocele is a herniation of the saccular mucosa. The aetiology is uncertain: repeated, sustained high transglottal pressures (such as in trumpet playing) may be a possible cause of acquired symptoms, and some cases may be the result of congenital enlargement of the saccule. Growth of a laryngocele is constrained by the surrounding tissues, and so it expands upwards into the paraglottic space anterior to the piriform fossa, and superiorly to expand the aryepiglottic fold and reach the vallecula (internal laryngocele). It can extend to the thyrohyoid membrane, which it may pierce to form an external laryngocele, and where it may be palpable in the neck. Symptoms include hoarseness, stridor and dysphagia. The laryngeal saccule may also become pathologically enlarged as a result of obstruction of the ventricular aditus by inflammation, scarring, or compression by a tumour. An expanding, mucus-filled cyst forms as the glandular secretions accumulate: saccular cysts can expand in a similar direction to a laryngocele and may also pierce the thyrohyoid membrane. In addition to hoarseness and stridor, acute respiratory obstruction may result if the contents of the cyst become infected, especially in the young.

Rima glottidis

The rima glottidis is the aperture between the vocal folds anteriorly and the arytenoid cartilages posteriorly (Fig. 41.8). It is bounded behind by the mucosa that passes between the arytenoid cartilages at the level of the vocal folds. The rima glottidis is customarily divided into two regions: an anterior intermembranous part, which makes up about three-fifths of its anteroposterior length and is formed by the underlying vocal ligament; and a posterior intercartilaginous part, formed by the vocal processes of the arytenoid cartilages. The rima glottidis is the narrowest part of the larynx, with an average anteroposterior diameter in adult males of 21.1 mm, and in adult females of 15.1 mm (Friedrich and Lichtenegger 1997); other studies have reported measurements that vary by up to 2 mm. Its width and shape vary with the movements of the vocal folds and arytenoid cartilages during respiration and phonation.

Lower part

The lower part of the laryngeal cavity, the infraglottic cavity (also known as the subglottic cavity), extends from the vocal folds to the lower border of the cricoid. In transverse section, it is elliptical above and wider and circular below, and is continuous with the trachea. Its walls are lined by respiratory mucosa and are supported by the cricothyroid ligament above and the cricoid cartilage below (Reidenbach 1998). The walls of this part of the laryngeal cavity are said to be exponentially curved, a feature that may serve to accelerate the airflow towards the glottis with the minimum loss of energy (Lenneberg 1967).

Laryngoscopic examination

The laryngeal inlet, the structures around it, and the cavity of the larynx can all be inspected using flexible endoscopy, usually via the nasal cavity and nasopharynx. The epiglottis appears relatively short because it is viewed along its long axis, but its tubercle is visible. From the epiglottic margins, the aryepiglottic folds can be traced posteromedially and the cuneiform and corniculate elevations recognized. The pink vestibular folds and pearly white vocal folds are easily seen. When the rima glottidis is wide open, the anterior arch of the cricoid cartilage, the tracheal mucosa and cartilages may also be seen (see Fig. 41.8) and the piriform fossae inspected.

Laryngeal obstruction and trauma

The mucosa of the upper larynx is highly sensitive and contact with foreign bodies excites immediate coughing. Large foreign bodies may obstruct the laryngeal inlet or rima glottidis and suffocation may ensue. Smaller particles may enter the trachea or bronchi, or lodge in the laryngeal ventricle and cause reflex closure of the glottis, termed laryngospasm. Inflammation of the upper larynx, e.g. secondary to infection or the effects of smoke inhalation, may swell the mucosa by effusion of fluid into the loose submucous tissue (oedema of the supraglottis). The effusion neither involves nor extends below the vocal folds because the mucosa here is bound directly to the vocal ligaments and there is no submucous tissue. Laryngotomy below the vocal folds through the cricothyroid ligament, or tracheotomy below the cricoid cartilage, may be necessary to bypass the obstruction above and restore ventilation.

The consequences of trauma to the larynx resulting from either blunt or penetrating injuries may lead to any or all of the following: oedema, haematoma, fracture, dislocations or paralysis. Trauma at the level of the rima glottidis may result in thyroid cartilage fracture and displacement of the fragments into the vocal folds posteriorly with consequent oedema. Suicidal wounds are usually made through the thyrohyoid membrane, damaging the epiglottis, superior thyroid vessels, external and internal carotid arteries, and internal jugular veins. Less frequently, these wounds are inflicted above the hyoid, so that the lingual muscles, lingual and facial vessels are damaged. Caustic substances swallowed accidentally or during a suicide attempt, the ingestion of hot liquids and the inspiration of hot gases may all result in serious laryngeal damage. Radiotherapy as part of the treatment for neck cancer can cause radiation burns within the larynx (Myer 2004).

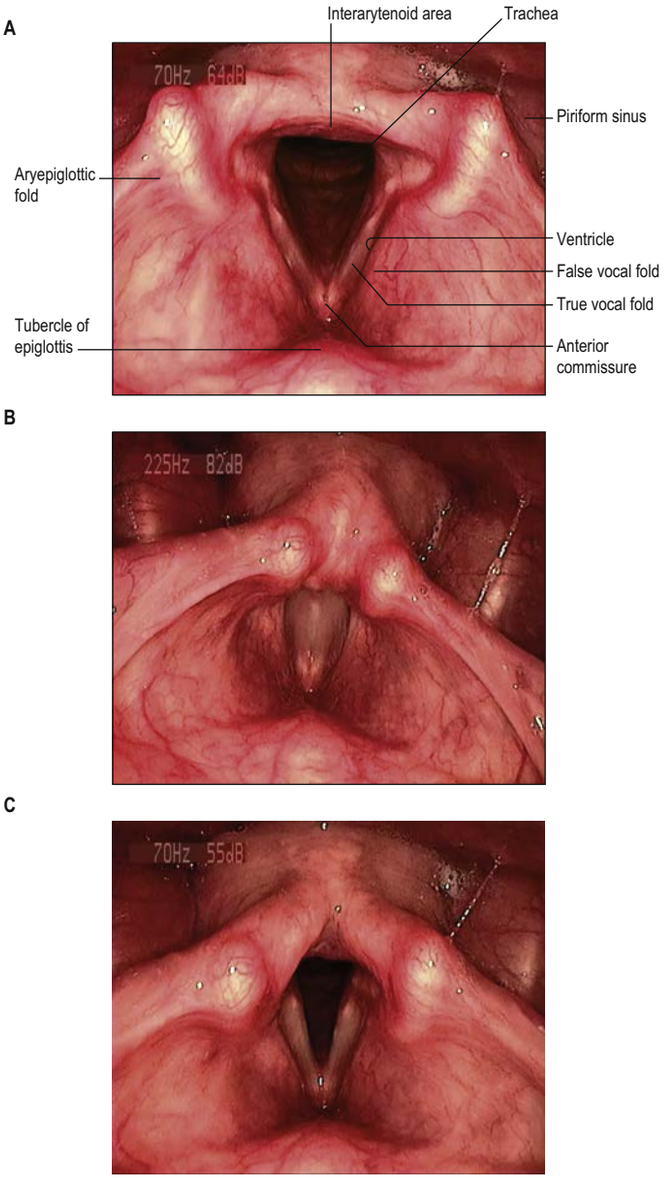

Fig. 41.8 Endoscopic view of the larynx with flexible chip-tip endoscope **A**, Forced inspiration: vocal folds are maximally abducted. **B**, Phonation: vocal folds are adducted. **C**, Quiet respiration: vocal folds are moderately abducted.

THE PAEDIATRIC LARYNX

The paediatric larynx differs markedly from its adult counterpart in size, position, consistency and shape. Although it is about one-third adult size, it is proportionately larger: the lumen is short and funnel-shaped, and disproportionately narrower. The infant larynx lies higher in the neck than the adult larynx (see Fig. 40.11). At rest, the upper border of the infant epiglottis is at the level of the second or third cervical vertebra, and when the larynx is elevated, it reaches the level of the first cervical vertebra. This high position enables an infant to use its nasal airway to breathe while suckling. It also means that the larynx is protected somewhat by the jaw. The epiglottis is X-shaped, with a furled petiole, and the laryngeal cartilages are softer and more pliable than in the adult larynx (which may predispose to airway collapse in inspiration, leading to the clinical picture of laryngomalacia). The thyroid cartilage is shorter and broader, lies closer to the hyoid bone in the neonate and has a relatively short thyrohyoid ligament. Neither the superior notch nor the laryngeal prominence is as marked as it is in the adult. The cricoid cartilage is the same shape as in the adult. Calcification of the cricoid cartilage has been noted as early as 7 years of age (Strauss 2000). The arytenoid cartilages are larger in proportion to the larynx as a whole

Squamous cell carcinoma is by far the most common laryngeal malignancy. The pattern of spread is determined by anatomical features at the site of origin and this influences its management and potential outcomes (Kirchner and Carter 1987, Welsh et al 1989).

Supraglottic tumours arising from the laryngeal surface of the epiglottis can spread through the perforations in the epiglottic cartilage and into the pre-epiglottic space. Because the supraglottis is not directly involved in voice production, tumours in this area most commonly present with a feeling of a persistent lump in the throat and possibly pain on swallowing often radiating to the ipsilateral ear. It is only in the later stages that they present with airway obstruction. If the tumour has spread towards the vocal fold, hoarseness will also be present. Inferior spread into the paraglottic space is more common and may extend as far as the subglottis or even beyond the larynx. Spread in this space medializes the vocal fold, as can be seen on careful laryngoscopy when assessing the tumour stage, and subsequently confirmed by scans. Lateral spread into the piriform sinus is a feature of tumours that arise lower down in the supraglottis on the vestibular folds. Deeper invasion infiltrates the thyroarytenoid muscle, fixing the fold, and eventually the thyroid and arytenoid cartilages.

Ventricular tumours often obstruct mucus outflow from the saccule to cause a saccular cyst or mucocele. Further infiltration of the paraglottic space and transglottic spread ultimately fixes the vocal fold through muscle invasion and, more rarely, direct involvement of the cricoarytenoid joint or infiltration of the recurrent laryngeal nerve. Fixation of the vocal fold is a good indicator of a tumour within the paraglottic space and this is reflected in the TNM staging system as an adverse sign.

Tumours of the true vocal folds almost always present in the first instance with voice change (dysphonia). Glottic tumours tend to spread by local growth in the first instance, when they may be contained in Reinke's space for some time. The paucity of lymphatics in the vocal fold slows tumour progression, allowing time for the patient to present to a clinician with a relatively small tumour load that will only have caused a chronic husky voice. This anatomical feature also accounts for the relative lack of nodal metastases associated with small glottic tumours. The proximity of anterior fold tumours to the thyroid cartilages, separated only by a thin layer of connective tissue, predisposes to cartilage invasion. Spread of tumour via Broyles' ligament to the outside of the larynx changes the tumour stage from a T1 lesion to a T4 lesion, with both therapeutic and survival implications. More posterior fold tumours tend to invade the vocalis muscle and fix it.

Subglottic tumours tend to spread circumferentially and, by so doing, impair the airway dramatically. The management of laryngeal carcinomas is largely dictated by the stage at presentation. Very small tumours of the glottis can be resected or treated by radiotherapy. Organ sparing protocols using radiotherapy and sometimes chemotherapy are often employed for larger tumours in the first instance. Surgical resection, laryngectomy, is indicated for those with advanced disease that have nodal metastases and also for salvage when other therapies have failed.

Any oedema in the superficial lamina propria (Reinke's space) is termed Reinke's oedema. It results in an increase in density of the vocal fold, and hence a drop in the pitch of the voice. The oedema can persist because there is very poor lymphatic drainage from the edges of the vocal folds (Liu et al 2006). Vocal abuse may initiate such changes, but the condition is nearly always confined to smokers.

Vocal fold nodules are chronic lesions of the vocal folds and develop most commonly as the result of persistent overuse (or misuse) of the voice, which results in an increase in the collision forces of the vocal folds. Nodules normally develop at the point of maximum contact of the vocal folds, i.e. at the junction of the anterior third and the posterior two-thirds of the vocal ligament. Excessive trauma at this point, e.g. when singing with poor technique or forcing the voice, initially produces subepithelial haemorrhage or bruising. Over time this results in pathological changes such as subepithelial scarring (singer's or screamer's nodes). Nodules increase vocal fold mass and affect vocal fold closure; the persistent posterior glottal opening causes hoarseness, a breathy voice, reduced vocal intensity and an inability to produce higher frequencies of vibration. These changes can cause a cycle in which increasing vocal effort is required by way of compensation, and this exacerbates the problem (Aronson and Bless 2009).

and so are more prominent; the aryepiglottic folds are disproportionately large. The vocal folds are 4–4.5 mm long, which is relatively shorter than either in childhood or in the adult, and consequently the proportion of the rima glottidis that is intramembranous is smaller in the neonate. The ventricle of the larynx is small, whereas the saccule of the larynx is often considerably larger than it is in adult life.

The mucosa of the vestibule is more loosely attached than it is in the adult larynx and it exhibits multiple submucosal glands. Inflammation of the vestibule can result in rapid and severe oedema. The mucosa is also lax in the infraglottic cavity and swelling here rapidly causes severe respiratory obstruction because of the disproportionately narrower lumen (3.5 mm in diameter in neonates). The neonatal infraglottic cavity extends posteriorly as well as inferiorly, which is an important consideration when passing an endotracheal tube (Litman et al 2003). The infraglottic airway rapidly increases in size during the first two years of life (Eckel et al 1999). By about the third year, sexual differences become apparent: the larynx is larger in boys, although the angle between the thyroid laminae is more pronounced in girls. At puberty, these changes increase and there is greater enlargement of the male larynx.

Congenital anomalies of the larynx include aplasia and hypoplasia of the epiglottis, high-rising epiglottis, bifid epiglottis, saccular cysts, vocal fold palsy, laryngeal atresia, laryngocele, laryngo-tracheo-oesophageal cleft and laryngeal web. Laryngo-tracheo-oesophageal cleft is due to failure of fusion of the posterior cricoid lamina and abnormal development of the tracheo-oesophageal septum, resulting in a posterior sagittal communication between the larynx and pharynx. For further reading, see Adewale (2009), Hudgins et al (1997), Pracy (1983), Sapienza et al (2004) and Wheeler et al (2009).

PARALUMENAL SPACES

A number of potential spaces lie between the laryngeal cartilages and the ligaments and membranes that support them. The three main spaces are the pre-epiglottic, the paraglottic and the subglottic spaces. Their precise definition, and the extent to which they communicate with one another, remain controversial. They are not closed compartments and so their existence does not preclude the spread of tumours. An awareness of the anatomy of these spaces, and the potential pathways of tumour spread from them, has significantly influenced the surgical approach to disease in this region (Welsh et al 1983).

Pre-epiglottic space

Its name implies that the pre-epiglottic space (**Fig. 41.9**) lies anterior to the epiglottis. The upper part of this space also extends beyond the lateral margins of the epiglottis, an arrangement that gives the space the form of a horseshoe and has led to the suggestion that periepiglottic space would be a more appropriate term for this region (Reidenbach 1996a). The space is primarily filled with adipose tissue and does not appear to contain any lymph nodes.

The upper boundary is formed by the weak hyoepiglottic membrane, strengthened medially as the median hyoepiglottic ligament; the anterior boundary is the thyrohyoid membrane, strengthened medially as the median thyrohyoid ligament; and the lower boundary is the thyroepiglottic ligament, continuous laterally with the quadrangular membrane behind. The greater cornu of the hyoid bone forms its upper lateral border. Inferolaterally, the pre-epiglottic space is in continuity with the paraglottic space, from where it is can be invaded by tumour. It is also in continuity with the mucosa of the laryngeal surface of the epiglottis via multiple perforations in the cartilage of the epiglottis (Reidenbach 1996a).

Paraglottic space

The paraglottic space (see Fig. 41.6) is a region of adipose tissue that contains the internal laryngeal nerve, the laryngeal ventricle, and all or part of the laryngeal saccule. It is bounded laterally by the thyroid cartilage and thyrohyoid membrane, superomedially by the quadrangular membrane, inferomedially by the conus elasticus, and posteriorly by the piriform fossa. The lower border of the thyroid cartilage is inferior, and the paraglottic space is continuous inferiorly with the space between the cricoid and thyroid cartilages. Posteroinferiorly, adipose tissue extends towards the cricothyroid joint. Superiorly, the paraglottic space is usually continuous with the pre-epiglottic space, although the two spaces may be separated by a fibrous septum. Consensus is lacking as to the precise boundaries between these two spaces. For example some authorities exclude thyroarytenoid from the paraglottic space and include it as the posterolateral inferior border of the pre-epiglottic space (Reidenbach 1996b).

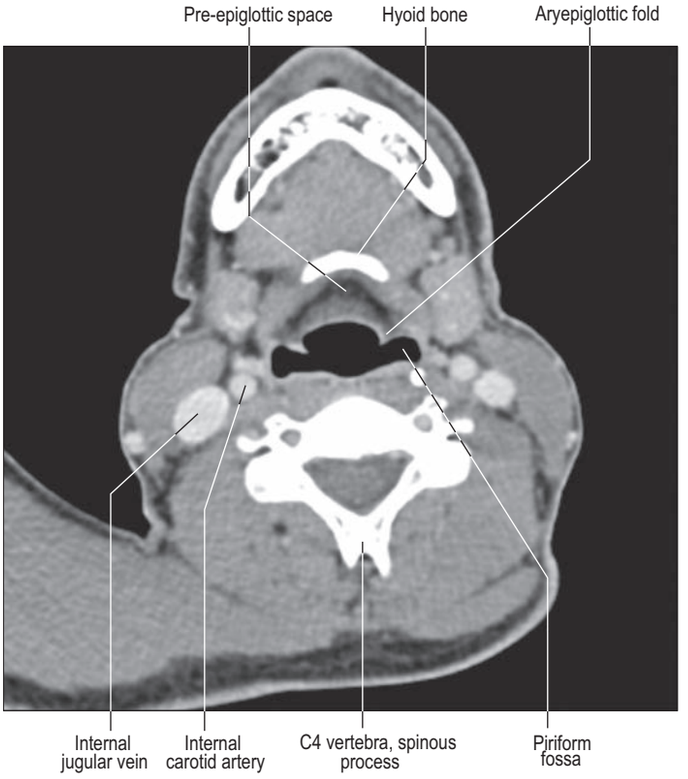

Fig. 41.9 Contrast-enhanced axial computed tomogram of the neck of a 42-year-old male showing the pre-epiglottic space and piriform fossa. (Courtesy of Dr Ivan Zammit.)

Subglottic space

The subglottic space is bounded laterally by the conus elasticus, medially by the mucosa of the infraglottic cavity, and above by the undersurface of Broyles' ligament in the midline. It is continuous below with the inner surface of the cricoid cartilage and its mucosa (Reidenbach 1998).

MUSCLES

The muscles of the larynx may be divided into extrinsic and intrinsic groups.

Extrinsic muscles

The extrinsic muscles connect the larynx to neighbouring structures and are responsible for moving it vertically during phonation and swallowing. They include the infrahyoid strap muscles, thyrohyoid, sternothyroid and sternohyoid (see Ch. 35), and the inferior constrictor muscle of the pharynx (see Ch. 40). Two of the three elevator muscles of the pharynx, stylopharyngeus and palatopharyngeus (see Ch. 40), are also connected directly to the thyroid cartilage, mainly to the posterior aspect of the thyroid laminae and cornua.

The role of the extrinsic muscles during respiration appears to be variable; the larynx has been seen to rise, descend or barely move during inspiration. The extrinsic muscles can affect the pitch and the quality of the voice by raising or lowering the larynx, and geniohyoid elevates and anteriorly displaces the larynx, particularly during deglutition.

Elevation of the larynx decreases the length and calibre of the laryngopharynx and thus shortens the vocal tract overall. This tends to raise both the formant frequencies as well as the fundamental frequency and may be one way by which an increase in pitch is achieved, though a change in pitch is not an inevitable consequence of this movement. The raising of the larynx may also be accompanied by forward or backward movement of the tongue because of the attachment of the tongue to the hyoid bone. These movements may facilitate alveolar or velar articulations, respectively.

The larynx is lowered by contraction of the infrahyoid muscles. This increases the length of the laryngopharynx, tending to lower both the formant frequencies and the fundamental frequency, though, again, a pitch change is not inevitable. Another effect of lowering the larynx will be to decrease supraglottal pressure and this will facilitate the articulation of voiced stops and fricatives (to a lesser extent). Voice quality can also be varied by the height of the larynx and this is an important factor contributing to the variations in quality of voice between different speakers.

Intrinsic muscles

The intrinsic muscles are the cricothyroid, posterior and lateral cricoarytenoid, transverse interarytenoid and oblique arytenoid, aryepiglotticus, thyroarytenoid and its subsidiary part, vocalis, and thyroepiglotticus; all are confined to the larynx in their attachments, and all but the transverse interarytenoid are paired (**Fig. 41.10**). Whereas most of the intrinsic muscles lie internally, under cover of the thyroid cartilage or the mucosa, the cricothyroids appear on the outer aspect of the larynx's cartilaginous framework.

The intrinsic laryngeal muscles may be placed in three groups according to their main actions. The posterior and lateral cricoarytenoids and oblique and transverse interarytenoids vary the degree of abduction and adduction of the vocal folds and thus the dimensions and the degree of opening of the rima glottidis. The cricothyroids, posterior cricoarytenoids, thyroarytenoids and vocalis regulate the length and tension of the vocal folds. In reality, the obliquity of the cricoarytenoid facets means that some overlap in function between these two muscle groups is inevitable. Thus, alterations in the dimensions of the rima glottidis will produce small changes in vocal fold length and shortening the vocal folds will also result in a degree of adduction. The third group of muscles is the oblique arytenoids, aryepiglottic and thyroepiglottic muscles, which modify the laryngeal inlet. Bilateral pairs of muscles usually act in concert with each other.

Neuromuscular spindles have been found in all human laryngeal muscles, the maximum number being found in the transverse interarytenoid (Blitzer et al 2009). The control of phonation requires very considerable neuromuscular coordination, and effective proprioception would appear to be essential to this capacity. The mass of muscle related to adduction far outweighs that related to abduction.

Anatomical variations Numerous variations in the anatomy of the intrinsic muscles have been described in the literature. The more frequently found ones are described in the main text. A particularly comprehensive source documenting these variations was published as long ago as 1875 by Fürbringer. Later authors have studied many of these variations but estimates of their frequency often vary significantly between the various studies; the functional significance of many of these variations is not clear.

Oblique arytenoid and aryepiglotticus

The oblique arytenoids and transverse interarytenoid are often considered to be two parts of the same muscle (known as the interarytenoid), in which case it is said to have two parts: transverse and oblique.

The oblique arytenoids lie superficial to the transverse arytenoid and are sometimes considered to be part of it. They cross each other obliquely at the back of the larynx, each extending from the back of the muscular process of one arytenoid cartilage to the apex of the opposite one (**Fig. 41.10C, D**). Some fibres continue laterally round the arytenoid apex into the aryepiglottic fold, forming the aryepiglottic muscle (aryepiglotticus).

Vascular supply Oblique arytenoid receives its blood supply from the laryngeal branches of the superior and inferior thyroid arteries.

Innervation Oblique arytenoid is innervated by the recurrent laryngeal nerve.

Actions The oblique arytenoids and aryepiglottic muscles act as a sphincter of the laryngeal inlet by adducting the aryepiglottic folds and approximating the arytenoid cartilages to the tubercle of the epiglottis. Their poor development limits their capacity to act as a sphincter of the inlet. The oblique arytenoids are weak adductors of the vocal folds and may be more effective in this action than the transverse interarytenoid because of the superior mechanical advantage.

Transverse interarytenoid

Transverse interarytenoid is a single, unpaired muscle deep to the oblique arytenoids (**Fig. 41.10C**). It bridges the gap at the back of the larynx between the two arytenoid cartilages and fills their concave posterior surfaces. It is attached to the back of the muscular process and adjacent lateral border of both arytenoids.

Vascular supply Transverse interarytenoid receives its blood supply from the laryngeal branches of the superior and inferior thyroid arteries.

Innervation Transverse interarytenoid is innervated by the recurrent laryngeal nerves. It also receives branches from the internal laryngeal nerve, although there is debate as to whether these branches contain any distinct motor input. The nerves form a dense, but highly variable, plexus.

Actions Transverse interarytenoid pulls the arytenoid cartilages towards each other, closing the posterior, intercartilaginous, part of the rima glottidis (see Fig. 41.10C).

Posterior cricoarytenoid

Posterior cricoarytenoid arises from the posterior surface of the cricoid lamina (**Fig. 41.10A**). Its fibres ascend laterally and converge to insert on the upper and posterior surfaces of the muscular process of the ipsilateral arytenoid cartilage. The highest fibres run almost horizontally, the middle run obliquely, and the lowest are almost vertical; some reach the anterolateral surface of the arytenoid cartilage. An additional strip of muscle, ceratocricoid, is occasionally seen in relation to the lower border of posterior cricoarytenoid, arising from the cricoid cartilage and inserting on to the posterior aspect of the inferior cornu of the thyroid cartilage.

Vascular supply Posterior cricoarytenoid receives its blood supply from the laryngeal branches of the superior and inferior thyroid arteries.

Innervation Posterior cricoarytenoid is innervated by the recurrent laryngeal branch of the vagus.

Actions The posterior cricoarytenoids are the only laryngeal muscles that open the rima glottidis. They rotate the arytenoid cartilages laterally around an axis that passes through the long axis of the facets of the cricoarytenoid joints, producing separation of the vocal processes and the attached vocal folds (see Fig. 41.10A). They also pull the arytenoids backwards, assisting the cricothyroids to lengthen the vocal folds. The most lateral fibres draw the arytenoid cartilages laterally, and so the rima glottidis becomes triangular when the posterior cricoarytenoid muscles contract. The posterior cricoarytenoids are active in the production of unvoiced sounds.

Lateral cricoarytenoid

Lateral cricoarytenoid is attached anteriorly to the upper border of the cricoid arch. It ascends obliquely backwards to be attached to the front of the muscular process of the ipsilateral arytenoid cartilage (**Fig. 41.10B**).

Vascular supply Lateral cricoarytenoid receives its blood supply from the laryngeal branches of the superior and inferior thyroid arteries.

Innervation Lateral cricoarytenoid is innervated by a variable number of branches of the anterior terminal division of the recurrent laryngeal nerve. In the majority of cases, these branches arise over the muscle itself.

Actions Lateral cricoarytenoid rotates the arytenoid cartilage in a direction opposite to that of posterior cricoarytenoid, and so closes the rima glottidis (see Fig. 41.10B). As it does so, it brings the tips of the vocal processes together, closing the ligamentous part of the rima glottidis, an action known as medial compression. The action of lateral cricoarytenoid in adducting the vocal folds is therefore distinct and complementary to that of the oblique arytenoid and transverse interarytenoid muscles. Contraction of lateral cricoarytenoid also results in shortening and relaxing of the vocal folds.

Cricothyroid

Cricothyroid is attached anteriorly to the external aspect of the arch of the cricoid cartilage (**Fig. 41.10F**). Its fibres pass backwards and diverge into two groups: a lower 'oblique' part, which slants backwards and laterally to the anterior border of the inferior cornu of the thyroid; and a superior 'straight' part, which ascends more steeply backwards to the posterior part of the lower border of the thyroid lamina. The medial borders of the paired cricothyroids are separated anteriorly by a triangular gap occupied by the median cricothyroid ligament.

Vascular supply Cricothyroid is supplied by the cricothyroid artery, a branch of the superior thyroid artery, which crosses high on the cricothyroid ligament to communicate with its contralateral fellow.

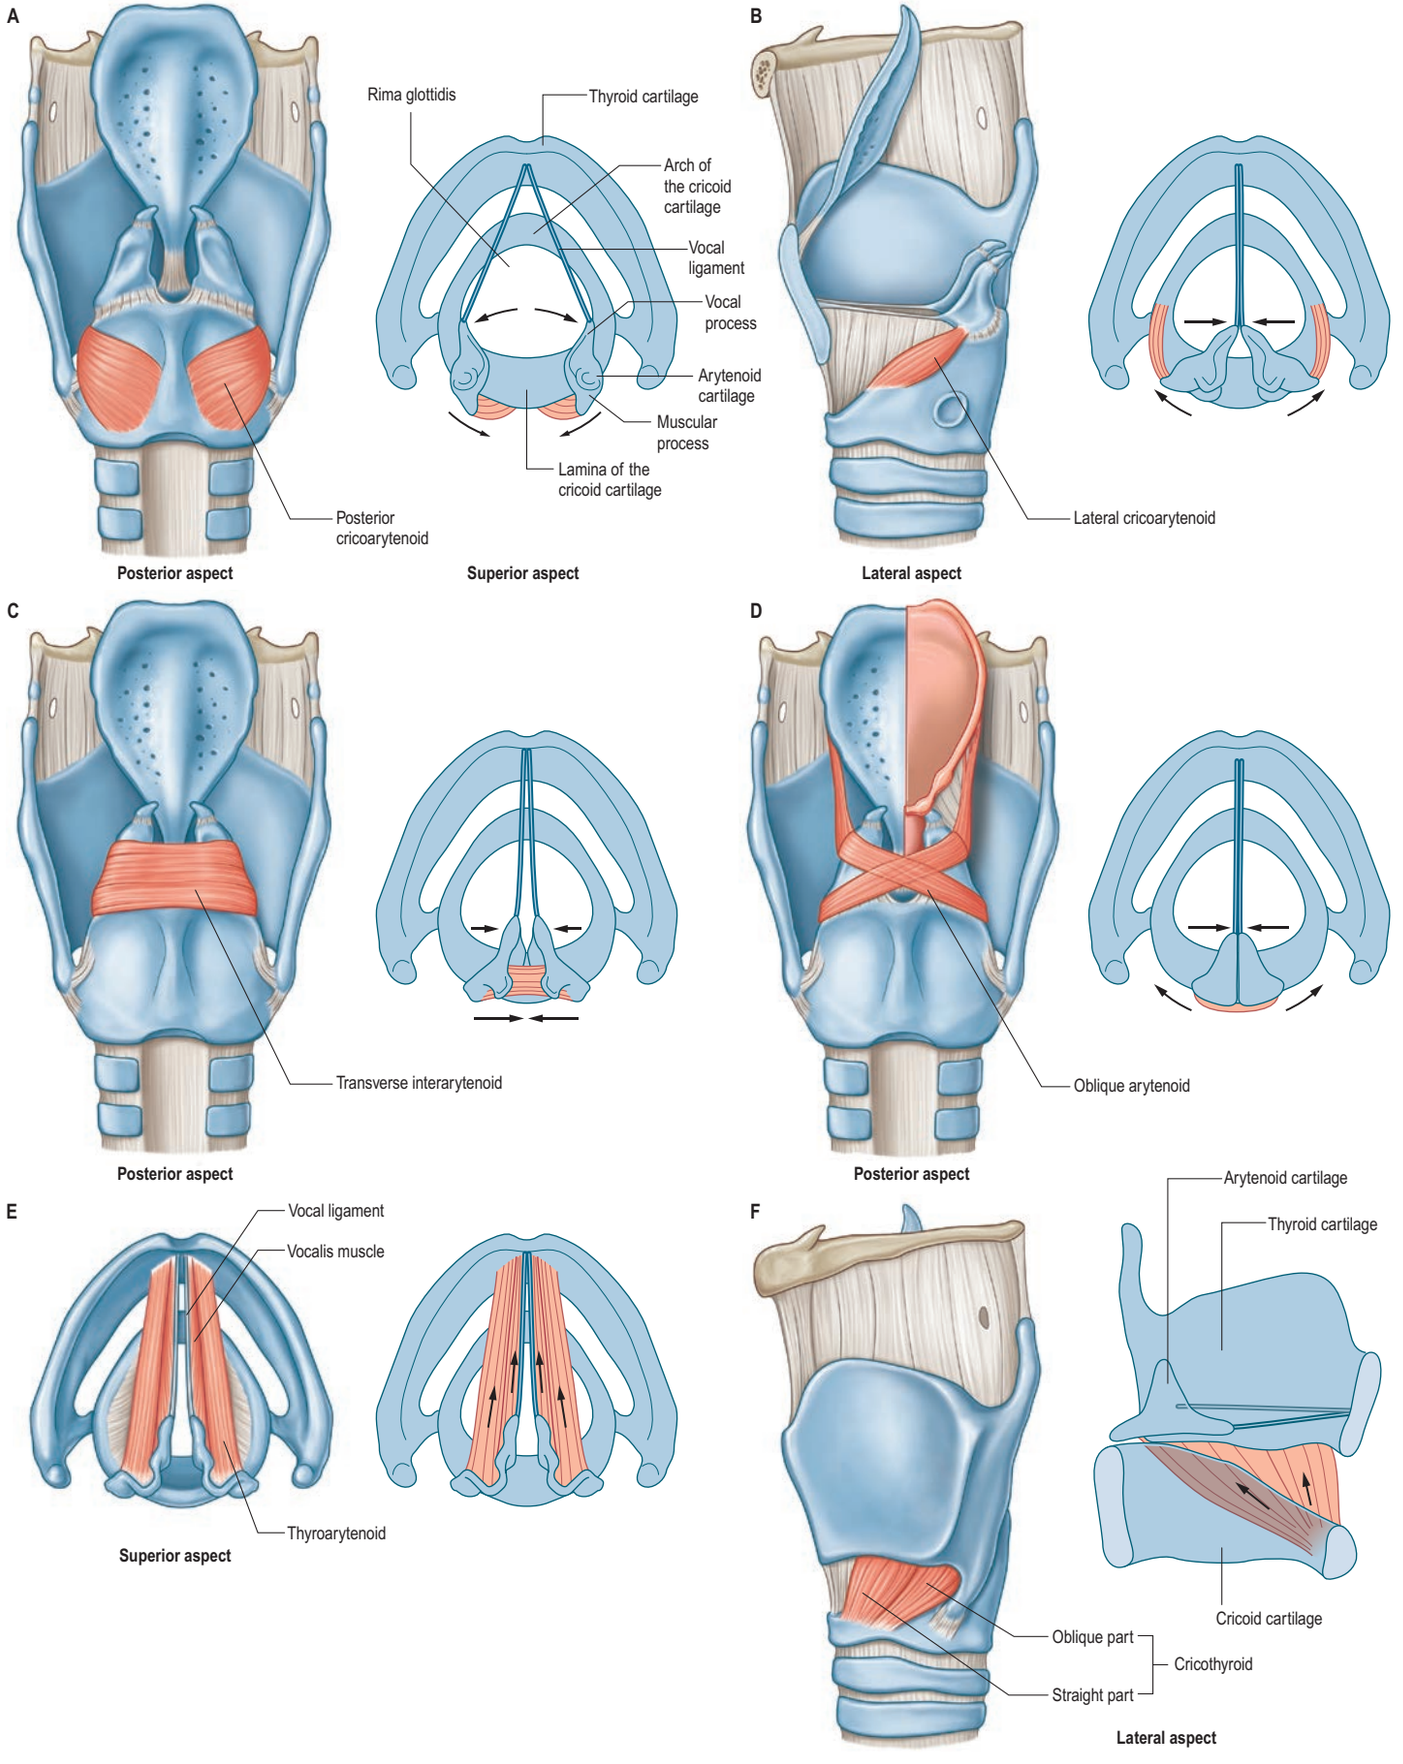

Fig. 41.10 The intrinsic muscles of the larynx in posterior or lateral views, with their actions shown alongside in a superior view. The arrows indicate the direction of movement of the cartilage in each case. For details, see text.

Innervation Unlike the other intrinsic muscles of the larynx, cricothyroid is innervated by the external branch of the superior laryngeal nerve, and not by the recurrent laryngeal nerve.

Actions Cricothyroid lengthens and hence stretches the vocal folds, increasing their tension. It does this by shortening the space between the inferior border of the thyroid cartilage and the cricoid cartilage, an action that increases the distance between the tip of the vocal process of the arytenoid cartilage and the posterior surface of the lamina of the thyroid cartilage. Rotation happens at the cricothyroid joint (see above). At the same time, the posterior part of cricothyroid pulls the thyroid cartilage forwards, a gliding action that also lengthens the vocal folds. In increasing the tension of the vocal folds, the pitch (frequency) of the voice rises. Some authors consider that cricothyroid has a slight adductive action in moving the vocal folds to a more paramedian position as they are lengthened and thinned (Mu and Sanders 2009, Wadie et al 2013). Others have attributed the relative sparing of abduction in lesions of the recurrent laryngeal nerve to a weak abductive action of cricothyroid. These contradictory views are currently unresolved.

Thyroarytenoid and vocalis

Thyroarytenoid is a broad, thin muscle, lying lateral to the vocal fold, conus elasticus, laryngeal ventricle and saccule (Fig. 41.10E). It is attached anteriorly to the lower half of the angle of the thyroid cartilage, and to the cricothyroid ligament. Its fibres pass backwards, laterally and upwards to the anterolateral surface of the arytenoid cartilage. The lower and more medial fibres form a band that, in coronal section, appears as a triangular bundle attached to the lateral surface of the vocal process and to the fovea oblonga on the anterolateral surface of the arytenoid cartilage. This bundle, the vocalis muscle, is viewed by some authors as simply a medial part of the thyroarytenoid and by others as a distinct and separate muscle. The vocalis is parallel with, and just lateral to, the vocal ligament. It is said to be thicker behind than in front, because many deeper fibres start from the vocal ligament and do not extend to the thyroid cartilage. (An alternative view is that all its fibres loop and intertwine as they pass from the thyroid to the arytenoid cartilage.) A few fibres extend along the wall of the ventricle from the lateral margin of the arytenoid cartilage to the side of the epiglottis. Superior thyroarytenoid, an inconstant small muscle, lies on the lateral surface of the main mass of thyroarytenoid; when present, it extends obliquely from the thyroid angle to the muscular process of the arytenoid cartilage.

Vascular supply Thyroarytenoid receives its arterial blood supply from the laryngeal branches of the superior and inferior thyroid arteries.

Innervation All parts of thyroarytenoid are supplied by the recurrent laryngeal nerve. It also receives a communicating branch from the external laryngeal nerve, although it is not clear whether such branches carry motor or sensory fibres.

Actions The thyroarytenoids draw the arytenoid cartilages towards the thyroid cartilage, thereby shortening and relaxing the vocal ligaments. At the same time, they rotate the arytenoids medially in opposition to the action of posterior cricoarytenoid to approximate the vocal folds and so aid closure of the rima glottidis. Pitch control is achieved by a complex interaction of the intrinsic laryngeal muscles which affect the tension and stiffness of the vocal folds: shortening and slackening of the vocal folds (when cricothyroid relaxes) results in a drop in pitch. Conversely, increasing tension of the vocal folds (when cricothyroid contracts) causes the pitch to rise.

Thyroepiglotticus

Many of the fibres of thyroarytenoid are prolonged into the aryepiglottic fold, where some terminate, and others continue to the epiglottic margin as thyroepiglotticus. The thyroepiglotticus muscles can widen the inlet of the larynx by their action on the aryepiglottic folds.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The blood supply of the larynx is derived mainly from the superior and inferior laryngeal arteries (Fig. 41.11). Rich anastomoses exist between the corresponding contralateral laryngeal arteries and between the ipsilateral laryngeal arteries. The superior laryngeal arteries supply the greater part of the tissues of the larynx, from the epiglottis down to the level of the vocal folds, including the majority of the laryngeal musculature. The inferior laryngeal artery supplies the region around cricothyroid, while its posterior laryngeal branch supplies the tissue around posterior cricoarytenoid (Trotoux et al 1986).

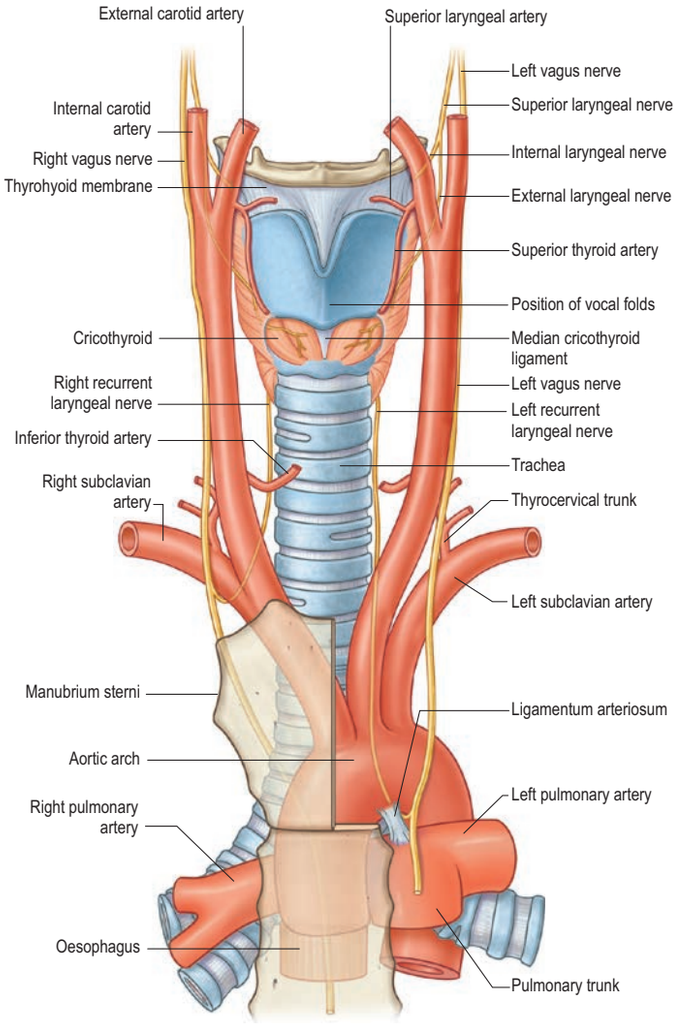

Fig. 41.11 An anterior view of the blood supply and innervation of the larynx. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Arteries and veins

Superior laryngeal artery

The superior laryngeal artery is normally derived from the superior thyroid artery, a branch of the external carotid artery, as this artery passes down towards the upper pole of the thyroid gland (see Figs 35.7A, 41.11). Sometimes, however, it arises directly from the external carotid artery between the origins of the superior thyroid and lingual arteries or, less commonly, from the common carotid artery or carotid bifurcation (Vazquez et al 2009). The superior laryngeal artery runs down towards the larynx, with the internal branch of the superior laryngeal nerve lying above it. It enters the larynx by penetrating the thyrohyoid membrane and divides into a number of branches that supply the larynx from the tip of the epiglottis down to the inferior margin of thyroarytenoid. It anastomoses with its contralateral fellow and with the inferior laryngeal branch of the inferior thyroid artery.

Cricothyroid artery

The cricothyroid artery arises from the superior thyroid artery and may contribute to the supply of the larynx. It follows a variable course, either superficial or deep to sternothyroid. If superficial, it may be accompanied by branches of the ansa cervicalis, and if deep, it may be related to the external laryngeal nerve. It can anastomose with the artery of the opposite side and with the laryngeal arteries.

Inferior laryngeal artery

The inferior laryngeal artery is smaller than the superior laryngeal artery. It is a branch of the inferior thyroid artery, which arises from

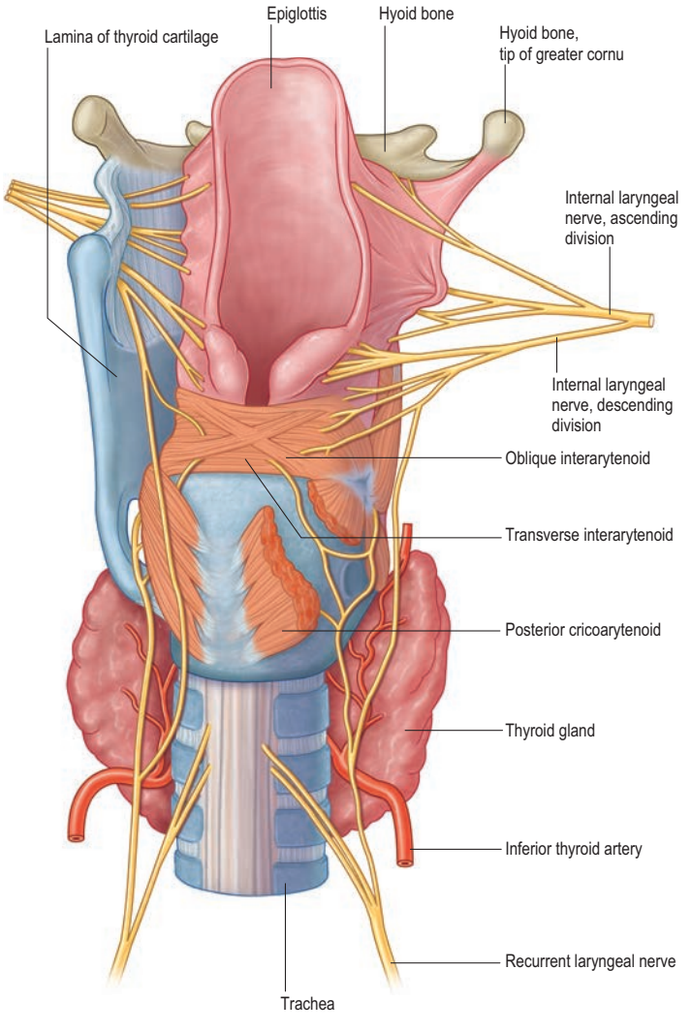

Fig. 41.12 Posterior view of the laryngeal innervation.

the thyrocervical trunk of the subclavian artery (see Fig. 35.17). It ascends on the trachea with the recurrent laryngeal nerve, enters the larynx at the lower border of the inferior constrictor, just behind the cricothyroid articulation, and supplies the laryngeal muscles and mucosa. The inferior laryngeal artery anastomoses with its contralateral fellow and with the superior laryngeal branch of the superior thyroid artery.

A posterior laryngeal artery of variable size has been described as a regular feature that arises as an internal branch of the inferior thyroid artery.

Superior and inferior laryngeal veins

Venous return from the larynx is via superior and inferior laryngeal veins, which run parallel to the laryngeal arteries and are tributaries of the superior and inferior thyroid veins, respectively. The superior thyroid vein drains into the internal jugular vein, and the inferior thyroid vein usually drains into the left brachiocephalic vein.

Lymphatic drainage

The vocal folds, with their paucity of lymphatics at their edges, provide a clear demarcation between the upper and lower areas of the larynx. Above the vocal folds, the rich network of lymph vessels draining the supraglottic part of the larynx accompany the superior laryngeal artery, pierce the thyrohyoid membrane, and end in the upper deep cervical lymph nodes, often bilaterally. The supraglottic lymphatics also communicate with those at the base of the tongue. Below the vocal folds, some of the lymph vessels of the infraglottic cavity pass through the conus elasticus to reach the prelaryngeal (Delphian) and/or pretracheal and paratracheal lymph nodes, while others accompany the inferior laryngeal artery and join the lower deep cervical nodes (Welsh et al 1983, Werner et al 2003).

Nodal spread of laryngeal tumours

The upper deep cervical lymph nodes act as pathways for the spread of malignant tumours of the supraglottic larynx. Up to 40% of these tumours will have undergone such spread at the time of clinical presentation. As stated previously, the glottis is very poorly endowed with lymphatic vessels; some 95% of malignant tumours confined to the glottis will present only with a change in voice or airway obstruction, but will not show signs of spread to adjacent lymph nodes at presentation. Tumours of the subglottic larynx will often spread to the paratracheal lymph node chain prior to clinical presentation. The presenting symptoms are usually voice change and airway obstruction rather than a mass in the neck. The paratracheal lymph nodes occupy a deep-seated position in the root of the neck and so their enlargement may remain occult. They must be looked for carefully at surgery and included in any radiation field.

INNERVATION

The larynx is innervated by the internal and external branches of the superior laryngeal nerve, the recurrent laryngeal nerve and sympathetic nerves (see Fig. 41.11; **Fig. 41.12**). Conventionally, the internal laryngeal nerve is described as sensory, the external laryngeal nerve as motor, and the recurrent laryngeal nerve as mixed. The internal laryngeal nerve is sensory down to the vocal folds, the recurrent laryngeal nerve is sensory below the vocal folds, and there is overlap between the territories innervated by the two nerves at the vocal folds themselves. All the intrinsic muscles of the larynx are supplied by the recurrent laryngeal nerve except for cricothyroid, which is supplied by the external laryngeal nerve. A number of anastomoses between the internal, external and recurrent laryngeal nerves have been described, with varying estimates of their incidence. Chronologically, the oldest recorded is that between the recurrent laryngeal nerve and the internal laryngeal branch of the superior laryngeal nerve (Galen's anastomosis). The majority of these anastomoses are found on the posterior surface of the larynx, forming what has been described as a laryngeal plexus to parallel the pharyngeal plexus. Their precise nature and function are unclear, but since some are thought to convey motor fibres, it is reasonable to assume that functions commonly ascribed to the three laryngeal nerves may be more complex than the conventional descriptions imply, which may have potential clinical implications (Sanders et al 1993, Sato and Shimada 1995, Furlan et al 2002, Naidu et al 2014).

The detailed course of the vagus in the neck is described in Chapter 35.

Superior laryngeal nerve

The superior laryngeal nerve arises from the middle of the inferior vagal ganglion. It receives one or more communications from the superior cervical sympathetic ganglion; most frequently, the connection is with the external laryngeal nerve. The sympathetic communication contributes to the innervation of the carotid body (Monfared et al 2002) and the thyroid gland (Sun and Chang 1991). Though the superior laryngeal nerve usually lies on the medial side of the internal carotid artery, it may be found on the lateral side of the artery. The superior laryngeal nerve divides into two branches: a smaller, external and a larger, internal branch, approximately 1.5 cm below the ganglion. Rarely, both branches may arise from the ganglion.

Internal laryngeal nerve

The internal laryngeal nerve passes forwards approximately 7 mm before piercing the thyrohyoid membrane, usually at a higher level than the superior thyroid artery (Durham and Harrison 1962). It splits into superior, middle and inferior branches on entering the larynx. The superior branch supplies the mucosa of the piriform fossa. The large middle branch is distributed to the mucosa of the ventricle, specifically the quadrangular membrane, and therefore probably conveys the afferent component of the cough reflex. The inferior ramus is mainly distributed to the mucosa of the ventricle and subglottic cavity. On the medial wall of the piriform fossa, descending branches give twigs to the interarytenoid muscle and share a number of communicating branches with the recurrent laryngeal nerve (Sanders and Mu 1998).

External laryngeal nerve

The external laryngeal nerve continues downwards and forwards on the lateral surface of the inferior constrictor, to which it contributes some small branches. Indeed, the nerve is sometimes located within the fibres

of the constrictor muscle. It passes beneath the attachment of sternothyroid to the oblique line of the thyroid cartilage and supplies cricothyroid. A communicating nerve continues from the posterior surface of cricothyroid, crosses the piriform fossa and enters thyroarytenoid, where it anastomoses with branches from the recurrent laryngeal nerve. It has been suggested that these communicating branches may provide both additional motor components to thyroarytenoid and sensory fibres to the mucosa in the region of the subglottis. An anastomosis between the external and internal laryngeal nerves has also been described in some cases (Kochilas et al 2008).

The close relationship of the external laryngeal nerve to the superior thyroid artery puts the nerve at potential risk when the artery is clamped during thyroid lobectomy, particularly when it is close to the artery (in approximately 20% of cases), or where, instead of crossing the superior thyroid vessels approximately 1 cm or more above the superior pole of the gland, it actually passes below this point (in some 20% of cases) (Cernea et al 1992, Kierner et al 1998). The external laryngeal nerve is also at risk in parathyroidectomy, carotid endarterectomy and anterior cervical spine procedures.

Recurrent laryngeal nerve

The recurrent laryngeal nerve enters the larynx by passing either deep to (usually) or between (sometimes) the fibres of cricopharyngeus at its attachment to the lateral aspect of the cricoid cartilage. It supplies cricopharyngeus as it passes. At this point, the nerve is in intimate proximity to the posteromedial aspect of the thyroid gland. The main trunk divides into two or more branches, usually below the lower border of the inferior constrictor, although branching may take place higher up. The anterior branch is mainly motor and is sometimes called the inferior laryngeal nerve (although this term is best avoided to prevent any confusion with a former synonym for the recurrent laryngeal nerve), while the posterior branch is mainly sensory. The anterior branch of the recurrent laryngeal nerve ascends posterior to the cricothyroid joint and its ligament (Shindo et al 2005). It is usually covered by fibres of posterior cricoarytenoid at this point. It bends over the joint, continuing forwards over the lateral cricoarytenoid muscle before terminating within thyroarytenoid. The anterior branch of the recurrent laryngeal nerve first innervates posterior cricoarytenoid by one or more branches, then innervates interarytenoid and lateral cricoarytenoid, and terminates in thyroarytenoid, which it also supplies (see also Maranillo et al 2005).

The recurrent laryngeal nerve forms several anastomoses with the superior laryngeal nerves (see Fig. 41.12). The posterior branch of the recurrent laryngeal nerve ascends deep to posterior cricoarytenoid to join the descending branch of the internal laryngeal nerve. The ansa Galeni, lying on the interarytenoid muscles, forms a direct connection between the recurrent and internal laryngeal nerves (see Fig. 41.12). There is also a complex anastomosis within and over the posterior surface of the interarytenoid muscles, and, less frequently, anastomoses on the cricoid lamina and thyroarytenoid that form connections with the internal laryngeal nerve (Sanudo et al 1999, Furlan et al 2002).

The recurrent laryngeal nerve does not always lie in a protected position in the tracheo-oesophageal groove but may be slightly anterior to it (more often on the right), and it may be markedly lateral to the trachea at the level of the lower part of the thyroid gland. The upper part of the nerve has a close but variable relationship to the inferior thyroid artery. On the right, it is as often anterior to, or posterior to, or intermingled with, the terminal branches of the artery. On the left, the nerve is usually posterior to the artery, though occasionally it lies anterior to it. The stated incidences of these relationships vary between different authors. The recurrent laryngeal nerve has a highly variable branching pattern (**Fig. 41.13**) (Henry et al 2016).

External to its capsule, the thyroid gland is covered by the visceral layer of deep cervical fascia which splits into two layers at the posterior border of the gland. The anterior layer covers the entire medial surface of each lobe. At, or just above, the isthmus, this layer is conspicuously thickened to form the lateral ligament of the thyroid gland, which attaches the gland to the trachea and the lower part of the cricoid cartilage. The posterior layer passes behind the oesophagus and pharynx to become attached to the prevertebral fascia. A compartment is thus formed on each side of the midline, lateral to the trachea and oesophagus; it contains fat, the recurrent laryngeal nerve and terminal parts of the inferior thyroid artery. The nerve may be lateral or medial to the lateral ligament of the thyroid gland and sometimes may be embedded in it.

A very rare anomaly that is of relevance to laryngeal pathology and surgery is the so-called 'non-recurrent' laryngeal nerve, where the right recurrent laryngeal nerve arises directly from the vagus nerve trunk high up in the neck and enters the larynx close to the inferior pole of the thyroid gland. Only the right side is affected, and it is always associated with an abnormal origin of the right subclavian artery from the aortic arch on the left side. If unrecognized, a non-recurrent laryngeal nerve may be susceptible to injury during surgery. It may also potentially be compressed by small tumours of the thyroid gland (Friedman et al 1986).

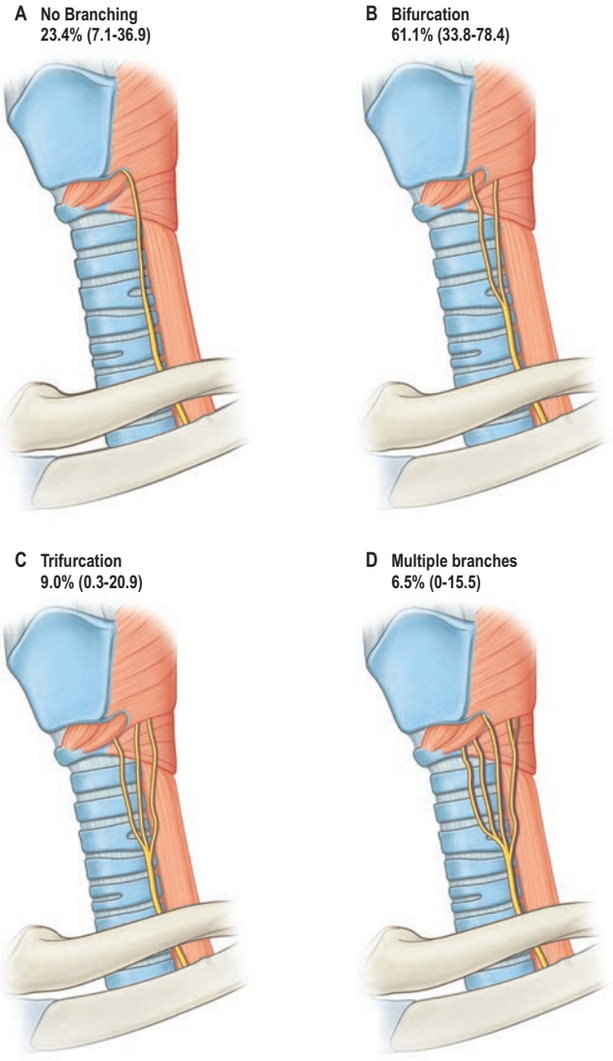

Fig. 41.13 Types of extralaryngeal branching patterns of the recurrent laryngeal nerve, with their pooled cadaver prevalence rates, presented as pooled prevalence rate (95% confidence interval). (Adapted with permission from Henry BM, Vikse J, Graves MJ et al 2016 Extralaryngeal branching of the recurrent laryngeal nerve: a meta-analysis of 28,387 nerves. Langenbecks Arch Surg 401:913–23.)

Interconnections and laryngeal nerve anastomoses

Anastomotic communications between the internal, external and recurrent laryngeal nerves probably explain why normal or near normal voice function can be present following neck surgery when one or more branches of these nerves have been divided (Naidu et al 2014, Henry et al 2017). Numerous communications have been described. Galen's anastomosis is the direct communication between the posterior branches of the internal and recurrent laryngeal nerves: it may be a single or double trunk or a plexus. The cricoid communication connects branches that originate bilaterally from the recurrent laryngeal nerve with the superior branch of the deep portion of the arytenoid plexus. The thyroarytenoid communication links the ascending branch of the recurrent laryngeal nerve and the descending branch from the anterior branch of the internal laryngeal nerve. The arytenoid plexus links the anterior branch of the recurrent laryngeal nerve with the arytenoid branch of the inferior laryngeal nerve. There are also communications between the external laryngeal and recurrent laryngeal nerves and the internal and external laryngeal nerves. The anastomosis between the recurrent laryngeal nerve and the sympathetic trunk probably explains why ptosis is a rare complication following thyroidectomy.

Lesions of the vagus nerve and recurrent laryngeal nerve paralysis

The consequences of vagal nerve lesions are complex, reflecting the long course of the nerve and the possible involvement of three of its branches, namely the pharyngeal, superior laryngeal and recurrent laryngeal nerves. Collectively, these nerves innervate the muscles of the larynx, soft palate and pharynx, and injury may therefore have deleterious effects on phonation and/or soft palate movements and/or swallowing. A lesion of the vagus nerve above the level at which the pharyngeal branch is given off will affect both the superior and recurrent laryngeal nerves. This causes immobility of the vocal fold on the affected side and imparts a breathy voice with lack of pitch and limited loudness. The affected fold is paralysed and lies in the so-called 'cadaveric' position halfway between abduction and adduction. If the lesion is unilateral, the voice is weak and hoarse, but if it is bilateral, phonation is almost absent, the vocal pitch cannot be altered, and the cough is weak and ineffective. There will also be a degree of hypernasality because of the effects on movements of the soft palate caused by paralysis of levator veli palatini. Unilateral palsies impact very significantly on the quality of life of the patient because of impaired vocalization and a tendency to aspirate. Bilateral palsies are extremely serious and a tracheostomy may be required to protect the airway.

A lesion affecting the superior laryngeal nerve may be unilateral or bilateral. Complete section is most likely during the ligation of the vessels forming the vascular pedicle of the superior pole of the thyroid gland during thyroid lobectomy. Unilateral lesions may result in the vocal folds appearing relatively normal and the effect on voice is barely noticeable and is often overlooked. A more detailed examination may detect some shortening of the vocal folds on the affected side with asymmetric tilt of the epiglottis and the anterior larynx canted towards the unaffected side. The result is a mildly hoarse voice with loss of pitch control. Bilateral superior laryngeal nerve lesions result in shortening of both vocal folds, the overhanging of the epiglottis over the folds and reduced tilt between the thyroid and cricoid cartilage. Effects on the voice are correspondingly greater, with reduced loudness and pitch but variable breathiness.

Damage to the internal laryngeal nerve causes loss of mechanoreceptive and proprioceptive sensation from the larynx. Unilateral loss produces a feeling that something is stuck in the throat, whereas bilateral loss will result in aspiration and can cause dysphagia, with a risk of choking.

Unilateral complete palsy of the recurrent laryngeal nerve is more common on the left side, presumably because the nerve is longer on this side. There is isolated paralysis of all the laryngeal muscles on the affected side except cricothyroid, which is innervated by the external laryngeal nerve. The patient may be asymptomatic or have a hoarse, breathy voice and there will be diminished ability to manipulate pitch. The hoarseness may be permanent or may become less severe with time as the contralateral fold develops the ability to hyperadduct and oppose the paralysed fold, thereby closing the glottis during phonation and coughing, although this is seldom enough to restore full voice quality. There may be aspiration of food and drink. Bilateral lesions of the recurrent laryngeal nerve result in both vocal folds being paralysed and taking up a paramedian position. Phonation can be nearly normal because the vocal folds lie so close to the midline, but there will be audible stridor and a compromised airway.

Clinically, the position of the vocal fold in the acute phase after section of the recurrent laryngeal nerve is very variable. Though stridor is more common after bilateral lesions and sometimes only audible to the educated ear, the folds may be sufficiently abducted so that there is little problem with airway obstruction at rest, although the voice is always weaker in this situation. The folds are slightly more widely separated in chronic lesions, which renders the voice weaker but with a less precarious airway. Atrophy and fibrosis of paraglottic muscles probably affect the position of paralysed vocal folds in chronic lesions to a greater degree than variations in the strength of the apposing adductor and abductor muscle groups.

For many years, conventional wisdom held that movements of abduction were affected to a greater degree than those of adduction when the recurrent laryngeal nerve was partially damaged (Semon's law). This effect was thought to reflect the internal segregation within the recurrent laryngeal nerve of axons supplying the laryngeal abductor muscles. The hypothesis was later undermined by the demonstration that axons destined for particular laryngeal muscles are randomly distributed within the nerve. The weak abductive action of cricothyroid that is said to produce lengthening of the vocal folds has been suggested as the explanation for the relative sparing of abduction in these lesions, but is difficult to reconcile with the alternative view that cricothyroid may be a slight adductor of the vocal folds (Mu and Sanders 2009, Wadie et al 2013). It is likely that predicting the effect of partial lesions of the recurrent laryngeal nerve is complicated by the variable patterns of anastomoses between the laryngeal nerves. For further reading, see Aronson and Bless (2009) and Blitzer et al (2009).

Autonomic innervation

Parasympathetic secretomotor fibres run with both the superior and the recurrent laryngeal nerves to mucous glands throughout the larynx. Postganglionic sympathetic fibres run to the larynx with its blood supply and originate in the superior and middle cervical ganglia. A variable number of paraganglia are located on the internal and recurrent laryngeal nerves. Histochemical evidence suggests that one population of neurones in these ganglia have a parasympathetic function while a second population may secrete dopamine (Maranillo et al 2008, Ibanez et al 2010).

ANATOMY OF SPEECH

The principal biological function of the larynx is to act as a sphincter controlling the entry of foreign bodies into the airways and to regulate airflow during ventilation. Thus, the glottis is opened widely during ventilation and is closed tightly during swallowing. The larynx can also close tightly during exertion (effort closure) to regulate thoracic and abdominal pressure during activities such as defecation or parturition, or to fix the thorax to increase mechanical advantage when using the arms to lift objects. The importance of the latter activity should not be underestimated. One of the many problems reported by patients who have undergone a laryngectomy is a loss of power in their arms when trying to lift heavy objects.

The larynx is much more than a simple valve that opens and closes. In addition to its sphincteric functions, its location means that it is perfectly placed to act as a sound source, or voice, that forms the basis of many sounds in human speech. The musculoskeletal structure of the larynx is under exquisite neuromuscular control, allowing it to modify the expiratory stream to produce highly complex patterns of sound of varying loudness, frequency and duration. The ability to execute these complex movements depends largely on specific areas of the cerebral hemispheres that are involved in the motor aspects of language, such as speech and writing, and sensory manifestations of language, including reading and understanding the spoken word. Central control of voice production involves two parallel pathways: a limbic pathway responsible for the control of innate non-verbal and emotional vocalizations, and a larynx-specific motor cortical pathway responsible for regulating the motor control necessary for voluntary voice production. For further reading, see Atkinson and McHanwell (2002), Clark et al (2007), Kaplan (1971), Laver (1980), Sataloff (2017), Titze (1994) and Zemlin (1998).

Overview of speech production

All speech requires an input of energy. For all sounds in Western European languages, and most sounds in other languages, this energy takes the form of a pulmonary expiration. This continuous airflow is converted into a vibration within the larynx by a mechanism called phonation, in which the vocal folds vibrate periodically, interrupting the column of air as it leaves the lungs and converting it into a series of discrete puffs of air. Speech sounds that are produced by vocal fold vibration in this way are said to be voiced. Speech sounds that are produced without vocal fold vibration are termed unvoiced sounds.

The larynx is an inadequate sound source to produce the complex sounds required for comprehensible speech; the laryngeal 'buzz' that is produced by phonation is very quiet and cannot be varied sufficiently to produce the complex range of sounds that is human speech. Amplification and modification of the sound takes place in the supralaryngeal vocal tract, which may be considered as a 17 cm long tube, narrow at the larynx and broadening out proximally as it passes through the pharynx, oral and nasal cavities. This tube acts as a passive amplifier of the sound. (The analogy here is of a megaphone: cupping the hands round the lips lengthens the vocal tract and increases the volume of speech.) The supralaryngeal vocal tract modifies the basic vibration of the larynx by altering its geometry, length and calibre: it provides a series of resonators that can dampen or amplify certain sound frequencies and can transiently interrupt the exhaled air flow and modify it to produce speech. This process is known as articulation. The range of sounds that the human vocal tract is capable of producing is very wide, although any one human language

will employ a subset of these sounds to convey meaning. The study of the integration of laryngeal sound production and articulation to produce complex speech is known as phonetics.

Muscular control of the airstream

Normal vegetative ventilation involves rhythmic movements of the thoracic cage that are produced by intercostal muscles, the diaphragm and a number of accessory muscles in the neck, arm and abdomen that have one attachment to some part of the thoracic cage. The thorax is capable of responding mechanically to widely varying demands for oxygen. From a tidal volume at rest of 500 ml and a respiratory rate of 12 per minute, ventilation can increase in fit individuals during vigorous exercise to tidal volumes of 4.5 litres and respiratory rates of 20–25 per minute.

Normal ventilatory patterns are considerably modified during speech, reflecting the special demands that speech places on ventilation. The main source of energy for the production of speech sounds is a pulmonary expiration, although other mechanisms are possible. In order for speech to be produced, sufficient pressure has to be generated beneath the vocal folds. This subglottal pressure (the difference between the air pressures above and below the vocal folds) has to be sustained above a minimum level throughout an utterance. It sets the vocal folds into vibration if the sound is to be voiced or generates airflow for an unvoiced sound. The minimum subglottal pressure needed for speech production is 7 cm H_2O and this increases when loud sounds are produced or when sounds are stressed.

The need to generate sufficient sustained pressure means that speech ventilation is markedly non-rhythmical. At the onset of an utterance, inspiration is typically 1.5 litres, which is deeper than for normal quiet ventilation, ensuring that sufficient air is taken in to maintain adequate subglottal pressure for the duration of the utterance. Inspiration is also quicker, 0.5 seconds rather than 2–3 seconds. Expiration is much longer than normal, perhaps lasting up to 30 seconds, reflecting the fact that the vocal tract is more constricted at the larynx to ensure that pauses for further inspirations are made at suitable points in an utterance. At the end of the first inspiration during running speech, lung volumes do not fully return to resting levels. Conversational speech normally takes place at a higher range of lung capacities than operate in normal quiet ventilation.

The non-rhythmical pattern during speech requires greater inspiratory effort, and for most people it involves a greater use of the diaphragm, usually in combination with the abdominal muscles that are attached to the lower ribs and stabilize the costal attachments of the diaphragm to increase the effectiveness of its action. The main differences are seen in expiration. Speech takes place at higher lung volumes, which means that greater recoil forces are stored in the elastic tissues of the lungs and the ribcage. The generation of subglottal pressure is the product of these elastic recoil forces and the muscular forces generated by the expiratory muscles. At the onset of an utterance, unrestrained recoil forces would generate excessive subglottal pressures that would be wasteful of air, and hence energy, and would affect the loudness of speech. Conversely, towards the end of an utterance, as recoil forces decline, subglottal pressure would fall without additional muscular exertion. Therefore, early in an utterance, inspiratory muscles, particularly the external intercostals and parasternal parts of the internal intercostals, continue to contract, relaxing slowly to counteract the effects of excessive passive elastic recoil. As the recoil forces decline below the point where they can maintain the minimum subglottal pressure needed for phonation, expiratory muscles contract to maintain subglottal pressure as lung air volume nears its resting expiratory level. The main muscles involved are the costal parts of the internal intercostals and the subcostal and transversus thoracis muscles. Their actions are aided by contraction of the anterior abdominal muscles to compress the abdomen. Accessory muscles such as latissimus dorsi may also come into play, but normally these accessory muscles are only active at the end of a very long or loud utterance, or in patients whose ventilatory function is compromised.

Though subglottal pressure tends to remain fairly constant during an utterance, it rises when sounds are stressed, and falls during the production of unvoiced sounds when the larynx is less constricted. At these times, compensatory mechanisms are required to ensure that pressure is maintained; the precise mechanisms have yet to be elucidated but the internal intercostal muscles have been implicated. The anterior abdominal muscles are also active in singing and shouting, and in attempts to speak without the pause necessary for inspiration. Contrary to popular belief, the diaphragm plays little part in the regulation of expiratory force. Unlike the intercostal muscles, the diaphragmatic musculature is sparsely supplied with muscle spindles, and therefore control of the diaphragm is poorly regulated; minute changes can be effected more successfully using the intercostal and anterior abdominal muscles.

Though the expiratory airflow from the lungs is the source of energy for most speech sounds, other sources of airflow are also used. The larynx can be used to generate airflow. The sound /p/ is produced by closing the larynx and then raising it with the lips closed, using the larynx like a piston. Opening the lips then releases a puff of air. This is called an ejective and is an example of egressive glottalic airflow. Ingressive glottalic airflow is also possible, though less effective; examples are not found in English but do in some African and native American languages. A third kind of airflow is velaric, in which the back of the tongue is raised against a lowered soft palate and the vocal tract is closed anterior to that point, either at the lips or with the tongue against the hard palate. This produces a click and is rare. A non-linguistic example in English is the sound made in encouraging a horse. Ingressive pulmonary airflow, such as is found in a groan or a gasp, is theoretically possible, but none of the world's languages employ this as a source of airflow.

After removal of the larynx, e.g. following laryngeal cancer, patients can be taught to swallow air, store it in a segment of the oesophagus and then use it as the energy source to produce egressive oesophageal airflow (oesophageal speech). Speech in these circumstances tends to have a belching quality. Laryngectomy patients always produce phrases that are shorter than normal, and so prostheses incorporating valves and surgical shunts are often inserted to provide a larger egressive airstream by diverting air from the respiratory tract into the oesophagus.

Phonation

The default position of the rima glottidis is open, to maintain patency of the airway during respiration. In quiet respiration, the anterior intermembranous part of the rima glottidis is triangular when viewed from above. Its apex is anterior and its base posterior, and it is represented by an imaginary line approximately 8 mm long connecting the anterior ends of the arytenoid vocal processes. The intercartilaginous part between the medial surfaces of the arytenoids is rectangular, as the two vocal processes lie parallel to each other. During forced respiration, the rima glottidis is widened and the vocal folds are fully abducted to increase the airway (see Fig. 41.8). The arytenoid cartilages rotate laterally, and this moves their vocal processes apart, and converts the rima glottidis into a diamond shape in which both intermembranous and intercartilaginous parts are triangular. The greatest width of the rima glottidis is at the point of the attachments of the vocal folds to the vocal processes.

During speech, the true vocal folds vibrate to act as a source of sound for subsequent speech. There have been a number of theories to explain the mechanism that produces this vibration but these are now only of historic interest. The aerodynamic–myoelastic theory is generally accepted as the mechanism underlying vocal fold vibration, although it does not account for all aspects of phonation.

At the onset of an utterance, during an expiration, the true vocal folds are adducted: the lateral cricoarytenoids and transverse interarytenoids bring together both the intermembranous and intercartilaginous parts of the rima glottidis, actions that either close the glottis completely or reduce the space between the vocal folds to a linear chink. The mucous membrane covering the interarytenoid muscles, the interarytenoid fold, intrudes into the larynx when these muscles adduct the arytenoids, and so aids closure of the intercartilaginous part of the rima glottidis. The vocal folds are also tensed, an essential prerequisite for vibration. These actions cause a build-up of subglottal pressure that continues until a point is reached when the muscular force of adduction is no longer sufficient to resist the rising pressure, and the membranous portions of the vocal folds are forced open a little, releasing air into the supralaryngeal vocal tract. The subglottal pressure falls when the subglottic and supraglottic cavities become continuous and the vocal folds begin to close. Two mechanisms bring about closure. If adductive tension is sustained, then the vocal folds will close. In addition, rapid closure is aided by a physical process, the Bernoulli effect. The forcing of air from a region of high to low pressure through a narrow space causes an increase in the kinetic energy of the molecules at the edge of the space. The effect of this is to lower pressure in the space between the folds at the level of the folds themselves, and this negative pressure simply sucks the folds together because they are mobile. This causes a rise once more in the subglottal pressure and the cycle is repeated. The effect is to cause the release of a series of puffs of air into the supralaryngeal vocal tract at a frequency of many times per second, which is perceived as a sound of a particular frequency (**Figs 41.14–41.15**, **Video 41.1**).

The source of energy for the vibration does not come from the larynx itself. The vocal folds do not behave like the prongs of a tuning fork; their predominant motion is in the horizontal plane at right-angles to the movement of the air column, and there is little vertical movement.

The energy is derived from the motion of the air generated by the muscular and recoil forces in the thorax, and the larynx is simply chopping that column into a series of segments.

The aerodynamic–myoelastic theory does not explain how vocal fold vibration is sustained; nor does it account for the very obvious muco-undulatory component of vocal fold vibration that is visible when the larynx is viewed stroboscopically. Without further input of energy, the vibration of the vocal folds as described above would not be sustained but would be damped and gradually diminish. For vibration to continue there has to be additional energy input. The analogy here is with a child on a swing. For the motion to continue, either the parent has to push the child at an appropriate point in the cycle, or the child has to sustain the motion for themselves by swinging their legs at the crucial point in the swing cycle. In the case of phonation, the source of this additional energy is unclear. It may come from the inertia of the air column itself, i.e. once the vocal folds close, the air column will continue moving upwards because inertia creates a negative pressure above the folds. Alternatively, the energy could come from the manner in which the folds open and close. As the subglottal pressure rises, the lower portion of the fold opens first and the upper edge of the fold is last to open, and when the subglottal pressure falls, the folds close from the bottom edge. It has been suggested that this non-uniform closure creates different shapes within the glottis that may result in differing negative pressures at different phases of the cycle. It also produces a vertical wave-like motion in the folds, termed the muco-undulatory component (or 'mucosal wave'). The analogy here is with a flag blowing in the wind, and it reflects the differing stiffness of the various layers of the vocal folds described above. This vertical component will impart a negligible amount of energy to the air column, but it is likely to impart harmonics to the basic laryngeal vibration.

The sound that results from the process of phonation has three characteristics: a frequency that is perceived as pitch, an intensity that is perceived as loudness, and a timbre perceived as voice quality.

The fundamental frequency of the human voice is determined by the resting length of the vocal folds and varies with age and sex. The frequency range of human speech is from 60 to 500 Hz, with an average of approximately 120 Hz in males, 200 Hz in females and 270 Hz in children. The mechanism of frequency alteration is not entirely clear. An increase in subglottal pressure will cause the frequency of phonation to rise. During an utterance, however, subglottal pressure appears to remain fairly constant, which suggests that the mechanism of frequency alteration resides in intrinsic changes within the vocal folds. Variations in frequency (pitch changes) during an utterance are determined by the complex interrelationships between length, tension and thickness of the vocal folds; one of these variables cannot be altered without affecting the other two parameters to some extent. Gross changes to the vocal folds demonstrate the effects of these variables. Inflamed and swollen vocal folds are much thicker than normal and result in a hoarse voice. At puberty, growth of the thyroid cartilage in males lengthens the vocal folds and lowers the fundamental frequency, and the voice 'breaks' as a result. During panic, the vocal folds may be tensed, which means that the cry for help is a high-pitched squeak.

Pitch is increased by lengthening the vocal folds, as may be confirmed during direct endoscopic examination of the larynx. At first sight this may seem counterintuitive but, as the vocal folds are lengthened, there will be a consequent thinning and stretching. Although an analogy is often drawn between the vocal folds and vibrating strings, a better analogy is that of a rubber band: if a rubber band is lengthened, the tension will increase but the thickness will decrease. The vocal folds may be lengthened by up to 50% of their resting length. It is likely that the initial pitch setting is achieved by action of the cricothyroids, and that fine adjustments can then be made using the vocalis muscles. Paralysis of both cricothyroids, which is usually associated with loss of the neurones that are distributed via the superior laryngeal nerve (as a result of damage to the vagal nuclei in brainstem stroke), results in permanent hoarseness and inability to vary the pitch of the voice. It is important to remember that, once the vocal folds are set in motion, they will deviate from their original setting as they vibrate. Auditory feedback of the sounds produced is used to make minute compensatory adjustments to length, tension and thickness in order to maintain a constant pitch.

Any lengthening of the vocal folds tends to thin them. The thickness can be increased by the vocalis part of thyroarytenoid: as vocalis shortens, it will relax the vocal folds and at the same time increase their thickness. Changes in the tension of the vocal folds are produced by the same muscles that change their length, namely: cricothyroid, posterior cricoarytenoid and vocalis, probably acting isometrically.

A discussion of the routes of lymphatic drainage from the larynx and related structures.

The mechanism by which loudness is increased is the subject of less debate. Loud sounds are produced by increasing subglottal pressure. This is achieved, in turn, by changing the opening quotient of the glottis (the ratio of the time spent in the open phase of the cycle to the total cycle time). In normal speech, this ratio is usually around 0.5, but in very loud speech it can fall to 0.3.

Timbre or voice quality refers to the harsh or mellow quality of the voice. The quality of the voice that can be consciously altered is, to a certain extent, a function of the harmonic frequencies produced by the vocal folds. Alteration of the shape of the supraglottic vocal tract accentuates different harmonics, altering the quality of the voice. Changes in harmonic frequencies facilitate production of different vowels and allows for a 'bright' or 'dark' sound in the voice.

Nearly all languages make the fundamental distinction between voiced and unvoiced sounds. Voicing has been described above. In unvoiced sounds, the vocal folds are not vibrating and will usually be opened under the action of posterior cricoarytenoid. The energy from the airstream is then used by other parts of the vocal tract to generate sound, normally by constricting or stopping the airflow. Phonation is not an all-or-nothing process, but is subject to considerable modification and adjustment. In modal voice, i.e. speaking using habitual pitch, forces acting on the vocal folds are moderate, pressures are sustained, and air is conserved. However, phonation can take place when the vocal folds are more open than usual, resulting in breathy phonation with more air escaping per phonatory cycle than usual. Some languages in South Asia exploit the difference between breathy and non-breathy sounds, whereas in spoken English, a breathy voice is simply recognized as a feature of some speakers. At the other end of the spectrum is vocal creak, where the vocal folds are more closed than normal. Different speakers will habitually employ different laryngeal settings that contribute to their particular voiced quality. In whispering, the intramembranous part of the rima glottidis is closed but the intercartilaginous part remains open, producing a characteristic Y-shaped rima glottidis and a greater loss of air at each phonatory cycle.

With regards to speech, the main function of the larynx is to act as a sound source, but it can also function in speech as an airstream generator and as an articulator.

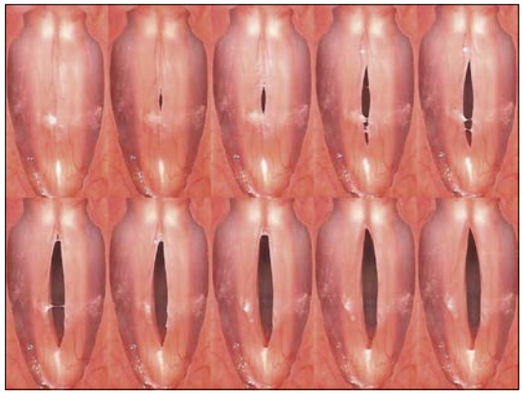

Fig. 41.14 A video montage of the normal phonatory cycle, obtained using a rigid 70° Hopkins rod endoscope with stroboscopic illumination. (Courtesy of Professor Paul Carding.)

The sound produced by phonation is not a pure tone because several harmonics at multiples of the fundamental frequency are also generated. Harmonics give a note of a particular frequency its defining characteristics. An 'A' played on an oboe or violin is immediately recognizable as coming from one or other instrument because of the different harmonics generated by the design of the instrument. The harmonic spectra of individual voices differ and will also vary depending upon the mode of phonation adopted. In the human vocal tract, the fundamental frequency and its harmonics are transmitted to the column of air that extends from the vocal folds to the exterior, mainly through the mouth. Part of the airstream can also be diverted through the nasal cavities when the soft palate is depressed to allow air into the nasopharynx. The supralaryngeal vocal tract acts as a selective resonator in which length, shape and volume can be varied by the actions of the muscles of the pharynx, soft palate, fauces, tongue, cheeks and lips; the relative positions of the upper and lower teeth, which are determined by the degree of opening and protrusion or retraction of the mandible; and alterations in the tension of the walls of the column, especially in the pharynx. Thus, the fundamental frequency (pitch) and

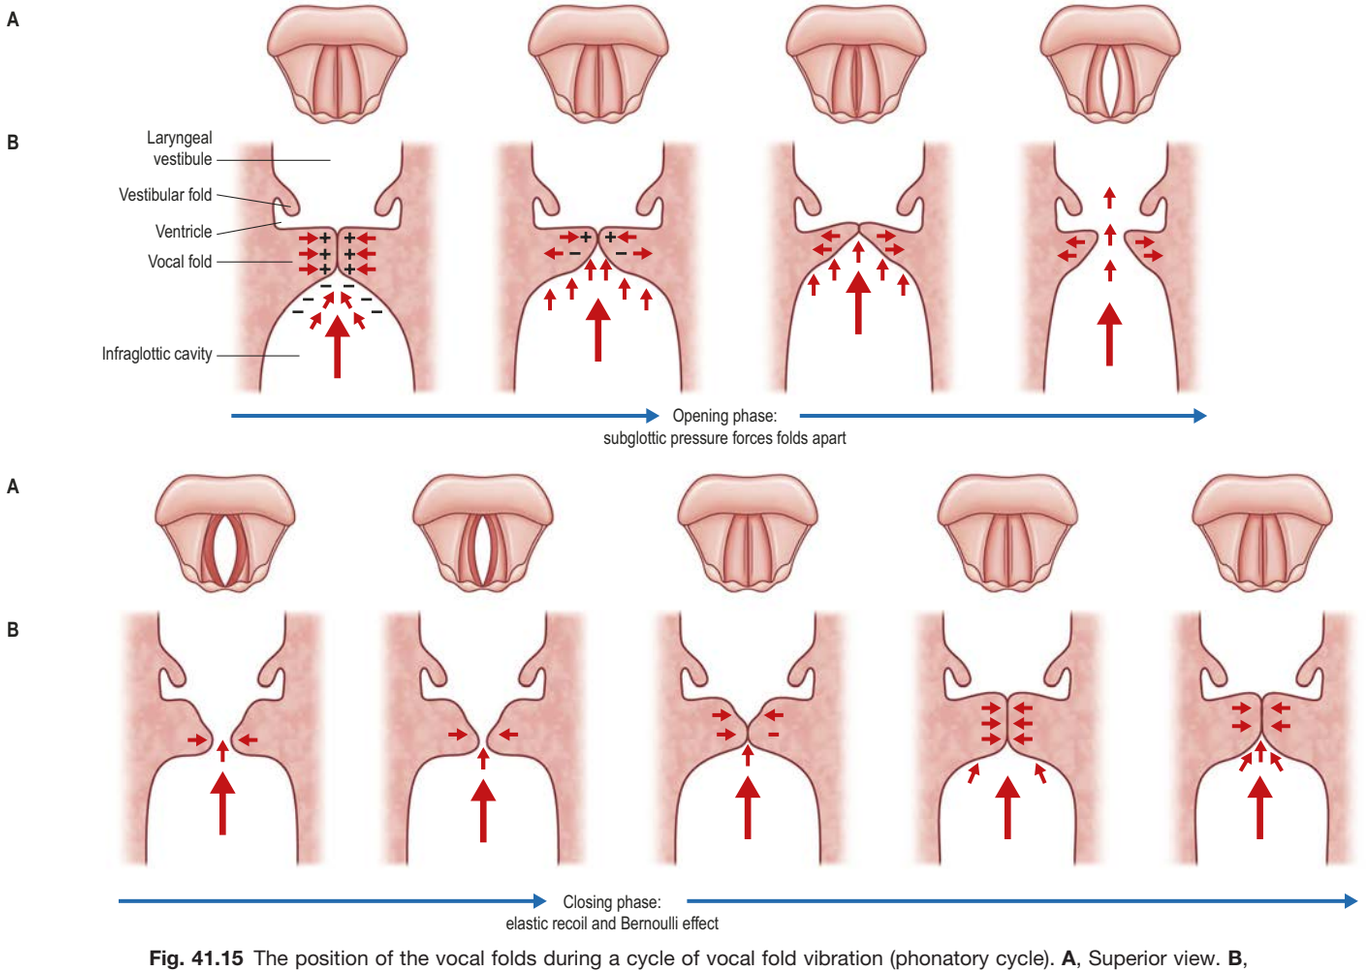

Fig. 41.15 The position of the vocal folds during a cycle of vocal fold vibration (phonatory cycle). **A**, Superior view. **B**, Coronal view.

harmonics produced by the passage of air through the glottis are modified by changes in the supralaryngeal vocal tract.

Harmonics may be amplified or dampened. The fundamental frequency and its associated harmonics may also be raised or lowered by appropriate elevation or depression of the hyoid bone and the larynx as a unit. This is achieved by the selective actions of the extrinsic laryngeal muscles that can shorten or lengthen the resonating column, and to some extent, also alter the geometry of the walls of the air passages. Analysis of the human voice shows that it has a very similar pattern of harmonics for all fundamental frequencies, determined by the vocal tract acting as a selective filter and resonator. This maintains a constant quality of voice without which intelligibility would be lost (recorded speech played back without its harmonics is completely unintelligible). Each human voice is unique and it has been suggested that the unique frequency spectrum of each individual voice could be used for personal identification.

During articulation, the egressive airstream is given a rapidly changing specific quality by the articulatory organs, the lips, oral cavity, tongue, teeth, palate, pharynx and nasal cavity. The discipline of phonetics primarily deals with the way in which speech sounds are produced, and consequently with the analysis of the mode of production of speech sounds by the vocal apparatus. In order to analyse the way in which the articulators are used in different speech sounds, words are broken down into units called phonemes, which are defined as the minimal sequential contrastive units used in any language.

The human vocal tract can produce many more phonemes than are employed in any one language. Not all languages have the same phonemes, and within the same language, the phonemes can vary in different parts of the same country and in other countries where that language is also spoken. Reproducing phonemes that are not used in native speech is difficult because such phonemes require unfamiliar positioning of the speech organs. A native speaker of any language can quickly recognize the origins of anyone attempting to use their language as a second language. The second-language speaker will usually speak it with an accent characteristic of their own first language because they are using the familiar configurations of their vocal tract for each phoneme instead of the correct positioning.

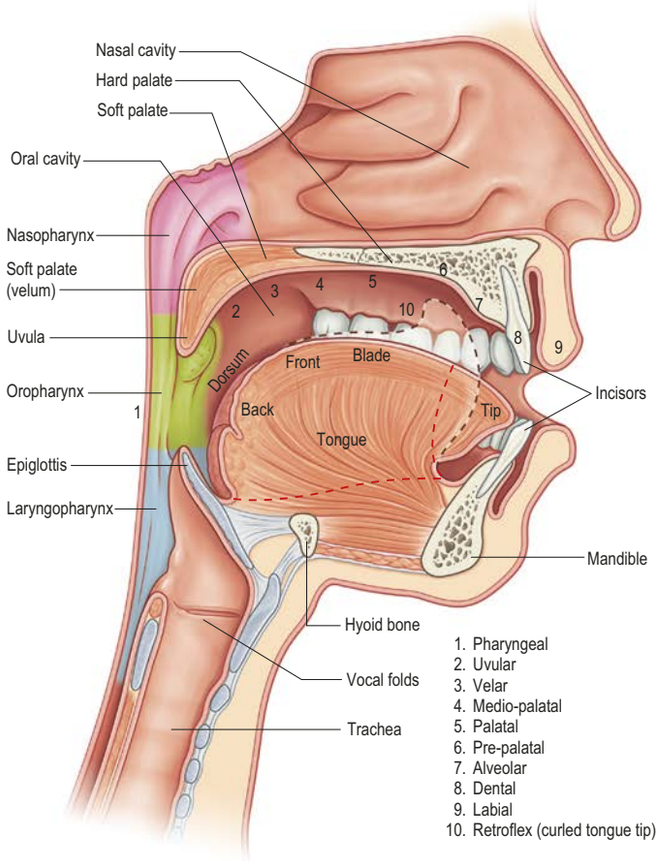

Fig. 41.16 Sagittal view of the left side of the head, showing the supralaryngeal vocal tract, the articulators and places of articulation. The red broken line indicates the tongue position during retroflexion (10).

All vowel sounds require phonation by vibration of the vocal folds. Each vowel sound has its own characteristic higher harmonics (frequency spectrum) that exhibit peaks of energy at certain frequencies. These energy peaks are always higher multiples of the fundamental frequencies and are called formants. Formants are the result of the combined effects of phonation, selective resonance of the vocal tract, and the properties of the head as a radiator of sound. The sounds of the different vowels are determined by the shape and size of the mouth, and the positions of the tongue and lips are the most important variables. The tongue may be placed high or low (close and open vowels), or further forwards or back (front and back vowels), and the lips may be rounded or spread.

The production of consonants always involves some degree of constriction of the vocal tract. There are many more consonants than vowels, and, in general, consonants cannot be combined to produce syllables. The classification of consonants is complex and beyond the remit of this book; what follows is a summary (for fuller details, a textbook of phonetics should be consulted).

Consonants may be classified on the basis of where the constriction happens, termed the place of articulation; the degree or extent of constriction, termed the manner of articulation; the shape of the constriction, termed the stricture; and whether or not there is vibration of the vocal folds, when consonants are described as voiced or unvoiced, respectively.

Consonants may also be classified as labial, dental, alveolar, velar, uvular, pharyngeal or glottic, depending on whether the point of maximum constriction occurs at the level of the lips, teeth, bony ridge behind the teeth, palate, uvula, pharynx or glottis, respectively (Fig. 41.16). Different parts of the tongue can be used in combination with the above places of articulation. Phoneticians divide the tongue into the tip, anterior edge, the front part of the dorsum, the centre and back parts of the remaining dorsum, and a most posterior part (the root). These divisions bear no obvious relationship to the anatomical landmarks on the tongue, but they are useful in describing the part of the dorsum of the tongue that contacts other areas of the mouth. Similarly, the manner of articulation can vary from a complete closure to a slight narrowing. An actual closure of the vocal tract is called a stop. A narrowing that is sufficient to produce turbulence of the air in the vocal tract, and which is perceived as a rustling sound, is termed a fricative. Approximants involve a degree of closure insufficient to produce turbulence but with closure greater than that for a vowel. Nasals involve a stoppage in the oral cavity with the soft palate lowered to allow airflow through the nose, and, unlike stops, they can be sustained. Stricture describes the shape of the constriction, e.g. a lateral consonant involves depression of the sides of the tongue, while a grooved consonant is produced by grooving the dorsum of the tongue. Consonants can be produced with the vocal folds vibrating, when they are termed voiced, or without vocal fold vibration, in which case they are termed unvoiced.

The best way to illustrate these classificatory systems in operation is by contrasting the production of different consonant pairs in which only one or two parameters have been changed. The /p/ of peat, the /b/ of beat and the /m/ of meat are all bilabial stops, meaning that they are produced by bringing together the lips. The /b/ and the /m/ are voiced but the /p/ is not. The contrast between the /b/ and the /p/ is in the differing way in which the airstreams are produced. The /b/ is produced with a closure of the vocal folds producing sounds (hence it is a 'voiced' consonant) during pulmonary airflow, while the /p/ is produced with the glottis open – hence is unvoiced – and the glottis is then raised using the larynx as a piston to compress the air in the supralaryngeal vocal tract prior to the stop being released. The /m/ differs from the other two stops in being a nasal in which the soft palate is lowered to allow air to escape through the nasal cavity; unlike the other two stops, it can be sustained as in a sound of approval. Bilabial stops can be contrasted with the labiodental fricatives /f/ of feet and the /v/ of veal, both of which are produced by retracting the lower lip beneath the upper teeth. Neither involves a complete closure but both produce a significant constriction of the vocal tract with audible turbulence: the /f/ is unvoiced, while the /v/ is voiced. The sh sound (/ʃ/) in ship is also a fricative involving a grooving of the tongue and is associated with significant audible turbulence; it may be contrasted with the lateral approximant /l/ in law, in which the sides of the tongue are lowered. In this case, it is the nature of the stricture that is different and the degree of closure, e.g. in the case of the approximant /l/, closure is insufficient to produce turbulence. The sh sound in ship can be compared to the /k/ in keen, where the position of the tongue is different: in /k/ the tongue blade contacts the soft palate, while in sh the tongue tip or the blade contact the postalveolar region. The most dramatic example of the difference between voiced and unvoiced sounds may be appreciated if the /s/ sound in sip is compared with the /z/ in zip. If the larynx is loosely palpated while making a sustained unvoiced 'ssssss' sound, no vibration is felt, but if the 'ssssss' is commuted into a prolonged voiced 'zzzzzz', then vibration in the larynx should be readily detectable. The position of the tongue and other articulators is exactly the same for both /s/ and /z/; the difference between them is the presence or absence of phonation.

CHAPTER 42

External and middle ear

By convention, the ear is subdivided into three parts: the external, middle and inner ear. It is largely, but not entirely, contained within the temporal bone. The ears not only receive, modulate, conduct, amplify and discriminately analyse the complex pressure waves that are sound, but also contain the end organs of balance.

TEMPORAL BONE

Each temporal bone consists of four components: the squamous, petromastoid and tympanic parts and the styloid process (Fig. 42.1). The squamous part has a shallow mandibular fossa associated with the temporomandibular joint (Ch. 38). The petromastoid part is relatively large; its petrous portion houses the auditory apparatus and is formed of compact bone. In contrast, the mastoid process is trabecular and variably pneumatized. The tympanic part has the form of a thin and incomplete ring whose ends are fused with the squamous part. The styloid process gives attachment to the styloid group of muscles. The temporal bone contains four canals: the external acoustic meatus (external auditory canal), visible on the lateral surface, through which sound waves travel to the tympanic membrane; the internal acoustic meatus (internal auditory canal), evident on the medial surface, through which the facial and vestibulocochlear nerves pass; the facial (Fallopian) canal, through which the facial nerve passes from the internal acoustic meatus to the stylomastoid foramen and neck; and the carotid canal, through which the internal carotid artery passes from the neck to the foramen lacerum and cavernous sinus.

Squamous part

The squamous part lies anterosuperiorly and is thin and partly translucent. Its external temporal surface is smooth, slightly convex, and forms part of the temporal fossa, to which temporalis muscle is attached. Above the external acoustic meatus, it is grooved vertically by the middle temporal artery, a branch of the superficial temporal artery (Daraei and Mattox 2018). The supramastoid crest curves backwards and upwards across its posterior part and gives attachment to the temporal fascia. The junction between the squamous and mastoid parts is approximately 1.5 cm below this crest, and traces of the squamomastoid suture may persist. The suprameatal triangle, a depression marking the position of the mastoid antrum (which is medial to the triangle at a depth of approximately 1.25 cm), lies between the anterior end of the supramastoid crest and the posterosuperior quadrant of the external acoustic meatus. The triangle usually contains a small suprameatal spine anteriorly.

The internal cerebral surface of the squamous part is concave and contains depressions that correspond to convolutions of the temporal lobe of the cerebral hemisphere. This surface is grooved by the middle meningeal vessels. Its lower border is fused to the anterior region of the petrous part but traces of a petrosquamosal suture often appear in adult bones. The superior border is thin and bevelled internally; it overlaps the inferior border of the parietal bone at the squamosal suture. Posteriorly, it forms an angle with the mastoid element. The anteroinferior border, thin above and thick below, meets the greater wing of the sphenoid bone; it is bevelled internally above, and bevelled externally below.

The squamous part has a zygomatic process and a mandibular fossa.

Zygomatic process

The zygomatic process juts forwards from the lower region of the squamous part. Its triangular posterior aspect has a broad base that is directed laterally, presenting superior and inferior surfaces. The zygomatic process then twists anteromedially, so that its surfaces become medial and lateral.

The superior surface of the posterior part is concave. The inferior surface is bounded by anterior and posterior roots, converging into the anterior part of the process. The tubercle of the zygomatic root gives attachment to the lateral temporomandibular ligament at the junction of the roots. The posterior root is prolonged forwards above the external acoustic meatus, its upper border continuing into the supramastoid crest. Very rarely, the squamous part is perforated above the posterior root by a squamosal foramen, which transmits the petrosquamous sinus. The anterior root juts almost horizontally from the squamous part. Its inferior surface, with an anteroposterior convexity, forms a short semi-cylindrical articular tubercle and comes into contact with the articular disc of the temporomandibular joint. The tubercle forms the anterior limit of the mandibular fossa.

The anterior part of the zygomatic process is thin and flat, and the temporal fascia is attached to its superior border. The inferior border is short and arched and gives origin to some fibres of masseter. The lateral surface is convex. The medial surface is concave and provides further attachment for part of masseter. The anterior end is deeply serrated and slopes obliquely posteroinferiorly to articulate with the temporal process of the zygomatic bone, forming the zygomatic arch. Anterior to the articular tubercle, a small triangular area forms part of the roof of the infratemporal fossa; it is continuous behind with the anterior root and in front with the infratemporal crest of the greater wing of the sphenoid.

Mandibular fossa

The mandibular fossa is limited in front by the articular eminence of the zygomatic process. It presents an anterior articular area, formed by the squamous part, and a posterior non-articular area, formed by the tympanic element. The articular surface is smooth, oval and concave, and contacts the articular disc of the temporomandibular joint. Unlike most other synovial joints, it is lined by fibrous tissue rather than hyaline cartilage, reflecting its intramembranous development. The non-articular area sometimes contains part of the parotid gland. A small, conical postglenoid tubercle separates the articular surface laterally from the tympanic plate.

Posteriorly, the mandibular fossa is separated from the tympanic part by the squamotympanic fissure. Rarely, a postglenoid foramen exists anterior to the external acoustic meatus in the line of fusion of the squamous and tympanic parts. When present, it replaces the squamosal foramen noted above and transmits the petrosquamous sinus. Medially, a projection from the petrous part of the temporal bone (tegmen tympani) comes to lie within the squamotympanic fissure, further dividing it into petrotympanic and petrosquamous fissures. The petrotympanic fissure leads into the tympanic cavity and contains an anterior malleolar ligament and the anterior tympanic branch of the maxillary artery. The anterior opening of the anterior canaliculus for the chorda tympani nerve lies at the medial end of the fissure.

Petromastoid part

The petromastoid part of the temporal bone, although morphologically one element, is more conveniently described as two parts, namely: mastoid and petrous parts.

Mastoid part

The mastoid part is the posterior region of the temporal bone and has an outer surface roughened by the attachments of the occipital belly of occipitofrontalis and auricularis posterior. A mastoid foramen, of variable size, number and position, traversed by a vein from the sigmoid sinus and a small dural branch of the occipital artery, frequently lies near its posterior border. The foramen may be in the occipital or occipitotemporal suture; it may sometimes be parasutural or may be absent. The mean length of the mastoid emissary vein from its point of origin to its point of termination is 7.2 cm (range 3.8–11.8 cm). It can be a significant source of bleeding in retrosigmoid and far lateral approaches to the skull base, usually controlled by the repetitive applications of surgical wax. It is of considerable clinical importance to craniofacial surgeons when operating on complex craniosynostotic patients, where the emissary vein may be the sole dominant drainage pathway of the brain (Louis et al 2009, Kim et al 2014).

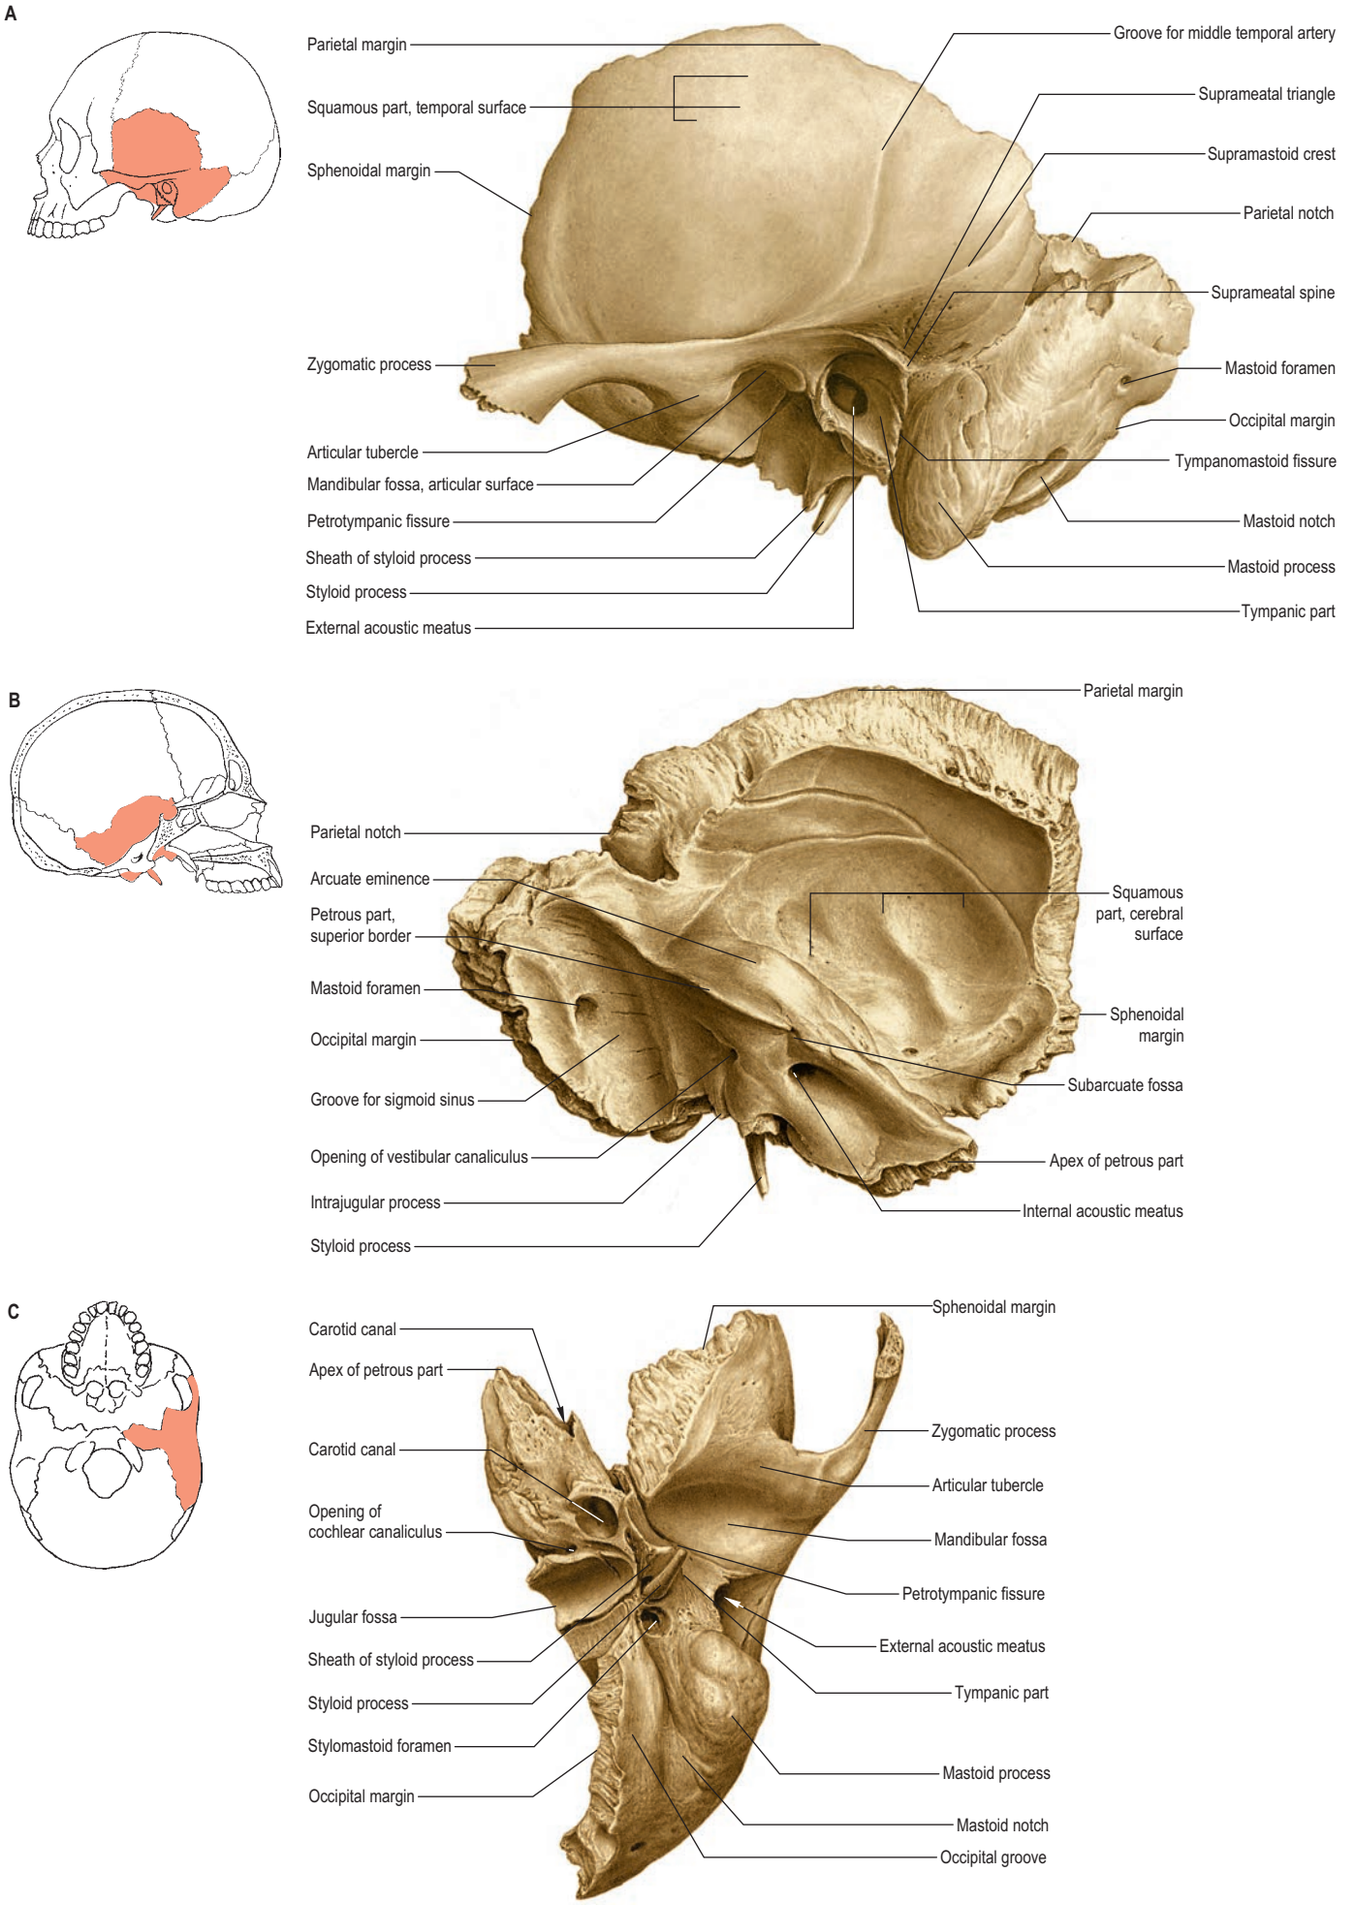

Fig. 42.1 The left temporal bone. **A**, Lateral aspect. **B**, Medial aspect. **C**, Inferior aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

The mastoid part projects down as the conical mastoid process and is larger in adult males. Sternocleidomastoid, splenius capitis and longissimus capitis are all attached to its lateral surface, and the posterior belly of digastric is attached to a deep mastoid notch on its medial aspect. The occipital artery runs in a shallow occipital groove that lies medial to the mastoid notch. The internal surface of the mastoid process bears a deep, curved sigmoid sulcus for the sigmoid venous sinus; the sulcus is separated from the underlying innermost mastoid air cells by a thin lamina of bone.

The superior border of the mastoid part is thick and serrated for articulation with the mastoid angle of the parietal bone. The posterior border is also serrated and articulates with the inferior border of the occipital bone between its lateral angle and jugular process. The mastoid element is fused with the descending process of the squamous part; below, it appears in the posterior wall of the tympanic cavity.

Petrous part

The petrous part is a mass of bone that is wedged between the sphenoid and occipital bones in the cranial base; it contains the labyrinth. It is inclined superiorly and anteromedially, and has a base, apex, three surfaces (anterior, posterior and inferior) and three borders (superior, posterior and anterior).

The base would correspond to the part that lies on the base of the skull and is separated from the squamous part by a suture. However, this suture disappears soon after birth. The subsequent development of the mastoid processes means that the precise boundaries of the base are no longer identifiable.

The apex, blunt and irregular, is angled between the posterior border of the greater wing of the sphenoid and the basilar part of the occipital bone. It contains the anterior opening of the carotid canal and limits the foramen lacerum posterolaterally.

The anterior surface contributes to the floor of the middle cranial fossa (Ch. 34) and is continuous with the cerebral surface of the squamous part (although the petrosquamosal suture often persists late in life). The whole surface is adapted to the inferior temporal gyrus. Behind the apex is a trigeminal impression for the trigeminal ganglion. Bone anterolateral to this impression roofs the anterior part of the carotid canal but is often deficient. A ridge separates the trigeminal impression from another hollow behind, which partly roofs the internal acoustic meatus and cochlea. This, in turn, is limited behind by the arcuate eminence, which is raised by the superior (anterior) semicircular canal but is not necessarily directly over it. Laterally, the anterior surface roofs the vestibule and, partly, the facial canal. Between the squamous part laterally and the arcuate eminence and the hollows just described medially, the anterior surface is formed by the tegmen tympani, a thin plate of bone that forms the roof of the mastoid antrum and extends forwards above the tympanic cavity and the canal for tensor tympani. The lateral margin of the tegmen tympani meets the squamous part at the petrosquamosal suture, turning down in front as the lateral wall of the canal for tensor tympani and the osseous part of the pharyngotympanic tube; its lower edge is in the squamotympanic fissure. Anteriorly, the tegmen bears a narrow groove related to the greater petrosal nerve (which passes posterolaterally to enter the bone by a hiatus anterior to the arcuate eminence). The groove passes forwards to the foramen lacerum. A smaller and similar hiatus and groove may be found more laterally; they are related to the lesser petrosal nerve (which runs to the foramen ovale). The posterior slope of the arcuate eminence overlies the posterior and lateral semicircular canals. Lateral to the eminence, the posterior part of the tegmen tympani roofs the mastoid antrum.

The posterior surface contributes to the anterior part of the posterior cranial fossa and is continuous with the internal surface of the mastoid part. The opening of the internal acoustic meatus lies near its centre. A small slit leading to the vestibular aqueduct lies behind the opening of the meatus, almost hidden by a thin plate of bone. This contains the saccus and ductus endolymphaticus together with a small artery and vein. The terminal half of the saccus endolymphaticus protrudes through the slit between the periosteum and dura mater. The subarcuate fossa lies above these openings.

The irregular inferior surface is part of the exterior of the cranial base. Near the apex of the petrous part, a quadrilateral area is partly associated with the attachment of levator veli palatini and the cartilaginous pharyngotympanic tube, and partly connected to the basilar part of the occipital bone by dense fibrocartilage. Behind this region is the large, circular opening of the carotid canal, and behind the opening of the canal is the jugular fossa, which is of variable depth and size, and contains the superior jugular bulb. The inferior ganglion of the glossopharyngeal nerve lies in a triangular depression anteromedial to the jugular fossa (below the internal acoustic meatus). At its apex is a small opening into the cochlear canaliculus, occupied by the perilymphatic duct (a tube of dura mater) and a vein draining from the cochlea to the internal jugular vein. A canaliculus for the tympanic nerve from the glossopharyngeal nerve lies on the ridge between the carotid canal and the jugular fossa. The mastoid canaliculus for the auricular branch of the vagus nerve is laterally positioned in the jugular fossa. Behind the jugular fossa, the rough quadrilateral jugular surface is covered by cartilage that joins it to the jugular process of the occipital bone.

The superior border, the longest, is grooved by the superior petrosal sinus. The attached margin of the tentorium cerebelli is fixed to the edges of the groove except at its medial end, where it is crossed by the roots of the trigeminal nerve. The posterior border, intermediate in length, bears a sulcus medially, which forms, together with the occipital bone, a gutter for the inferior petrosal sinus. Behind this, the jugular fossa contributes (together with the occipital bone) to the jugular foramen and is notched by the glossopharyngeal nerve. Bone on either or both sides of the jugular notch may meet the occipital bone and divide the jugular foramen into two or three parts. The anterior border is joined laterally to the squamous part of the temporal bone at the petrosquamosal suture; medially, it articulates with the greater wing of the sphenoid bone.

Two canals exist at the junction of the petrous and squamous parts, one above the other, separated by a thin osseous plate and both leading to the tympanic cavity; the upper canal contains tensor tympani, while the lower canal is the pharyngotympanic tube.

Tympanic part

The tympanic part of the temporal bone is a curved plate below the squamous part and anterior to the mastoid process. Internally, it fuses with the petrous part and appears between this and the squamous part, where it is inferolateral to the auditory orifice. Behind, it fuses with the squamous part and mastoid process, and is the anterior limit of the tympanomastoid fissure. Its concave posterior surface forms the anterior wall, floor and part of the posterior wall of the external acoustic meatus. The tympanic membrane is attached to a narrow tympanic sulcus on its medial surface. The quadrilateral concave anterior surface is the posterior wall of the mandibular fossa and may contact the parotid gland. Its rough lateral border forms most of the margin of the osseous part of the external acoustic meatus and is continuous with its cartilaginous part. Laterally, the upper border is fused with the back of the postglenoid tubercle; medially, it forms the posterior edge of the petrotympanic fissure. The inferior border is sharp and splits laterally to form, at its root, the sheath of the styloid process (vaginal process). Centrally, the tympanic part is thin and is often perforated. The stylomastoid foramen lies between the styloid and mastoid processes; it represents the external end of the facial canal, contains part of the aponeurosis of the posterior belly of digastric, and transmits the facial nerve and stylomastoid artery.

Styloid process

The styloid process is slender and pointed, and projects anteroinferiorly from the inferior aspect of the temporal bone. Its length may vary considerably, normally ranging from 2.83 to 4.16 cm. In some patients it may be much longer and be the cause of severe, neuralgic pain in the ipsilateral pharynx when swallowing (Eagle's syndrome) as the glossopharyngeal nerve rubs against the process. Mechanical impingement of the cervical carotid artery with an excessively long styloid process has been implicated as a cause of arterial dissection with the consequences that flow from that (Muthusami 2013, Jelodar et al 2018, Ledesma-Montes et al 2018). Most often the styloid process is almost straight but can show a curvature, an anteromedial concavity being most common. Its proximal part (tympanohyal) is ensheathed by the tympanic plate, especially anterolaterally, while muscles and ligaments are attached to its distal part (stylohyal). *In vivo*, its relationships are important. The styloid process is covered laterally by the parotid gland; the facial nerve crosses its base; the external carotid artery crosses its tip, embedded in the parotid; and medially, the process is separated from the beginning of the internal jugular vein by the attachment of stylopharyngeus.

External acoustic meatus

The temporal bone contains the bony (osseous) part of the external acoustic meatus.

Ossification

The four temporal components ossify independently (Fig. 42.2). The squamous part is ossified in a sheet of condensed mesenchyme from a single centre near the zygomatic roots, which appears in embryonic

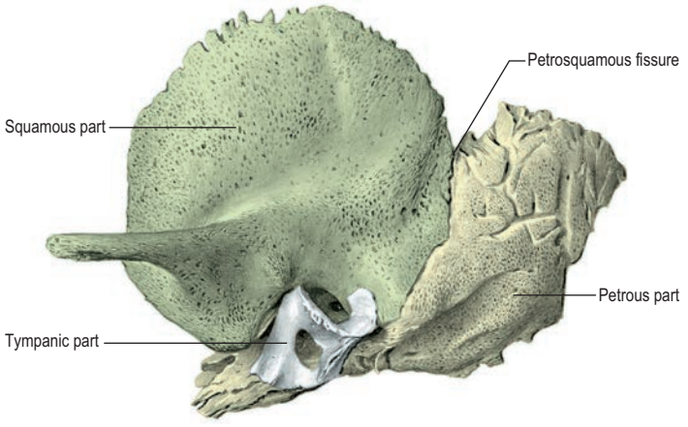

Fig. 42.2 The left temporal bone at birth. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

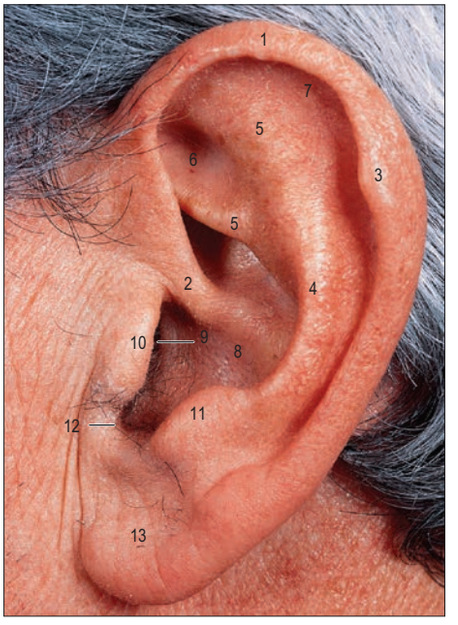

Fig. 42.3 The lateral surface of the left auricle. stages 21–23 (postfertilization week 8). The petromastoid part has several centres that appear in the cartilaginous otic capsule during postmenstrual weeks 17–20; as many as 14 have been described. These centres vary in order of appearance. Several are small and inconstant and soon fuse with others. The otic capsule is almost fully ossified by postmenstrual week 24. The tympanic part is also ossified in mesenchyme from four centres that appear at about postmenstrual week 14. At birth, it is an incomplete tympanic ring that is deficient above; its concavity is grooved by a tympanic sulcus for the tympanic membrane. The malleolar sulcus housing the anterior malleolar process, chorda tympani and anterior tympanic artery, inclines obliquely downwards and forwards across the medial aspect of the anterior part of the ring. The styloid process develops from two centres at the cranial end of the cartilage in the second visceral or hyoid arch: a proximal centre for the tympanohyal appears before birth, and the centre for the distal stylohyal appears after birth. The tympanic ring unites with the squamous part shortly before birth; the petromastoid fuses with it and the tympanohyal during the first postnatal year. The stylohyal does not unite with the rest of the process until after puberty and may never do so.

Once ossified, the tympanic cavity, mastoid antrum and the posterior end of the pharyngotympanic tube become surrounded by bone. The petrous part forms the roof, floor and medial wall of the cavity, while the squamous and tympanic parts, together with the tympanic membrane, form its lateral wall. At birth, the middle and inner ears are adult size, and the tympanic cavity, mastoid antrum, tympanic membrane and auditory ossicles are all almost adult size. The anterior process does not join the malleus until 6 months later. The internal acoustic meatus is approximately 6 mm in horizontal diameter, 4 mm in vertical diameter and 7 mm in length at birth, and the adult diameters are 7.7 mm and 11 mm, respectively.

After birth and apart from general growth, the tympanic ring extends posterolaterally to become cylindrical, growing into a fibrocartilaginous tympanic plate, which forms the adjacent part of the external acoustic meatus at this stage. This growth is not equal but is rapid in the anterior and posterior regions, which meet and blend. Thus, for a time, an opening (foramen of Huschke) exists in the floor; it usually closes at about the fifth year but is sometimes permanent. The external acoustic meatus is relatively as long in children as it is in adults, but the canal is fibrocartilaginous, whereas its medial two-thirds are osseous in adults. Surgical access to the tympanic cavity is via the mastoid antrum, and in children it is necessary to remove only a thin scale of bone in the suprameatal triangle to reach the antrum. The tympanic plate ensheathes the styloid process by posterior extension and extends medially over the petrous bone to the carotid canal.

Initially, the mandibular fossa is shallow, facing more laterally, but it then deepens and ultimately faces downwards. Posteroinferiorly, the squamous part grows down behind the tympanic ring to form the lateral wall of the mastoid antrum. The mastoid part is at first flat, so that the stylomastoid foramen and rudimentary styloid process are immediately behind the tympanic ring. The mastoid part becomes invaded by air cells, especially at puberty. The lateral mastoid region grows downwards and forwards to form the mastoid process, which means that the styloid process and stylomastoid foramen become inferior. Descent of the foramen lengthens the facial canal. The mastoid process is not perceptible until late in the second year; consequently, the facial nerve is relatively superficial and susceptible to damage during surgical exploration during this period. The subarcuate fossa gradually fills and is almost obliterated.

In the neonate, the petrous and squamous parts of the temporal bone are usually partially separated by the petrosquamous fissure, which opens directly into the mastoid antrum of the middle ear. Rarely, the fissure closes in infants during the first year, but it sometimes remains unclosed up to the age of 19 years and can be a route for the spread of infection from the middle ear to the meninges. There is a bimodal growth pattern in the lateral surface dimensions of the temporal bone in children; marked increases in dimension take place from birth to the age of 4 years but little growth is seen between the ages of 4 and 20 years (Simms and Neely 1989). The neonatal pharyngotympanic tube (Eustachian tube) is about half the length of its adult counterpart. Its opening from the middle ear cavity is as large as it is in the adult but the pharyngeal opening in the nasal part of the pharynx is relatively smaller. The course of the pharyngotympanic tube is horizontal in the newborn, whereas in the adult it passes from the middle ear downwards, forwards and medially.

EXTERNAL EAR

The external ear consists of the auricle (pinna) and the external acoustic meatus. The auricle projects to a variable and individual degree from the side of the head. It collects sound waves and conducts them along the external acoustic meatus inwards towards the ear drum, the tympanic membrane. The auricle thus acts as the first element of a series of stimulus modifiers in the auditory apparatus.

Auricle (pinna)

The lateral surface of the auricle is irregularly concave, faces slightly forwards, and displays numerous eminences and depressions (Fig. 42.3). It has a prominent curved rim, the helix. This usually bears a small tubercle posterosuperiorly, Darwin's tubercle, which is quite pronounced during postmenstrual weeks 21–24. The antihelix is a curved prominence, parallel and anterior to the posterior part of the helix; it divides above into two crura that flank a depressed triangular fossa. The curved depression between the helix and antihelix is the scaphoid fossa. The antihelix encircles the deep, capacious concha of the auricle, which is incompletely divided by the crus or anterior end of the helix. The conchal area above this, the cymba conchae, overlies the suprameatal triangle of the temporal bone, which can be felt through it, and which overlies the mastoid

antrum. The tragus is a small curved flap below the crus of the helix and in front of the concha; it projects posteriorly, partly overlapping the meatal orifice. The antitragus is a small tubercle opposite the tragus and is separated from it by the intertragic incisure or notch. Below it is the lobule, composed of fibrous and adipose tissues. It is soft, unlike the majority of the auricle, which is firm and is supported by elastic cartilage. The cranial surface of the auricle presents elevations that correspond to the depressions on its lateral surface and after which they are named (e.g. eminentia conchae, eminentia fossae triangularis).

At birth, most of the linear dimensions of the auricle are approximately three-quarters of their adult size; the length and height of the tragus are less than half of their adult size. Width dimensions mature between the ages of 5 and 11 years; length dimensions mature between 12 and 16 years (Purkait 2013).

Common congenital anomalies

Developmental anomalies of the branchial arches may produce a grossly misshapen or microtic auricle, sometimes with associated anomalies of the middle ear and significant hearing loss. Deformity of the auricle may be the result of hereditary factors, exposure to teratogens or unusual intrauterine positioning. A number of common anomalies have been recognized; they carry descriptive names or eponyms (Porter and Tan 2005) (**Table 42.1**).

Skin

The skin of the auricle continues into the external acoustic meatus to cover the outer surface of the tympanic membrane. It is thin, has no dermal papillae, and is closely adherent to the cartilaginous and osseous parts of the canal; inflammation of the canal skin is very painful because of this firm attachment to the underlying structures. The thick subcutaneous tissue of the cartilaginous part of the meatus contains numerous ceruminous glands that secrete wax, or cerumen. Their coiled tubular structure resembles that of sweat glands. The secretory cells are columnar when active but cuboidal when quiescent; they are covered externally by myoepithelial cells. Ducts open either on to the epithelial surface or into the nearby sebaceous gland of a hair follicle. Cerumen prevents the maceration of meatal skin by trapped water. Antibacterial properties have been attributed to cerumen but the evidence for this is lacking (Campos et al 2000, Pata et al 2003).

Two types of wax, wet and dry, are recognized. They are genetically determined (Yoshiura et al 2006). Overproduction, accumulation or impaction of wax may completely occlude the meatus. This may hinder sound from reaching the tympanic membrane and so restrict its natural vibration. Although ceruminous glands and hair follicles are largely limited to the cartilaginous meatus, a few small glands and fine hairs are also present in the roof of the lateral part of the bony meatus. The warm, humid environment of the relatively enclosed meatal air aids the mechanical responses of the tympanic membrane.

Cartilaginous framework

The auricle is a single thin plate of elastic fibrocartilage covered by skin, its surface moulded by eminences and depressions (Fig. 42.4). It is connected to the surrounding parts by ligaments and muscles, and is continuous with the cartilage of the external acoustic meatus. There is no cartilage in the lobule or between the tragus and the crus of the helix, where the gap is filled by dense fibrous tissue. Anteriorly, where the helix curves upwards, there is a small cartilaginous projection: the spine of the helix. Its other extremity is prolonged inferiorly as the tail of the helix and it is separated from the antihelix by the fissura antitragohelicina (antitragohelicine fissure). The cranial aspect of the cartilage bears the eminentia conchae and eminentia scaphae, which correspond to the depressions on the lateral surface. The two eminences are separated by a transverse furrow, the sulcus antihelicis transversus, which corresponds to the inferior crus of the antihelix on the lateral surface. The eminentia conchae is crossed by an oblique ridge, the ponticulus, for the attachment of auricularis posterior. There are two fissures in the auricular cartilage, one behind the crus of the helix and another in the tragus.

Ligaments

Anterior and posterior extrinsic ligaments connect the auricle with the temporal bone. The anterior ligament extends from the tragus and the spine of the helix to the root of the zygomatic process of the temporal bone. The posterior ligament passes from the posterior surface of the concha to the lateral surface of the mastoid process. Two main intrinsic ligaments connect individual auricular cartilages: a strong fibrous band passes from the tragus to the helix, thereby completing the meatus

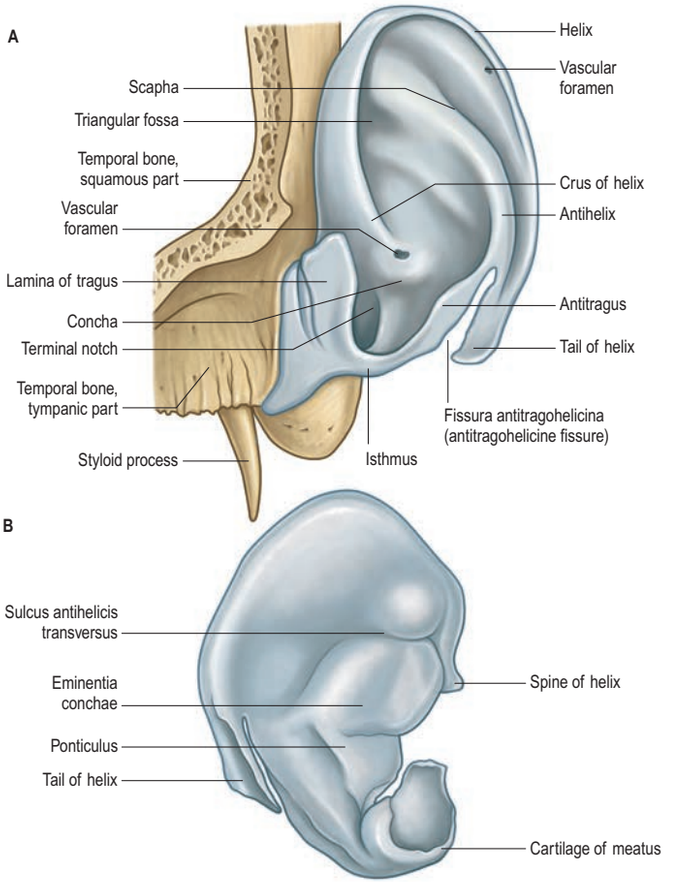

Fig. 42.4 The auricular cartilages of the left ear. **A**, Lateral surface. **B**, Medial surface.

anteriorly and forming part of the boundary of the concha; and another band passes between the antihelix and the tail of the helix. Less prominent bands exist on the cranial aspect of the auricle.

Auricular muscles

Extrinsic auricular muscles connect the auricle to the skull and scalp, and move the auricle as a whole. Intrinsic auricular muscles connect the different parts of the auricle.

Extrinsic muscles

The extrinsic auricular muscles are the auriculares anterior, superior and posterior (Fig. 42.5B). The smallest of the three is auricularis anterior, a thin fan of pale fibres that arise from the lateral edge of the epicranial aponeurosis and converge to attach to the spine of the helix. The largest of the three, auricularis superior, is also thin and fan-shaped, and converges from the epicranial aponeurosis via a thin, flat tendon to attach to the upper part of the cranial surface of the auricle. The auricularis posterior consists of two or three fleshy fasciculi that arise by short aponeurotic fibres from the mastoid part of the temporal bone and insert into the ponticulus on the eminentia conchae.

Vascular supply The arterial supply of the extrinsic auricular muscles is derived mainly from the posterior auricular artery.

Innervation Auriculares anterior and superior are supplied by temporal branches of the facial nerve, and auricularis posterior is supplied by the posterior auricular branch of the facial nerve.

Actions In humans, these muscles have very little obvious effect. Despite the paucity of auricular movement, auditory stimuli may evoke patterned responses from these small muscles and electromyography can detect the 'crossed acoustic response' that was once used to determine objective measurements of auditory threshold levels. It has been superseded in clinical neuro-otology by computer-averaged brainstem evoked response audiometry.

Intrinsic muscles

The intrinsic auricular muscles are helicis major and minor, tragicus, antitragicus, transversus auriculae and obliquus auriculae (Fig.

TABLE 42.1 Common anomalies of the auricle (see Chapter 16)

Anomaly	Structural defect	Figure
Anotia	Complete absence of the auricle. Anotia and microtia may arise consequent to developmental disturbances between postfertilization weeks 6 and 8 (embryonic stages 15–23).	
Cryptotia (Hidden ear, pocket ear)	The upper pole of the auricle is buried beneath the temporal skin	
Microtia	Diminutive ear; this is usually an isolated congenital anomaly but is sometimes associated with recognized syndromes, e.g. fetal alcohol syndrome, maternal diabetic syndrome, thalidomide or isotretinoin exposure

Anomaly	Structural defect	Figure
Polyotia (Mirror ear)	Caused by the persistence of pre-auricular tissue that would normally be included in the auricle; the persistent tissue lies in front of the tragus in the posterior aspect of the cheek	
Stahl's bar ('Satiro's ear', 'lop ear')	Common congenital deformity of the auricle in which the helix is flattened and the upper crus of the antihelix is duplicated. This produces a ridge of cartilage running from the antihelix to the rim of the helix, causing a pointing of the ear and a reversal of the normal concavity of the scaphoid fossa. The upper part of the auricle may flop over	
Prominent ears (Bat ear)	The antihelical fold is either absent or inadequate	

TABLE 42.1 Common anomalies of the auricle (see Chapter 16)—cont'd

Anomaly	Structural defect	Figure
Pre-auricular sinus	The result of failure of fusion of the first and second branchial arches. Clinically, pre-auricular sinuses may become chronically infected and require surgical excision. This may be technically demanding, given the close proximity to the facial nerve and auricular tubercles around the dorsal end of the first branchial cleft. The sinuses may be simple pits or complex branching sinuses that occasionally extend deeply towards the external acoustic meatus so that they lie close to the facial nerve. There is debate as to whether the anomalies are epithelial inclusions between the hillocks or remnants of the first branchial cleft	

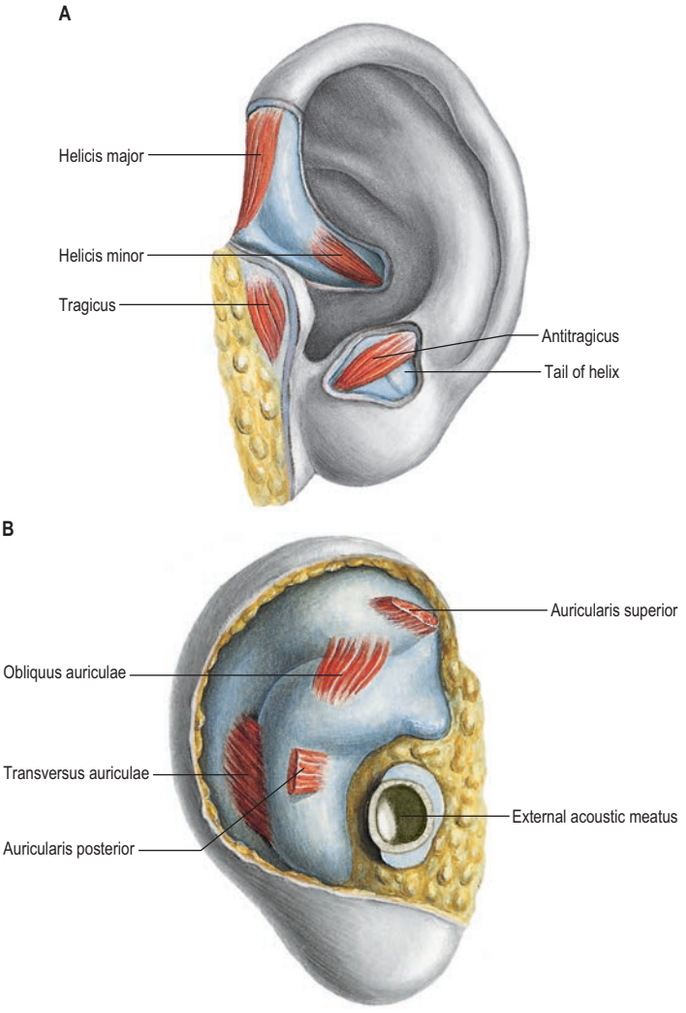

Fig. 42.5 The extrinsic and intrinsic auricular muscles of the left ear. Auricularis anterior is not illustrated. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

42.5A). Helicis major is a narrow vertical band on the anterior margin of the helix, passing from its spine to its anterior border, where the helix is about to curve back. Helicis minor is an oblique fasciculus covering the crus of the helix. Tragicus is a short, flattened, vertical band on the lateral aspect of the tragus. Antitragicus passes from the outer part of the antitragus to the tail of the helix and the antihelix. Transversus auriculae, located on the cranial aspect of the auricle, consists of scattered fibres – partly tendinous, partly muscular, which extend between the eminentia conchae and the eminentia scaphae. Obliquus auriculae, also located on the cranial aspect of the auricle, consists of a few fibres that extend from the upper and posterior parts of the eminentia conchae to the eminentia scaphae.

Vascular supply The intrinsic auricular muscles are supplied by branches of the posterior auricular and superficial temporal arteries.

Innervation The intrinsic auricular muscles on the lateral aspect of the auricle are innervated by the temporal branches of the facial nerve, and those on the cranial aspect of the auricle are innervated by the posterior auricular branch of the facial nerve.

Actions The intrinsic muscles modify auricular shape minimally, if at all, in most human ears: helicis major can draw the auricle forwards and upwards. Rare individuals can modify the shape and position of their external ears.

Vascular supply and lymphatic drainage

Arteries The superficial temporal and posterior auricular arteries provide the blood supply to the auricle. Each has three to five branches contribute to a helical rim arcade that ensures a good arterial blood supply to potential watershed areas. The posterior auricular artery gives off three to seven branches that run radially along the posterior side of the auricular cartilage to the helical rim, where they connect with the helical rim arcade. It also gives off two to four perforating branches that pierce the auricular cartilage to reach the anterior surface of the auricle at the base of the helical root and at the cavum conchae near the antitragus. They supply the anterior surface of the auricle, part of the external acoustic meatus and contribute to the helical rim arcade (Zilinsky et al 2017). This rich anastomotic network of vessels at the helical rim provides a solid basis for reconstructive surgical strategies.

Veins Auricular veins correspond to the arteries of the auricle. Arteriovenous anastomoses are numerous in the skin of the auricle and are thought to be important in the regulation of core temperature.

Lymphatic drainage The posterior aspect of the auricle drains to nodes at the mastoid tip. The tragus and upper part of the auricle drain into pre-auricular nodes, while the remainder of the auricle drains to upper deep cervical lymph nodes.

Innervation

The sensory innervation of the auricle is complex and not fully determined. This is perhaps because the external ear represents an area where skin originally derived from a branchial region meets skin originally derived from a postbranchial region. The sensory nerves involved are the great auricular nerve, which supplies most of the cranial surface and the posterior part of the lateral surface (helix, antihelix, lobule); the lesser occipital nerve, which supplies the upper part of the cranial surface; the auricular branch of the vagus, which supplies the concavity of the concha and posterior part of the eminentia; the auriculotemporal nerve, which supplies the tragus, crus of the helix and the adjacent part of the helix; and the facial nerve, which, together with the auricular branch of the vagus, probably supplies small areas on both aspects of the auricle, in the depression of the concha and over its eminence. The details of the cutaneous innervation derived from the facial nerve require further clarification. It is possible that, as the auricular branch of the vagus traverses the temporal bone and crosses the facial canal, approximately 4 mm above the stylomastoid foramen, it contributes an ascending branch to the facial nerve and that, in this way, fibres of the vagus are carried via the facial nerve to the auricle.

External acoustic meatus

The external acoustic meatus extends from the concha to the tympanic membrane; it is approximately 2.5 cm from the floor of the concha and approximately 4 cm from the tragus. It has two structurally different parts: its lateral third is cartilaginous, and its medial two-thirds is osseous (Fig. 42.6). It forms an S-shaped curve, directed at first medially, anteriorly and slightly up (pars externa), then posteromedially and up (pars media), and lastly anteromedially and slightly down (pars interna). It is oval in section; its greatest diameter is obliquely inclined posteroinferiorly at the external orifice but is nearly horizontal at its medial end. There are two constrictions: one near the medial end of the cartilaginous part, and the other, the isthmus, in the osseous part about 2 cm from the bottom of the concha. The tympanic membrane, which closes its medial end, is obliquely set, which means that the floor and the anterior wall of the meatus are longer than its roof and posterior wall.

The lateral, cartilaginous part is approximately 8 mm long. It is continuous with the auricular cartilage and attached by fibrous tissue to the circumference of the osseous part. The meatal cartilage is deficient posterosuperiorly, and the gap is occupied by a sheet of collagen. Two or three deep fissures (of Santorini) exist in its anterior part. Tumours of the external acoustic meatus escape the confines of the canal through these fissures and spread into the adjacent soft tissues; the extent of these fissures, which are subject to individual variation, influence outcomes by accelerating the spread of the tumour into the soft tissue of skull base.

The osseous part is approximately 16 mm long and is narrower than the cartilaginous part. In sagittal section, it is oval or elliptical, and it is directed anteromedially and slightly downwards, with a slight posterosuperior convexity. Its medial end is smaller than the lateral end and it terminates obliquely. The anterior wall projects medially approximately 4 mm beyond the posterior and is marked, except above, by a narrow tympanic sulcus or anulus, to which the perimeter of the tympanic membrane is attached. Its lateral end is dilated and mostly rough for the attachment of the meatal cartilage. The anterior, inferior and most of the posterior parts of the osseous meatus are formed by the tympanic

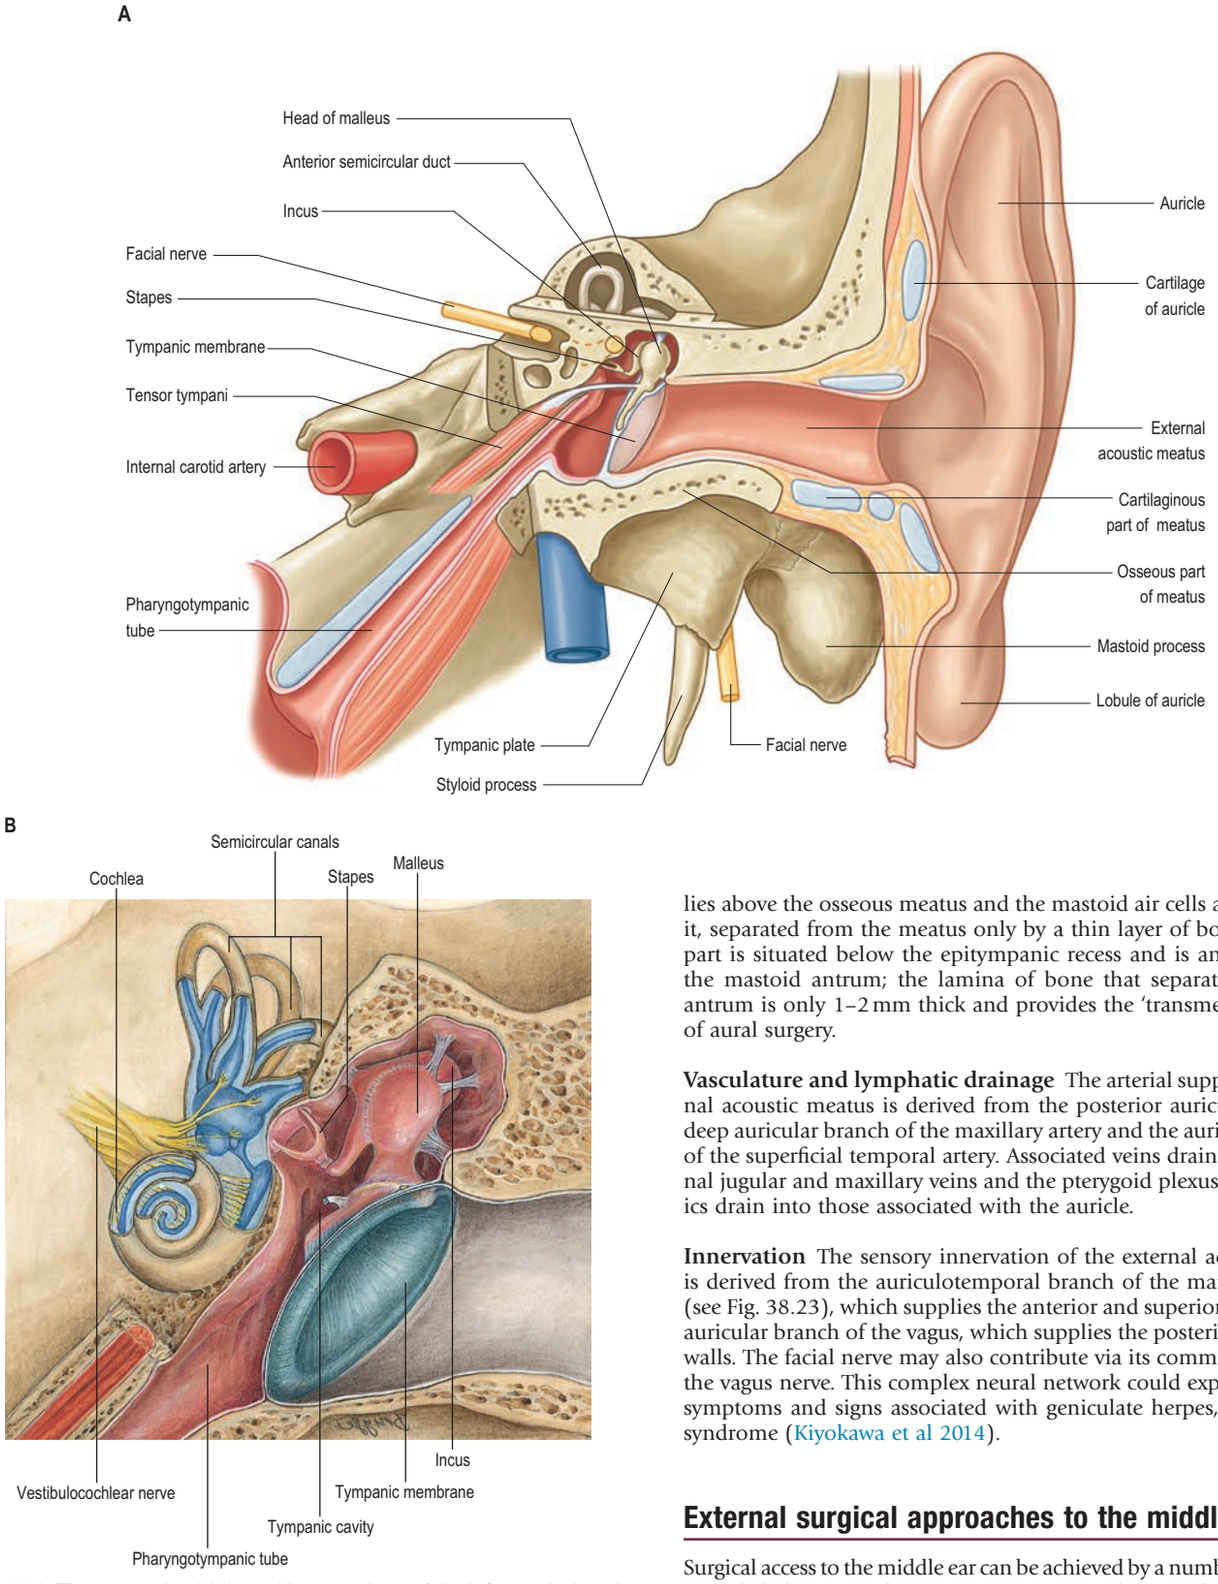

Fig. 42.6 The external, middle and inner regions of the left ear. **A**, Anterior aspect. **B**, A more detailed view of the relationships of structures in the middle and inner ear. (B, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

plate of the temporal bone, which in the fetus is only a tympanic ring. The posterosuperior region is formed by the squamous part of the temporal bone. The outer wall of the meatus is bounded above by the posterior zygomatic root, below which there may be a suprameatal spine.

Relations of the meatus The condylar process of the mandible lies anterior to the meatus and is partially separated from the cartilaginous part by a small portion of the parotid gland. A blow on the chin may cause the condyle to break into the meatus. The middle cranial fossa lies above the osseous meatus and the mastoid air cells are posterior to it, separated from the meatus only by a thin layer of bone. Its deepest part is situated below the epitympanic recess and is anteroinferior to the mastoid antrum; the lamina of bone that separates it from the antrum is only 1–2 mm thick and provides the 'transmeatal approach' of aural surgery.

Vasculature and lymphatic drainage The arterial supply of the external acoustic meatus is derived from the posterior auricular artery, the deep auricular branch of the maxillary artery and the auricular branches of the superficial temporal artery. Associated veins drain into the external jugular and maxillary veins and the pterygoid plexus. The lymphatics drain into those associated with the auricle.

Innervation The sensory innervation of the external acoustic meatus is derived from the auriculotemporal branch of the mandibular nerve (see Fig. 38.23), which supplies the anterior and superior walls, and the auricular branch of the vagus, which supplies the posterior and inferior walls. The facial nerve may also contribute via its communication with the vagus nerve. This complex neural network could explain the varied symptoms and signs associated with geniculate herpes, Ramsay Hunt syndrome (Kiyokawa et al 2014).

External surgical approaches to the middle ear

Surgical access to the middle ear can be achieved by a number of methods. Provided the external acoustic meatus is wide enough, the tympanic membrane can be elevated by incising the skin of the bony meatus circumferentially, leaving a vascular pedicle superiorly. The canal skin is then elevated from the underlying bone until the fibrous anulus of the tympanic membrane is visualized. This can then be elevated from the tympanic groove and the middle ear mucosa incised to allow the tympanic membrane to be reflected forwards and upwards. This per-meatal approach is called a tympanotomy and is used for stapedectomy, ossiculoplasty, myringoplasty and the removal of small middle-ear tumours: today, many of these procedures are undertaken endoscopically.

If the external acoustic meatus is too narrow to allow adequate visualization of the middle ear, or if access is required to the mastoid aditus and antrum, it is necessary to displace the superficial soft tissues. There are two main external approaches to the middle ear: the endaural approach and the postauricular approach.

The endaural approach involves making an incision in the notch between the tragus and the helix. This is carried down to expose the lower margin of temporalis muscle and the bone of the external acoustic meatus. The cartilaginous meatus is separated from the bony meatus and reflected laterally as a conchomeatal flap. The bony meatus can then be widened by drilling away bone (canalplasty). This gives more space to manipulate the delicate structures of the middle ear, as well as improving subsequent visualization of the tympanic membrane when the incision has healed.

The postauricular approach involves making an incision approximately 1 cm behind the postauricular skin crease and deepening the incision to the periosteum of the mastoid process, dividing the posterior auricular muscles on the way. Grafts can be harvested from the temporalis fascia. The periosteum is incised and elevated to expose the bony external acoustic meatus from behind. The skin over the junction of the bony and cartilaginous meatus is incised to allow the cartilage of the auricle and meatus to be swung forwards on its blood supply and so expose the bony meatus and mastoid process. Access can then be gained by drilling and elevating a tympanomeatal skin flap, as described for the endaural approach.

Temporalis fascia is the most popular tissue used as a free graft for repair of the tympanic membrane because it is easily obtained. In recent years, tragal perichondrium has become a popular alternative; it has the additional advantage that the cartilage can also be harvested and used to reinforce the repair.

More extensive resections of the temporal bone are undertaken using extended pre- or postauricular incisions into the temporal region and neck. The blood supply of the auricle is sufficient to maintain viability despite significant elevation and undermining.

MIDDLE EAR

The middle ear is an irregular, laterally compressed space in the petrous part of the temporal bone. It is lined with mucous membrane and filled with air, which reaches it from the nasopharynx via the pharyngotympanic tube (see Fig. 42.6; Fig. 42.7). The middle ear contains three small bones – the malleus, incus and stapes, collectively called the auditory ossicles – which form an articulated chain connecting the lateral and medial walls of the cavity, and which transmit the vibrations of the tympanic membrane across the cavity to the cochlea.

The essential function of the middle ear is to transfer energy efficiently from relatively weak vibrations in the elastic, compressible air in the external acoustic meatus to the incompressible fluid around the delicate receptors in the cochlea. Mechanical coupling between the two systems must match their resistance to deformation or 'flow', i.e. their impedance, as closely as possible. Aerial waves of low amplitude and low force per unit area arrive at the tympanic membrane, which has 15–20 times the area of the stapedial footplate that contacts the perilymph in the inner ear; the force per unit area generated by the footplate is increased by a similar amount, while the amplitude of vibration is almost unchanged.

Protective mechanisms incorporated into the design of the middle ear include the presence of the pharyngotympanic tube (to equalize pressure on both sides of the delicate tympanic membrane); the shape of the articulations between the ossicles; and the reflex contractions of stapedius and tensor tympani in response to sounds of fairly high intensity (preventing damage caused by sudden or excessive excursions of the ossicles).

The space within the middle ear can be subdivided into three parts. These are the mesotympanum or tympanic cavity proper, which is opposite the tympanic membrane; the epitympanum or attic, which is above the level of the membrane, and contains the head of the malleus and the body and short process of the incus; and the hypotympanum, which is in the floor of the cavity between the jugular bulb and the lower margin of the tympanic membrane. The vertical and anteroposterior diameters of the mesotympanum and hypotympanum are each approximately 15 mm; the transverse diameter is 6 mm superiorly and 4 mm inferiorly, narrowing to 2 mm opposite the umbo. The cavity is bounded laterally by the tympanic membrane and medially by the lateral wall of the internal ear, the promontory. It communicates posteriorly with the mastoid antrum and the mastoid air cells, and anteriorly with the nasopharynx via the pharyngotympanic tube (see Fig. 42.6).

The tympanic cavity and mastoid antrum, auditory ossicles and structures of the internal ear are all almost fully developed at birth and subsequently alter little; almost all of the volume changes are due to expansion of the epitympanic space (Osborn et al 2011). In the fetus, the cavity contains a gelatinous tissue that has practically disappeared by birth, when it is filled by a fluid that is absorbed when air enters via the pharyngotympanic tube. The tympanic cavity is a common site of infection in childhood.

Boundaries of the tympanic cavity

The tympanic cavity has a roof, a floor and lateral, medial, posterior and anterior walls. The sections that follow describe the bony anatomy of the middle ear. The mucosal lining has been well documented from an anatomical and functional standpoint (Gleeson et al 1991). With the advent of middle ear endoscopy in the live patient at surgery, finer detail of the mucosal folds within the middle ear cavity have been documented in a way never possible before. In future, the role of these folds will become apparent in both health and disease (Marchioni et al 2013, Nogueira et al 2013, Tarabichi et al 2013, Li et al 2018).

Roof

A thin plate of compact bone, the tegmen tympani, separates the cranial and tympanic cavities, and forms much of the anterior surface of the petrous temporal bone. It is prolonged posteriorly as the roof of the mastoid antrum and anteriorly it covers the canal for tensor tympani. In youth, the unossified petrosquamosal suture may allow the spread of infection from the tympanic cavity to the meninges. In adults, veins from the tympanic cavity traverse this suture to reach the superior petrosal or petrosquamous sinus and thus may also transmit infection to these structures through a process of thrombophlebitis.

Longitudinal fractures of the middle cranial fossa almost always involve the tympanic roof, accompanied by dislocation of the ossicular chain, rupture of the tympanic membrane, or a fractured roof of the osseous external acoustic meatus, which can be seen as a notch on otoscopy. Such injuries usually cause bleeding from the ear, with escape of cerebrospinal fluid if the dura mater has been torn (CSF otorrhoea).

Floor

The floor of the tympanic cavity is a narrow, thin, convex plate of bone that separates the cavity from the superior bulb of the internal jugular vein. The bone may be patchily deficient, in which case the tympanic cavity and the vein are separated only by mucous membrane and fibrous tissue. Alternatively, the floor is sometimes thick and may contain some accessory mastoid air cells. A small aperture for the tympanic branch of the glossopharyngeal nerve lies near the medial wall.

Lateral wall

The lateral wall consists mainly of the tympanic membrane but also contains the ring of bone to which the membrane is attached. The lateral epitympanic bony wall is wedge-shaped in section and its sharp inferior portion is known as the outer attic wall or scutum. This part is easily eroded or blunted by cholesteatoma, a feature easily detected on computed tomography (CT) scans. There is a deficiency or notch in the upper part of this ring, close to which are the small openings of the anterior and posterior canaliculi for the chorda tympani and the petrotympanic fissure. The posterior canaliculus for the chorda tympani is situated in the angle between the posterior and lateral walls of the tympanic cavity just behind the tympanic membrane, at a variable position approximately level with the upper end of the handle of the malleus. This variable position or entrance into the tympanic cavity should be kept in mind when mobilizing the chorda tympani in stapes surgery. It may not reflect inferiorly to the extent desired and can be easily damaged in the process. Within the mastoid, the chorda tympani passes into a minute canal that descends in front of the facial canal and ends in it about 6 mm above the stylomastoid foramen. This canal and the chorda tympani should not be mistaken for the main trunk of the facial nerve when skeletonizing the facial (Fallopian) canal during surgery. The canaliculus transmits the chorda tympani and a branch of the stylomastoid artery to the tympanic cavity. The chorda tympani leaves the tympanic cavity through the anterior canaliculus, which opens at the medial end of the petrotympanic fissure.

The petrotympanic fissure is a mere slit approximately 2 mm in length, which opens just above and in front of the ring of bone to which the tympanic membrane is attached. It contains the anterior process and anterior ligament of the malleus and transmits the anterior tympanic branch of the maxillary artery to the tympanic cavity.

Tympanic membrane

The tympanic membrane separates the tympanic cavity from the external acoustic meatus (Fig. 42.8; see Fig. 42.6). It is thin, semi-transparent and almost oval, though somewhat broader above than below. It lies obliquely, at an angle of approximately 55° with the meatal floor in adults. Its longest, anteroinferior diameter is 9–10 mm, and its shortest is 8–9 mm. Most of its circumference is a thickened fibrocartilaginous ring or anulus, which is attached to the tympanic sulcus at the medial end of the meatus. The anulus contains radially orientated smooth muscle cells in several locations that possibly play a role in controlling blood flow or maintaining tension (Henson et al 2005). The sulcus is deficient superiorly, i.e. it is notched. Two bands, the anterior and posterior malleolar folds, pass from the ends of this notch to the lateral process of the malleus. The small triangular part of the membrane, the pars flaccida, lies above these folds and is lax and thin. The major part of the tympanic membrane, the pars tensa, is taut. The handle of the malleus is firmly attached to the internal surface of the tympanic membrane as far as its centre, which projects towards the tympanic cavity. The inner surface of the membrane is thus convex and the point of greatest convexity is termed the umbo. Although the membrane as a whole is convex on its inner surface, its radiating fibres are curved with their concavities directed inwards.

Microstructure

Histologically, the tympanic membrane is composed of an outer cuticular layer, an intermediate fibrous layer and an inner mucous layer.

The cuticular stratum is continuous with the thin skin of the meatus. It is keratinized, stratified squamous in type, devoid of dermal papillae and hairless. Its subepithelial tissue is vascularized and may develop a few peripheral papillae. Ultrastructurally, it is typically 10 cells thick and has two zones: a superficial layer of non-nucleated squames, and a deep zone that resembles the epidermal prickle cell layer (stratum spinosum). There are numerous desmosomes between cells, the deepest of which lie on a continuous basal lamina but lack epithelial pegs and hemidesmosomes. The cells of this stratum have a propensity for lateral migration and differentiation not shared with any other stratified squamous epithelia in the body.

The fibrous stratum consists of an external layer of radiating fibres that diverge from the handle of the malleus, and a deep layer of circular fibres, which are plentiful peripherally but sparse and scattered centrally. Ultrastructurally, the filaments are 10 nm in diameter and are linked at 25 nm intervals. They have a distinctive amino acid composition and may consist of a protein peculiar to the tympanic membrane. Small groups of collagen fibrils appear at 11 postmenstrual weeks, interspersed with small bundles of elastin microfibrils. Older specimens contain more typically cross-banded collagen fibrils and an amorphous elastin component. The fibrous stratum is replaced by loose connective tissue in the pars flaccida.

The mucous stratum is a part of the mucosa of the tympanic cavity and is thickest near the upper part of the membrane. It consists of a single layer of very flat cells, with overlapping interdigitating boundaries and desmosomes and tight junctions between adjacent cells. The cytoplasm contains only a few organelles; the luminal surfaces of these apparently metabolically inert cells have a few irregular microvilli and are covered by an amorphous electron-dense material. There are no ciliated columnar cells.

Innervation

The tympanic membrane is mainly innervated by the auriculotemporal nerve and appears to perceive only pain. There is a minor, inconstant and overlapping sensory supply from the facial, glossopharyngeal and vagus nerves.

The auricular branch of the vagus arises from the superior vagal ganglion and is joined soon after by a ramus from the inferior ganglion of the glossopharyngeal nerve. It passes behind the internal jugular vein and enters the mastoid canaliculus on the lateral wall of the jugular fossa. It traverses the temporal bone and crosses the facial canal about 4 mm above the stylomastoid foramen. At this point, it supplies an ascending branch to the facial nerve. Fibres of the nervus intermedius may pass to the auricular branch of the vagus here, which may explain the cutaneous vesiculation that sometimes accompanies geniculate herpes. The auricular branch then traverses the tympanomastoid fissure and divides into two rami. One ramus joins the posterior auricular nerve and the other is distributed to the skin of part of the cranial surface of the auricle, the posterior wall and floor of the external acoustic meatus, and to the adjoining part of the outer surface of the tympanic membrane. The auricular branch therefore contains somatic afferent nerve fibres, which probably terminate in the spinal trigeminal nucleus. Stimulation of the vagus nerve, e.g. in syringing the ear, can cause a reflex bradycardic reaction on heart rate. From a practical point of view, the tympanic membrane can be anaesthetized for minor procedures like myringotomy by the application of topical anaesthetic agents. For more complicated surgical procedures, e.g. tympanoplasty, it is possible to provide sufficient anaesthesia by local infiltration at the level of the bony and cartilaginous external acoustic meatus.

Otitis media

It is assumed that acute otitis media usually arises as a result of ascending infection from the nasopharynx via the pharyngotympanic tube to the middle ear cleft. From there, it may extend to the mastoid aditus and antrum. Swelling secondary to the infection may result in the closure of both exits from the middle ear, i.e. the pharyngotympanic tube and the aditus, with subsequent accumulation of pus under pressure, which causes lateral bulging and inflammation of the tympanic membrane. The latter may burst, releasing mucopurulent discharge into the external acoustic meatus, which results in a release of the pressure in the middle ear and a diminution in the levels of pain. After a brief period, the discharge dries up and, for the most part, the resultant perforation of the tympanic membrane heals. Normal ventilation and drainage of mucus from the middle ear are restored once the swelling and function of the pharyngotympanic tube resolve. On occasion, the process will fail to produce a perforation of the tympanic membrane and the inflammatory exudates will not drain. The immune defence system sterilizes the exudates of organisms, resulting in a sterile mucoid effusion, otitis media with effusion or glue ear (see below). The effusion may cause protracted deafness because its relatively incompressible nature prevents free vibration of the tympanic membrane (Bluestone and Klein 2002).

Myringoplasty

Persistent perforation of the tympanic membrane caused by infection or trauma leads to hearing impairment and predisposes to continuing infection as a result of contamination with organisms from the external acoustic meatus. This condition is known as chronic suppurative otitis media of the tubotympanic type. Myringoplasty is a surgical procedure that uses a connective tissue scaffold or graft to support healing of the perforation. The most common technique involves the elevation of the tympanic anulus and the placement of a piece of fibrous connective tissue, e.g. part of the fibrous deep fascia that invests the lateral surface of temporalis or the perichondrium of the tragal cartilage, on to the undersurface of the tympanic membrane to close the perforation. The healed

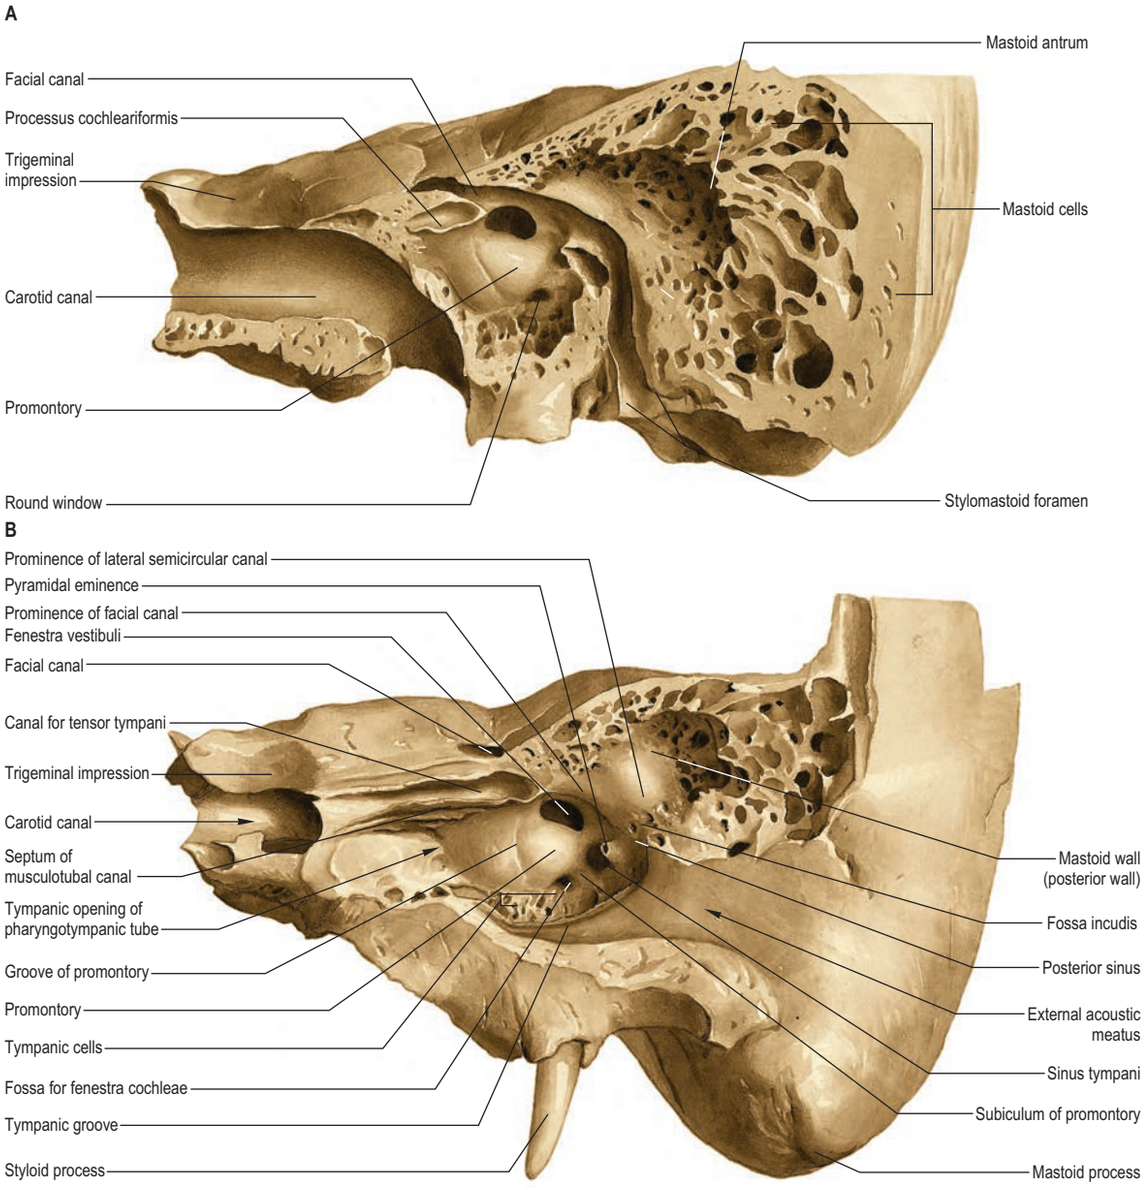

Fig. 42.9 The medial wall of the left tympanic cavity, anterolateral aspect. **A**, The lateral wall and adjacent parts of the anterior and superior walls have been removed; the facial canal and carotid canal have been opened. **B**, A section along the axis of the petrous part of the temporal bone. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

edges of the perforation are stripped of epithelium to encourage healing and scar formation. The fibrous tissue supports the healing tympanic membrane and may, in part, be incorporated into the repair. Once the perforation is healed, the vibratory function of the tympanic membrane is usually restored to normal.

Medial wall

The medial wall of the tympanic cavity is also the lateral boundary of the internal ear. Its features are the promontory, fenestra vestibuli (fenestra ovalis, oval window), fenestra cochleae (fenestra rotunda, round window) and the facial prominence (Fig. 42.9).

The promontory is a rounded prominence furrowed by small grooves that lodge the nerves of the tympanic plexus. It lies over the lateral projection of the basal turn of the cochlea. A minute spicule of bone frequently connects the promontory to the pyramidal eminence of the posterior wall. The apex of the cochlea lies near the medial wall of the tympanic cavity, anterior to the promontory. A depression behind the promontory is known as the sinus tympani.

The fenestra vestibuli is a kidney-shaped opening situated above and behind the promontory and leading from the tympanic cavity to the vestibule of the inner ear. Its long diameter is horizontal and its convex border is directed upwards. It is occupied by the base of the stapes, the footplate; the circumference of the footplate is attached to the margin of the fenestra by an anular ligament.

The fenestra cochleae is situated below and a little behind the fenestra vestibuli, from which it is separated by a posterior extension of the promontory, called the subiculum. Occasionally, another ridge of bone, the ponticulus, leaves the promontory above the subiculum and runs to the pyramid on the posterior wall of the cavity. The fenestra cochleae lies completely under the overhanging edge of the promontory in a deep hollow or niche, and is placed very obliquely. In dried specimens, it opens anterosuperiorly from the tympanic cavity into the scala tympani of the cochlea, but in life it is closed by the secondary tympanic membrane. This is somewhat concave towards the tympanic cavity and convex towards the cochlea. It is bent so that its posterosuperior third forms an angle with its anteroinferior two-thirds. The membrane is composed of an external layer derived from the tympanic mucosa; an internal layer, derived from the cochlear lining membrane; and an intermediate, fibrous layer.

The prominence of the facial nerve canal indicates the position of the upper part of the bony facial (Fallopian) canal, which contains the facial nerve. The canal crosses the medial tympanic wall from the cochleariform process anteriorly, runs just above the fenestra vestibuli, and then curves down into the posterior wall of the cavity. Its lateral wall may be partly deficient.

Posterior wall

The posterior wall of the tympanic cavity is wider above than below. Its main features are the aditus to the mastoid antrum, the pyramid and the fossa incudis (see Fig. 42.9).

The aditus to the mastoid antrum is a large irregular aperture that leads back from the epitympanic recess into the upper part of the mastoid antrum. A rounded eminence on the medial wall of the aditus, above and behind the prominence of the facial nerve canal, corresponds to the position of the lateral semicircular canal.

The pyramidal eminence is situated just behind the fenestra vestibuli and in front of the vertical part of the facial nerve canal. It is hollow and contains the stapedius muscle. Its summit projects towards the fenestra vestibuli and is pierced by a small aperture that transits the tendon of stapedius. The cavity in the pyramidal eminence is prolonged down and back in front of the facial nerve canal; it communicates with the canal by an aperture through which a small branch of the facial nerve passes to stapedius.

The fossa incudis is a small depression in the lower and posterior part of the epitympanic recess. It contains the short process of the incus, which is fixed to the fossa by ligamentous fibres.

Mastoid antrum

The mastoid antrum is an air sinus in the petrous part of the temporal bone. Its topographical relations are of considerable surgical importance. The aditus to the mastoid antrum, which leads back from the epitympanic recess, opens in the upper part of its anterior wall. The lateral semicircular canal lies medial to the aditus. The descending part of the facial nerve canal is anteroinferior. The medial wall is related to the posterior semicircular canal. The sigmoid sinus lies some distance posteriorly; the distance can be extremely variable and is dependent on the degree of pneumatization of the mastoid. The roof is formed by the tegmen tympani, and so the antrum lies below the middle cranial fossa and the temporal lobe of the brain. The floor has several openings that communicate with the mastoid air cells. The lateral wall, which offers the usual surgical approach to the cavity, is formed by the postmeatal process of the squamous part of the temporal bone. This is only 2 mm thick at birth but increases at an average rate of 1 mm a year, attaining a final thickness of 12–15 mm. In adults, the lateral wall of the antrum corresponds to the suprameatal triangle (Macewen's triangle) on the outer surface of the skull. This is palpable through the cymba conchae. The superior side of the triangle, the supramastoid crest, is level with the floor of the middle cranial fossa; the anteroinferior side, which forms the posterosuperior margin of the external acoustic meatus, indicates approximately the position of the descending part of the facial nerve canal; and the posterior side, formed by a posterior vertical tangent to the posterior margin of the external acoustic meatus, is anterior to the sigmoid sinus.

The adult capacity of the mastoid antrum is variable, but on average is 1 ml, with a general diameter of 10 mm. Unlike the other air sinuses in the skull, it is present at birth, and indeed is then almost adult in size, although it is at a higher level relative to the external acoustic meatus than it is in adults. In the very young, the thinness of the lateral antral wall and the absence or underdevelopment of the mastoid process mean that the stylomastoid foramen and emerging facial nerve are very superficially situated.

Mastoid air cells

Though the mastoid antrum is well developed at birth, the mastoid air cells are merely minute antral diverticula at this stage. As the mastoid develops in the second year, the air cells gradually extend into it and by the fourth year they are well formed, although their greatest growth occurs at puberty. They vary considerably in number, form and size. Usually, they interconnect and are lined by a mucosa with squamous non-ciliated epithelium, continuous with that in the mastoid antrum and tympanic cavity. They may fill the mastoid process, even to its tip, and some may be separated from the sigmoid sinus and posterior cranial fossa only by extremely thin bone, which is occasionally deficient (see Fig. 42.9). Some may lie superficial to, or even behind, the sigmoid sinus, and others may be present in the posterior wall of the descending part of the facial nerve canal. Those in the squamous part of the temporal bone may be separated from deeper cells in the petrous part by a plate of bone in the line of the squamomastoid suture (Körner's septum). Sometimes, they extend only minimally into the mastoid process, in which case the process consists largely of dense bone or trabecular bone containing bone marrow. Varieties of the mastoid process are recognized. The three types most commonly described are pneumatized (with many air cells); sclerotic or diploic (with few or no air cells); and mixed (contain both air cells and bone marrow).

The mastoid process may sometimes have no air cells at all. Alternatively, air cells may extend beyond the mastoid process into the squamous part of the temporal bone above the supramastoid crest; into the posterior root of the zygomatic process of the temporal bone; into the osseous roof of the external acoustic meatus just below the middle cranial fossa; or into the floor of the tympanic cavity very close to the superior jugular bulb. Rarely, a few may excavate the jugular process of the occipital bone. An important group may extend medially into the petrous part of the temporal bone, even to its apex, and are related to the pharyngotympanic tube, carotid canal, labyrinth and abducens nerve. Some investigators maintain that these are not continuous with the mastoid cells but grow independently from the tympanic cavity. All of these extensions of the mastoid air cells are pathologically important since infection may spread to the structures around them. (For further reading on the mastoid air cells and other pneumatized regions of the temporal bone, see Allam (1969)).

Innervation. The mastoid air cells are innervated by a meningeal branch of the mandibular division of the trigeminal nerve.

Mastoiditis

Mastoiditis is a potentially dangerous, life-threatening condition that develops as a result of the spread of bacterial infection from the tympanic cavity via the aditus to the mastoid antrum and associated mastoid air cells. Occasionally, the infection may spread through the tegmen tympani to the dura mater of the middle cranial fossae, to cause meningitis or a temporal lobe abscess. Similar spread may be seen into the posterior cranial fossa and cerebellum.

Infection may spread laterally through the cortical bone of the lateral aspect of the mastoid process to form a subperiosteal postauricular abscess (Bezold's abscess), or through the cortical bone of the tip of the mastoid process to the attachment of the posterior belly of digastric and sternocleidomastoid, which stimulates painful muscular contraction and torticollis.

Anterior wall

The inferior, larger area of the anterior wall of the tympanic cavity is narrowed by the approximation of the medial and lateral walls of the cavity (see Fig. 42.6). It is a thin lamina and forms the posterior wall of the carotid canal. It is perforated by the superior and inferior caroticotympanic nerves and the tympanic branch or branches of the internal carotid. The canals for tensor tympani and the osseous part of the pharyngotympanic tube open above it, the canal for tensor tympani being superior to that for the pharyngotympanic tube. Both canals incline downwards and anteromedially, to open in the angle between the squamous and petrous parts of the temporal bone, and are separated by a thin, osseous septum. The canal for tensor tympani and the bony septum runs posterolaterally on the medial tympanic wall and ends immediately above the fenestra vestibuli. Here, the posterior end of the septum is curved laterally to form a pulley, the processus cochleariformis (cochleariform process), which is a surgical landmark for the identification of the geniculate ganglion of the facial nerve. The tendon of tensor tympani turns laterally over the pulley before attaching to the upper part of the handle of the malleus.

Pharyngotympanic tube blockage in children

The pharyngotympanic tube serves to ventilate the middle ear, exchanging nasopharyngeal air with the air in the middle ear, which has been altered in its composition via transmucosal gas exchange with the haemoglobin in the blood vessels of the mucosa. The tube also carries mucus from the middle ear cleft to the nasopharynx as a result of ciliary transport.

In children, the pharyngotympanic tube is relatively narrow. It is prone to obstruction when the mucosa swells in response to infection or allergic challenge; obstruction results in a relative vacuum being created in the middle ear secondary to transmucosal gas exchange, and this in turn promotes mucosal secretion and the formation of a middle ear effusion. Because of the collapsibility of the pharyngotympanic tube, the vacuum thus created can overcome the distending effect of the muscles of the tube and 'lock' the tube shut. The resultant persistent middle ear effusion, otitis media with effusion (glue ear), can cause

hearing loss by splinting the tympanic membrane and impeding its vibration. It can also provide an ideal environment for the proliferation of bacteria, with the result that an acute otitis media may develop (see above). It is possible to relieve the vacuum and unlock the tube, and then remove the effusion by myringotomy, i.e. by surgically creating a hole in the tympanic membrane. This hole will generally heal rapidly, and it is common practice to insert a flanged ventilation tube (a grommet or tympanostomy tube) to keep the hole open. Migration of the outer squamous layer of the tympanic membrane eventually displaces the tube and the myringotomy heals.

Auditory ossicles

A chain of three mobile ossicles – the malleus, incus and stapes – transfers sound waves across the tympanic cavity from the tympanic membrane to the fenestra vestibuli. The malleus is attached to the tympanic membrane, and the base (footplate) of the stapes is attached to the rim of the fenestra vestibuli. The incus is suspended between them and articulates with both bones.

Malleus

The malleus is the largest of the ossicles and is shaped somewhat like a mallet (Fig. 42.10). It is 8–9 mm long and has a head, neck, handle (manubrium) and anterior and lateral processes. The head is the large upper end of the bone and is situated in the epitympanic recess. It is ovoid in shape, articulates posteriorly with the incus, and is covered elsewhere by mucosa. The cartilaginous articular facet for the incus is narrowed near its middle and consists of a larger upper part and a smaller lower part, orientated almost at right-angles to each other. Opposite the constriction, the lower margin of the facet projects in the form of a process, the spur of the malleus. The neck is the narrowed part below the head, and inferior to this is an enlargement from which the anterior and lateral processes project. The lateral process has a cartilaginous cap that articulates with the tympanic membrane (Michaelides et al 2018).

The handle of the malleus is connected by its lateral margin to the tympanic membrane by a narrow core of dense connective tissue, surrounded by loose connective tissue. It varies in width along the manubrium (De Greef et al 2016) (see Figs 42.6, 42.8). It is directed downwards, medially and backwards. It decreases in size towards its free end, which is curved slightly forwards and is flattened transversely. Near the upper end of its medial surface there is a slight projection to which the tendon of tensor tympani is attached. The anterior process is a delicate bony spicule, directed forwards from the enlargement below the neck, and connected to the petrotympanic fissure by ligamentous fibres. In fetal life, it is the longest process of the malleus and is continuous in front with Meckel's cartilage. The lateral process is a conical projection from the root of the handle of the malleus. It is directed laterally and is attached to the upper part of the tympanic membrane and, via the anterior and posterior malleolar folds, to the sides of the notch in the upper part of the tympanic sulcus.

Ossification

The cartilaginous precursor of the malleus originates as part of the dorsal end of Meckel's cartilage. With the exception of its anterior process, the malleus ossifies from a single endochondral centre that appears near the future neck of the bone during postmenstrual weeks 13–16. The anterior process ossifies separately in dense connective tissue and joins the rest of the bone during postmenstrual weeks 21–24.

Incus

The incus is shaped less like an anvil, from which it is named, than a premolar tooth with its two diverging roots. It has a body and two processes (see Fig. 42.10). The body is somewhat cubical but laterally compressed. On its anterior surface, it has a saddle-shaped facet for articulation with the head of the malleus. The long process, rather more than half the length of the handle of the malleus, descends almost vertically, behind and parallel to the handle. Its lower end bends medially and ends in a rounded lenticular process, the medial surface of which is covered with cartilage and articulates with the head of the stapes. The short process, somewhat conical, projects backwards and is attached by ligamentous fibres to the fossa incudis in the lower and posterior part of the epitympanic recess. The presence of a single nutrient vessel within the long process of the incus and the absence of any collateral circulation render this segment of the bone susceptible to aseptic necrosis following middle ear infections.

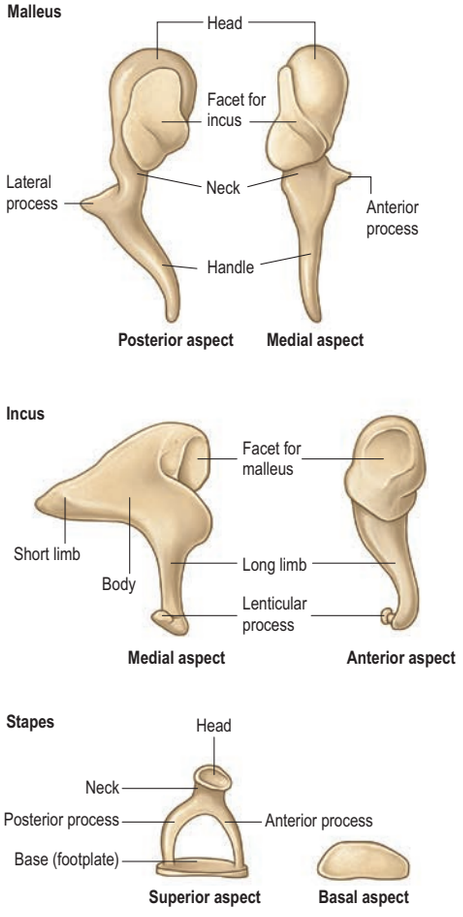

Fig. 42.10 The left auditory ossicles.

Ossification

The incus has a cartilaginous precursor continuous with the dorsal extremity of Meckel's cartilage. Ossification often spreads from a single centre in the upper part of its long process during postmenstrual weeks 13–16; the lenticular process may have a separate centre.

Stapes

The stapes has a head, neck, two limbs (processes or crura) and a base (footplate) (see Fig. 42.10). The head (caput) is directed laterally and has a small cartilaginous facet for articulation with the lenticular process of the incus. The neck is the constricted part supporting the head, and the tendon of stapedius is attached to its posterior surface. The processes diverge from the neck and are connected at their ends by a flattened oval plate, the base, which forms the footplate of the stapes. The footplate is attached to the margin of the fenestra vestibuli by a ring of fibres (the anular ligament). The anterior process is shorter, thinner and less curved than the posterior.

Ossification

The stapes is preformed in the perforated dorsal moiety of the hyoid arch cartilage of the fetus. Ossification starts from a single endochondral centre that appears in the base during postmenstrual weeks 13–16 and then gradually spreads through the limbs of the stapes to reach the head.

At birth, the auditory ossicles have achieved their full adult size and configuration. They increase in density during the first years of life as marrow cavities are replaced with endosteal bone and fine trabeculae (Isaacson 2014).

Ossicular ligaments

The ossicles are connected to the tympanic walls by ligaments (see Fig. 42.6B): three for the malleus and one each for the incus and stapes. Some are mere mucosal folds that carry blood vessels and nerves to and

from the ossicles and their articulations, and others contain a central, strong band of collagen fibres.

The anterior ligament of the malleus stretches from the neck of the malleus, just above the anterior process, to the anterior wall of the tympanic cavity near the petrotympanic fissure. Some of its collagen fibres traverse this fissure to reach the spine of the sphenoid, and others continue into the sphenomandibular ligament. The latter, like the anterior malleolar ligament, is derived from the perichondrial sheath of Meckel's cartilage. The anterior malleolar ligament may contain muscle fibres, called laxator tympani or musculus externus mallei. The lateral ligament of the malleus is a triangular band that stretches from the posterior part of the border of the tympanic incisure to the head of the malleus. The superior ligament of the malleus connects the head of the malleus to the roof of the epitympanic recess.

The posterior ligament of the incus connects the end of its short process to the fossa incudis. The superior ligament of the incus is little more than a mucosal fold passing from the body of the incus to the roof of the epitympanic recess.

The vestibular surface and rim of the stapedial base are covered with hyaline cartilage. The cartilage encircling the base is attached to the margin of the fenestra vestibuli by a ring of elastic fibres, the anular ligament of the base of the stapes. The posterior part of this ligament is much narrower than the anterior part; it acts as a kind of hinge on which the stapedial base moves when stapedius contracts and during acoustic oscillation.

Ossicular articulations

The ossicular articulations are typical synovial joints. The incudomalleolar joint is saddle-shaped and the incudostapedial joint is a ball and socket articulation. The articular surfaces are covered with articular cartilage, and each joint is enveloped by a capsule that is rich in elastic tissue and lined by synovial membrane. Versican, fibronectin, elastin and hyaluronan have been co-localized in the attachments of tensor tympani and stapedius to the malleus and stapes, respectively, and in the anular ligament of the incudostapedial joint in histological sections of adult middle ears (Kawase et al 2012). Co-localization between elastic fibres and hyaluronan in the middle ear appears to be a postnatal maturational event, possibly an adaptation to acoustic oscillation producing multidirectional mechanical stress (Takanashi et al 2013).

Movements of the auditory ossicles

The handle of the malleus follows all movements of the tympanic membrane. The malleus and incus rotate together around an axis that runs from the short process and posterior ligament of the incus to the anterior ligament of the malleus. When the tympanic membrane and handle of the malleus move inwards (medially), the long process of the incus moves in the same direction and pushes the stapedial footplate towards the labyrinth and the perilymph contained within the labyrinth. The movement of the perilymph causes a compensatory outward bulging of the secondary tympanic membrane. These events are reversed when the tympanic membrane moves outwards. If the movement of the tympanic membrane is considerable, the incus does not follow the full outward excursion of the malleus and merely glides on it at the incudomalleolar joint, so preventing a dislocation of the footplate of the stapes from the fenestra vestibuli. When the handle of the malleus is carried medially, the spur at the lower margin of the head of the malleus locks the incudomalleolar joint, and this necessitates an inward movement of the long process of the incus. The joint is unlocked again when the handle of the malleus is carried outwards. The three bones together act as a bent lever so that the stapedial footplate does not move in the fenestra vestibuli like a piston, but rocks on a fulcrum at its anteroinferior border where the anular ligament is thick. The rocking movement around a vertical axis, which is like a swinging door, is said to happen only at moderate intensities of sound. With loud, low-pitched sounds, the axis becomes horizontal, and the upper and lower margins of the stapedial footplate oscillate in opposite directions around this central axis, thus preventing excessive displacement of the perilymph.

Otosclerosis and other causes of stapes fixation, stapedectomy and stapedotomy

Otosclerosis is a localized disease of the bone derived from the embryonic otic capsule in which lamellar bone is replaced by woven bone of greater thickness and vascularity. It may develop spontaneously but is often seen in pedigrees and accelerated by pregnancy; the inherited form is associated with mutations of the *RELN* gene. The position of the focus of new bone formation determines its effect on the function of the ear. When new bone develops around the footplate of the stapes, it may fix the footplate to the margin of the fenestra vestibuli and prevent it from moving. This impedes the passage of vibrations of the tympanic membrane passing through the ossicular chain to the inner ear, producing a conductive hearing loss. Otosclerosis affecting other parts of the otic capsule is thought to cause a sensorineural element to the overall hearing loss.

The footplate may be fixed by conditions other than otosclerosis. Rarely it may be fixed from birth, congenital fixation, but more commonly is the result of chronic otitis media causing dense scarring throughout the middle ear cleft known as tympanosclerosis, or associated with other temporal bone anomalies, e.g. Wardenberg syndrome (Melzer et al 2016). Whatever the cause, the result is a conductive hearing loss.

Stapedectomy is a surgical procedure designed to bypass the fixation of the stapes footplate caused by otosclerosis. The tympanic membrane is temporarily elevated for access to the middle ear and, under microscopic control, the incudostapedial joint is disarticulated. The limbs of the stapes and stapedius are then both divided and the superstructure of the stapes removed. Formerly the entire footplate was removed (stapedectomy) but nowadays a small hole (stapedotomy) is then made in the fixed footplate of the stapes using a microdrill, laser or hand reamer to expose the membranous inner ear bathed in perilymph. A small graft of connective tissue is used to cover the hole with a flexible membrane. A piston usually measuring 4.5 mm in length and 0.4 mm in width and made of Teflon or titanium that incorporates an open hook at one end is crimped onto the long process of the incus and placed so that the free end of the piston engages the membrane covering the footplate perforation (Luers and Hüttenbrink 2015). The tympanic membrane is then returned. The connection between the tympanic membrane and the inner ear is thus reconstituted and hearing restored.

Stapedectomy or stapedotomy for congenital fixation carries the risk of a 'gusher' as perilymph flows vigorously and seemingly endlessly from the vestibule of the labyrinth once the footplate is perforated. Staunching the flow is best achieved by placing a free muscle graft between the long process of the incus and the oval window. Direct suction over the oval window must be avoided at all costs because it might cause rupture of the inner ear membranes and result in a very significant or complete hearing loss in the ear.

Muscles

There are two intratympanic muscles: tensor tympani and stapedius (Anderson 1976).

Tensor tympani

Tensor tympani is a long, slender muscle that occupies the bony canal above the osseous part of the pharyngotympanic tube, from which it is separated by a thin bony septum (see Fig. 42.6). It arises from the cartilaginous part of the pharyngotympanic tube and the adjoining region of the greater wing of the sphenoid, as well as from its own canal. It passes back within its canal, and ends in a slim tendon which bends laterally round the pulley-like processus cochleariformis and attaches to the handle of the malleus, near its root (see Fig. 42.12).

Vascular supply Tensor tympani receives its arterial blood supply from the superior tympanic branch of the middle meningeal artery.

Innervation Tensor tympani is innervated by a branch of the nerve to medial pterygoid (a ramus of the mandibular division of the trigeminal nerve), which traverses the otic ganglion without interruption to reach the muscle.

Actions Tensor tympani draws the handle of the malleus medially, and so tenses the tympanic membrane and helps to damp sound vibrations; its action also pushes the base of the stapes more tightly into the fenestra vestibuli.

Stapedius

Stapedius arises from the wall of a conical cavity in the pyramidal eminence on the posterior wall of the tympanic cavity, and from its continuation anterior to the descending part of the facial nerve canal. Its minute tendon emerges from the orifice at the apex of the pyramid and passes forwards to attach to the posterior surface of the neck of the stapes. The muscle is of an asymmetric bipennate form. It contains numerous small motor units, each of only 6–9 muscle fibres; a few neuromuscular spindles exist near the myotendinous junction.

Vascular supply Stapedius receives its arterial blood supply from branches of the posterior auricular, anterior tympanic and middle meningeal arteries.

Innervation Stapedius is supplied by a branch of the facial nerve that is given off in the facial canal.

Actions Stapedius helps to damp down excessive sound vibrations. It opposes the action of tensor tympani (which pushes the stapes more tightly into the fenestra vestibuli). Paralysis of stapedius results in hyperacusis.

Stapedial and tensor tympani reflexes. When noises are loud, and immediately before speaking, a reflex contraction of stapedius and tensor tympani takes place that helps damp down the movement of the ossicular chain before vibrations reach the internal ear. The afferent pathways involve the auditory component of cranial nerve VIII, and higher centres prior to speech. The efferent pathway involves the facial nerve (stapedius) and the mandibular nerve (tensor tympani).

Vascular supply and lymphatic drainage

A number of arteries supply the walls and contents of the tympanic cavity. The deep auricular, anterior tympanic and stylomastoid arteries are larger than the others.

The deep auricular branch of the first part of the maxillary artery often arises with the anterior tympanic artery. It ascends in the parotid gland behind the temporomandibular joint, pierces the cartilaginous or bony wall of the external acoustic meatus and supplies its cuticular lining, the exterior of the tympanic membrane and the temporomandibular joint.

The anterior tympanic branch of the first part of the maxillary artery ascends behind the temporomandibular joint and enters the tympanic cavity through the petrotympanic fissure. It ramifies on the interior of the tympanic membrane and forms a vascular circle around it with the posterior tympanic branch of the stylomastoid artery. It also anastomoses with twigs of the artery of the pterygoid canal and caroticotympanic branches of the internal carotid artery in the mucosa of the tympanic cavity.

The stylomastoid branch of the occipital or posterior auricular arteries supplies the posterior part of the tympanic cavity and mastoid air cells. It also enters the stylomastoid foramen to supply the facial nerve and semicircular canals. In the young, its posterior tympanic branch forms a circular anastomosis with the anterior tympanic artery.

The smaller arteries supplying the tympanic cavity include the petrosal branch of the middle meningeal artery, which enters through the hiatus for the greater petrosal nerve; the superior tympanic branch of the middle meningeal artery, which traverses the canal for tensor tympani; an inferior tympanic branch from the ascending pharyngeal artery, which traverses the tympanic canaliculus together with the tympanic branch of the glossopharyngeal nerve, to supply the medial wall of the tympanic cavity; a branch from the artery of the pterygoid canal, which accompanies the pharyngotympanic tube; and a tympanic branch or branches from the internal carotid artery, which is given off in the carotid canal and perforates the thin anterior wall of the tympanic cavity.

The mastoid air cells and dura mater are also supplied by a mastoid branch from the occipital artery. It is small in size and sometimes absent. When present, it enters the cranial cavity via the mastoid foramen near the occipitomastoid suture. In early fetal life, a stapedial artery traverses the stapes.

The veins from the tympanic cavity terminate in the pterygoid venous plexus and the superior petrosal sinus. A small group of veins runs medially from the mucosa of the mastoid antrum through the arch formed by the superior (anterior) semicircular canal and emerges on to the posterior surface of the petrous temporal bone at the subarcuate fossa. These veins drain into the superior petrosal sinus and are the remains of the large subarcuate veins of childhood. They represent a potential route for the spread of infection from the mastoid antrum to the meninges.

Lymphatic vessels of the tympanic and antral mucosae drain to the parotid or upper deep cervical lymph nodes. Vessels draining the tympanic end of the pharyngotympanic tube probably end in the deep cervical nodes.

Innervation

The tympanic cavity contains the tympanic plexus and the facial nerve. Branches from the plexus and the facial nerve supply structures within the tympanic cavity but also leave the cavity to supply structures on the face.

Tympanic plexus

The nerves that constitute the tympanic plexus ramify on the surface of the promontory on the medial wall of the tympanic cavity. They are derived from the tympanic branch of the glossopharyngeal nerve and the caroticotympanic nerves (Fig. 42.11). The former arises from the inferior ganglion of the glossopharyngeal nerve and reaches the tympanic cavity via the tympanic canaliculus for the tympanic nerve. The superior and inferior caroticotympanic nerves are postganglionic sympathetic fibres that are derived from the carotid sympathetic plexus and traverse the wall of the carotid canal to join the plexus.

The tympanic plexus supplies branches to the mucosa of the tympanic cavity, pharyngotympanic tube and mastoid air cells. It sends a branch to the greater petrosal nerve via an opening anterior to the fenestra vestibuli. The lesser petrosal nerve, which may be regarded as the continuation of the tympanic branch of the glossopharyngeal nerve, traverses the tympanic plexus. It occupies a small canal below that for the tensor tympani. It runs past, and receives a connecting branch from, the geniculate ganglion of the facial nerve. The lesser petrosal nerve emerges from the anterior surface of the temporal bone via a small opening lateral to the hiatus for the greater petrosal nerve and then traverses either the foramen ovale or the sphenopetrosal fissure or the innominate canal (of Arnold) to join the otic ganglion. Postganglionic secretomotor fibres leave this ganglion in the auriculotemporal nerve to supply the parotid gland. In former times, the operation of tympanic neurectomy was undertaken to reduce salivation in patients who drooled and to diminish facial sweating in those with Frey's syndrome following parotidectomy; less invasive and more effective procedures are employed nowadays.

Facial nerve

The facial nerve consists of intracranial (cisternal), intratemporal and extratemporal portions. The intratemporal portion is further

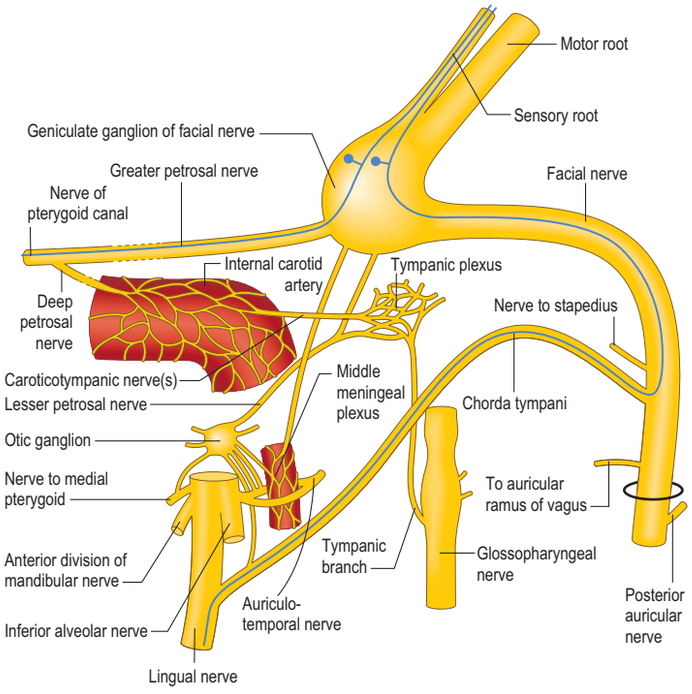

Fig. 42.11 The intracranial branches of the facial and glossopharyngeal nerves and the connections of the tympanic plexus and the otic ganglion. The course of the taste fibres from the mucous membrane of the palate and from the anterior presulcal part of the tongue is represented by the blue lines.

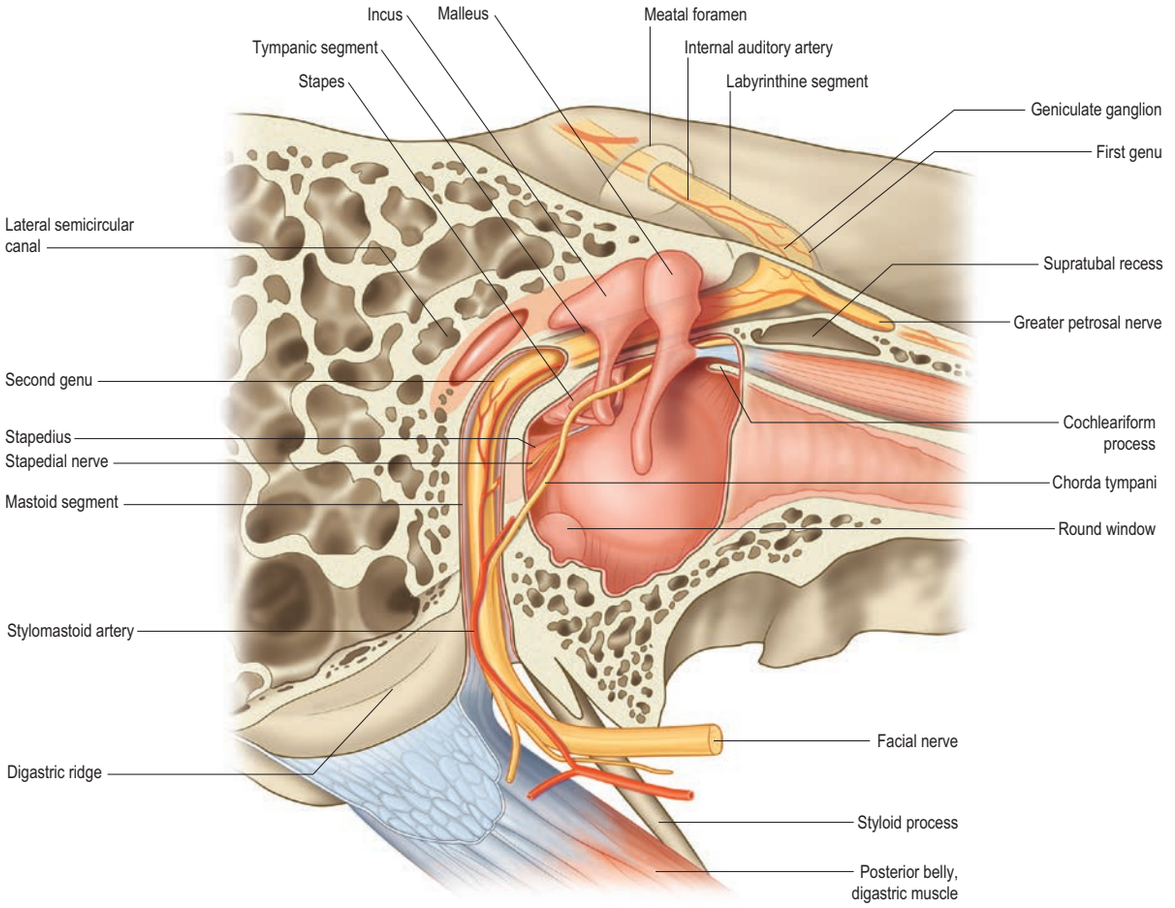

Fig. 42.12 A schematic diagram to illustrate the relationships of the facial nerve within the temporal bone. For simplicity, the course of the labyrinthine segment of the facial nerve has been portrayed more superiorly than it is in life. At the first genu, it turns sharply on itself and passes deeply to the internal auditory meatus. In an anatomically correct diagram, its course viewed from the lateral perspective (as shown here) would be obscured by the ossicular mass. The facial nerve is vulnerable to injury at several sites within the temporal bone and the neck. The labyrinthine and perigeniculate segments are susceptible to compression, ischaemia and transection in both longitudinal and transverse fractures of the temporal bone. The narrowing of the facial (Fallopian) canal at the meatal foramen has been implicated in the pathogenesis of idiopathic facial palsy (Bell's palsy). At the first genu, the facial nerve is tethered by the greater petrosal nerve, increasing its susceptibility to iatrogenic shearing injuries when it is mobilized in re-routing procedures to enable access to tumours. The facial (Fallopian) canal containing the tympanic segment of the facial nerve may be dehiscent above and distal to the oval window; as a result, the nerve is easily and inadvertently damaged in middle ear surgery for cholesteatoma or stapedectomy. The mastoid segment of the facial nerve is lateral to the tympanic anulus where it is at risk of surgical trauma in meatoplasty surgery around the external acoustic meatus. (Redrawn from Francis HW 2010 Anatomy of the temporal bone, external ear, and middle ear. In: Flint PW, Haughey BH, Lund VJ et al (eds) Cummings Otolaryngology: Head and Neck Surgery, 5th ed. Mosby; Ch 127, pp. 1821–30.)

divided into meatal, labyrinthine, tympanic (horizontal) and mastoid (vertical) segments (Fig. 42.12). The cisternal segment emerges from the ventrolateral aspect of the caudal border of the pons. The meatal segment enters the porus acusticus of the internal acoustic meatus accompanied by the nervus intermedius, the vestibulocochlear nerve and the labyrinthine vessels. In this part of its course, the nerve lacks a fibrous sheath or endoneurium and is surrounded by a thin layer of arachnoid. The motor root, which supplies the muscles of the face, and the nervus intermedius, which contains sensory fibres concerned with the perception of taste and parasympathetic (secretomotor) fibres to various glands, are still separate components; they usually merge within the meatus. The labyrinthine segment runs from the fundus of the internal acoustic meatus to the geniculate ganglion, where the nerve makes the first bend or genu (see Fig. 42.11). The labyrinthine segment is the shortest and narrowest part of the facial nerve; it lacks anastomosing arterial cascades, which renders it susceptible to vascular compression. The tympanic segment initially curves around the oval window niche, then lies just anterior and inferior to the lateral semicircular canal and bends again at the second genu to become the mastoid segment, which is the longest of the petrous segments and runs from the pyramidal process to the stylomastoid foramen. The tympanic and mastoid segments of the facial nerve are supplied by the facial arch, formed by the petrosal branch of the middle meningeal artery and the stylomastoid branch of the posterior auricular artery. The extratemporal course of the facial nerve is described in Chapter 36 (pages 632 and 633).

The branches that arise from the facial nerve within the temporal bone can be divided into those that come from the geniculate ganglion and those that arise within the facial canal.

The main branch from the geniculate ganglion is the greater (superficial) petrosal nerve, a branch of the nervus intermedius. The greater petrosal nerve passes anteriorly, receives a branch from the tympanic plexus and traverses a hiatus on the anterior surface of the petrous part of the temporal bone. It enters the middle cranial fossa, runs forwards in a groove on the bone above the lesser petrosal nerve, and then passes beneath the trigeminal ganglion to reach the foramen lacerum. Here it is joined by the deep petrosal nerve from the internal carotid sympathetic plexus, to become the nerve of the pterygoid canal (Vidian nerve). The greater petrosal nerve contains parasympathetic fibres destined for the pterygopalatine ganglion, and taste fibres from the palate. The geniculate ganglion also communicates with the lesser petrosal nerve.

The nerve to stapedius arises from the facial nerve in the facial nerve canal behind the pyramidal eminence of the posterior wall of the tympanic cavity and passes forwards through a small canal to reach the muscle.

The chorda tympani (see Figs 42.11, 42.12) leaves the facial nerve some 6 mm above the stylomastoid foramen and runs anterosuperiorly in a canal to enter the tympanic cavity via the posterior canaliculus. It then curves anteriorly in the substance of the tympanic membrane between its mucous and fibrous layers, and crosses medial to the upper part of the handle of the malleus to the anterior wall of the tympanic

cavity, where it enters the anterior canaliculus. It exits the skull at the petrotympanic fissure, and its further course is described on page 682. The chorda tympani contains parasympathetic fibres that supply the submandibular and sublingual salivary glands via the submandibular ganglion and taste fibres from the anterior two-thirds of the tongue.

Dehiscences of the facial nerve canal
