Edoxaban, a direct oral inhibitor of factor Xa, is FDA approved at a dose of 60 mg/day to treat PE following 5 to 10 days of a parenteral (e.g., intravenous UFH or subcutaneous LMWH) anticoagulant. A lower daily dose (30 mg) is appropriate for patients with renal failure (glomerular filtration rate, 30 to 50 mL/min) or for patients who weigh less than 60 kg. Edoxaban shares the advantage of once-daily dosing, and it can be taken without regard to food. Furthermore, extended treatment with edoxaban prevents

recurrent VTE as effectively as LMWH in patients with advanced cancer.[161]

Dabigatran, an oral direct inhibitor of thrombin, is FDA approved for treatment of PE after 5 to 10 days of a parenteral (e.g., intravenous UFH or subcutaneous LMWH) anticoagulant at a dose of 150 mg twice daily. Caution is advised in patients with concomitant atrial fibrillation because abrupt discontinuation increases the risk of stroke.

Vena Cava Filters. Current guidelines and treatment algorithms consistently recommend the insertion of vena cava filters to treat acute PE when anticoagulants are contraindicated,[73,103] on the basis of observations that suggest reduced mortality from recurrent PE.[167,168] Guideline authors also recommend against the use of IVC filters as an adjunct to anticoagulant treatment of PE accompanied by acute proximal DVT.[103,169,170]

In contrast, guidelines are inconsistent in their recommendations for vena cava filters in other circumstances. For example, the authors of an American College of Chest Physicians guideline recommend against routine use of IVC filters for hemodynamically stable patients with PE who are treated with anticoagulants, but they note that hemodynamically unstable patients with PE may benefit from combining anticoagulants and an IVC filter.[159] In contrast, the authors of the European Society of Cardiology and European Respiratory Society guideline did not recommend IVC filters in combination with anticoagulants for hemodynamically unstable patients, but they do recommend IVC filter placement for patients with objectively confirmed recurrent PE despite therapeutic anticoagulation.[103,107] These discordant viewpoints underscore the importance of integrating additional clinical factors when deciding whether to use an IVC filter in an individual patient.

Most vena cava filters are placed in the IVC below the renal veins and are rarely placed in other locations (e.g., superior vena cava or above the renal veins). Most are retrievable and should be removed after the risk of major bleeding is reduced and anticoagulants are reinstituted. Filter removal reduces the risk of vena cava syndrome (i.e., obstruction of blood flow through the vena cava) and other late complications, including obstruction or perforation of the IVC or fracture of the filter.[171] If vena cava filters are not removed, then clinical surveillance with individualized patient management is necessary.[172]

Duration of Anticoagulant Therapy. Recommendations regarding the duration of anticoagulant therapy have changed over time. There is general agreement that an acute PE requires a minimum of 3 months of full-dose anticoagulation. Estimates of the risk of major bleeding and the risk for recurrent PE are necessary to guide the decision to stop or extend anticoagulation after the first 3 months.

Estimates of the risk of major bleeding incorporate characteristics of the patient and of the anticoagulant medication. Patient-related characteristics that predict an increased risk for major bleeding include advanced age, previous major bleeding not associated with a treatable cause, active cancer, previous stroke, chronic liver or kidney disease, a requirement for antiplatelet or nonsteroidal anti-inflammatory drugs, and/or other serious illnesses (e.g., alcoholism) that increase bleeding risks. The choice of anticoagulant also may influence the risk of major bleeding. For extended treatment, DOACs may offer similar efficacy for prevention of VTE recurrence with a lower risk of major bleeding than vitamin K antagonists.[173]

Estimates of the risk of recurrent PE are derived from clinical and laboratory features of the index PE.[103] Patients with major transient or reversible risk factors for PE, such as a traumatic long bone fracture, have a very low risk (<3% per year) for recurrent PE after 3 months of anticoagulation. The risk of major bleeding during continued anticoagulation exceeds the risk for recurrent PE and justifies discontinuation of anticoagulants for such patients. Patients with a minor transient or reversible risk factor, such as prolonged air travel, or a nonmalignant persistent risk factor, such as inflammatory bowel disease, have an intermediate risk (3–8% per year) for recurrent PE that generally justifies extended anticoagulation in the absence of risks for life-threatening bleeding. In contrast, patients with major ongoing risk factors for recurrent PE, such as active cancer, previous PE without a reversible risk factor, or antiphospholipid antibody syndrome, have a high risk (>8% per year) for recurrent PE. These patients generally require indefinite anticoagulation.

Overall long-term anticoagulant therapy requires an evidence-based plan tailored to the individual patient combined with periodic reassessment of risks and benefits of anticoagulation. For example, PE in a patient with triple-positive antiphospholipid antibody syndrome (i.e., lupus anticoagulant with anticardiolipin and anti–β_2-glycoprotein antibodies) warrants indefinite anticoagulation with warfarin.

SPECIAL PROBLEMS

Isolated Subsegmental Pulmonary Embolism

The rare patient with PE isolated to subsegmental branches of the pulmonary arterial tree requires careful consideration. The natural history of isolated subsegmental PE is not well defined, and there is no evidence from well-designed clinical trials to guide the management of these patients.[159] Overdiagnosis and overtreatment of inconsequential thrombosis represent key risks to be eliminated at the outset. These considerations may lead clinicians to look for evidence of DVT in the legs or elsewhere, if appropriate. Anticoagulation is indicated when DVT is found. Guideline authors recommend anticoagulation when risk factors for recurrent VTE are present and the risk for major bleeding is low.[159] Guideline authors recommend observation without anticoagulation for patients with isolated subsegmental PE, no DVT, and a low risk for recurrent VTE. The absence of DVT on repeat lower extremity venous ultrasonography 5 to 7 days later may be used to confirm the safety of withholding anticoagulants for such patients.

Incidental Pulmonary Embolism

PEs are occasionally identified incidentally on contrast computed tomography examinations in patients with cancer. In retrospect, these patients often have a past history of VTE and nonspecific symptoms of PE such as dyspnea and fatigue.[174] Anticoagulation is indicated in the absence of contraindications.

Hemoptysis

Hemoptysis related to PE and pulmonary infarction generally does not pose an increased risk for major bleeding. However, clinicians should recognize that other serious pulmonary disorders (e.g., lung cancer or bronchiectasis) may substantially increase the risk for major, and even life-threatening, hemoptysis made worse by anticoagulation or thrombolysis. The presence of these conditions may necessitate the use of a vena cava filter if the bleeding risk is high.

Pulmonary Embolism in Transit

PE in transit through the right side of the heart is a rare, but important, clinical problem (see Fig. 82.3). Thromboemboli in transit identify a subgroup of patients with PE who are more likely to have RV dysfunction and who have an increased risk of death from venous thromboembolic disease.[84] Anticoagulation alone is insufficient because of the high risk for the embolus in transit to kill the patient. Thrombolytic therapy is often chosen in the absence of contraindications. However, embolectomy may also be chosen as the first option or as a second option if thrombolysis has failed.[175]

Paradoxical Embolism

Paradoxical embolism (i.e., VTE to systemic vascular beds) may complicate VTE (Fig. 82.5). Patients with acute PE who have a patent foramen ovale are more likely to have an acute ischemic stroke than are patients with PE but without a patent foramen ovale.[176] Similarly, paradoxical emboli may cause myocardial infarction, renal infarction, bowel infarction, or even acute occlusion of systemic arteries. Individual patient circumstances and preferences usually determine the management of paradoxical emboli.

Cancer

Patients with cancer who are treated for PE are at higher risk for recurrent VTE and major bleeding events than are patients without cancer.[177] Extended treatment with LMWH lowers the risk for recurrent VTE when compared with warfarin.[160] Furthermore, several DOACs, including edoxaban,[161] rivaroxaban,[178] and apixaban,[162] have demonstrated efficacy and safety comparable to those of LMWH for treatment of VTE complicating cancer. The DOACs avoid the discomfort, cost, and inconvenience of subcutaneous injections of LMWH, but care is required in choosing which DOAC to use for an individual patient.[179]

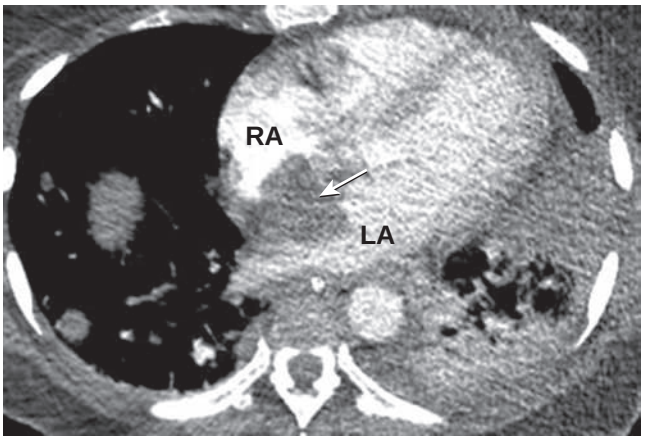

Figure 82.5 Paradoxical embolism. Axial enhanced chest computed tomography in a patient with acute pulmonary emboli shows a dumbbell-shaped filling defect (*arrow*) straddling the interatrial septum, consistent with a pulmonary embolus in transit through a patient foramen ovale. LA, left atrium; RA, right atrium. (Courtesy Michael B. Gotway, MD.)

Pregnancy

Weight-adjusted doses of LMWH are the preferred treatment for uncomplicated PE during pregnancy, provided exposure to LMWH during epidural anesthesia is avoided.[103] Pregnant women should be advised to discontinue anticoagulant therapy on the onset of spontaneous labor. If there is a planned delivery, therapeutic LMWH should be discontinued at least 24 hours before the expected time of epidural analgesia or delivery. LMWH does not cross the placenta, and LMWH is not found in breast milk.[180-183] In contrast, warfarin, fondaparinux, and DOACs are contraindicated for pregnant patients or lactating women. Warfarin causes fetal embryopathies when given in the first trimester, and fetal hemorrhages, as well as placental abruption, may complicate warfarin administration during the third trimester of pregnancy.

UFH also is effective for the treatment of uncomplicated PE during pregnancy, but UFH requires dose adjustments with frequent aPTT monitoring, and UFH also has caused osteoporosis during extended treatment of pregnant women. In pregnant patients with recent PE, many clinicians recommend that LMWH be converted to UFH more than 36 hours before delivery so that the UFH infusion can be stopped 4 to 6 hours before anticipated delivery with a normal aPTT before regional anesthesia.[184] UFH is also preferable for pregnant patients with unstable renal function or renal failure and for pregnant patients at high risk of death who may require thrombolytic therapy.

Thrombolytic agents, typically recombinant tissue plasminogen 100 mg given intravenously over 2 hours, can be given for life-threatening PE during pregnancy; but thrombolysis during the peripartum period poses significant risk for uncontrollable bleeding, and it should be reserved for critical situations.[107]

Recurrent Thromboembolism During Anticoagulant Therapy

Few data are available for this uncommon clinical circumstance. Experts advise several steps: (1) confirm new thromboembolism; (2) confirm bioavailability of the anticoagulant therapy with testing of antithrombotic effect (e.g., anti–factor Xa); (3) confirm that there is no HIT with thrombosis; and, if all three are confirmed, (4) change treatment. If a change of treatment is chosen, treat the new episode as acute, with UFH or a LMWH according to one of the regimens listed in Table 82.7 for initial treatment of PE. Then consider twice-daily subcutaneous LMWH (e.g., enoxaparin 1 mg/kg every 12 hours) for extended treatment.

Key Points

- Venous thromboembolism prophylaxis can be applied to at-risk persons nearly universally unless contraindicated, or it can be applied judiciously after risk assessment of individual patients. The former universal approach is preferred.
- Vasopressor therapy in patients in the intensive care unit reduces bioavailability of subcutaneous low-molecular-weight heparin prophylaxis, so heightened alertness for thrombosis and consideration of monitoring anti–factor Xa levels with upward titration of low-molecular-weight heparin can be considered.
- Anticoagulant prophylactic drugs other than unfractionated heparin undergo significant renal elimination, thus requiring cautious use or avoidance in patients with renal dysfunction.
- Prophylactic use of retrievable inferior vena cava filters is only rarely warranted.
- The initial management of a patient with symptoms or signs that suggest acute pulmonary embolism involves coordination of diagnostic testing, assessment of the patient's risks for morbidity and mortality, risk for major bleeding, and initiation of treatment.
- Treatment of pulmonary embolism is directed at clinically important end points, including death from pulmonary embolism, prevention of recurrent venous thromboembolism, and avoidance of major or clinically relevant bleeding, rather than intermediate end points such as reversing arterial hypoxemia.
- Hypotension, shock, or cardiopulmonary arrest requires immediate respiratory and cardiovascular support. Diagnostic efforts must necessarily await stabilization of the patient.
- Normotensive patients with pulmonary embolism who are at increased mortality risk (i.e., patients in the intermediate mortality risk group) often benefit most from initial anticoagulation with unfractionated heparin and careful monitoring for pulmonary embolism–related hypotension as an indication for systemic thrombolysis, rather than immediate thrombolysis.

KEY POINTS

INTRODUCTION

Pulmonary hypertension (PH) is a syndrome characterized by elevated pulmonary pressures. Whether acute or chronic, elevated pulmonary pressures lead to increased afterload on the right ventricle that can cause right ventricular failure and death. Of importance, there are numerous causes of elevated pulmonary pressures; thus, a standardized approach to diagnosis and proper classification are imperative to guide appropriate treatment and predict survival. This chapter presents a general approach to the patient with suspected PH and discusses the epidemiology, presenting symptoms, role of screening, diagnostic algorithm, and classification system for PH. Also reviewed is the treatment of certain forms of PH. In-depth reviews of specific forms of PH, such as pulmonary arterial hypertension, PH related to chronic lung disease, and chronic thromboembolic PH, are covered in other chapters (see Chapters 84–86).

DEFINITION OF PULMONARY HYPERTENSION

The *World Symposium on Pulmonary Hypertension* (WSPH) recommends defining PH as a *mean pulmonary artery pressure* (mPAP) greater than 20 mm Hg, measured by *right heart catheterization* (RHC).[1] PH had previously been defined as an mPAP of 25 mm Hg or greater for several decades, but the choice of 25 mm Hg had been arbitrary.[13] The justification for this cut point was based upon the belief that physicians could more easily distinguish between severe PH related to PAH and less severe PH related to underlying lung or heart disease, thus potentially avoiding overdiagnosis and overtreatment of PH.[13] A literature review published in 2009 summarizing the available RHC data from more than 1100 healthy individuals found that normal mPAP was only 14 ± 3.3 mm Hg.[4] Thus, an mPAP greater than 20 mm Hg, two standard deviations above the mean value, would be above the upper limit of normal (the 97.5th percentile) and identify an abnormal pulmonary pressure threshold in an otherwise healthy population.[2]

Mounting data support the threshold of mPAP greater than 20 mm Hg as a clinically relevant cut point. Retrospective cohort studies in specific patient populations, such as those with COPD, idiopathic pulmonary fibrosis, and scleroderma, have demonstrated worse functional status and survival for patients with mildly elevated pulmonary pressures (mPAP, 21–24 mm Hg) compared to those with normal pulmonary pressures.[3–8] Similarly, in unselected referral populations, mildly elevated PAP was associated with poorer survival compared to patients with normal PAP.[9–11] A systematic review that included more than 16,000 patients found that mild PH (defined as a mean PAP between 19 and 24 mm Hg) was associated with an increased risk of all-cause mortality (risk ratio, 1.5; 95% confidence interval, 1.3 to 1.7; $P < 0.001$) compared to the reference group with normal mPAP.[12]

However, despite these observations, it remains to be determined if mildly elevated mPAP leads to poor outcomes or is just an epiphenomenon related to an underlying comorbidity. The impact of mildly elevated pressures on symptoms and functional capacity is not well described, nor is it known whether patients with mildly elevated pressures go on to develop progressive pulmonary vascular disease. Furthermore, there are no approved therapies for patients with mildly elevated pulmonary pressures (between 21 and 24 mm Hg), which complicates the management of patients who now fulfill the new hemodynamic criteria for PH.

Table 83.1 Hemodynamic Definition of PH Based on the 6th World Symposium on Pulmonary Hypertension

Definition	mPAP	PCWP	PVR	WHO Group
Normal hemodynamics	14.0 ± 3.3 mm Hg	8.0 ± 2.9 mm Hg	0.93 ± 0.38 WU	N/A
Precapillary PH	>20 mm Hg	≤15 mm Hg	≥3 WU	1, 3, 4, 5
Isolated postcapillary PH	>20 mm Hg	>15 mm Hg	<3 WU	2 and 5
Combined precapillary and postcapillary PH	>20 mm Hg	>15 mm Hg	≥3 WU	2 and 5

mPAP, mean pulmonary artery pressure; N/A, not available; PCWP, pulmonary capillary wedge pressure; PH, pulmonary hypertension; PVR, pulmonary vascular resistance; WHO, World Health Organization. WU, Wood units.

Data from Simonneau G, Montani D, Celermajer DS, et al. Haemodynamic definitions and updated clinical classification of pulmonary hypertension. *Eur Respir J.* 2019;53(1):1801913.

The hemodynamic definition of PH was significantly revised at the 6th WSPH (Table 83.1), with the new criteria permitting better grouping of patients by the primary hemodynamic perturbation leading to their pulmonary vascular disease. The clinical classification schema underwent more minor revisions.[1] *Pulmonary arterial hypertension* (PAH) remains in group 1 of the schema and includes idiopathic PAH, which represents around half of the PAH population.[13] *Connective tissue disease* (CTD)-associated PAH accounts for about 25% of PAH. Other rare causes, such as heritable PAH, drug- and toxin-induced PAH, *human immunodeficiency virus* (HIV), portal hypertension, congenital heart disease, and schistosomiasis, along with PAH with overt venous/capillary involvement seen in pulmonary veno-occlusive disease, pulmonary capillary hemangiomatosis, and persistent PH of the newborn comprise the remainder (Table 83.2). A new category within group 1 was created to identify PAH with long-term response to *calcium channel blockers* (CCBs), given their unique clinical characteristics. Although many diseases and conditions predispose to the development of PAH, all PAH share the common histopathologic changes of arterial remodeling and inflammation, generally differentiating PAH from other categories of PH. Group 2 is characterized by elevated *pulmonary capillary wedge pressure* (PCWP) and includes patients with PH due to *left heart disease* (LHD), including heart failure with reduced ejection fraction, heart failure with preserved ejection fraction, valvular heart disease, and congenital/acquired cardiovascular conditions leading to postcapillary PH. Group 3 includes PH related to lung diseases and/or hypoxia. Group 4 includes PH related to *pulmonary artery* (PA) obstructions, whereas group 5 includes a heterogenous group of disorders with unclear and/or multifactorial mechanisms for development of PH. Specific details regarding group 2 and group 5 PH are discussed later in this chapter. Group 1, group 3, and group 4 PH are discussed elsewhere (see Chapters 84, 85 and 86, respectively).

EPIDEMIOLOGY

PH affects individuals of all ages and races. Overall, women are affected more frequently than men; the disparity appears to be most pronounced in patients with PAH.[14] Despite increased interest in the syndrome with the advent of certain directed therapies, the incidence and prevalence of PH are poorly described. In part, this is related to incomplete characterization of patients with suspected PH and limitations in the sensitivity and specificity of diagnostic codes used in administrative claims, thereby hindering epidemiologic studies.[15] Most of the data on prevalence of PH results from registries of patients with PAH, which represents the rarest form of PH; estimates for PAH prevalence range from 15 to 50 per 1 million persons.[16–19] Estimates of prevalence in other forms of PH are scant. Recent data generated from Canadian universal health care records show an increase in the prevalence of all forms of PH from 99.8 to 127.3 cases per 100,000 population between 2002 and 2012; only about 20% of the cases had PAH, whereas the majority had PH related to LHD or PH related to lung disease.[20] In a large community study using echocardiography to define PH, PH related to LHD was also found to be the most common form of PH (Fig. 83.1).[21] Extrapolating these estimates of PH to the U.S. population suggests that PH may be as common as multiple sclerosis and more than two times as common as idiopathic pulmonary fibrosis.[22] Still, given the increasing incidence of diseases known to predispose to PH, such as heart failure with preserved ejection fraction and sleep apnea, the prevalence of PH in the United States and in the world is likely to rise.[23–26]

DIAGNOSTIC APPROACH

As noted, PH commonly complicates various cardiopulmonary, vascular, and other diseases and is often associated with poorer outcomes. Given the limited treatment options for most forms of PH, diagnosis of this syndrome will guide clinical management, prompting referral to PH centers and, in some cases, consideration for lung or other organ transplantation. However, evaluation of PH is often undertaken to identify or exclude PAH (WSPH group 1 disease). PAH is distinguished from other PH groups based upon clinical characteristics, putative pathogenesis, and histologic features. PAH portends a poor prognosis, but advances in medical therapies over the past 2 decades provide therapeutic options for this devastating disease. Unfortunately, directed medical therapy does not exist for most other forms of PH other than *chronic thromboembolic PH* (CTEPH). Thus, proper classification of PH is imperative to direct proper therapy. PAH is defined both by hemodynamic criteria: mPAP of 20 mm Hg or greater, PCWP of 15 mm Hg or less, or *pulmonary vascular resistance* (PVR) of 3 or more *Wood units* (WU) and by the absence of alternative causes for elevated pulmonary pressures, including LHD, pulmonary disease, chronic thromboembolic disease, other

Table 83.2 Clinical Classification of PH Based Upon the Sixth World Symposium on Pulmonary Hypertension

GROUP 1: PAH

Idiopathic PAH
Hereditable PAH
Drug and toxin-induced PAH
PAH associated with:
- Connective tissue disease
- Human immunodeficiency virus infection
- Portal hypertension
- Congenital heart disease
- Schistosomiasis

PAH long-term responders to calcium channel blockers
PAH with overt features of venous/capillary (PVOD/PCH) involvement
Persistent PH of the newborn syndrome

GROUP 2: PH DUE TO LEFT HEART DISEASE

PH due to heart failure with preserved left ventricular ejection fraction
PH due to heart failure with reduced left ventricular ejection fraction
Valvular heart disease
Congenital/acquired cardiovascular conditions leading to postcapillary PH

GROUP 3: PH DUE TO LUNG DISEASES AND/OR HYPOXIA

Obstructive lung disease
Restrictive lung disease
Other lung disease with mixed restrictive/obstructive pattern
Hypoxia without lung disease
Developmental lung disorders

GROUP 4: PH DUE TO PULMONARY ARTERY OBSTRUCTION

Chronic thromboembolic PH
Other pulmonary artery obstructions
- Sarcoma (high- or intermediate-grade) or angiosarcoma
- Other malignant tumors
  - Renal carcinoma
  - Uterine carcinoma
  - Germ cell tumors of the testis
- Nonmalignant tumors: uterine leiomyoma

Arteritis without connective tissue disease
Congenital pulmonary artery stenoses
Parasites: hydatidosis

GROUP 5: PH WITH UNCLEAR AND/OR MULTIFACTORIAL MECHANISMS

Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders
Systemic and metabolic disorders: pulmonary Langerhans cell histiocytosis, Gaucher disease, glycogen storage disease, neurofibromatosis, sarcoidosis
Others: chronic renal failure with or without hemodialysis, fibrosing mediastinitis
Complex congenital heart disease
- Segmental pulmonary hypertension: isolated pulmonary artery of ductal origin, absent pulmonary artery, pulmonary atresia with ventricular septal defect and major aortopulmonary collateral arteries, hemitruncus, other
- Single ventricle: unoperated, operated
- Scimitar syndrome

PAH, pulmonary arterial hypertension; PCH, pulmonary capillary hemangiomatosis; PH, pulmonary hypertension; PVOD, pulmonary veno-occlusive disease.
From Simonneau G, Montani D, Celermajer DS, et al. Haemodynamic definitions and updated clinical classification of pulmonary hypertension. *Eur Respir J.* 2019;53(1):1801913.

predisposing conditions, or exposure to medications implicated in the pathogenesis of PH.[27] Thus, PAH is a diagnosis of exclusion requiring several investigations beyond an RHC to confirm (see later). Of importance, certain diseases

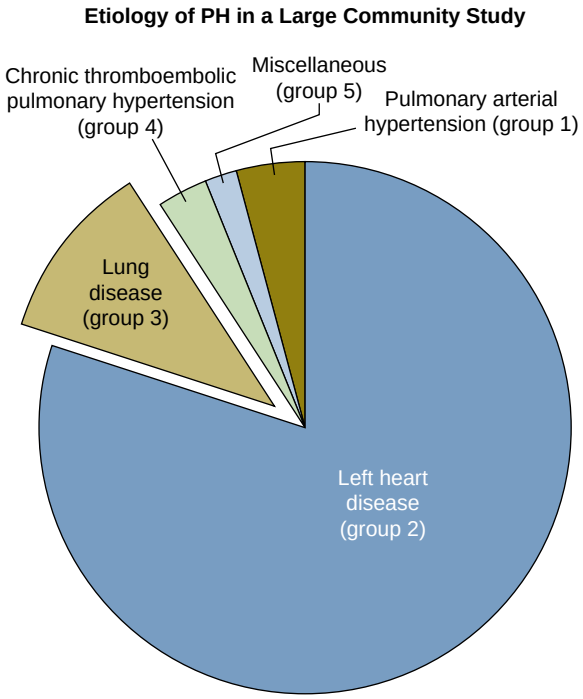

Figure 83.1 Prevalence of *pulmonary hypertension* (PH) by cause in a large community-based study. Note that left heart disease is by far the most common cause of PH, whereas chronic lung disease is the second most common cause. (Data from Strange G, Playford D, Stewart S, et al. Pulmonary hypertension: prevalence and mortality in the Armadale echocardiography cohort. *Heart.* 2012;98:1805–1811.)

and conditions predispose to the development of PAH and, as such, a detailed medical history and laboratory evaluation to evaluate for the presence of these underlying risk factors is integral to the general evaluation of PH (see also Chapter 84).

POPULATIONS AT RISK FOR PULMONARY ARTERIAL HYPERTENSION

Schistomiasis

Although rigorous epidemiologic studies including RHC-proven PAH are lacking, patients with schistosomiasis may represent the largest global population at risk of PAH, with an estimated prevalence of schistosomiasis of more than 200 million and an estimated 40 million of those at high risk of PAH. Of those with schistosomiasis, hepatosplenic involvement imparts the highest risk, with about 10–20% of these patients developing PAH; extrapolating these estimates suggests that 4 to 6 million schistosomiasis patients may have PAH.[28–30]

Scleroderma

Whereas PAH complicates many forms of CTD, it is most prevalent in patients with *systemic sclerosis* (SSc, scleroderma). Cohort studies suggest that from 5–15% of patients with SSc will develop PAH.[31–33] Of importance, SSc is the only at-risk cohort for which data exist supporting routine screening for PAH. The *Detection of PAH in SSc* (DETECT) study, a multinational cross-sectional study of patients with scleroderma, included 488 patients considered at increased risk for PAH due to duration of SSc for more than 3 years

and a predicted *diffusion capacity for carbon monoxide* (DL_{CO}) less than 60% predicted.[34] Patients with a forced vital capacity of less 40% predicted, renal insufficiency, LHD, or pregnancy were excluded. Four hundred sixty-six patients underwent RHC, which revealed PH in 31% and PAH in 19% (6% had group 2 PH based on an elevated PCWP, and 6% had group 3 PH based on greater degree of underlying interstitial lung disease). To identify factors predictive of PH, more than 100 variables, including demographic, serologic, functional, and echocardiographic measurements, were included in a stepwise manner with multivariable logistic regression models. These analyses identified eight clinical variables that, when applied in a two-step algorithm, predicted the presence of PH on RHC with a low rate (4%) of missed PAH diagnoses. Based on these findings, this algorithm has been recommended for implementation in clinical practice by the 6th WSPH statement. However, it should also be noted that implementation of the DETECT algorithm will likely increase identification of patients with mildly elevated pulmonary pressures (mPAP, 21–24 mm Hg) for whom there are no approved therapies.[36]

Other Connective Tissue Diseases

The incidence and prevalence of PAH in other forms of CTD is less well described. *Mixed connective tissue disease* (MCTD) is a CTD characterized by clinical features of several different CTDs, including SSc, *systemic lupus erythematosus* (SLE), *rheumatoid arthritis* (RA), and polymyositis. The distinguishing laboratory feature of MCTD is the presence of antibodies to *uridine-rich* (U1) *ribonuclear protein* (RNP) polypeptides.[37] Although lung disease, including *interstitial lung disease* (ILD) and PH, are commonly found in MCTD, epidemiologic studies defining the incidence and prevalence of such complications are lacking. Estimates of PAH prevalence in MCTD range from 1–50%.[32,38–40] Still, because many patients with MCTD have SSc features, expert consensus recommends yearly screening similar to that used for SSc.[41] The estimated prevalence of PAH in SLE is also poorly defined, ranging from 0.0005–14% of patients.[42–44] A multicenter study designed to determine incidence and prevalence of PH in SLE is currently ongoing and will provide important estimates of PH in this patient population.[45] RA, polymyositis, and Sjögren syndrome have lower estimated prevalence of PAH than either SSc or MCTD. Thus, routine screening for PAH in these populations is not recommended.

Other at-Risk Cohorts

Currently, there are no recommendations for routine screening for PAH in the other known at-risk populations. However, the 6th WSPH suggests that patients with HIV with high-risk features, such as female sex, intravenous drug use, cocaine use, hepatitis C virus coinfection, and known *negative regulatory factor* (Nef) or *transactivator of transcription* (Tat) HIV proteins, as well as U.S. Blacks, should undergo screening for PAH. The frequency and type of screening modalities are not specified. Patients with hereditary hemorrhagic telangiectasia should undergo screening with an echocardiogram if symptoms of dyspnea develop or if heart failure or hepatic arteriovenous malformations develop. Patients with portal hypertension should undergo screening echocardiography, given the reported prevalence of PAH of 2–6% in this population.[46,47] Although patients with congenital heart disease are at risk of PAH, only patients who have undergone surgical correction or who have persistent systemic-to-pulmonary shunts should undergo screening, because their risk of developing PAH is increased compared to other *congenital heart disease* (CHD) patients.[48] This may be due to chronic increased pulmonary blood flow leading to pulmonary vascular remodeling and increased afterload on the *right ventricle* (RV). Patients who have corrected defects and an increased PVR at baseline should undergo yearly testing.

Table 83.3 Drugs and Toxins Associated With PAH

Definite	Possible
■ Aminorex	■ Cocaine
■ Fenfluramine	■ Phenylpropanolamine
■ Dexfenfluramine	■ L-tryptophan
■ Benfluorex	■ St. John's wort
■ Methamphetamines	■ Amphetamines
■ Dasatinib	■ Interferon-α, interferon-β
■ Toxic rapeseed oil	■ Alkylating agents
	■ Bosutinib
	■ Direct-acting antiviral agents for hepatitis C (e.g., sofosbuvir)
	■ Leflunomide
	■ Indirubin (Chinese herb Qing-Dai)

PAH, pulmonary arterial hypertension.
From Simonneau G, Montani D, Celermajer DS, et al. Haemodynamic definitions and updated clinical classification of pulmonary hypertension. *Eur Respir J.* 2019;53(1):1801913.

Heritable Pulmonary Arterial Hypertension

Screening for heritable PAH varies widely by country and is an important practice gap in the evaluation of patients with PAH. Given that PAH mutations are found in nearly 20% of patients with presumed sporadic PAH and nearly 90% of patients with a family history of PAH, genetic testing and genetic counseling should be incorporated into the evaluation of PAH patients.[49] As recommended by the *European Society of Cardiology/European Respiratory Society* (ESC/ERS) guidelines, asymptomatic carriers of genetic mutations should undergo annual echocardiography.[27] Optimal screening strategies for patients with certain gene mutations are currently under investigation (NCT01600898; www.clinicaltrials.gov).

Exposures

Several drugs and toxins are associated with increased risk of PAH, classified as "definite" and "possible" risk factors. Anorexigens, including aminorex fumarate, fenfluramine, fenfluramine/phentermine, and benfluorex, are considered definite risk factors for PAH. Newer chemotherapeutic agents, such as the tyrosine kinase inhibitor dasatinib (definite) and bosutinib (possible), along with immunomodulatory therapies for rheumatologic diseases (leflunomide, possible) and hepatitis C virus (sofosbuvir, interferon-α, and interferon-β, possible) have been implicated as risk factors for PAH.[50–54] Other exposures that may lead to PAH are shown in Table 83.3.

A recent, large cohort study confirmed a strong association between methamphetamine exposure and development of PAH, prompting inclusion of methamphetamines

as a definite risk factor for PAH.[55] Patients with methamphetamine-associated PAH were more likely to be female, have more severe hemodynamic perturbations at diagnosis, and have poorer outcomes than idiopathic PAH patients, demonstrating an increased risk of hospitalizations. Furthermore, pathologic samples showed vascular changes in the pulmonary vasculature similar to idiopathic PAH and features of proliferative capillaritis, similar to pulmonary capillary hemangiomatosis or pulmonary veno-occlusive disease. These findings further strengthen the association between methamphetamine exposure and development of PAH. Even though the 6th WSPH statement recommended heightened awareness of exposures and risk of PAH, no specific screening protocols were endorsed.

Diagnosis

Most patients will not have a risk factor for PAH and thus will not be routinely screened for PAH. Given the multiple potential causes of PH in general, PAH is a diagnosis of exclusion. Therefore, establishing the diagnosis of PAH requires a high index of suspicion and a specific algorithmic approach (Fig. 83.2). This approach is discussed in detail in the following section.

CLINICAL PRESENTATION

The first step in the evaluation of any patient with possible PH is a comprehensive history and physical examination. Symptoms of PH tend to be nonspecific. Most commonly, patients note exertional dyspnea, but fatigue, weakness, chest pain, and light-headedness, and even cough can be prominent.[56] Signs of PH can include peripheral edema; other findings of right heart failure, such as ascites and exertional syncope, tend to present later in the disease course. Other rare manifesting signs include hoarseness related to recurrent laryngeal nerve compression from an enlarged PA (Ortner syndrome) and hemoptysis; as such, PH should be considered in the differential diagnosis of patients who present with these findings.

The physical examination is a key component of the evaluation of patients with suspected PH. An augmented second heart sound (P2 component) is commonly found in patients with established PAH and perhaps other types of PH, although that is not reported.[57] Other findings include jugular venous distension, ascites, and peripheral edema. Cardiac auscultation can elicit a high-pitched systolic ejection click in the second and third intercostal space on the left sternal border and can be followed by a systolic ejection murmur produced by the ejection of blood into the dilated PA. An S3 gallop arising from the right side of the heart may be heard in the fourth and fifth intercostal spaces along the left sternal border. A presystolic S4 can also be heard, reflecting right atrial contraction and expulsion of blood into the dilated RV. More advanced disease may be associated with a palpable thrill over the chest as the pulmonary valve closes. *Tricuspid regurgitation* (TR) is often present and results in a pansystolic murmur at the left sternal border; when PH is severe, the murmur can evolve to include a diastolic component known as a Graham Steell murmur. On the back, a holosystolic murmur between the scapulae can sometimes be heard in patients with CTEPH, resulting from turbulent blood flow across the central pulmonary arteries.

Special attention to identification of conditions that might cause elevated pulmonary pressures, such as underlying heart disease, lung disease, venous thromboembolism, liver or renal disease, or CTD is imperative. These comorbid conditions can also have specific symptoms and signs that suggest certain diseases (e.g., Velcro-like crackles on lung auscultation with ILD, left-sided S3 or S4 gallop with heart failure with reduced ejection fraction) that can focus further evaluation. Similarly, findings such as profound hypoxemia or orthopnea are more likely to be found in patients with PH related to underlying lung disease or LHD, respectively.

DIAGNOSTIC TESTING

BLOOD TESTING

In general, blood testing is not useful to establish the diagnosis of PH but is useful to classify some forms of PH and to assess disease severity. Routine testing, including complete blood count, basic metabolic panel, liver function, and thyroid function, should be performed. Serum *brain natriuretic peptide* (BNP) and *N-terminal pro-BNP* (NT-proBNP) help establish disease severity because both reflect RV dysfunction and predict outcomes in PAH.[58] Patterns of hepatic congestion on liver function testing can also reflect disease severity but alternatively can reflect intrinsic liver disease that may be directly related to development of PAH.

It is imperative to screen for diseases known to predispose to PAH, including CTD, HIV, and hepatitis. Recommended testing for CTD includes antinuclear antibody; if suspicion is high for CTD based upon history and physical examination, additional testing should be considered (see also Chapter 92). For example, if signs of scleroderma are present, additional testing for anticentromere, antitopoisomerase, anti-RNA polymerase III, and U1-RNP antibodies should be undertaken. Given the possibility of overlap with other CTDs, double-stranded DNA (for SLE) and anti-Ro and anti-La (for Sjögren syndrome) should be sent. Of note, many experts consider the presence of U1-RNP antibodies necessary to define MCTD, which is distinct from overlap syndrome in which features of several CTDs may coexist in the same patient but in which U1-RNP antibodies are absent. Because expert consensus recommends that MCTD patients undergo early-detection protocols for PAH similar to SSc patients, proper classification of CTD is important and may require consultation with a rheumatologist.[42]

If there is concern for thrombophilia, additional blood work to screen for coagulopathies and thrombophilia should be undertaken, including testing for anticardiolipin, lupus anticoagulant, and anti-β_2 glycoprotein antibodies.

PULMONARY FUNCTION TESTING

Pulmonary function testing is routinely performed in the evaluation of dyspnea and thus is an important part of the evaluation of PH.[59] Of importance, spirometry alone is insufficient to evaluate for PH; lung volumes and D_{LCO} are key studies to assess for obstructive and restrictive lung disease and effective alveolar-capillary surface area for gas exchange, respectively. Patients with PAH may have mild restrictive lung disease in the absence of obvious parenchymal, thoracic cage, or musculoskeletal disease. Severe

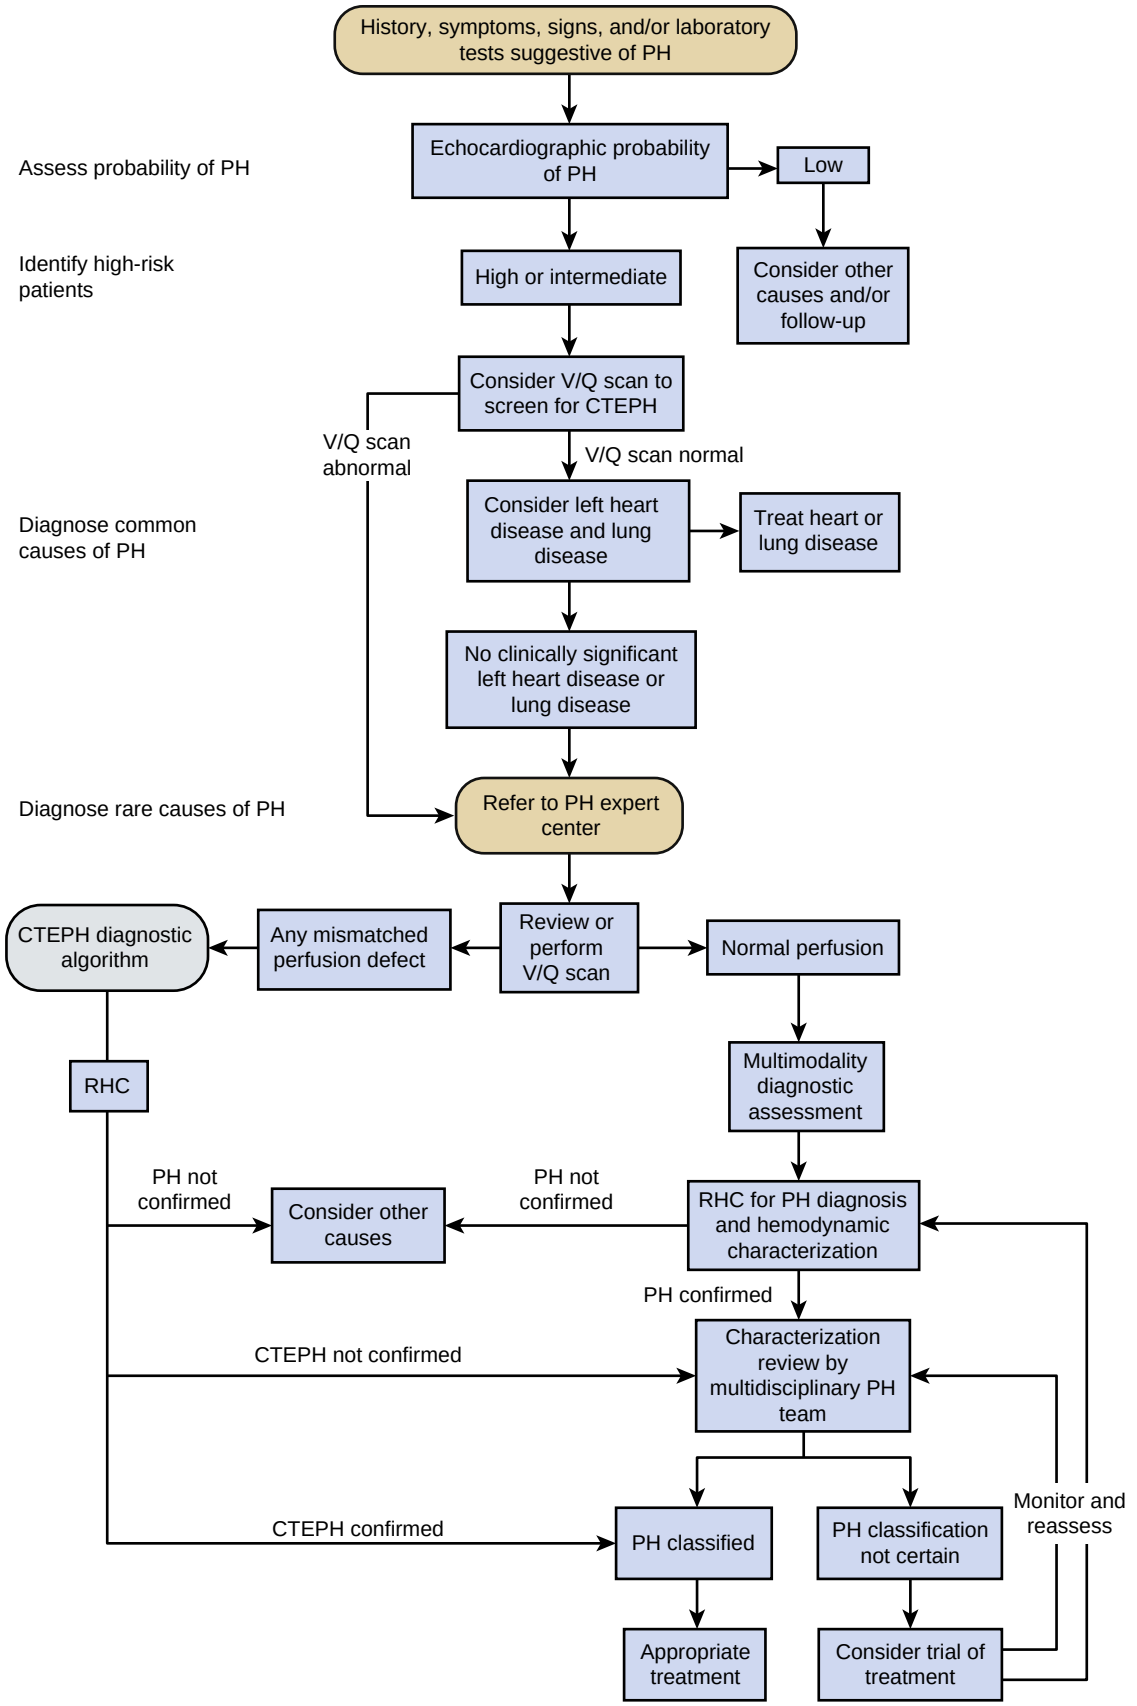

Figure 83.2 Algorithm for the diagnosis of pulmonary hypertension (PH) and its causes. Laboratory tests done locally can include electrocardiography, computed tomography, *ventilation/perfusion* (V/Q) scans, sleep testing, tests to evaluate for left heart disease and chronic lung disease, and blood work. The decision to refer to an expert center versus watchful waiting is based on the probability of PH and the underlying cause (i.e., *chronic thromboembolic pulmonary hypertension* [CTEPH], left heart disease, interstitial lung disease). The patient should be referred to an expert center when no clear cause of PH is identified, when rare causes of PH are identified or suspected, and when further expertise on evaluation and management of PH is needed. RHC, right heart catheterization. (Modified from Frost A, Badesch D, Gibbs JSR, et al. Diagnosis of pulmonary hypertension. *Eur Respir J.* 2019;53[1]:1801904.)

diffusing limitations suggest concomitant parenchymal or airways disease or chronic thromboembolic disease; rare forms of PAH, such as pulmonary capillary hemangiomatosis and pulmonary veno-occlusive disease, may also present with similar reductions in D_{LCO}.[60] Low D_{LCO} also can suggest evolving pulmonary vascular disease in patients with underlying cardiopulmonary disease and may be associated with poor prognosis in patients with *heart failure with preserved ejection fraction* (HFpEF), COPD, and ILD.[61–63]

Arterial blood gases, while not routinely obtained for the evaluation of PH, may be useful in the assessment of patients with established or suspected PAH. Mild hypoxemia and mild hypocapnia are commonly found yet are not strongly associated with hemodynamics. However, hypocapnia and not hypoxemia has been shown to represent an independent marker of mortality in a large cohort of patients with idiopathic PAH.[64] The mechanisms for this finding are not fully understood. Increased ventilatory drive leading to hypocapnia may result from multiple mechanisms: impaired ventilatory efficiency, low cardiac output, and low oxygen delivery. Each of these factors represent worsening cardiopulmonary function that can be linked to the impact of progressive pulmonary vascular disease through worsening dead-space ventilation and RV failure.

SIX-MINUTE WALK TESTING

The *6-minute walk test* (6MWT) is a submaximal exercise test commonly used to evaluate functional capacity in patients with various cardiopulmonary diseases.[65] *Distance achieved during the 6MWT* (6MWD) at the time of diagnosis is a strong predictor of survival in PAH.[66,67] Furthermore, 6MWD was the primary outcome measure for registration trials of novel PAH therapies for most currently available therapies. However, its role in the diagnosis of PH is limited because it lacks sensitivity and specificity for this diagnosis. Rather, the 6MWD provides useful prognostic data and provides a baseline measure of functional capacity that can be followed clinically over time to assess response to therapy and disease progression.[68–70]

NOCTURNAL OXIMETRY AND SLEEP TESTING

Sleep-disordered breathing is a highly prevalent disease, affecting greater than 30% of adult men and 17% of adult women in the United States.[71] Current PH guidelines recommend all patients undergo nocturnal oximetry as a screening test for sleep-disordered breathing because nocturnal hypoxemia is often associated with *obstructive sleep apnea* (OSA). In addition to screening for OSA, overnight oximetry is useful in identifying individuals at risk for nocturnal hypoxemia and hypoventilation in the absence of OSA. Normal sleep is characterized by a mild reduction in arterial P_{O_2} and mild hypoventilation. Individuals with PH who are on the steep portion of the oxyhemoglobin dissociation curve will experience a more profound decrease in arterial oxygen saturation during sleep compared to healthy individuals with normal lung function (see also Chapter 117 and Fig. 117.6). Thus, nocturnal hypoxemia and/or hypoventilation should be a consideration in any individual with a resting, awake, upright oxygen saturation less than 95%.[72] Given the association between OSA and PH and the potential for treatment of OSA to improve cardiopulmonary function, it is important to screen for this disease.[49,73] However, many practitioners do not obtain overnight oximetry despite guideline recommendations.[74] The use of home sleep apnea testing, which includes overnight oximetry, is a validated diagnostic tool for patients with moderate to high pretest probability of having OSA.[75] The use of home sleep apnea testing to screen asymptomatic individuals at a population level is not recommended; individuals with a low pretest probability of having OSA should be referred for in-laboratory sleep testing (polysomnography).[76]

CARDIOPULMONARY EXERCISE TESTING

Cardiopulmonary exercise testing (CPET) is used in the diagnostic evaluation of patients with unexplained dyspnea and, as such, may be useful in the evaluation of patients with suspected PH. In addition, CPET may be used to prognosticate and to assess response to therapy in PAH.[77] However, the utility of CPET is limited by the need for expertise in the conduct and interpretation of study results. Still, even with these caveats, CPET can be a useful tool to evaluate cardiopulmonary disease and assess for possible pulmonary vascular disease in this setting.[49] The role of invasive CPET in the evaluation of PH is discussed later.

ELECTROCARDIOGRAPHY

Electrocardiography (ECG) has an unknown sensitivity and specificity for the diagnosis of PH. Although considered a useful tool to assess for conduction abnormalities and arrhythmias that commonly complicate PH, findings more specific to the diagnosis of PH tend to develop late in the course of the disease (see Fig 85.5). For example, RV hypertrophy, denoted on ECG by tall R waves in V_1, with an R:S ratio of greater than 1, and prominent S waves in V_5 and V_6, with an R:S ratio of less than 1, is found in moderate to severe PH and not a useful screening tool to detect early disease. Other findings, such as right axis deviation, p pulmonale (large-amplitude P waves, typically found in the inferior leads), and large S waves in the inferior leads suggest possible PH as well. In the setting of underlying lung disease such as COPD, the presence of ECG evidence of right heart dysfunction (right axis deviation, p pulmonale, RV hypertrophy) portends a poor prognosis.[78]

TRANSTHORACIC ECHOCARDIOGRAPHY

Transthoracic echocardiography (TTE) is the most important noninvasive screening tool for PH (Fig. 83.3). TTE is widely available, relatively inexpensive, and safe by allowing repeated use without exposure to ionizing radiation. A useful tool to estimate pulmonary pressures and to evaluate cardiac chamber and valvular structure and function, the echocardiogram is often the first test that suggests PH. In addition to estimation of the pulmonary pressures, the echocardiogram is essential to evaluate for nonpulmonary causes of PH. Cardiac disease, including ischemic or nonischemic dysfunction of the *left ventricle* (LV), aortic or mitral valve disease, and CHD with left-to-right shunt, is the most common cause of PH.[79,80]

Of importance, echocardiography is a key component in the evaluation of HFpEF, an emerging epidemic in the United States.[24,81] Patients with HFpEF may be at particularly high risk of developing PH but typically have elevated left-sided

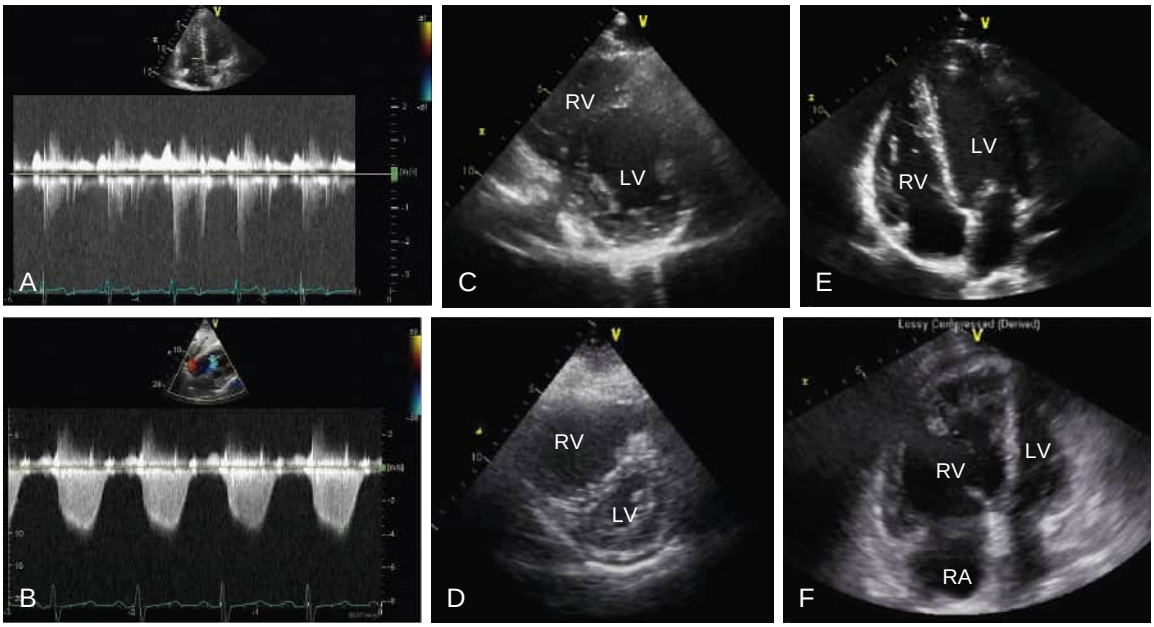

Figure 83.3 Echocardiography in the evaluation of pulmonary hypertension. (A) Poor-quality tricuspid regurgitant jet that cannot be used to estimate *pulmonary artery systolic pressure* (PASP). (B) Good-quality tricuspid regurgitant jet useful for estimating PASP. However, even when a good-quality jet can be obtained, the echocardiographic assessment of PASP may be inaccurate. (C) Short-axis echocardiographic image of a normal heart demonstrating a rounded left ventricle (LV) and normal-appearing right ventricle (RV). (D) Short-axis echocardiographic image from a patient with pulmonary hypertension demonstrating flattening of the interventricular septum and a D-shaped LV during systole and a large RV. (E) Apical four-chamber echocardiographic view of a normal heart demonstrating a normal-sized RV and LV. (F) Apical four-chamber echocardiographic view from a patient with pulmonary hypertension demonstrating a markedly enlarged RV with a small, compressed LV. There is also enlargement of the right atrium (RA) (see Video 83.1).

filling pressures on invasive hemodynamics, thereby fulfilling criteria for postcapillary PH.[82] However, HFpEF patients can also demonstrate combined pre–postcapillary physiology (elevated mean PAP with elevated PCWP and elevated PVR) or even precapillary physiology (elevated mean PAP with normal PCWP and elevated PVR). Thus, patients with evidence of PH and echocardiographic findings of HFpEF require thoughtful and thorough evaluation.

It is important to recognize that there are significant limitations in the diagnostic accuracy of echocardiography, especially for the estimates of *pulmonary artery systolic pressure* (PASP). Often, elevated estimates of PASP on echocardiography prompt the clinician to consider PH. Estimated PASP measurement is based upon the modified Bernoulli equation. This calculation uses the pressure gradient across the tricuspid valve between the right atrium and ventricle (pressure gradient = $4v^2$, where v = peak velocity of the TR jet)[83] and adds this to the right atrial pressure estimate based upon the size and collapsibility of the inferior vena cava to obtain an estimate of the right ventricular systolic pressure, which in the absence of pulmonary valve stenosis equals an estimated PASP. This calculation requires presence of a TR jet, which may not be detectable in up to 60% of patients with RHC-proven PH.[84–86] Presence of underlying COPD, ILD, or obesity affects image quality. For example, in a large series of patients with advanced lung disease, PASP could only be estimated in 44% of patients due to inability to obtain adequate Doppler windows.[87] Further, the correlation between echocardiographic estimates of PASP (when obtained) and invasively measured PASP is only moderate and is often inaccurate (Fig. 83.4).[85,86] Of importance, much of the inaccuracy of the echocardiographically estimated PASP seems to be attributable to right atrial pressure estimates; in one series of patients with PH who underwent echocardiography and RHC within 1 hour, 50% of the overestimation of PASP was due to overestimation of the right arterial pressure (eFig. 83.1).[88] Thus estimates of PASP may be inaccurate and should not be used as the sole echocardiographic measure upon which to determine the likelihood of PH.

Notwithstanding the limitations in the measurement of PASP, echocardiography does provide important structural and functional information about the heart and thereby suggests the presence of PH independent from PASP estimates. For example, evidence of LV systolic dysfunction in the presence of elevated right ventricular systolic pressure estimates imply heart failure with reduced ejection fraction and possible group 2 PH. Dilation of right-sided structures and RV hypertrophy suggest increased RV afterload. Flattening or leftward shift of the interventricular septum during systole and diastole reflect RV pressure and volume overload, respectively, and are consistent with severe RV dysfunction. (See Fig. 83.3D.)

Whereas numerous echocardiographic measurements have been studied to determine their utility in the diagnosis of PH, current guidelines suggest combining the following parameters to stratify the probability of PH: peak velocity of the tricuspid regurgitant jet, RV/LV ratio, RV outflow acceleration time and pattern, PA diameter, inferior vena cava diameter, and right atrial area[27] (Table 83.4). Presence of an elevated TR jet velocity greater than 2.8 m/sec in isolation portends an intermediate probability of PH; additional echocardiographic signs of PH just listed increases this likelihood (eTable 83.1).

Advances in echocardiography offer additional insight into RV structural and functional assessment, such as

eTable 83.1 Echocardiographic Probability of Pulmonary Hypertension (PH) in Symptomatic Patients With a Suspicion of PH

Peak Tricuspid Regurgitant Jet Velocity (m/sec)	Presence of Other Signs of PH on Echocardiography	Echocardiographic Probability of PH
≤2.8 or not measurable	No	Low
>2.8 or not measurable	Yes	Intermediate
2.9–3.4	No	Intermediate
2.9–3.4	Yes	High
>3.4	Not required	High

three-dimensional imaging and strain assessment of the RV using speckle tracking echocardiography, in which digital echocardiographic images generated by ultrasound interaction with myocardial tissue are tracked over the cardiac cycle to identify global and segmental myocardial deformation through spatiotemporal displacement.[89] Although these methods may have clinical utility, there remain limitations to their routine application in the assessment of patients with suspected PH, largely related to a lack of data defining normal parameters.[90] Further, despite advances in echocardiographic technology, accurate and reliable noninvasive estimates of left-sided filling pressures and cardiac output remain elusive. Therefore, echocardiography cannot be used to distinguish between precapillary and postcapillary PH. In sum, echocardiography remains the most useful screening tool for PH but is not a reliable tool to diagnose PH or classify PH phenotypes.

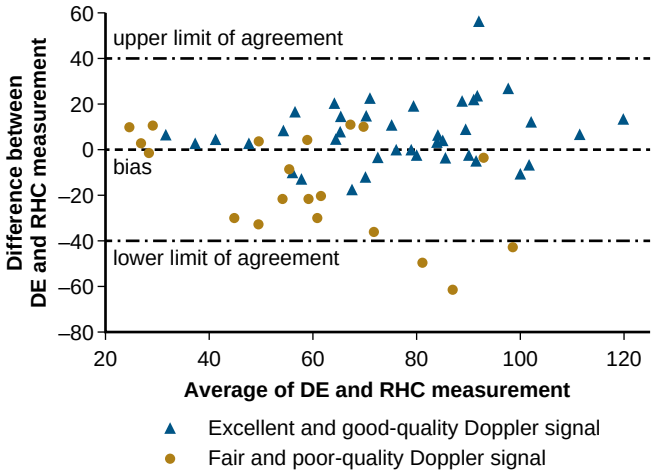

Figure 83.4 Bland-Altman plot of Doppler echocardiographic estimates of pulmonary artery pressure and right heart catheterization (RHC) measurements showing poor correlation between the two methods. Even though the bias (average difference between these two methods) is only –0.6 mm Hg, the 95% limits of agreement are from +38.8 to –40.0 mm Hg. The wide limits of agreement show that echocardiography can both significantly overestimate and underestimate PASP. Poor Doppler imaging of the trans-tricuspid regurgitant jet and inaccurate estimates of right atrial pressure account, in part, for the wide limits of agreement. DE, Doppler echocardiography; PASP, pulmonary artery systolic pressure. (From Fisher MR, Forfia PR, Chamera E, et al. Accuracy of Doppler echocardiography in the hemodynamic assessment of pulmonary hypertension. *Am J Respir Crit Care Med.* 2009;179[7]:615–621.)

CARDIAC MAGNETIC RESONANCE IMAGING

Although it offers superior image resolution and thus a more accurate assessment of the volume, mass, and systolic function of the heart, *cardiac magnetic resonance* (CMR) imaging is not a widely used tool in the screening for PH largely due to its high cost and limited availability. CMR is particularly useful for the diagnosis of CHD, such as partial anomalous pulmonary venous return, atrial septal defect, and other systemic-to-pulmonary shunts, all of which can be associated with PH. CMR has been studied in populations at high-risk of PH, such as scleroderma, in which ventricular mass index (ratio of RV mass to LV mass) demonstrated a high positive and negative predictive value for PH when assessed against invasive hemodynamic measurements.[91] A more recent registry-based study of patients at risk for PH demonstrated acceptable test characteristics for CMR when compared to invasively measured hemodynamics.[92] Larger studies are required to confirm these findings, but there may be a role in the future for CMR in the diagnostic evaluation of PH in at-risk populations.

COMPUTED TOMOGRAPHY

Computed tomography (CT) of the chest is an integral part of the evaluation of a patient with suspected PH. CT assesses the pulmonary parenchyma and can identify disease of the airways, parenchyma, pleura, and mediastinum. CT may identify abnormalities in extrathoracic organs, such as the liver, as a clue to portopulmonary hypertension (Fig. 83.5A–B). CT can establish the diagnosis of ILD (see Fig. 83.5C–D) and identify emphysema. Presence of a dilated esophagus suggests underlying SSc and should prompt careful assessment for this disease. CT scanning may uncover abnormal vascular or cardiac enlargement consistent with extracardiac or intracardiac shunting (see Fig. 83.5E–F). Typical findings of sarcoidosis, ranging from perilymphatic micronodules to pulmonary fibrosis with symmetrical hilar and mediastinal lymphadenopathy, can be seen on a chest CT (see Fig. 83.5G–H). Pleural effusions are rare in PAH and suggest LHD or primary lung disease as the underlying cause of PH. Of importance, rare forms of PAH, such as pulmonary capillary hemangiomatosis or pulmonary veno-occlusive disease, have characteristic CT findings necessary to establish proper diagnosis (see Fig. 83.5I–K). For example, centrilobular ground-glass opacities can be seen in severe idiopathic PAH as a manifestation of cholesterol granulomas

Table 83.4 Echocardiographic Signs Suggesting PH

Ventricles	Pulmonary Artery	Inferior Vena Cava and Right Atrium
RV/LV basal diameter ratio > 1.0 Flattening of the interventricular septum (LV eccentricity index > 1.1 in systole and/or diastole)	Right ventricular outflow Doppler acceleration time < 105 msec and/or midsystolic notching Early diastolic pulmonary regurgitation velocity > 2.2 m/sec Pulmonary artery diameter > 25 mm	Inferior vena cava diameter > 21 mm with decreased inspiratory collapse (<50% with a sniff or <20% with quiet inspiration) RA area (end-systole) > 18 cm^2

Echocardiographic signs from at least two different columns from the list should be present to alter the level of echocardiographic probability of PH.

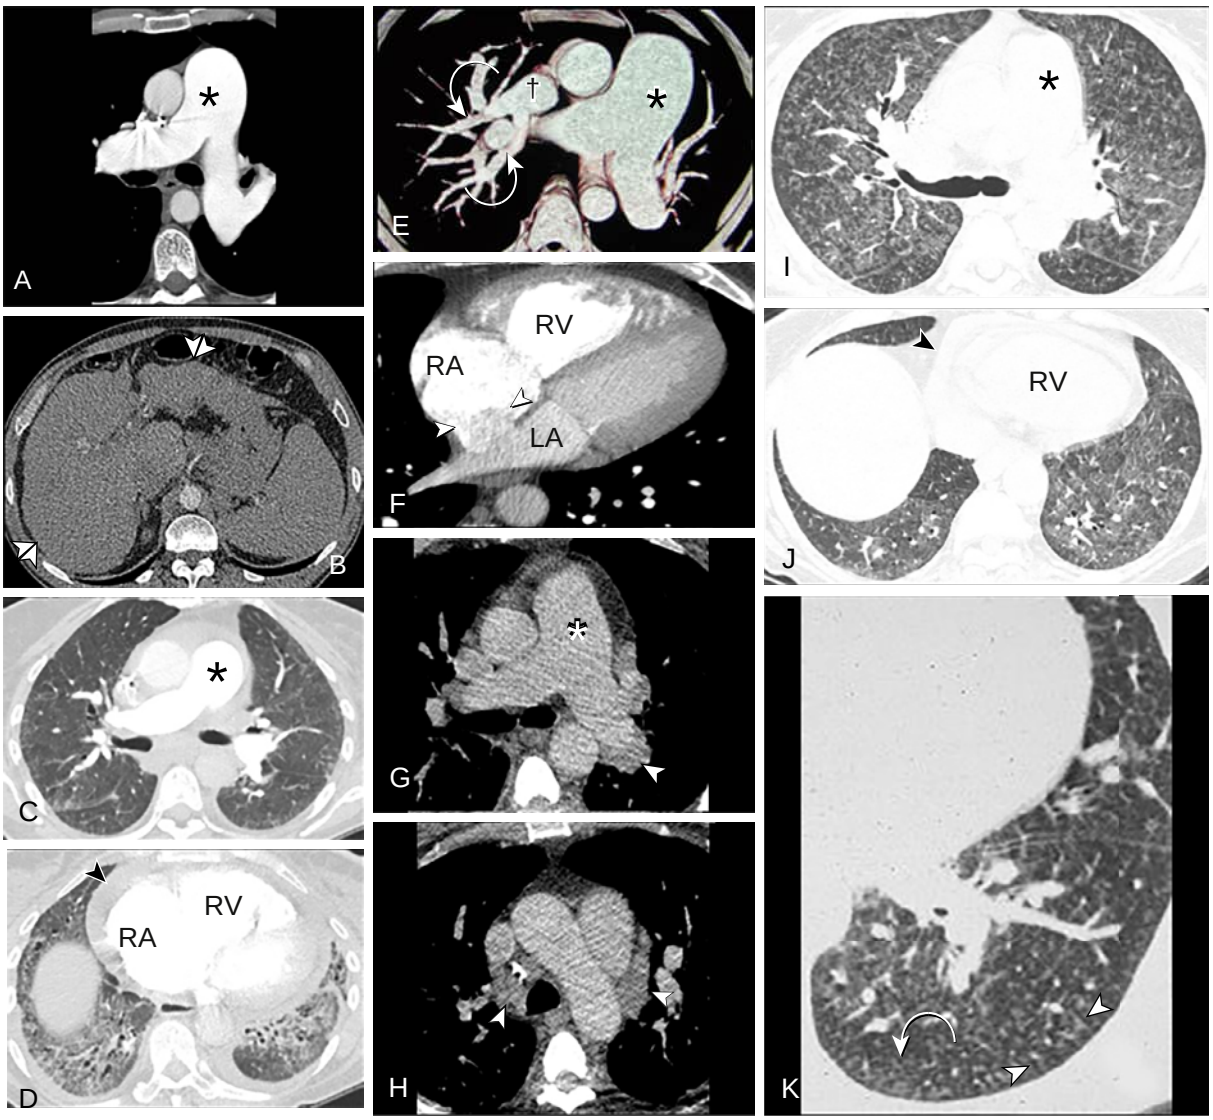

Figure 83.5 ***Computed tomography*** **(CT) imaging leading to diagnosis of disorders producing** ***pulmonary hypertension*** **(PH).** (A–B) Portopulmonary hypertension. Note enlarged main pulmonary artery (*asterisk*) and nodular liver contour (*double arrowheads*), consistent with cirrhosis. (C–D) PH associated with interstitial lung disease. Note enlarged main pulmonary artery (*asterisk*), right atrium (RA), right ventricle (RV), and basilar ground-glass opacity, reticulation, and traction bronchiectasis representing nonspecific interstitial pneumonia in a patient with scleroderma; note that the esophagus is mildly dilated. A small pericardial effusion (*single arrowhead*) is a not-infrequent finding in patients with PH. (E) Pulmonary hypertension due to extracardiac shunt. Axial maximum intensity projected CT shows an enlarged main pulmonary artery (*asterisk*) due to anomalous right upper lobe pulmonary veins (*curved arrows*) draining into the superior vena cava (*dagger*). (F) PH due to intracardiac shunt. Axial enhanced CT shows an enlarged RA and RV with a rightward bowing interatrial septum (*arrowheads*), allowing left-to-right shunt; note how left atrial contrast attenuation appears to extend into the denser right atrial contrast. Quantification of pulmonary-to-systemic flow at magnetic resonance imaging was calculated at 1.6. (G–H) Pulmonary hypertension in sarcoidosis. Note enlarged main pulmonary artery (*asterisk*). Bilateral peribronchial and mediastinal lymph node enlargement (*arrowheads*) is present, showing noncaseating granulomas on biopsy. (I–J) Pulmonary capillary hemangiomatosis. Axial enhanced CT shows multiple poorly defined centrilobular ground-glass opacity nodules. Note enlarged main pulmonary artery (*asterisk*), RV, and small pericardial effusion (*arrowhead*). (K) Pulmonary veno-occlusive disease. Axial thoracic CT displayed in lung windows shows basal smooth interlobular septal thickening (*arrowheads*), and patchy areas of inhomogeneous lung opacity, with some of the areas of increased attenuation consistent with ground-glass opacity, best seen in the medial lung base. Faint ground-glass opacity centrilobular nodules (*curved arrow*) are present. LA, left atrium. (Courtesy Michael B. Gotway, MD.)

resulting from repeated microhemorrhages in the pulmonary vasculature or from profuse proliferation of capillaries as seen in pulmonary capillary hemangiomatosis (see Fig. 83.5I–J).[93–95] Similarly, pulmonary veno-occlusive disease typically presents with interstitial edema, diffuse central ground-glass opacities, intralobular sepal thickening, and mediastinal lymphadenopathy (see Fig. 83.5K).[96] Given the marginal response to pulmonary vasodilator therapies and overall poor prognosis, urgent lung transplantation evaluation should be pursued if this diagnosis is suspected.[97] Thus, parenchymal abnormalities seen on CT chest should alert the clinician to consider rare forms of PAH in the proper clinical context.

CT also provides cardiac images useful in the assessment of PH. Findings of adaptation or failure of the right-sided cardiac structures, such as right atrial enlargement, RV enlargement (RV to LV diameter ratio greater than 1 at the midventricular level), RV hypertrophy (wall thickness > 4 mm), straightening or bowing of the interventricular septum, pericardial effusion, and dilation of the inferior

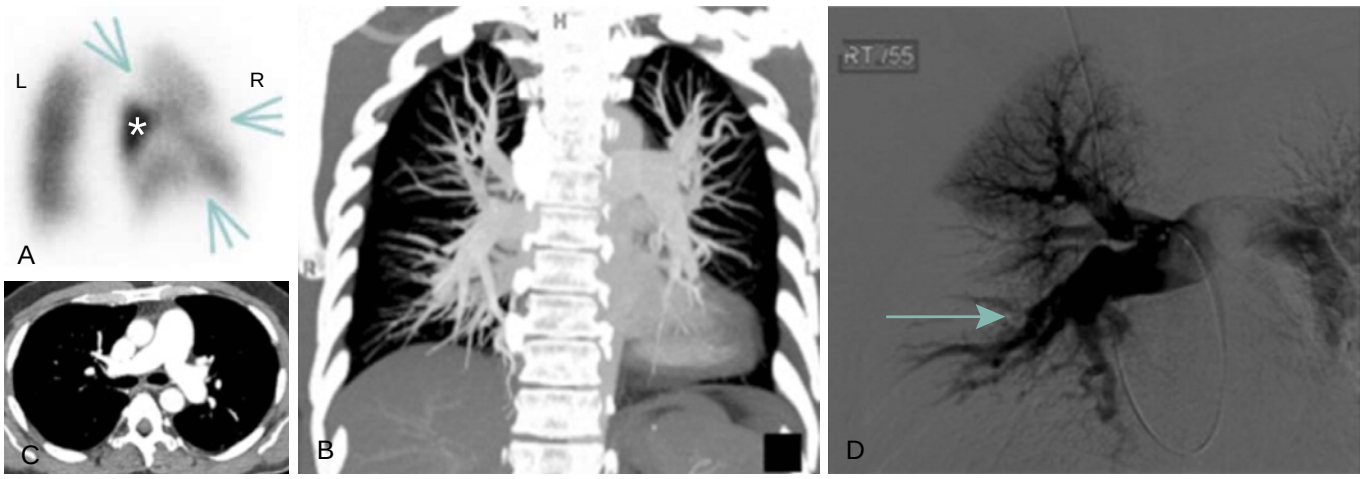

Figure 83.6 An example of discordant findings of thromboembolic disease between ventilation-perfusion scanning and *computed tomography* (CT) with angiography of a single patient. (A) Perfusion image obtained after injection of technetium-99m macroaggregated albumin in right posterior oblique view showing perfusion defects in the right upper lobe, right middle lobe, and right lower lobe (*arrows*). There is an area of increased intensity in the superior segment of the right lower lobe that represents artifact from insignificant clotting of the Tc-99m macroaggregated albumin (*asterisk*). The ventilation scan was completely normal. (B) Coronal maximum intensity projection CT pulmonary angiogram shows tortuous and dilated pulmonary arteries but no pulmonary arterial filling defects or other signs of chronic thromboembolic disease within the pulmonary arteries. (C) Axial CT pulmonary angiography shows a dilated main pulmonary artery but no filling defects within the proximal pulmonary arteries and no other signs of chronic thromboembolic disease. (D) Pulmonary angiogram confirmed the abnormalities by revealing a truncated and pruned right middle lobe segmental pulmonary artery (*arrow*) and wedge-shaped area of hypoperfusion. (From Furfaro D, Azadi J, Housten T, et al. Discordance between imaging modalities in the evaluation of chronic thromboembolic pulmonary hypertension: a combined experience from two academic medical centers. *Ann Am Thorac Soc.* 2019;16[2]:277–280.)

vena cava and hepatic veins can be seen in PH. Congenital cardiac defects, such as anomalous pulmonary venous drainage and intracardiac shunt, can also be identified (see Fig. 83.5E–F). Thus, CT imaging is imperative to evaluate for underlying cardiopulmonary conditions associated with PH.

With the addition of intravenous contrast, acute and chronic thromboembolic disease can be identified as well. Although not as sensitive for the diagnosis of chronic thromboembolic disease as *ventilation-perfusion* (V/Q) scan (see later), the *CT pulmonary angiogram* (CTPA) provides important information regarding the operability of the lesions with pulmonary endarterectomy or to guide balloon pulmonary angiography. In addition, CTPA can identify webs, obstructions, bands, intimal irregularities, and bronchial artery dilations consistent with chronic thromboembolic disease.[98] Other findings include parenchymal abnormalities, such as scars from prior infarction, mosaic pattern of perfusion, and cylindrical bronchial dilations.

The utility of PA size in the diagnosis of PH has been studied extensively, with varying results.[99–105] These studies have examined the PA diameter in isolation, the ratio of the PA to aortic diameter, the ratio of segmental PA size to bronchus, and PA diameter in combination with other noninvasive modalities such as echocardiography. Findings of a main PA diameter greater than or equal to 29 mm or a main PA diameter to aorta diameter ratio greater than 1 suggest possible PH with sensitivity and specificity ranging from 57–89%. However, progressive dilation of the PA may be a function of disease duration rather than disease severity and thus limit the utility of using PA size metrics as screening tools.[106] Thus, despite advances in CT technology and extensive clinical research, CT chest findings can only suggest possible PH; establishing the diagnosis of PH requires additional testing, including RHC.

VENTILATION-PERFUSION SCANNING

V/Q scans are an integral part of the evaluation for PH (Fig. 83.6). The role for V/Q scanning as a mandatory study to establish the proper classification of PH was confirmed at the 6th WSPH.[49] V/Q scans detect chronic thromboembolic disease more consistently than CT angiograms.[107,108] Prior studies have suggested a negative predictive value of nearly 100%, making V/Q scans extremely useful to rule out chronic thromboembolic disease.[107] In a more recent multicenter study, there was discordance between the V/Q scan and CTPA regarding presence of chronic thromboembolic disease in greater than 30% of patients who had both studies performed and who had RHC and pulmonary angiogram-proven CTEPH.[109] In all cases of discordance, the CTPA was negative, whereas the V/Q scan was positive for chronic thromboembolic disease, highlighting the limitations of CTPA. Despite these studies supporting the utility of V/Q scanning in the evaluation of PH, data suggest that few providers actually perform V/Q scans. A large observational study of 60 academic and community practices in the United States, the *Pulmonary Arterial Hypertension-Quality Enhancement Research Initiative* (PAH-QuERI), demonstrated that fewer than 60% of patients evaluated for PH underwent V/Q scanning.[74]

The decision to pursue RHC for the definitive diagnosis of PH should be based upon the clinical suspicion for PH as a result of the completion of the recommended evaluation algorithm (see Fig. 83.2). As discussed earlier, results from each of the tests inform the likelihood of the presence of PH, the contributors to PH if present, and potential treatment options. Unfortunately, as shown in the PAH-QuERI study, only a minority of patients diagnosed with PAH completed the entire diagnostic evaluation.[74] The most commonly missed tests were overnight oximetry (completed in 41.5% of patients) and V/Q scanning (completed in 57.2% of

patients). Overall, only 6% of patients carrying a diagnosis of PAH underwent all the recommended studies to rule out other PH etiologies. There are significant implications of an incomplete evaluation for PH as demonstrated in a study by Deaño and colleagues[110] in which a cohort of 98 patients with a pre-referral diagnosis of PH underwent reevaluation for PH at tertiary referral centers. The authors found that 33% of patients with a pre-referral diagnosis of PH had an incorrect diagnosis. Of importance, of the 42 patients with a pre-referral diagnosis of PAH who were receiving pulmonary vasodilator therapy, only 23 (54.8%) had confirmed PAH after completing the recommended evaluation. This study highlights the impact of incomplete evaluation leading to incorrect diagnoses and, more important, to inappropriate use of PAH-specific therapy. Given the high cost and potential toxicity of PAH-specific medications, use of these agents should be carefully considered and prescribed in accordance with regulatory body guidelines. Further, referral of patients to centers of excellence for the management of PH is strongly encouraged by consensus guidelines.

RIGHT HEART CATHETERIZATION

RHC is the test of choice for the diagnosis of PH and is mandatory for any patient in whom PH treatment is being considered. RHC allows accurate measurement of PAP and important prognostic features, such as RA pressure and cardiac output, exclusion of LHD-associated PH, and assessment of vasoreactivity in certain subgroups. Although RHC is an invasive test, it is safe, with a low risk of complications when performed by experienced providers. In the largest multicenter description of RHC safety, the percentage of serious adverse events was 1.1% of 7218 RHCs performed in PH patients at expert centers.[111] Twenty-nine serious adverse events were due to venous access (e.g., hematoma), 22 due to placement of the catheter (e.g., supraventricular tachycardia), 15 due to vasoreactivity testing (e.g., systemic hypotension), and 6 related to pulmonary angiography (e.g., pulmonary edema). There were four fatal events in association with RHC, resulting in an overall procedure-related mortality of 0.055%.[111]

Performance

RHC is recommended in patients who have clinical features suggestive of PH with an echocardiogram that has intermediate or high probability of PH. RHC is generally performed either through the internal jugular or femoral vein using a balloon flotation catheter. The catheter is advanced under fluoroscopic guidance into the RA, RV, and PA with waveforms as shown in Figure 83.7. In general, the external pressure transducer should be zeroed at the level of the left atrium, which is at the midthoracic line halfway between the anterior sternum and the surface of the bed in a supine patient.[112] All pressure measurements should be made at the end of a normal expiration.[113]

Accurate measurement of PCWP, an estimate of *left atrial pressure* (LAP), is essential for proper PH group classification. PCWP is obtained with the catheter balloon inflated and advanced until the characteristic waveform is visualized (see Fig. 83.7). Blood gas analysis with the balloon inflated may be used to confirm that the catheter is properly placed. Common pitfalls in PCWP measurement include either a wedged location too proximal, which creates a

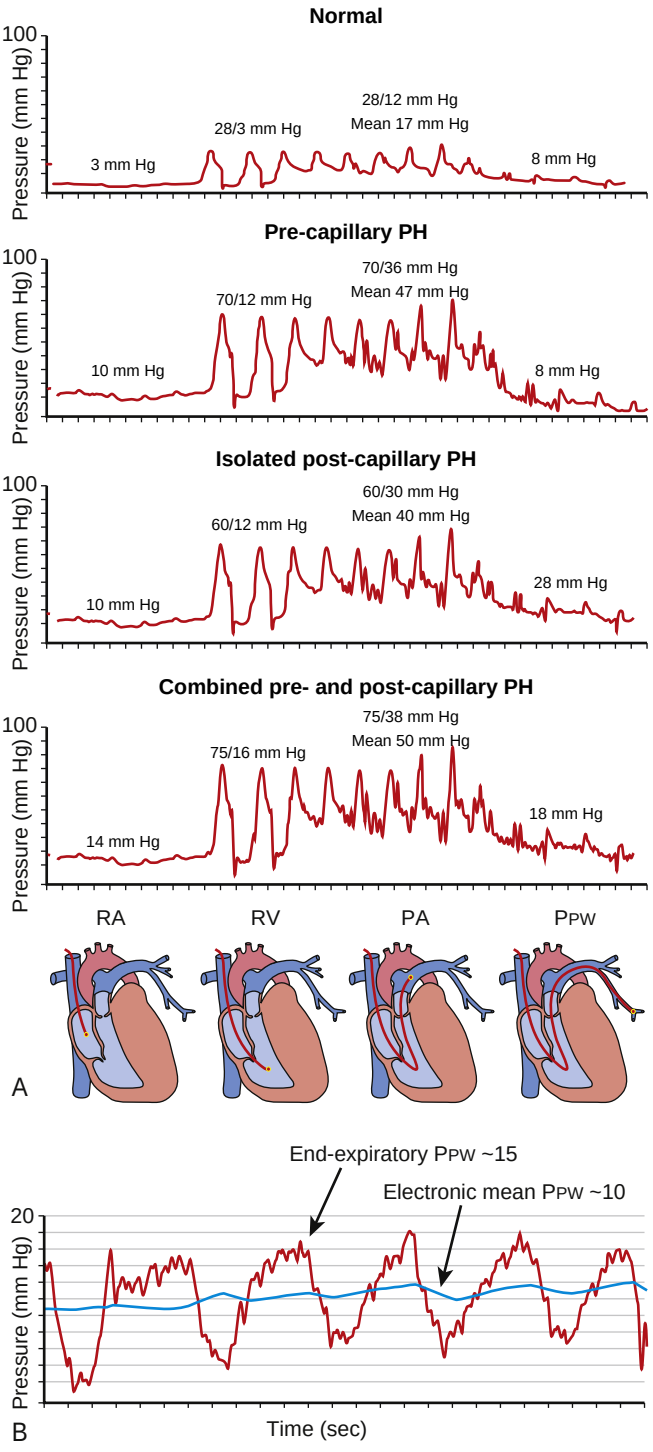

Figure 83.7 Tracings from *right heart catheterization* (RHC) in patients with *pulmonary hypertension* (PH). (A) RHC waveforms are obtained as the catheter passes from the right atrium (RA) through the right ventricle (RV), pulmonary artery (PA), and into the pulmonary capillary wedge position in a normal individual and in individuals with precapillary PH, isolated postcapillary PH, and combined precapillary and postcapillary PH. (B) Pulmonary artery wedge pressure (PPW) tracing from a patient with chronic lung disease demonstrating marked respiratory variation in the wedge pressure. Abrupt rise in pressure in some respiratory cycles at the end of expiration likely represents forceful expiration, which is sometimes seen in patients with lung disease. It is important to identify and measure the pressure at end-expiration correctly. Use of the computer-measured mean wedge pressure is misleading because the mean wedge pressure is calculated to be normal (~10 mm Hg), whereas the actual end-expiratory wedge pressure is elevated (~15 mm Hg), suggesting a diagnosis of pulmonary hypertension from left heart disease. Normal pressures are provided.

hybrid pressure tracing between the PAP and PCWP, or too distal, which results in overwedging with subsequent improper measurement of PCWP and risk for PA rupture. Although PCWP should approximate LAP, and therefore *left ventricular end-diastolic pressure* (LVEDP), studies have demonstrated relatively poor concordance between PCWP and LVEDP. In 3926 patients with PH who underwent simultaneous right and left heart catheterization, PCWP underestimated LVEDP by an average of 2.9 mm Hg (eFig. 83.2).[114] This may have significant clinical implications because almost half of patients diagnosed as having precapillary PH based on a PCWP less than or equal to 15 mm Hg actually had an LVEDP greater than 15 mm Hg, consistent with postcapillary disease.[114] Similar findings were described from another center; older age was associated with a PCWP measurement that underestimated LVEDP, whereas atrial fibrillation, rheumatic valve disease, and left atrial enlargement were associated with overestimation of LVEDP.[115] Recent guidelines from the 6th WSPH recommend direct measurement of LVEDP in patients who have a low probability of LHD-associated PH but a PCWP greater than 15 mm Hg on RHC.[116] Another potential strategy to "unmask" occult LHD is using provocative measures, such as exercise or fluid loading.

Cardiac output (CO) is a critical parameter measured during RHC because it is used in the calculation of PVR and is recognized as an independent predictor of outcome in PAH.[117,118] Thermodilution, performed by injecting a known volume of saline into the RA and measuring temperature change in the PA, should be measured in triplicate to calculate CO.[113] This method agrees strongly with CO calculated by the direct Fick method (the gold standard for CO measurement) and is unaffected by low CO or severe TR.[119] (The *indirect* Fick method, which includes assumptions of normal oxygen consumption, agrees poorly with thermodilution CO and is an inferior prognostic measurement[120] and thus is not recommended for CO estimation.)

Chronic left-to-right shunting, which can be seen with some forms of CHD, may cause PH and can be evaluated during RHC. Blood samples are obtained from the vena cava and multiple positions in the RA, the RV, and the PA. An increase in oxygen saturation between the vena cava and the PA indicates a left-to-right shunt and allows quantification. Shunt quantification should be performed only in patients on 30% or less supplemental oxygen because higher concentrations may invalidate pulmonary blood flow estimates.[121]

Provocative Maneuvers

Vasoreactivity Testing. Vasoreactivity testing during RHC to determine acute responsiveness to a pulmonary vasodilator is not recommended in all types of PH and is not used to determine responsiveness to vasodilators other than CCBs. It is recommended only in patients with idiopathic PAH, heritable, and drug-induced PAH because these are the only patients who may have a durable response to CCBs, and it may change management in these subgroups.[83,122] A positive acute vasoreactivity test requires (1) reduction of mPAP by 10 mm Hg or more to an absolute mPAP of 40 mm Hg or less with (2) an increased or unchanged CO. Inhaled nitric oxide is the preferred agent for vasoreactivity testing, but intravenous epoprostenol or intravenous adenosine are alternatives.[83] CCBs should not be used to gauge acute response because high-dose calcium channel blockade can acutely lead to hypoxemia and worsened RV function.[123]

In the era before availability of PAH-specific medications, patients who had an acute response to vasodilation had dramatically improved survival when treated long-term with CCBs.[124] Although about 10% of idiopathic, heritable, and drug-induced PAH patients will be responsive, half of them are expected to lose responsiveness over time for unclear reasons. A large series of idiopathic PAH patients demonstrated that an acute vasodilator response was found in 12.5%, but only approximately 6.8% of the overall group had a durable long-term response.[125] Therefore, although long-term response to CCB is rare in PAH, it is important to perform vasoreactivity testing to identify this subgroup because it dramatically changes prognosis and treatment.

Exercise. Exercise can be used during RHC to provoke changes in patients with normal resting hemodynamics, assess for occult left heart disease, and provide additional prognostic data in PAH patients. An exercise-induced rise in mPAP was taken out of the definition of PH in 2008 due to uncertainties about what constitutes a normal pulmonary vascular response to exercise. Although still not incorporated into the diagnosis of PH,[83] recent research has further elucidated normal and abnormal exercise responses. Rather than relying on a single mPAP at maximum exercise, using a combination of mPAP and the slope of change in mPAP and CO, or *total pulmonary resistance* (TPR = mPAP/CO) is recommended. A current suggested diagnosis of exercise-induced PH is a normal mPAP (<21 mm Hg) at rest but a maximal exercise mPAP greater than 30 mm Hg *and* TPR greater than 3 WU.[126] This definition, however, is unable to differentiate between exercise-induced increases in mPAP resulting from a primary pulmonary arteriopathy and increases in mPAP resulting from PCWP due to left heart disease. PCWP is difficult to measure during exercise due to large respiratory swings and technical challenges in wedging the catheter. A suggested upper limit of normal for exercise PCWP is 25 mm Hg, although this varies with age, and some have described a CO-adjusted measure of PCWP as potentially useful, with a proposed cutoff of a PCWP/CO slope of greater than 2 mm Hg/L/min as abnormal.[127] In patients with PAH, exercise can be used to prognosticate survival. The ability of the RV to increase pressure depends on preserved ventricular-pulmonary vascular coupling and the capacity to increase stroke volume during exercise without RV dilation. PAH patients who are unable to increase their PAP with exercise have reduced RV functional reserve,[128] which corresponds to worse outcomes.[129,130]

Fluid Challenge. Another provocative maneuver that can be used to unmask occult LHD (i.e., a PCWP of 15 mm Hg or less with an intermediate or high pretest probability of LHD) is a fluid challenge during RHC. In the presence of impaired LV diastolic compliance, a fluid challenge will lead to an increase in PCWP, generally to greater than 18

to 20 mm Hg.[131] In patients with PAH[132] and SSc-PAH,[133] a 500-mL bolus of normal saline resulted in an elevated PCWP in 22% and 46% of patients, respectively, although a subsequent study reported this in only 6% of precapillary PH patients.[134] Fluid challenge during RHC can be helpful to identify occult HFpEF and is recommended when patients with an intermediate to high probability of PH due to HFpEF have a PCWP of 13 to 15 mm Hg.[79]

TESTING TO DETERMINE PROGNOSIS

Once the diagnosis of PH is established by RHC, numerous modalities can determine the patient's prognosis, including biomarkers, echocardiography, cardiac magnetic resonance, and exercise testing. In general, a multiparameter prognostic approach, such as the REVEAL risk score[135] or the ESC/ERS risk assessment strategy,[113] performs better than any one test alone.

BIOMARKERS

The most common clinically used biomarkers for PAH are BNP and NT-proBNP. ProBNP is released from left- and right-sided cardiac myocytes in response to ventricular stretch/stress and then cleaved into NT-proBNP (inactive) and BNP (active). This compensatory mechanism is exploited as a prognostic test in PH, with higher BNP levels corresponding to higher RA pressure and RV dysfunction.[136] Elevation of both NT-proBNP[137] and BNP[138] levels at the time of PAH diagnosis are predictors of poor long-term survival. Changes in BNP after initiation of therapy seems to predict survival with better accuracy than baseline measurements.[138,139]

IMAGING

As described earlier, echocardiography forms the basis for PH screening by measuring estimated PASP and determining the probability of PH. Echocardiography is also useful for the functional assessment of the RV, which is a strong predictor of outcomes. Imaging of the RV with echocardiography is difficult due to the complex anatomy of the RV. *Tricuspid annular plane systolic excursion* (TAPSE) measures the displacement of the tricuspid annulus in the longitudinal plane towards the RV apex (Video 83.1)[140] and strongly correlates with RV ejection fraction[141] and stroke volume index.[142] Lower TAPSE corresponds to worse RV function, with a cutoff of 1.8 cm demonstrating an increased risk of death of almost sixfold.[142] A newer modality, RV strain imaging via speckle-tracking echocardiography, is emerging as an accurate noninvasive measure of RV function and prognosis. As mentioned earlier, this technique measures myocardial deformation of the RV, both globally and regionally. A meta-analysis of 1001 patients with precapillary PH demonstrated that RV strain is a strong predictor of mortality and may outperform TAPSE.[143] Pericardial effusion, which may develop in PH partially from elevated RA pressure limiting pericardial fluid drainage into the RA, is most common in patients with CTD-associated PH[144] and is an independent predictor of mortality in PAH.[135,144] Any attempt at drainage for significant pericardial effusions without hemodynamic decompensation in PAH patients should be approached cautiously because drainage in this population is associated with a high mortality.[145] Rapid removal of pericardial effusion via pericardiocentesis can lead to rapid enlargement of the RV and subsequent compression of the LV that can lead to hemodynamic collapse.[146] In situations of hemodynamic stability with large pericardial effusions, a more conservative approach with diuresis and systemic blood pressure support if needed is recommended. However, in situations of hemodynamic instability due to tamponade physiology, a pericardiocentesis with slow, controlled drainage through a pericardial drain may be necessary.[147]

Cardiac magnetic resonance (CMR) overcomes many of the limitations of echocardiography and is the gold standard for measurement of right-sided cardiac function and size.[148] CMR allows for accurate measurement of RV ejection fraction, RV hypertrophy, RV/RA dilation/enlargement, flattening of the interventricular septum, and PA stiffness. Phase-contrast imaging also permits quantification of CO, RV stroke volume, and intracardiac shunts.[149] Of note, PAP cannot be measured by CMR and requires RHC. Numerous CMR parameters, including RV stroke volume,[150] PA stiffness,[151] RV size,[150–152] RV hypertrophy,[153] and decreased LV filling[150] are independent predictors of mortality in PAH.

EXERCISE TESTING

6WMD is a key parameter used in the management of PH patients to establish prognosis and gauge changes over time. The 6MWD strongly corresponds to patient-reported functional class and moderately correlates to *maximum oxygen consumption* ($\dot{V}O_{2max}$).[154] Baseline 6MWD,[154,155] as well as oxygen desaturation during the 6MWT,[156] independently predicts mortality in patients with idiopathic PAH. The 6MWT is routinely repeated in PAH patients to gauge response to therapy. The minimal important difference in 6WMD is approximately 33 m in PAH patients.[157] Studies have suggested that a worsening of 6WMD over time is strongly associated with poor prognosis,[158] but an improvement in 6WMD may not correlate with improved outcomes.[158,159]

CPET (see also Chapter 33) can be safely[160] applied to patients with PH and may give additional prognostic value and uncover complications of PH (e.g., exercise-induced right-to-left shunt). Patients with PH characteristically have a reduced aerobic capacity (low maximum $\dot{V}O_2$), early anaerobic threshold, reduced ventilatory efficiency (increased ventilation needed to eliminate carbon dioxide [CO_2], [$\dot{V}E/\dot{V}CO_2$], and elevated $\dot{V}E/\dot{V}CO_2$ slope), abnormal V/Q ratio (decreased *end-tidal CO_2 partial pressure*, $PETCO_2$) at anaerobic threshold, and desaturation during exercise.[160,161] PH patients with more severe functional impairments have a greater reduction in $PETCO_2$ and $\dot{V}E/\dot{V}CO_2$ slope,[162] and PAH patients with lower maximum $\dot{V}O_2$ and higher $\dot{V}E/\dot{V}CO_2$ slope have worse survival.[155] CPET can also be used to detect exercise-induced right-to-left shunting, which can be recognized by an abrupt and sustained decrease in end-tidal CO_2 with associated oxygen desaturation.[163]

GROUP 2: PULMONARY HYPERTENSION

As detailed earlier, the 6th WSPH updated the clinical classification of PH, as detailed in Table 83.2. It is essential to assign patients to the proper WSPH clinical classification group by the workup described earlier because patients with groups 1 and 4 have specific treatments proven to be effective, whereas those in groups 2, 3, and 5 generally do not benefit from PAH-specific therapy. Detailed discussions for group 1, group 3, and group 4 PH epidemiology, clinical characteristics and treatment, and outcomes are discussed elsewhere (see Chapters 84–86, respectively).

Group 2 PH includes the PH due to cardiac disease. LHD is by far the most common cause of PH in the developed world, with one study finding that 69% of patients with an elevated PA pressure on echocardiogram have LHD-PH.[164] In general, patients with LHD may develop PH due to heart failure with preserved or reduced *left ventricular ejection fraction* (LVEF) or valvular heart disease. Most patients with LHD-PH have *isolated postcapillary PH* (Ipc-PH), in which the elevated LAP causes a proportional rise in PAP. However, some patients experience an elevation in PAP out of proportional to the increase in LAP, which is termed *combined precapillary and postcapillary PH* (Cpc-PH). In contrast to patients with Ipc-PH, those with Cpc-PH (defined as a PVR ≥3 WU) have a worse survival, with every 1 WU increase in PVR corresponding to a 9% increase in likelihood of death.[165]

HFpEF is a very common cause of PH; estimates vary of the prevalence of PH in HFpEF but, in one large community-based study, 83% of HFpEF patients had an elevated estimated PAP on echo.[166] Differentiating HFpEF from PAH is a diagnostic challenge because many patients with PAH have cardiovascular risk factors,[167] and the echocardiographic assessment of diastolic function is imprecise. Even PCWP, the parameter used to differentiate precapillary from postcapillary PH, has limitations, which may necessitate direct measurement of LVEDP and/or provocative RHC maneuvers. The first step in the assessment of potential HFpEF-PH is to judge the pretest probability. Compared to patients with PAH, those with HFpEF are significantly older,[166,168] with a higher incidence of comorbidities,[168] including features of metabolic syndrome.[169] The next step is incorporation of echocardiographic features that increase or decrease the likelihood of HFpEF-PH. In patients with low probability of HFpEF-PH or an intermediate probability with RV abnormalities, RHC is recommended for accurate diagnosis.[116]

Heart failure with reduced LVEF (HFrEF) is complicated by PH in 16–63% of patients, depending on which criteria are used and what population is being studied.[170–173] Compared to HFrEF patients without PH, HFrEF-PH patients have more obesity, diabetes, and atrial fibrillation, as well as more severe diastolic abnormalities and mitral regurgitation on echocardiogram.[174] Patients with HFrEF-PH are less likely to have Cpc-PH than their HFpEF-PH counterparts,[175] although HFrEF-PH patients have worse RV function.[176,177] The presence of PH in HFrEF clearly worsens outcomes, with a significant increase in mortality in multiple studies.[171,173,174] In addition, HFrEF patients with Cpc-PH have significantly worse survival than those with Ipc-PH, with a 56% increase in mortality.[174]

All forms of left-sided *valvular heart disease* (VHD) may cause PH, with estimated prevalence as displayed in eFig. 83.3[178]; in general, mitral valve disease causes more severe PH than does aortic valve disease. Identifying PH in VHD is essential because it affects prognosis and may impact timing of intervention. In many cases, PH is reversible with intervention. *Aortic stenosis* (AS) leads to PH by causing LV pressure overload, which then results in diastolic dysfunction and elevated LAP. In fact, in patients with AS, the degree of PH correlates best with diastolic dysfunction, not with AS severity.[178] The impact of PH on survival in AS is controversial,[179,180] but improvements in PAP after treatment of AS are associated with better long-term outcomes.[181] PH may be caused by aortic regurgitation through LV volume overload and subsequent diastolic dysfunction, and most patients have normalization of PAP after valve surgery.[182] However, PH has been relatively understudied in aortic regurgitation, and valve replacement is not indicated solely for elevated PAP.[178] *Mitral stenosis* (MS) has long been recognized as a classic cause of PH by directly increasing LAP. It is important to intervene before the onset of severe PH in patients with MS because outcomes after mitral valve intervention are worse in MS patients with severe PH. However, most patients have resolution of PH after intervention.[178] In primary mitral regurgitation, the rate of PH correlates with severity of mitral regurgitation.[183] Even if patients are asymptomatic with preserved LV function, those with PH have worse survival. For this reason, resting PH with an estimated systolic PA pressure greater than 50 mm Hg should be considered for mitral valve repair.[178]

TREATMENT CONSIDERATIONS FOR GROUP 2 PULMONARY HYPERTENSION

There is a strong recommendation against treating LHD-PH with PAH-specific medications[116] because there are no multicenter *randomized controlled trials* (RCTs) that show benefit in this group. In patients with HFrEF-PH, intravenous epoprostenol versus standard care (diuretics, digoxin, angiotensin-converting enzyme inhibitor) was investigated in a large RCT but was terminated early due to a signal of higher mortality in the epoprostenol group.[184] The only study to date targeting the Cpc-PH subgroup in HFpEF was the MELODY-1 study, which was a multicenter RCT randomizing 63 patients to 12 weeks of macitentan (an endothelin receptor antagonist) or placebo. The main outcome of fluid retention or functional class worsening was more common in patients randomized to macitentan, with no signal of benefit in secondary outcomes.[185] In patients with corrected VHD, sildenafil was investigated in a multicenter RCT by randomizing 200 patients to 6 months of treatment or placebo. The primary end point (a composite of death, hospitalization for heart failure, functional class, and quality of life) was significantly worse in the group given sildenafil, with no improvement in 6MWD, NT-proBNP, or echocardiographic measurements of PAP.[186]

There are smaller single-center RCTs in HFrEF-PH[187,188] and HFpEF-PH[189] that suggested some potential benefit to phosphodiesterase-5 inhibitors but, taken together, the data do not support a role for pulmonary vasodilator therapy in the management of group 2 PH and suggest possible harm in certain forms of group 2 PH. As such, pulmonary

vasodilator therapy for group 2 PH is not recommended in the 6th WSPH statement.[79]

There are no clinical RCTs to guide the use of targeted interventions for LHD-PH. Thus, individualized management of underlying LHD is left to the discretion of the treating physician but without supporting evidence that these treatments will impact PH.

GROUP 5: PULMONARY HYPERTENSION

Group 5 PH comprises a wide range of diseases that predispose to the development of PH through unclear or multifactorial mechanisms. This heterogeneous group includes common disorders, such as renal disease, and rare disorders, such as chronic hemolytic anemia and rare forms of ILD. Overall, little is known regarding the epidemiology of PH within these disorders, therapeutic options, or outcomes.

HEMATOLOGIC DISORDERS (See Chapter 127)

Chronic hemolytic anemias associated with PH include *sickle cell disease* (SCD) and β-thalassemia. PH in SCD may develop related to intravascular hemolysis and subsequent inhibition of nitric oxide signaling and impairment in endothelial function, thrombosis, high CO from chronic anemia, and hypoxia.[190] Repeated episodes of acute chest syndrome do not appear to increase risk for PH in SCD.[191-193] Whereas an elevated TR jet velocity is found in 27–40% of SCD patients screened with echocardiography,[193,194] the true rates of PH based on RHC are lower. In three major cohort studies, the prevalence of an mPAP of 25 mm Hg or greater has been described in SCD patients undergoing screening. In SCD patients screened for PH, based on TR jet velocity with[192] or without[193,194] symptoms and low 6MWD, 5–10% had an mPAP of 25 mm Hg or greater on RHC, with a roughly even distribution of precapillary and postcapillary PH patients. Another key finding of these studies is what constitutes "normal" hemodynamics in SCD. Patients who did not have PH on RHC had a high CO and therefore a lower than normal PVR. Patients with SCD-PH were characterized by a PVR only mildly above the PH definition threshold of 3 WU. Despite this, patients with SCD-PH have significantly worse functional class and 6MWD and a mortality twofold higher than SCD patients without PH.[191,192] Risk for death is closely tied to hemodynamic markers of precapillary PH.[192] Screening echocardiography is recommended every 1 to 3 years, with further workup if indicated.[195] Special note is made of their recommended PVR cutoff for PH, which is 2 WU, below the standard threshold of 3 WU. However, this recommendation was not included in the 6th WSPH statement.

β-Thalassemia appears to be another risk factor for PH, although it is less well studied than SCD.[196] Two major variants of β-thalassemia exist: thalassemia major and thalassemia intermedia. The prevalence of PH in β-thalassemia is unknown, but there appear to be echocardiographic differences between the variants, with thalassemia intermedia patients more likely to develop an elevated estimated PAP and thalassemia major patients more likely to have LV dysfunction.[197]

Myeloproliferative disorders (MPDs), including chronic myeloid leukemia, polycythemia vera, essential thrombocytosis, and myelofibrosis, may be complicated by PH. Possible mechanisms include chronic thromboemboli in association with prothrombotic states and splenectomy,[176] pulmonary veno-occlusive disease,[198] portal hypertension,[199] and drug-induced PH. Although some studies using echocardiographic definitions have shown a PH prevalence of up to 48% of MPD patients,[200] larger series found a lower estimated prevalence of approximately 4–5%.[201,202] There appears to be an association between treatment with the tyrosine kinase inhibitor dasatinib and development of PAH; dasatinib is now listed as a definitive cause of PAH in the WSPH guidelines,[83] possibly by causing endothelial dysfunction and oxidative stress.[203] In a series of 21 MPD patients taking dasatinib with RHC-confirmed PAH, most patients were functional class III or IV with a median mPAP of 45 mm Hg.[204] Of importance, discontinuation of dasatinib was associated with significant improvements in functional class, 6WMD, and hemodynamics, with 63% of patients normalizing their mPAP.[204]

SYSTEMIC AND METABOLIC DISORDERS

Pulmonary Langerhans cell histiocytosis (PLCH) is a rare sporadic smoking-related cystic lung disease characterized by infiltration of bronchioles by $CD1a^+$ Langerhans-like cells.[205] Case series have demonstrated that PLCH may be complicated by severe precapillary PH.[205,206] It appears that PLCH may directly affect the pulmonary vasculature, as suggested by a lack of correlation with pulmonary function parameters and PH severity. In addition, histopathology demonstrates a proliferative vasculopathy, prominently in venules, even in lung parenchyma that is otherwise normal.[206]

Gaucher disease is a rare inherited disorder in which glucocerebroside is deposited in cells of the macrophage-monocyte system, leading to multisystem involvement. Symptomatic PH is more common in patients with type 1 Gaucher disease who have a history of splenectomy and have not been treated with enzyme replacement therapy,[207,208] and concurrent hepatopulmonary syndrome has been described in some patients.[208]

Glycogen storage diseases, rare genetic conditions characterized by enzyme deficiencies that impair either glycogen synthesis or breakdown, may be complicated by PH, particularly in type 1a glycogen storage disease.[209] Although the mechanisms underlying PH in glycogen storage diseases are unknown, abnormal serotonin handling may be involved.[210]

Neurofibromatosis type 1 (i.e., von Recklinghausen disease) is an autosomal dominant genetic disorder that causes multisystem disease, including skin lesions, neurofibromas, gliomas and, rarely, severe PH.[211] Cases described in the literature suggest a female predominance and median age of PH diagnosis of 57 years, with 75% of patients presenting with functional class III or IV symptoms.[211] PH may present in patients with or without parenchymal lung involvement, which is also a well-described complication of neurofibromatosis.[211] Case reports demonstrate a limited response to PAH-specific therapy and overall a poor prognosis; if patients are candidates for lung transplantation, this should be considered when the diagnosis of PH is made.

Lymphangioleiomyomatosis is a disorder that mostly affects young or middle-aged women and is caused by proliferation of smooth muscle–like cells along lymphatic channels. Pulmonary involvement includes a diffuse cystic lung disease and precapillary PH. A recent description of 20 lymphangioleiomyomatosis patients who underwent RHC showed that the average mPAP was 32 ± 6 mm Hg with a PVR of 4.7 ± 2.3 WU, and the presence of PH was associated with worse hypoxemia and exercise capacity.[212]

Sarcoidosis is a multisystem granulomatous disease of unknown cause. Sarcoid-associated PH is covered in Chapter 93.

Others

Chronic renal failure (CRF) is commonly associated with PH which, in most cases, is due to concomitant LHD. The exact prevalence of PH in CRF is difficult to determine because most reports rely on echocardiographic estimates of PAP for PH diagnosis; prevalence estimates range from 13–48%.[213] The *Prevalence of Precapillary Pulmonary Arterial Hypertension in Patients With End-Stage Renal Disease* (PEPPER) study[214] used RHC to determine hemodynamics in patients with CRF who had persistent dyspnea despite hemodialysis. In the dialysis group, the prevalence of PH was 72%, which dropped to 60% when mPAP was remeasured after a hemodialysis session. In patients with CRF who were not yet receiving hemodialysis, the prevalence was 72%. In both groups, the vast majority of patients with PH had postcapillary disease with a PCWP greater than 15 mm Hg. Other potential mechanisms for CRF-associated PH include *arteriovenous* (AV) fistula creation and poorly defined mechanisms, such as the inflammation, oxidative stress, and endothelial dysfunction associated with CRF and HD.[213] It has been posited that AV fistula creation may lead to a high cardiac output state, which may cause pulmonary vascular remodeling and PH. However, data are mixed concerning any association of AV fistula and PH in CRF, with some studies showing an association between AV fistula creation and PH[215,216] and others demonstrating no such relationship.[217,218] Whatever the cause, patients with CRF undergoing hemodialysis who have PH had a twofold higher all-cause mortality, independent of other risk factors.[219]

Fibrosing mediastinitis is caused by benign proliferation of fibrous tissue in the mediastinum with encasement of mediastinal structures, including the vasculature. Common causes of fibrosing mediastinitis include histoplasmosis, sarcoidosis, tuberculosis, and radiation therapy. PH may result from compression of the pulmonary arteries and/or veins. In a French series of 27 patients with RHC-proven PH from fibrosing mediastinitis, the average mPAP was 42 mm Hg with a PVR of 6.2 WU, with most patients having a precapillary phenotype. Functional capacity was significantly impaired with a 5-year survival of only 56%[220] (see also Chapter 116).

COMPLEX CONGENITAL HEART DISEASE

The complex CHD category represents a heterogeneous group of pediatric patients who are challenging to define and manage. Interested readers are directed to the 6th WSPH article by Rosenzweig and colleagues.[221]

TREATMENT CONSIDERATIONS FOR GROUP 5 PULMONARY HYPERTENSION

Although case reports and open-label studies have reported varying degrees of clinical improvement associated with treating PH patients with glycogen storage disease,[222] Gaucher disease,[223] PLCH,[205] neurofibromatosis, lymphangioleiomyomatosis,[212] β-thalassemia,[224] and CRF,[225] there are no RCTs of PAH-specific medications in these conditions and such treatment is not recommended by the recent guidelines. PH appears to improve in CRF patients who undergo renal transplantation, which seems to be due to significant improvements in LV function.[226] Patients with fibrosing mediastinitis may be cautiously considered for endovascular/surgical stenting or bypass of obstructed vessels,[227,228] and corticosteroids have been associated with variable success in sarcoidosis-associated fibrosing mediastinitis.[229]

RCTs of PAH-specific medications have been conducted in SCD and sarcoidosis, with variable reports of success. There have been RCTs of PAH-specific therapy in SCD-associated PH, but none have provided definitive results. The ASSET-1 and -2 studies randomized a total of 26 patients with precapillary ($n = 14$) or postcapillary ($n = 12$) SCD-PH to either bosentan or placebo.[230] Due to slow enrollment, both studies were terminated early and no analysis of the primary end point was conducted. The WALK-PHaSST study randomized 74 SCD subjects with an elevated TR jet velocity on echocardiogram to sildenafil or placebo and was stopped early due to safety concerns.[231] Although the sample size was limited, there was no treatment effect on 6MWD or NT-proBNP, but there was an increased risk of hospitalization for pain crisis in the sildenafil-treated patients. There have been case reports of prostacyclins[232] and the soluble guanylate cyclase stimulator riociguat[233] in SCD-PH, but neither has been tested in an RCT. Although there are concerns about risk of sickling with cardiopulmonary bypass and hypothermia, SCD patients with CTEPH appear to improve with pulmonary thromboendarterectomy surgery.[234]

Key Points

- *Pulmonary hypertension* (PH) is defined as a mean pulmonary artery pressure of greater than 20 mm Hg on right heart catheterization and can be further characterized based on pulmonary artery capillary pressure and pulmonary vascular resistance as precapillary, isolated postcapillary, or combined precapillary and postcapillary PH.
- It is essential to assign patients to the proper *World Symposium on Pulmonary Hypertension* (WSPH) clinical classification group because patients with groups 1 and 4 have specific treatments proven to be effective, whereas those in groups 2, 3, and 5 generally do not benefit from PAH-specific therapy.
- Populations at risk for *pulmonary arterial hypertension* (PAH) (WSPH group 1) include patients with connective tissue disease (especially systemic sclerosis), human immunodeficiency virus, portal hypertension, and certain drug or toxin exposures (e.g., methamphetamines).

- Symptoms of PH are nonspecific and include dyspnea on exertion, fatigue, chest pain, and light-headedness.
- Transthoracic echocardiography is the screening test of choice for PH, which can be used to estimate systolic pulmonary artery pressure, assess right heart size and function, and evaluate for signs of left heart disease or congenital heart disease.
- In patients with suspected PH, ventilation-perfusion scanning is imperative to rule out chronic thromboembolic PH.
- Computed tomography can reveal clues to the diagnosis and show parenchymal abnormalities characteristic of interstitial lung disease or of rare forms of PH.
- Right heart catheterization is mandatory for establishing the diagnosis of PH and for determining the proper clinical classification.
- Prognosis should be assessed at baseline and every 3 to 6 months by measuring laboratory biomarkers, echocardiography and/or cardiac magnetic resonance imaging, and exercise testing. A multimodal risk assessment incorporating these and other parameters is superior to any individual prognostic test.
- Group 2 PH is the most common cause of PH in the developed world and is caused by heart failure with preserved or reduction ejection fraction, as well as left-sided valvular heart disease.
- Group 5 PH is a heterogeneous group of disorders, including chronic hemolytic anemias, myeloproliferative disorders, metabolic (e.g., Gaucher disease) and systemic (e.g., sarcoidosis) diseases, chronic renal failure, fibrosing mediastinitis, and complex congenital heart disease.

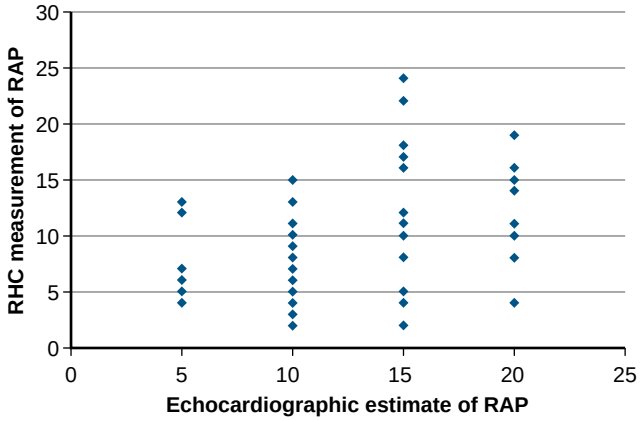
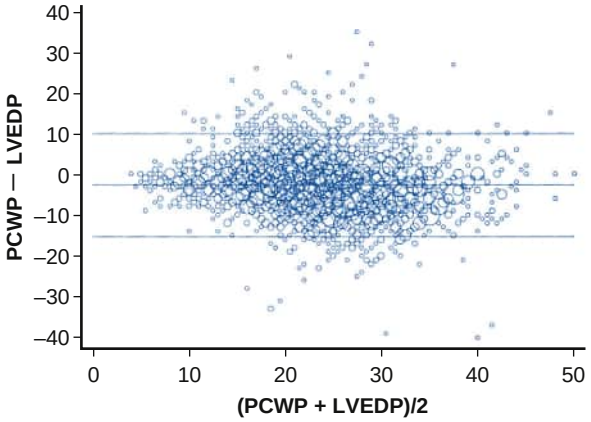
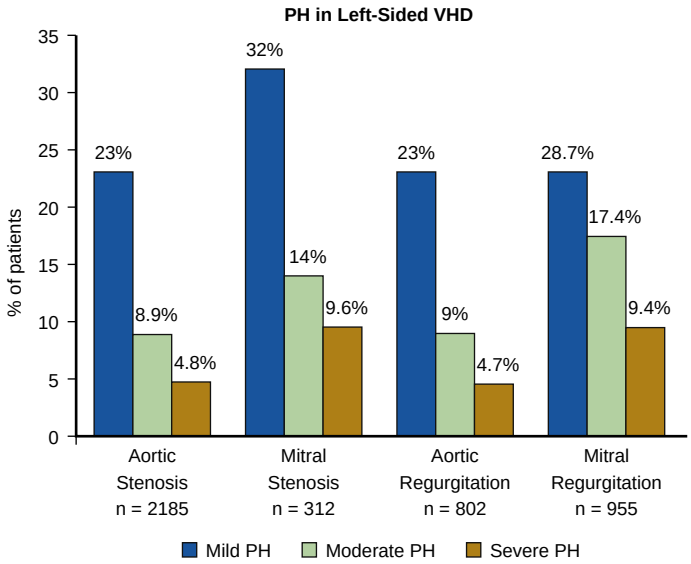
eFIGURE IMAGE GALLERY



eFigure 83.1 Comparison of *right atrial pressure* (RAP) as estimated by Doppler echocardiography and *right heart catheterization* (RHC). Comparison of right atrial pressure as estimated by Doppler echocardiography and RHC demonstrating poor correlation. For example, for echocardiographic estimates of right atrial pressure of 15 mm Hg, corresponding directly measured RHC right atrial pressure ranged from 2 to 24 mm Hg. (From Fisher MR, Forfia PR, Chamera E, et al. Accuracy of Doppler echocardiography in the hemodynamic assessment of pulmonary hypertension. *Am J Respir Crit Care Med.* 2009;179[7]:615–621.)



eFigure 83.2 Bland-Altman plot of *pulmonary capillary wedge pressure* (PCWP) and *left ventricular end-diastolic pressure* (LVEDP) among 3926 patients with pulmonary hypertension. The *y*-axis shows the difference between PCWP and LVEDP (PCWP – LVEDP). The *x*-axis shows the average of these measures: (PCWP + LVEDP)/2. The graph describes the agreement between these two quantitative measures. On average, PCWP underestimated LVEDP by 2.9 mm Hg (bias –2.9 mm Hg; confidence interval, –3.0 to –2.7); limits of agreement of –15.2 to 9.5 mm Hg. *Larger circle*s indicate identical observations among multiple patients. (From Halpern SD, Taichman DB. Misclassification of pulmonary hypertension due to reliance on pulmonary capillary wedge pressure rather than left ventricular end-diastolic pressure. *Chest* 2009;136[1]:37–43.)



eFigure 83.3 Prevalence of mild, moderate, and severe *pulmonary hypertension* (PH) according to left-sided *valvular heart disease* (VHD) etiology. PH was diagnosed by right heart catheterization in all patients. Mild, moderate, and severe PH were defined as a mean pulmonary artery pressures: 25–34, 35–44, and ≥45 mm Hg, respectively. As seen, mitral valve disease causes more severe PH than does aortic valve disease. (From Magne J, Pibarot P, Sengupta PP, et al. Pulmonary hypertension in valvular disease: a comprehensive review on pathophysiology to therapy from the HAVEC Group. *JACC Cardiovasc Imaging.* 2015;8[1]:83–99.)

INTRODUCTION

Group 1 *pulmonary arterial hypertension* (PAH) is characterized by elevated pulmonary arterial pressures, normal left heart filling pressures, and no evidence of significant lung disease, chronic thromboembolic disease, or one of the conditions that can cause pulmonary hypertension due to unclear and/or multifactorial mechanisms. The most common causes of PAH include *idiopathic PAH* (IPAH), drugs and toxins, *connective tissue disease* (CTD), and *congenital heart disease* (CHD). Genetic variants, *human immunodeficiency virus* (HIV), and portal hypertension are important but less common causes, while schistosomiasis is an important cause in countries where it remains prevalent. These conditions have many similarities in pathobiology, presentation, hemodynamics, prognosis, and response to therapies. However, differences are large enough that familiarity with each individual subtype is required for optimal patient care.

PATHOBIOLOGY

The primary abnormalities in IPAH involve the pulmonary vasculature, particularly the distal muscular-type arteries with a size of 70 to 500 μm. These small arteries develop intimal and adventitial fibrosis, medial hypertrophy/hyperplasia, in situ thrombotic lesions, and plexiform lesions.[1] Smaller precapillary pulmonary arterioles ranging in diameter from 20 to 70 μm are also abnormal and reveal luminal obliteration, abnormal muscularization, and perivascular inflammation (Fig. 84.1 and eFig. 84.2).

Pathologic findings in IPAH, drug/toxin PAH, and CHD-PAH are essentially indistinguishable from each other, while CTD-PAH may have all of these findings plus more pronounced interstitial fibrosis and inflammation (eFig. 84.2A–D).[2] Hemodynamic findings correlate only moderately with intimal and medial thickening and with the presence and number of plexiform lesions.[2] Due to the risk associated with this procedure, lung biopsy does not currently play a role in assessing PAH type or severity, although some centers do occasionally utilize biopsy in the diagnosis of pulmonary veno-occlusive disease. Chest radiographs may show enlarged pulmonary arteries and right atrial and right ventricular dilation, particularly in advanced disease (eFigs. 84.1, 84.3, and 84.4). In contrast, chest radiographs may be normal or near normal in milder or well-compensated disease. With computed tomography, the above findings may be seen in greater detail. Additionally, parenchymal ground-glass abnormalities have also been described in up to 40% of patients, most often in a centrilobular pattern.[3]

Pulmonary veno-occlusive disease (PVOD) is characterized by extensive venous involvement, including obstruction of pulmonary venules and veins by loose, fibrous remodeling of the intima that may totally occlude the lumen, in addition to arterial changes. PVOD is often accompanied by *pulmonary capillary hemangiomatosis* (PCH), and both pathologic patterns are now thought to be different manifestations of the same disease process, classified as PVOD/PCH (eFig. 84.2E–H). Venous remodeling may also be seen in other forms of PAH, most notably scleroderma-associated PAH, where clinical findings suggestive of PVOD are associated with worse outcomes.[4]

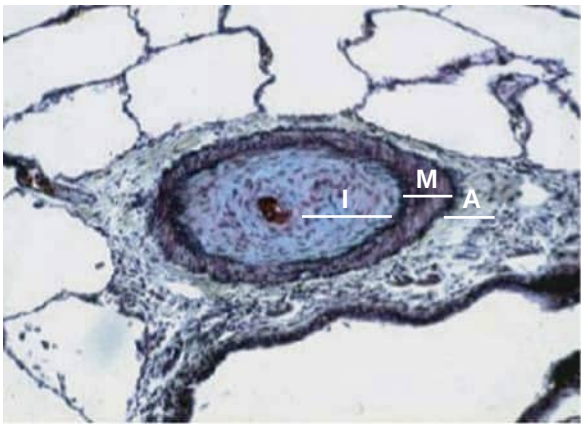

Figure 84.1 Typical advanced pulmonary arteriopathy in idiopathic pulmonary arterial hypertension. Note the proliferative changes in all three vessel layers, including intimal hyperplasia (I), medial hypertrophy (M), and adventitial fibrosis (A).

PULMONARY ARTERIAL HYPERTENSION SUBGROUPS

IDIOPATHIC

Approximately 48% of all patients diagnosed with PAH have no discernable risk factors and are therefore deemed idiopathic.[5] All ages may be affected, but it is more common in women, and the median age at diagnosis is around 50 years.[6] Without treatment, median survival for IPAH is approximately 2.8 years, based on results from the United States National Institutes of Health registry conducted from 1981 to 1985.[7] Modern treatment can improve survival and delay the time to clinical worsening, with median survival of up to 7.8 years.[5,6,8]

HERITABLE

As early as 1954, it was reported by Dresdale et al. that PAH may present in multiple family members.[9] However, it was not until 2000 that genetic analysis was able to implicate heterozygous mutations in the *bone morphogenetic protein receptor 2 (BMPR2)* gene in the development of PAH. Abnormalities in *BMPR2* are found in 70–80% of families with PAH and 10–20% of patients diagnosed with IPAH.[10] *Heritable PAH* (HPAH) is autosomal dominant but with incomplete penetrance; 14% of men and 42% of women with the *BMPR2* mutation will develop disease.[11] PAH patients who carry the *BMPR2* mutation develop disease sooner than noncarriers and have an accelerated course with increased risk of death or lung transplantation.[12] A number of less-common mutations have also been identified as risk factors for the development of PAH: *EIF2AK4*, *TBX4*, *ATP13A3*, *GDF2*, *Smad 9*, *CAV1*, and *KCNK3*.[10] HPAH is also recognized to run in families with the autosomal dominant disorder *hereditary hemorrhagic telangiectasia* (HHT). Mutations in HHT-related HPAH are found in both the *ACVRL1* (activin receptor-like kinase 1) and *ENG* (endoglin) genes.[13] Genetic counseling and screening is recommended for patients with IPAH or a family history of pulmonary hypertension. Because of incomplete penetrance, testing of asymptomatic relatives should be offered only with genetic counseling.

DRUGS AND TOXINS

The effects of drugs and toxins on the human pulmonary circulation have been demonstrated historically. Between 1967 and 1970 in Switzerland, Austria, and Germany, a 20-fold increase in pulmonary hypertension was observed after the introduction of aminorex, an appetite suppressant resembling epinephrine and amphetamine.[14] The pulmonary lesions produced by this agent resembled plexogenic pulmonary arteriopathy in every respect. Pulmonary hypertension was subsequently also associated with the appetite suppressants fenfluramine (eFig. 84.5) and dexfenfluramine.[15] Other stimulants have been suspected of causing pulmonary hypertension, based on both pharmacologic similarities with the anorexigens as well as case reports, case series, and case-control studies.[16,17] The link with methamphetamine has been strongest, and some centers recommend drug testing on all newly diagnosed PAH patients.[18] Other medications suspected of causing pulmonary hypertension include chemotherapeutic agents, reported mainly in association with PVOD,[19] and dasatinib, a tyrosine kinase inhibitor associated with the development of PAH.[20]

PULMONARY VENO-OCCLUSIVE DISEASE/ PULMONARY CAPILLARY HEMANGIOMATOSIS

PVOD/PCH is characterized by virtually identical hemodynamic findings as IPAH, but with significant venous and/or capillary involvement. The venous/capillary involvement results in clinical findings of a lower *diffusing capacity for carbon monoxide* (D_{LCO}), more hypoxemia, and more abnormal chest imaging than in most patients with IPAH. These abnormalities arise because blood flow is obstructed at or beyond the capillary, leading to elevated pressures for all upstream vessels and resulting in a tendency towards pulmonary edema. Chest radiographs may show prominent Kerley B lines in the absence of other signs of left-sided heart failure, and computed tomography scanning may reveal interlobular septal thickening, pleural effusions, and enlarged pulmonary arteries (Fig. 84.2 and eFig. 84.6). These findings should lead to a clinical suspicion of PVOD/PCH at the time pulmonary hypertension is diagnosed, although individual findings are neither sensitive nor specific. Suspicion may be further increased following a trial of PAH therapies, because this can lead to worsening hypoxemia, abnormal computed tomography findings, and occasionally overt pulmonary edema due to pulmonary arterial vasodilation in the setting of a mostly fixed obstruction in the capillaries and veins (Fig. 84.2C–D). PVOD/PCH may develop in association with viral syndromes, toxin exposure, and chemotherapy, but most cases are idiopathic.[21] A familial form of PVOD/PCH involves the *EIF2AK4* gene, which is inherited in an autosomal recessive fashion.[20] Biallelic mutations in the *EIF2AK4* gene have also been identified in around 1% of patients diagnosed with IPAH. These patients appear to have at least some characteristics typical of PVOD/PCH, and possibly a worse prognosis.[2,22] Because response to PAH therapies in these patients is often poor, any use of such therapies should be undertaken with extreme caution, and early referral for transplant evaluation is recommended.

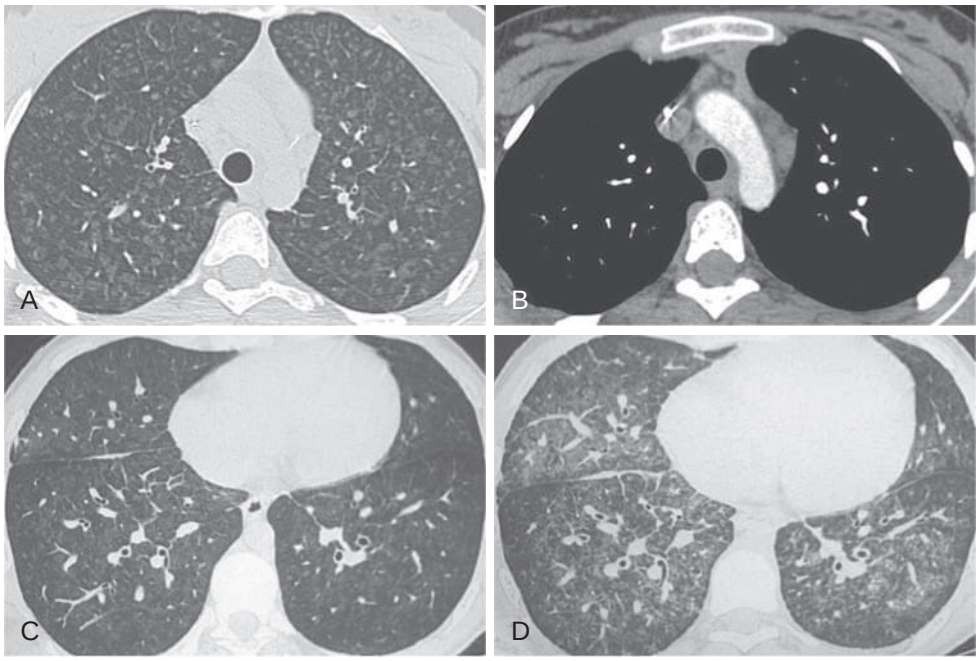

Figure 84.2 Imaging in pulmonary veno-occlusive disease/pulmonary capillary hemangiomatosis. (A) Ground-glass opacities with centrilobular pattern, poorly defined nodular opacities, and septal lines. (B) Mediastinal lymph node enlargement. (C) Imaging before initiation of specific therapy for PAH showed mild abnormalities with septal lines and ground-glass opacities. (D) After therapy with an endothelin receptor antagonist, imaging showed an increase in radiologic abnormalities consistent with pulmonary edema. (Modified from Montani D, Girerd B, Jais X, et al. Clinical phenotypes and outcomes of heritable and sporadic pulmonary veno-occlusive disease: a population-based study. *Lancet Respir Med*. 2017;5[2]:130.)

CONNECTIVE TISSUE DISEASE

CTD-associated PAH (CTD-PAH) is associated with several connective tissue diseases, particularly scleroderma and closely related conditions. Current guidelines recommend screening for PAH in scleroderma and utilizing echocardiography, pulmonary function testing with D_{LCO}, and biomarkers.[23,24] Survival rates for scleroderma-associated PAH are lower than for patients with IPAH. However, the treatment response, meaning relative improvement compared to no therapy, is robust. For example, in the CTD-PAH subgroup in the AMBITION study, up-front combination therapy with ambrisentan and tadalafil significantly reduced the risk of clinical failure compared to the pooled monotherapy group (hazard ratio, 0.43; 95% confidence interval, 0.24 to 0.77)[25]; similarly, in the GRIPHON trial, selexipag significantly reduced the risk of mortality/morbidity events in this subgroup (hazard ratio, 0.59; 95% confidence interval, 0.41 to 0.85, eFig. 84.7).[26] Other CTDs associated with PAH, albeit less commonly, include systemic lupus erythematosus, mixed CTD, Sjögren disease, polymyositis/dermatomyositis, and rheumatoid arthritis[27] (see Chapter 92).

CONGENITAL HEART DISEASE

CHD is a well-recognized risk factor for development of PAH (eFig. 84.8). In 1958, Paul Wood coined the term Eisenmenger's complex to describe pulmonary hypertension due to high *pulmonary vascular resistance* (PVR)[28] with reversed shunting through a large ventricular septal defect. Subsequently, the term has been used to describe pulmonary hypertension with cyanosis coupled with any systemic to pulmonary circulatory shunt. Compared to PAH associated with other shunts, PAH due to true Eisenmenger syndrome is associated with more preserved right ventricular compensation and therefore longer periods of clinical stability. The defect itself may provide a protective mechanism, providing a route for blood to reach the underfilled left ventricle and therefore off-loading right ventricular pressure/volume overload. However, right heart failure does eventually develop in most patients, and once it develops prognosis is poor.[29] Patients with PAH arising after closure of a congenital defect have been included in many PAH clinical trials and are treated following the usual algorithm. Patients with a very small defect may be classified as "PAH with small/coincidental defects" and are also treated similarly.[24] For those with large, uncorrected defects, the BREATHE-5 clinical trial found that treatment with bosentan led to improvement in exercise capacity compared with placebo,[30] while macitentan treatment in the MAESTRO clinical trial failed to improve *6-minute walk distance* (6MWD), the primary end point, but did lead to improvement in functional class, *N-terminal pro b-type natriuretic peptide* (NTproBNP) levels and, in a hemodynamic substudy, a trend towards improvement in PVR index (PVR relative to body surface area).[31] Observational studies have also suggested improvement following PAH therapies, and current CHD guidelines recommend their use.[32] Closure of the defect is not generally recommended once significant PAH has developed, though a small number of patients have tolerated late closure after improvement in PVR with PAH therapies.[33]

PORTAL HYPERTENSION

Portopulmonary hypertension (POPH) is similar to other types of PAH histologically and is characterized hemodynamically by elevations in pulmonary arterial pressure and PVR (eFig. 84.9). Incidence is estimated at 0.73% of all patients

with portal hypertension, based on a large autopsy study,[34] and rates of up to 5% have been reported in patients undergoing workup for liver transplantation.[35,36] Hemodynamic assessment in end-stage liver disease is complicated by the frequent coexistence of a high cardiac output related to splanchnic vasodilation and by concomitant volume overload and/or diastolic heart failure.[36] As a result, patients with POPH tend to have higher cardiac outputs and lower PVR than other World Health Organization Group I PAH patients.[37] Despite their more favorable hemodynamics, patients with POPH have 3.6 times the risk for 1-year mortality when compared to patients with other types of PAH.[38] Interestingly, the severity of the POPH does not correlate with the severity of the liver disease.[39]

A retrospective study evaluating screening right heart catheterization in POPH patients treated at the Mayo Clinic revealed the highest 5-year survival for patients who were medically treated for POPH and then underwent liver transplantation, at 67%.[40] In contrast, 5-year survival for patients treated with PAH medication alone, liver transplant alone, or neither were 45%, 25%, and 14%, respectively. Still, the mortality risk for patients with severe PAH who undergo liver transplantation has been reported to be as high as 36% historically, particularly in patients who were untreated for PAH or had severe disease.[41] These data regarding better long-term outcomes balanced by surgical risk for POPH patients have led to development of aggressive strategies for screening and treatment of these patients prior to transplantation, including recommendations for echocardiography in all patients being evaluated for liver transplant, right heart catheterization for patients whose estimated right ventricular systolic pressure exceeds 50 mm Hg, treatment of patients whose pulmonary hypertension is due to PAH, and liver transplantation of these patients only if treatment is successful in lowering the mean pulmonary arterial pressure to below approximately 35 mm Hg.[36,40]

HUMAN IMMUNODEFICIENCY VIRUS

Although a strong association between HIV and PAH has been shown, the etiology remains unclear (eFig. 84.10). Prevalence in studies requiring catheterization is as high as 0.5%,[42,43] but high rates of concomitant illicit intravenous drug use and/or methamphetamine use complicate the association.[44] Additionally, some studies with even higher prevalence rates relied on echocardiographic findings, potentially including some left heart disease–associated PH. Pulmonary hypertension can present in all stages of HIV, including in patients with no detectable viral load. Clinical and hemodynamic features of HIV-associated pulmonary hypertension are similar to those of IPAH.[45] Treatment is also similar, with extra precautions due to potential drug interactions with HIV medications.

SUPPORTIVE THERAPIES

EXERCISE AND PHYSICAL ACTIVITY

Although data are limited, consensus guidelines support the benefits of exercise in PAH patients.[24] Patients should avoid activities that lead to undue symptoms such as severe dyspnea, chest pain, lightheadedness, or syncope. Small studies have demonstrated that exercise training can be safe and lead to measurable improvements in fatigue, exercise capacity, and quality of life compared with untrained controls.[46,47] No significant safety concerns were identified, but training was generally highly supervised, often in an inpatient setting. There were also no significant changes in echocardiographic measures of right heart function or in BNP levels.[48]

HYPOXIA AND HIGH ALTITUDE

The benefits of supplemental oxygen for PAH patients, unlike for patients with pulmonary hypertension associated with lung diseases such as COPD,[49,50] are not clear. In fact, most PAH patients are not hypoxemic at rest. Mild hypoxemia, when present, is likely on the basis of reduced mixed venous oxygen saturation caused by low cardiac output with mild ventilation/perfusion inequality (see Chapter 44). The presence of more profound hypoxemia in a PAH patient should raise suspicion for underlying parenchymal lung disease, systemic to pulmonary shunting, PVOD/PCH, or pulmonary arteriovenous malformations as may be seen in pulmonary hypertension due to HHT. Additionally, a patent foramen ovale, present in more than 20% of the normal population, can contribute to hypoxemia in pulmonary hypertension by allowing shunting to develop after right heart pressures rise.

Given the known pulmonary vasodilatory effects of oxygen, there is a general consensus to recommend supplemental oxygen for patients with an arterial P_{O_2} less than 60 mm Hg or systemic arterial O_2 saturation less than 90% at rest. There are also limited data suggesting that oxygen may lead to improvements in exercise capacity in PAH patients with normal resting and only borderline reduced oxygen saturation with exercise.[51] One exception to this approach is in patients with Eisenmenger syndrome, with hypoxemia due to right-to-left shunting. In this group, the use of supplemental oxygen may have negligible benefit both on symptoms and on the pulmonary vasculature (because alveoli are not the cause of the hypoxemia).[52,53]

For travel, studies on the need for O_2 during prolonged flights in PAH are lacking, but guidelines suggest it should be considered for those with an arterial PO_2 less than 60 mm Hg.[24] Similarly, patients with these levels should avoid traveling to elevations above 5000 feet without supplemental oxygen[54] (see Chapter106).

PREGNANCY AND BIRTH CONTROL

Pregnancy is risky in patients with PAH, with a high peripartum mortality rate that peaks in the 3 months postdelivery.[55] Published case series do suggest some improvement in outcomes; for example, mortality rates in the 12–25% range were seen in three multicenter series,[56–58] an improvement compared with the 30–50% mortality rates seen in earlier studies. This likely relates to the availability of PAH therapies as well as the development of specialized teams to care for these patients. However, decompensation during pregnancy remains common and unpredictable due to the increased blood volume and cardiac output demands placed on the cardiovascular system. Therefore, it is strongly recommended that women with childbearing potential use

appropriate methods of birth control to avoid pregnancy; none of the highly effective methods is absolutely contraindicated in PAH, though surgical procedures (sterilization) may be too high risk for many patients. Additionally, some experts recommend avoiding estrogen-containing hormonal contraceptives in favor of progestin-only contraception or intrauterine devices to avoid the procoagulant activity of estrogens. This is particularly important in patients who are not anticoagulated[59] (see Chapter 129).

ORAL ANTICOAGULANTS

Until recently, anticoagulation was recommended for all patients with idiopathic, heritable, and anorexigen-associated PAH based on both observational studies and tissue studies showing microscopic thrombotic lesions in the pulmonary vasculature of PAH patients. However, more recent observational studies have shown variable results,[60,61] and current guidelines have lowered this to a class IIb recommendation (i.e., may be considered; usefulness is less well established by evidence/opinion).[24] Some experts recommend anticoagulation in patients treated with intravenous prostanoids due to the indwelling central venous catheters. Conversely, anticoagulation is generally not recommended in patients with other forms of pulmonary hypertension due to a lack of evidence as well as the increased bleeding risk, which is particularly a concern in patients with concomitant liver disease, CTD, or CHD.

DIURETICS

Diuretics have long been a mainstay of therapy for heart failure, including right ventricular failure. Both total-body and intravascular volume overload are common in PAH patients. In pivotal trials of PAH drugs, the majority of patients were on chronic diuretic therapy.[62,63] Volume overload of the right ventricle can cause compression of the left ventricle and contribute to decreased cardiac output and prerenal azotemia, symptomatic peripheral edema, and renal[64] and hepatic congestion. Thus, it is a common observation that, in decompensated PAH patients, aggressive diuresis leads to clinical and physiologic improvements.

A loop diuretic is frequently used first. Although furosemide is often the loop diuretic of choice, there is some evidence that torsemide might be more efficacious without increased side effects.[65] In addition, in patients with marked extravascular fluid accumulation and poor intestinal absorption, intravenous diuretic therapy is frequently needed. Anti-aldosterone drugs (e.g., spironolactone, eplerenone) are commonly combined with loop diuretics in PAH patients. Whether data suggesting a morbidity and mortality benefit of spironolactone in left-sided heart failure can be extrapolated to right-sided heart failure is not known.[66] In some cases, the addition of a thiazide diuretic to the regimen is appropriate. Although it is possible that in some PAH patients the right ventricle is preload dependent and therefore over-diuresis can be detrimental, this has not been our experience. More often in decompensated patients, aggressive diuresis (1 to 3 L negative fluid balance per day) leads to improvement in renal function and blood pressure.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers are effective in less than 7% of patients with IPAH[67] and are considered only in patients with IPAH, HPAH, and drug-induced PAH who respond to a vasodilator challenge in the catheterization lab. They are not recommended in other PAH subgroups regardless of vasodilator testing results due to a lack of long-term efficacy data. Vasodilator testing is typically performed using inhaled nitric oxide, intravenous adenosine, or intravenous epoprostenol. Advantages of inhaled NO include its rapid onset, short half-life, and lack of the systemic side effects seen with the other agents. A positive vasodilator test is defined as a decline of at least 10 mm Hg to a level below 40 mm Hg, with no decrease in cardiac output.[67] Patients with a positive response may be initiated on a calcium channel blocker at an initially low dose, with subsequent uptitration to the maximal tolerated dose. Close monitoring is required because patients with worsening PAH should be transitioned to other PAH therapies. Importantly, a "trial" of calcium channel blockers in nonresponders should not be attempted because this may lower systemic blood pressure and, if PAH severity prevents a concomitant increase in cardiac output, can lead to decompensation and death.

TARGETED THERAPIES

PAH-specific therapies have been available since 1995, when intravenous epoprostenol was approved by the U.S. *Food and Drug Administration* (FDA) based on the first prospective randomized, controlled trial in PAH. Since then, 12 therapies have been FDA approved for PAH (eTables 84.1 to 84.3) targeting three major pathways to offset the imbalance in endothelial-derived mediators seen in PAH: excessive endothelin-1 production, low nitric oxide production, and deficient prostacyclin (Fig. 84.3). Excessive endothelin-1 is addressed by *endothelin-receptor antagonists* (ERAs); the low nitric oxide is addressed by *phosphodiesterase-5 inhibitors* (PDE5Is) or soluble guanylyl cyclase activators, which activate the guanylate cyclase pathway, the major mediator of vasodilation by nitric oxide; and deficient prostacyclin is addressed by prostacyclin analogues. Evidence in favor of combination therapy has grown considerably, and most patients are now treated with two or more drugs, often started simultaneously soon after diagnosis. This is discussed in more detail in the "Combination Therapy" section that follows the discussion of individual medications.

ENDOTHELIN RECEPTOR ANTAGONISTS

In humans, two *endothelin* (ET)-1 receptor subtypes are found, ET-A and ET-B. Antagonism of one or both receptors has been shown to be an effective treatment strategy for PAH, with three FDA-approved ERAs: bosentan,[63,68] ambrisentan,[69] and macitentan.[70] ERAs improve exercise capacity and reduce risk of clinical worsening events. They are well tolerated by most patients but can cause nasal congestion and anemia. Additionally, significant peripheral edema was noted during the clinical trials, particularly in older patients. This has also been seen at higher rates in patients with three or more risk factors for or findings of

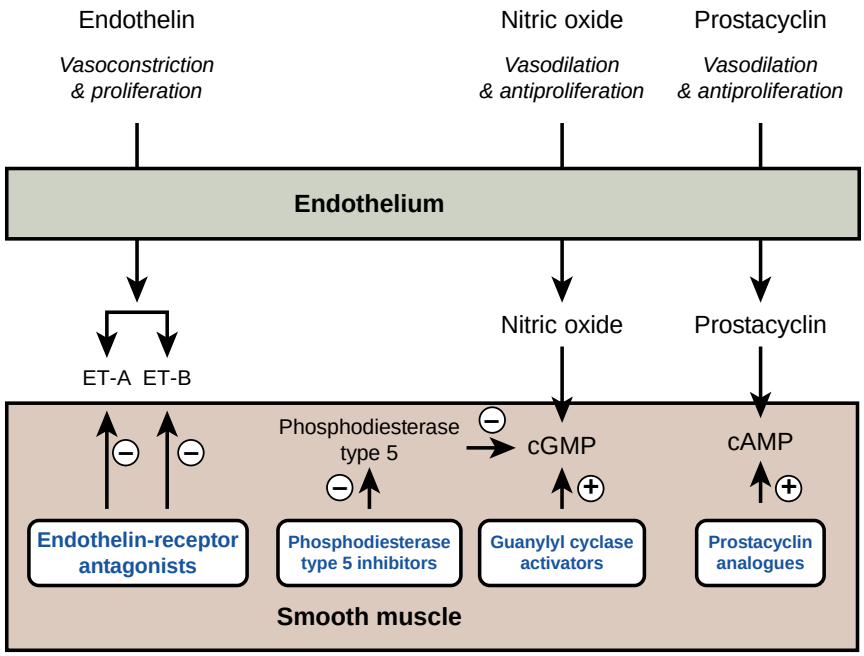

Figure 84.3 Schematic of three abnormal endothelial mediator pathways targeted by current therapies. The endothelin-1 pathway acts via two receptor subtypes (ET-A and -B) as a vasoconstrictor/proliferator pathway and is inhibited by the endothelin receptor antagonists. The nitric oxide and prostacylin pathways are vasodilatory and anti-proliferative; these are enhanced by either inhibition of an inhibitory process (phosphodiesterase type 5 inhibitors) or by more direct activation. +, stimulation; –, inhibition; ET-A, endothelin receptor A; ET-B, endothelin receptor B; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate.

left heart disease, such as systemic hypertension, diabetes, atrial fibrillation, coronary artery disease, and obesity.[71] Close monitoring of volume status is therefore indicated during drug initiation and up-titration.

ERAs as a class are considered teratogenic; therefore women of childbearing potential require monthly pregnancy testing and the use of two reliable forms of birth control during therapy. Increases in liver aminotransferases greater than eight times the upper limit of normal were also noted with bosentan therapy during randomized controlled clinical trials; as a result, all patients receiving bosentan are required to undergo monthly liver function testing. The rate of liver function test abnormalities with ambrisentan and macitentan administration has been found to be similar to that of the general population, but periodic liver function testing and hemoglobin monitoring are still recommended. All three ERAs also have significant drug interactions that should be checked prior to prescribing. Notably, bosentan increases the metabolism of oral contraceptive pills, thereby reducing their effectiveness. (See package inserts for additional details on monitoring, pregnancy prevention, and drug interactions.)

PHOSPHODIESTERASE TYPE 5 INHIBITORS

The PDE5Is, sildenafil and tadalafil, are selective inhibitors of *cyclic guanosine monophosphate* (cGMP)-specific PDE5, an enzyme that promotes the breakdown of cGMP; by enhancing cGMP, the PDE5Is increase nitric oxide signaling. Both sildenafil and tadalafil are usually well tolerated, and no significant laboratory abnormalities were noted during the pivotal clinical trials. Sildenafil (Revatio) was evaluated in the SUPER-1 (Sildenafil Use in Pulmonary Arterial Hypertension) trial, a 12-week randomized, double-blind, placebo-controlled trial comparing placebo, 20 mg, 40 mg, and 80 mg 3 times daily.[72] Significant improvement was seen in exercise capacity, functional class, and hemodynamics but not in the incidence of clinical worsening. Walk distance improvement was similar across the three doses. However, hemodynamic improvement was greater with higher doses of sildenafil, as was the percentage of patients with improved functional class. Despite these trends, the only dose approved by the U.S. FDA and European Medicines Association is 20 mg tid PO, though higher doses are sometimes used clinically. Tadalafil (Adcirca) was approved in 2009 based on the PHIRST trial, a 16-week study of 2.5 mg, 10 mg, 20 mg, and 40 mg tadalafil or placebo.[73] Tadalafil 40 mg led to improvement in exercise capacity, quality of life, hemodynamics, and time to clinical worsening. Smaller improvements in walk distance were seen with 10 mg and 20 mg.

Common adverse events during the clinical trials included headache, myalgias, flushing, epistaxis, and dyspepsia. Both drugs can be initiated at their approved dose (sildenafil 20 mg tid or tadalafil 40 mg daily), but tadalafil is often started at 20 mg PO daily for the first week in an attempt to lessen headaches and other side effects.

Rare potential adverse effects with sildenafil and tadalafil include impaired vision and hearing. Mild vision changes including particularly color vision changes are thought to relate to cross-reactivity with and inhibition of retinal phosphodiesterase-6. More severe vision changes including sudden vision loss have also been reported, and hearing loss has been reported as well; both are of unclear mechanism.[74] Patients should discontinue use and seek immediate medical attention in the event of sudden loss of vision in one or both eyes or with sudden changes in hearing.

SOLUBLE GUANYLYL CYCLASE ACTIVATORS

Riociguat is a direct activator of guanylyl cyclase, increasing levels of cGMP by stimulating its synthesis.[75] It was studied in the PATENT phase III randomized controlled

clinical trial. Improvement was seen in the primary end point, change in 6MWD at 12 weeks, and in a number of secondary end points including PVR, NT-BNP level, and World Health Organization functional class.[76,77] Riociguat cannot be given concurrently with PDE5Is due to the risk of hypotension and should instead be substituted for this class of medication. It is also teratogenic, with pregnancy testing and birth control requirements similar to the ERAs.

PROSTACYCLIN ANALOGUES

Prostacyclin synthase is under-expressed in endothelial cells in the lungs of PAH patients, and epoprostenol (prostaglandin I2, prostacyclin) was the first therapy shown in randomized controlled clinical trials to be beneficial in PAH. With prostacyclin analogs now available in oral, inhaled, subcutaneous, and intravenous forms, this class of medications remains a key component of PAH therapy. Management can be complicated due to the variable dosing schemes as well as the frequent side effects. "Prostacyclin-type" side effects including jaw pain, nausea, vomiting, headache, diarrhea, and leg pain are seen universally with medications in this class. In general, prostanoid medications are started at a low starting dose and then gradually up-titrated until reaching either the target dose or the maximum tolerated dose, as limited by symptoms. Other class effects include the potential to lower systemic blood pressure and reduce platelet function. Clinically significant hypotension is uncommon except in the presence of other systemic antihypertensives, though mild hypotension may also be seen with combinations of PAH therapies. Side effects are most often manageable with a symptom-based approach, and abrupt cessation should be avoided because pulmonary hypertension can rebound, leading to worsening symptoms and potentially death.

Epoprostenol

Epoprostenol was the first prostanoid to be developed. Continuous intravenous infusions of prostacyclin (prostaglandin I2, epoprostenol) produce sustained improvement in hemodynamics and exercise tolerance and prolonged survival. In the first randomized, prospective study of epoprostenol,[62] 81 patients with *New York Heart Association* (NYHA) class III or IV symptoms despite treatment with conventional therapy were randomized to either continuous intravenous epoprostenol plus conventional therapy or conventional therapy alone for 12 weeks. At 12 weeks, 6MWD, the primary end point, had improved by 32 meters in the continuous intravenous epoprostenol group and decreased by 15 meters in the conventional therapy group. There were also significant improvements in the epoprostenol group in hemodynamics, quality of life, and NYHA functional class. Eight patients died during the 12-week study, all in the conventional treatment group. Notably, this is the only randomized controlled PAH trial to show a significant effect on survival. A subsequent study found significant improvements in 6MWD, functional class, and exercise capacity in patients with scleroderma-associated PAH.[78]

Long-term follow-up studies have shown sustained benefits, including improved functional class and survival, compared with historical controls. Five-year survival of greater than 60% was reported in two large series[79,80] compared with a median survival of less than 3 years in the "pre-epoprostenol" era, and even better outcomes have been reported with epoprostenol in combination with other therapies.[81,82] Despite its clear benefits, chronic use of epoprostenol is complex and requires an indwelling central venous catheter, continuous infusion pump, and daily preparation of the medication. In addition, prostacyclin-type side effects are nearly universal and require both careful dose titration as well as focused symptom management.

Subcutaneous and Intravenous Treprostinil Sodium

Treprostinil sodium is an analogue of prostacyclin with a longer half-life of approximately 4 hours compared with the 3- to 6-minute half-life for epoprostenol. Treprostinil's initial approval was for continuous subcutaneous delivery, based on a double-blind, randomized controlled trail that included 470 patients with IPAH (58%), CTD-PAH, or CHD-PAH.[83] Treprostinil led to improvements in 6MWD, dyspnea indices, and hemodynamics. Walk distance improvement among treprostinil-treated patients varied by dosing quartile, with the greatest improvement seen in patients in the highest dosing quartile (>13.8 ng/kg/min). Infusion site pain was the major adverse event, with 200 (85%) patients in the treprostinil group reporting site pain versus 62 (27%) in the placebo arm. Intravenous treprostinil was subsequently approved based on bioequivalence with subcutaneous treprostinil, intended for use in patients not tolerating subcutaneous infusion. Small, mostly open-label studies suggest good tolerability and sustained hemodynamic response, including both patients newly started on intravenous treprostinil as well as those transitioned from epoprostenol.[84–86] Prostacyclin-type side effects are similar to those seen with epoprostenol.

Epoprostenol and Treprostinil Dosing

Intravenous epoprostenol is typically initiated in the hospital setting at 1 to 2 ng/kg/min and titrated up to approximately 4 to 8 ng/kg/min prior to discharge, aiming to reach an effective dose as quickly as possible while also avoiding excessive side effects. After the initial inpatient up-titration, patients continue to up-titrate at home at approximately 3- to 7-day intervals until a target dose is reached. Initiation of subcutaneous or intravenous treprostinil is similar, but doses are often 1.5- to 2-fold greater.[86,87] Typical maintenance doses are often reached by 3 to 6 months, and are in the 20 to 40 ng/kg/min range for epoprostenol and 20 to 80 ng/kg/min range for treprostinil.[24,88] Although evidence to support specific dosing strategies is limited, subcutaneous treprostinil doses greater than 40 ng/kg/min were associated with improved survival in the long-term extension study of the subcutaneous treprostinil clinical trial (N = 230; 28% reached this dose).[89] However, excessive doses of prostacyclins can lead to an abnormally high cardiac output and severe side effects.[90] Therefore, dosing must be individualized, and periodic hemodynamic monitoring is recommended for all patients on parenteral prostacyclins, particularly following significant dose adjustments.[88,90]

Inhaled Iloprost and Treprostinil

Two prostacyclin analogues, iloprost and treprostinil, are approved for use in inhaled formulations. Inhaled iloprost is delivered via ultrasonic nebulizer 6 to 9 times daily. In the Aerosolized Iloprost Randomized study, patients receiving inhaled iloprost for 12 weeks were more likely to reach the composite end point of improvement in functional class

and greater than 10% increase in 6MWD compared with patients receiving placebo (17% vs. 5%).[91] Inhaled treprostinil is administered four times daily via the Tyvaso Inhalation System, an ultrasonic nebulizer, and a dry powder inhaler is currently under investigation. In the TRIUMPH-1 study, inhaled treprostinil led to improvement in 6MWD (primary end point) as well as quality of life and NTproBNP compared with placebo.[92] Unlike prior studies, TRIUMPH-1 enrolled only patients receiving background therapy with either an ERA or a PDE5I. Theoretical benefits for inhaled administration include direct delivery to the pulmonary vasculature and potentially fewer systemic side effects.

Oral Treprostinil and Selexipag

Although parenteral prostacyclins are widely considered to be the "strongest" therapies for pulmonary hypertension, the delivery of the drug has traditionally been cumbersome. In the last few years, two oral medications in this class have been approved by the FDA.

Oral treprostinil was approved in 2013 on the basis of the pivotal FREEDOM-M trial. FREEDOM-M included 349 patients who were naive to PAH therapy. Subjects were randomized to oral treprostinil versus placebo, and 6MWD at 12 weeks was improved by 23 meters in the treatment group. Larger improvements were seen in those with longer drug exposure and higher dosages.[93] Two other pivotal trials (FREEDOM-C and FREEDOM-C2) of oral treprostinil in PAH patients who were stable on background ERA, PDE5I, or ERA plus PDE5I therapy failed to meet their primary end point.[94,95] However, a third study evaluating longer-term outcomes as well as 3 times daily dosing (compared with twice daily in the earlier studies) found a 26% relative reduction in clinical worsening events compared with placebo patients (hazard ratio, 0.74, $P = 0.03$) as well as improvement in functional class and NT-proBNP levels.[96]

Oral treprostinil causes the aforementioned prostacyclin side effects and aggressive management of these to allow up-titration to an effective dosage is often required.

Selexipag is not a prostacyclin but rather a prostacyclin receptor agonist. It was FDA approved for the treatment of PAH in 2015. The pivotal clinical trial, GRIPHON, enrolled 1156 patients randomized to selexipag versus placebo with a primary end point that was a composite of death, hospitalization, or disease progression. Subjects could be naive to PAH therapy, on background monotherapy with an ERA or PDE5I, or on background combination therapy with both. At the end of 3 years the treatment group had a 40% reduction in the risk of disease progression. The side effect profile is consistent with the prostacyclin class of medications and often requires symptom management to allow uptitration.[97]

COMBINATION THERAPY

There is strong rationale for combining drugs to treat PAH, and current guidelines now recommend combination therapy for nearly all patients with PAH.[24,98] The combination of an ERA and a PDE5I has been best studied as up-front or add-on two-drug therapy,[99,100] while the addition of a prostacyclin is often considered if response is inadequate.

A small residual role for monotherapy remains, particularly in patients who are more likely to have a negative response to therapy, patients suspected of having PVOD/PCH, and patients older than 75 years or with multiple risk factors for heart failure with preserved ejection fraction. Patients with very mild disease and stable patients with a low-risk profile while on long-term monotherapy may also be appropriate candidates for continued monotherapy.[98]

The AMBITION clinical trial published in 2015 set the standard for initiating dual therapy in treatment naive patients with PAH.[99] The trial was composed of three arms comparing the initiation of ambrisentan monotherapy, tadalafil monotherapy, and ambrisentan plus tadalafil up-front dual therapy with a primary end point of time to first clinical failure. The trial enrolled 500 patients and followed them for over 3.5 years. The dual-therapy group exhibited a 50% improvement in time to clinical worsening compared to the pooled monotherapy group. The dual-therapy group also had more improved 6MWD (49 meters vs. 24 meters) and lower NTproBNP levels.[99] Adverse events were more common in the up-front dual-therapy group and were most commonly headache, nasal congestion, edema, and anemia.

The dual ERA macitentan was studied in SERAPHIN, a long-term event-driven, randomized, double-blind, placebo-controlled trial. The primary end point was the time to first significant morbidity or mortality event, and patients were followed for 3 years. The majority (64%) of patients enrolled were on background therapy, most often with a PDE5I. There was a 45% risk reduction in the primary end point in the macitentan treatment group.[101]

Selexipag has also been well studied as an add-on therapy for patients with an inadequate response. In the pivotal GRIPHON trial, the majority of patients enrolled were already taking background PAH medication, with 15% on an ERA alone, 32% on a PDE5I alone, and 33% taking both an ERA and a PDE5I.[97] Additional positive studies that included large numbers of patients receiving combination therapy are shown in eTables 84.2 and 84.3, including the pivotal trials for both inhaled treprostinil and riociguat.

Although most studies involving parenteral epoprostenol and treprostinil were completed in the monotherapy era, there is evidence supporting combination therapy with prostacyclins as well. PACES (Pulmonary Arterial Hypertension Combination Study of Epoprostenol and Sildenafil) was the largest of these, evaluating the addition of sildenafil or placebo in 267 patients already receiving epoprostenol. Subjects were randomized to either sildenafil 80 mg orally tid or placebo for 16 weeks.[102] The trial demonstrated improvement in 6MWD, hemodynamics, and time to clinical worsening for the sildenafil plus epoprostenol group. Although mortality was not a prespecified end point, there were seven deaths during the 16-week clinical trial, all within the placebo plus epoprostenol group.

Maximal medical therapy is currently considered to be triple therapy including an intravenous or subcutaneous prostanoid infusion, and nearly all patients with an inadequate response to oral therapies including oral treprostinil or selexipag should be considered for treatment with an intravenous or subcutaneous prostanoid.[98] Although long-term randomized controlled clinical trials are lacking, observational studies suggest greater hemodynamic benefits with prostanoid infusion combinations as well as improved long-term outcomes compared to historical controls.

To wit, in 19 patients with IPAH treated in the French registry, up-front triple therapy including a prostacyclin infusion led to a 71% decline in PVR and a 95% transplant-free survival rate at 3 years; this compares favorably to monotherapy and dual-combination therapy patients treated at the same center.[81,82] In another study involving 196 patients with IPAH, CTD-PAH, or CHD-PAH at two U.S. medical centers, the subset of patients receiving triple therapy including parenteral infusion showed the largest declines in PVR compared to baseline. Further, among patients transitioning from nonparenteral triple therapy (i.e., triple therapy with an inhaled or oral prostanoid), the initiation of a parenteral prostanoid led to an additional 36% decline in PVR.[103]

ATRIAL SEPTOSTOMY AND POTTS SHUNT

Balloon atrial septostomy may be considered after failure of medical therapy or as a bridge to transplantation in a subset of patients. Balloon atrial septostomy is a percutaneous procedure in which a right-to-left intracardiac shunt is created by puncture of the interatrial septum and subsequent balloon dilation. Because the right-to-left shunt will induce some degree of hypoxemia, it can only be utilized in patients without baseline hypoxemia. Although the procedure can reduce right ventricular pressure/volume overload and improve cardiac output, there is a risk of periprocedural mortality, and it should be performed at an experienced center.[104]

A transcatheter Potts shunt is an alternative procedure also designed to decompress the failing right heart. It involves the creation of an anastomosis between the left pulmonary artery and the descending aorta. A theoretical advantage of this procedure is that its anatomic placement avoids directly exposing the brain and myocardium to deoxygenated blood. Benefit has been demonstrated in small case series of patients with decompensated PAH, but periprocedural mortality remains a concern.[105]

MECHANICAL SUPPORT

Indications for mechanical cardiovascular support in patients with PAH remain a subject of debate. Mechanical support as a bridge to lung or heart/lung transplantation is the indication best supported by the literature.[106] Other indications require a careful discussion of the risks and benefits of mechanical support among the patient, the patient's family, and the medical team. Such relative indications include patients who have a reversible cause of decompensation with reasonable chance of recovery, as may be the case in postoperative acute-on-chronic right ventricular failure or with an acute, reversible condition such as sepsis. Because failure to wean from mechanical support is a significant risk, mechanical support is contraindicated in patients without a reasonable chance of recovery or without the option of transplantation.

Extracorporeal membrane oxygenation is currently the preferred method of mechanical support for decompensated patients with PAH who have not responded to medical therapy. Because of the failure of the right ventricle, an arteriovenous configuration is preferred to a venovenous configuration in the majority of patients.[107] Extracorporeal membrane oxygenator flows of 2.5 to 4 L/min are appropriate for PAH patients and allow unloading of the right ventricle, preservation of pulmonary blood flow, and adequate systemic oxygen delivery while avoiding overload of the left heart, which may have secondary dysfunction in patients with severe right ventricular failure,[106,108]

Pulmonary artery–left atrium oxygenators, or lung-assist devices, are also available for mechanical support of PAH patients. These pumpless devices utilize the patient's right ventricle but decrease the afterload on the right ventricle by bypassing the pulmonary circulation. An advantage of this approach is that avoidance of a femoral approach allows ambulation of the patient. One disadvantage is that the cannulation itself is a more involved surgical procedure with a median sternotomy or thoracotomy and is therefore less practical in a patient with cardiogenic shock.[106,109]

Right ventricular assist devices have been attempted in patients with right ventricular failure due to PAH, with disappointing results published in case reports. Complications such as increased pulmonary pressures with the increased flow, hemorrhage, and pulmonary edema have been reported. Although some of the complications may be mitigated by using lower flows with the device, extracorporeal membrane oxygenation or extracorporeal lung support remain the preferred mechanical devices in patient with PAH.[110-112]

LUNG TRANSPLANTATION

In patients not responding to maximal medical therapy, lung transplantation remains the primary option. According to the International Society of Heart and Lung Transplantation, current recommendations for consideration of transplantation in PAH include persistent NYHA class III or IV on maximal medical therapy, low or declining 6MWD, no response to therapy with intravenous epoprostenol, cardiac failure with cardiac index less than 2 L/min/m^2, and elevated right atrial pressure (>15 mm Hg).[113] Additionally, all patients with PVOD should be referred for transplant evaluation at the time of diagnosis. After transplantation, PAH patients have increased risk of early mortality due to higher rates of hemodynamic instability. However, among those surviving 1 year, median survival is better for PAH patients than for patients with most other lung transplant indications.[114–116]

RISK ASSESSMENT

Risk assessment is important in evaluating prognosis and for deciding on specific PAH therapy. Modern treatment algorithms for PAH reflect this priority, with treatment recommendations focused on future mortality risk rather than patient symptoms alone. Goals include achieving and then maintaining a low-risk profile for early mortality. Although the PAH disease process involves the pulmonary vasculature, symptoms and disease progression associate strongly with cardiac function. Therefore, laboratory, hemodynamics, and imaging measures of cardiac function are included in the assessment of prognosis.

The best studied individual measures of prognosis are shown in Table 84.1, with suggested cutoffs for each measure that associate with lower, intermediate, and higher

Table 84.1 European Society of Cardiology/European Respiratory Society Risk Table

Determinants of prognosis[a] (estimated 1-year mortality)	Low risk <5%	Intermediate risk 5–10%	High risk >10%
Clinical signs of right heart failure	Absent	Absent	Present
Progression of symptoms	No	Slow	Rapid
Syncope	No	Occasional syncope[b]	Repeated syncope[c]
WHO functional class	I, II	III	IV
6MWD	>440 m	165–440 m	<165 m
Cardiopulmonary exercise testing	Peak $\dot{V}O_2$ >15 mL/min/kg (>65% pred.) $\dot{V}E/\dot{V}CO_2$ slope <36	Peak $\dot{V}O_2$ 11–15 mL/min/kg (35–65% pred.) $\dot{V}E/\dot{V}CO_2$ slope 36–44.9	Peak $\dot{V}O_2$ <11 mL/min/kg (<35% pred.) $\dot{V}E/\dot{V}CO_2$ slope ≥45
BNP and NT-proBNP plasma levels	BNP <50 ng/L NT-proBNP <300 ng/L	BNP 50–300 ng/L NT-proBNP 300–1400 ng/L	BNP >300 ng/L NT-proBNP >1400 ng/L
Imaging (echocardiography, CMR imaging)	RA area <18 cm^2 No pericardial effusion	RA area 18–26 cm^2 No or minimal pericardial effusion	RA area >26 cm^2 Pericardial effusion
Hemodynamics	RAP <8 mm Hg CI ≥2.5 L/min/m^2 $S\bar{v}O_2$ >65%	RAP 8–14 mm Hg CI 2.0–2.4 L/min/m^2 $S\bar{v}O_2$ 60–65%	RAP >14 mm Hg CI <2.0 L/min/m^2 $S\bar{v}O_2$ <60%

[a]Most of the proposed variables and cutoff values are based on expert opinion. They may provide prognostic information and may be used to guide therapeutic decisions, but application to individual patients must be done carefully. Also note that most of these variables have been validated mostly for idiopathic PAH, and the cutoff levels used above may not necessarily apply to other forms of PAH. Furthermore, the use of approved therapies and their influence on the variables should be considered in the evaluation of the risk.

[b]Occasional syncope during brisk or heavy exercise or occasional orthostatic syncope in an otherwise stable patient.

[c]Repeated episodes of syncope, even with little or regular physical activity.

6MWD, 6-minute walking distance; BNP, brain natriuretic peptide; CI, cardiac index; CMR, cardiac magnetic resonance; NTproBNP, N-terminal pro B-type natriuretic peptide; PAH, pulmonary arterial hypertension; pred, predicted; RA, right atrium; RAP, right atrial pressure; $S\bar{v}O_2$, mixed venous oxygen saturation; $\dot{V}E/\dot{V}CO_2$, ventilatory equivalents for carbon dioxide; $\dot{V}O_2$, oxygen consumption; WHO, World Health Organization.

From Joint Task Force for the Diagnosis and Treatment of Pulmonary Hypertension of the European Society of Cardiology (ESC) and the European Respiratory Society (ERS). 2015 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension. *Eur Respir J*. 2015;46:903-975.

mortality risk. Lower risk findings include functional class I or II, 6MWD greater than 440 meters, right atrial pressure less than 8 mm Hg, and cardiac index greater than 2.5 L/min/m^2, among others (Fig. 84.4). Although not initially intended as a scoring system, the number of lower risk measures at both baseline and first follow-up was strongly associated with survival in a French registry study (eFig. 84.11).[117] Obtaining the average of the European Society of Cardiology/European Respiratory Society risk measures also provides good risk stratification, as shown in the COMPERA registry.[118] Benefits of this approach are the ability to include a larger number of prognostic measures as well as allowing for assessment of prognosis even when some measures are not available.

Finally, another risk calculator is the REVEAL equation, developed from the large U.S.-based REVEAL registry.[119] The most recent update, REVEAL 2.0, includes 13 variables (eFig. 84.12). Although the inclusion of nonmodifiable risk factors (PAH subtype, male older that 60 years), has been criticized, this does improve the overall accuracy of the prognostic assessment. Another advantage of the REVEAL calculator is the diverse PAH patient population studied, making it broadly applicable for Group 1 PAH patients.

Whichever risk stratification strategy is utilized, a patient on treatment who is doing well will generally have functional class I or II symptoms, good exercise capacity, a low BNP or NT-proBNP level, and a normal cardiac index and right atrial pressure at catheterization. Cardiac imaging with echocardiography or magnetic resonance imaging will typically show a normal or near normal right atrial and right ventricular size and function and a lack of significant left ventricular compression, pericardial effusion, or tricuspid regurgitation.[24,118] Achieving a lower PVR, particularly a PVR less than 5 Wood units, has also recently been found to associate with improved long-term outcome.[8,80,119]

APPROACH TO THERAPY

Decisions about therapy are made based on many factors, including severity of illness, comorbidities, route of administration, and anticipated side effect profile. Many patients are treated with a combination of an ERA and a PDE5I, either as up-front or sequential therapy, while some patients with severely abnormal hemodynamics may receive up-front triple therapy, including a parenteral prostanoid. Current guidelines recommend serial reassessments and escalation of therapy when appropriate in patients failing to achieve low risk clinical findings.

An additional point to remember is that most clinical trials in PAH have included IPAH, CTD-PAH, and repaired CHD and,

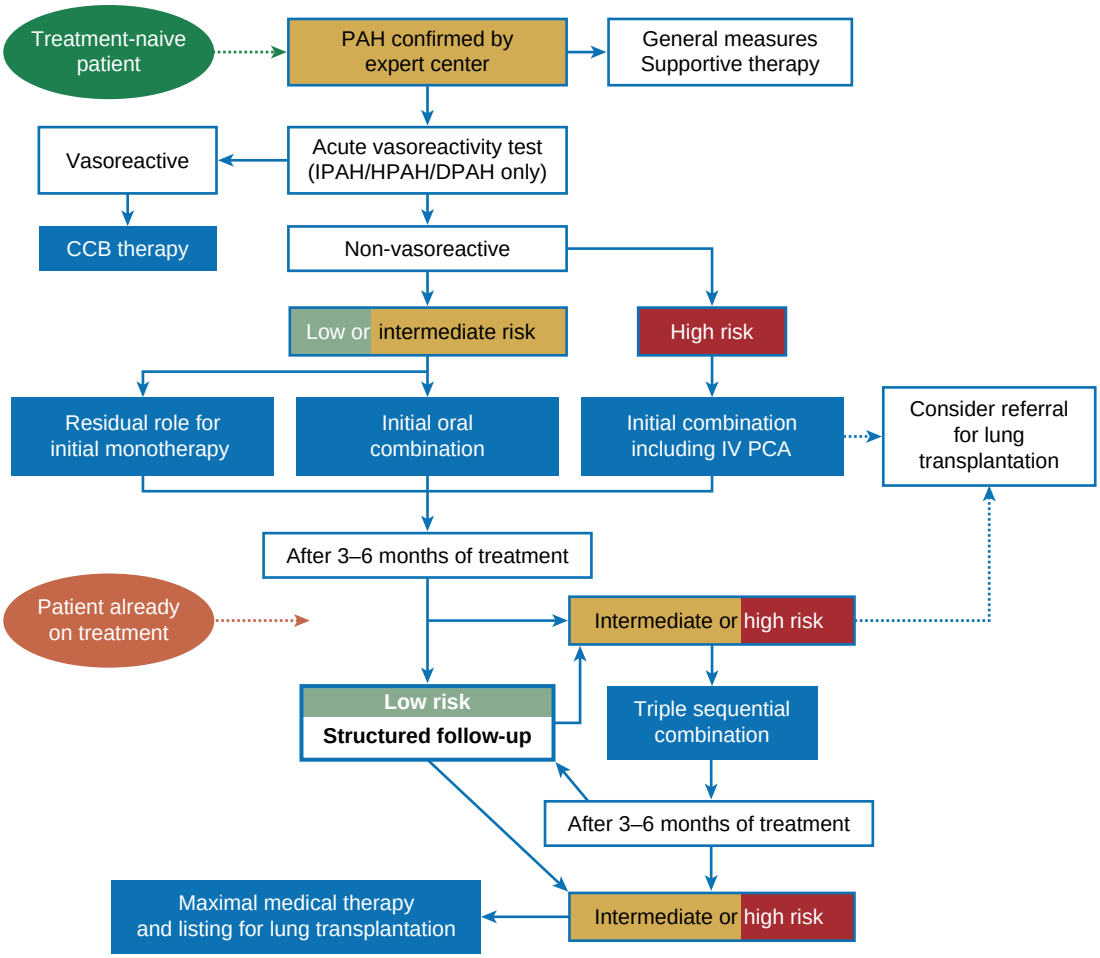

Figure 84.4 Treatment algorithm from the 2015 European Society of Cardiology/European Respiratory Socieity Pulmonary Arterial Hypertension Guidelines. Acute vasoreactivity testing is recommended for idiopathic *pulmonary arterial hypertension* (IPAH), *heritable PAH* (HPAH), and *drug-induced PAH* (DPAH). For those with a negative response as well as for those with other forms of PAH, treatment is chosen partially based on risk stratification. Recommendations include use of combination therapy in most patients, either as oral therapy or, for higher-risk patients, combination therapy that includes a parenteral prostanoid. CCB, calcium channel blocker; PCA, prostacyclin analogues. (From Galiè N, Channick RN, Frantz RP, et al. Risk stratification and medical therapy of pulmonary arterial hypertension. *Eur Respir J.* 2019;53[1]:1801889.)

as a result, considerable evidence of the optimal treatment strategies exists for these subgroups. In contrast, a much smaller number of studies have included POPH, HIV, and unrepaired CHD, and no randomized studies have included PVOD/PCH.

When combining PAH therapies, several principles should be kept in mind. First, PAH therapies have not been found to be beneficial in studies of PAH associated with left heart disease or lung disease. While most patients with these forms of PAH can be excluded after the usual diagnostic algorithm, occasional patients may have atypical features and/or marked volume excess at diagnosis, making it difficult to be certain. In such patients, in whom a Group 1 diagnosis is felt to be most likely and where PAH therapy is planned, monotherapy is sometimes considered. This allows assessment of tolerability and can be followed by repeating key diagnostic tests after 3 to 6 months in order to characterize the severity and overall disease process. Second, initiation of multiple medications together may increase the risk of certain adverse reactions; this may not necessarily be reduced by staggering initiation by a week or two, but this does at least allow assessment of tolerability as each medication is added.

In summary, the prognosis for patients with PAH continues to improve with the development of new treatments and the evolution of treatment strategy. Multiple long-term clinical trials have now confirmed the benefits of PAH therapies alone and in combination with more robust clinical end points, including morbidity and mortality measures. Treatment strategy is evolving towards early double- and triple-combination therapy, with goals of preventing or reversing right heart failure and improving symptoms and quality of life. This proactive treatment algorithm is best utilized when a correct diagnosis is diligently and expediently pursued. Early diagnosis and watchful, goal-directed follow-up will ensure the best possible patient outcomes as PAH research and best practices continue to emerge.

Key Points

- Group 1 *pulmonary arterial hypertension* (PAH) includes idiopathic and heritable PAH as well as PAH associated with drugs and toxins, connective tissue disease, congenital heart disease, portal hypertension/liver disease, human immunodeficiency virus, and *pulmonary veno-occlusive disease/pulmonary capillary hemangiomatosis* (PVOD/PCH).
- Significant remodeling in the small pulmonary arteries can be found in all forms of PAH. In addition, PVOD/PCH also has remodeling of pulmonary capillaries and/or small pulmonary veins.
- Mutations in *BMPR2* are the most common cause of heritable PAH. Inheritance is autosomal dominant with variable penetrance; mutations have been identified in 70–80% of families with PAH and 10–20% of patients diagnosed as idiopathic PAH.
- The basis for treatment of idiopathic PAH stems from its known abnormalities: excess endothelin-1, defective nitric oxide release, and deficiencies in prostacyclin.
- PAH-targeted therapies include endothelin-1 receptor antagonists, phosphodiesterase type 5 inhibitors and guanylate cyclase stimulators, and prostacyclin analogues. Treatment has been shown to lead to improvements in symptoms, exercise capacity, clinical functioning, and survival.
- Combination therapy has been shown to be superior to monotherapy in improving PAH outcomes. This includes up-front combination therapy (two-drug combination) with an endothelin-1 receptor antagonist and phosphodiesterase type 5 inhibitor and add-on therapy with various combinations, including triple therapy, for patients with an inadequate response to in initial therapy.
- Maximal medical therapy is considered three-drug combination therapy including a parenteral prostanoid.

eFigure 84.1 Idiopathic pulmonary arterial hypertension: chest radiographic and chest computed tomography (CT) findings. Frontal (A) and lateral (B) chest radiographs show bilateral, symmetrical central pulmonary arterial enlargement. The lateral radiograph (B) reveals "filling" of the substernal regions (the "retrosternal clear space"), representing enlargement of the right ventricular outflow tract (*arrow*). (C) Axial enhanced chest CT shows enlargement of the *main pulmonary artery* (MPA), consistent with elevated pulmonary arterial pressure. The MPA is measured as indicated, typically at the widest portion of the vessel at or near the level of the bifurcation: ≥29 mm in transverse diameter is considered abnormal. Alternatively, the size of the MPA may be compared with the ascending aorta (*a*) at the same level. Assuming the aorta is not pathologically enlarged, the MPA may be considered abnormally enlarged if its diameter, typically measured at the MPA bifurcation, exceeds the ascending aortic diameter at the same level, as is seen in this case. 85 PULMONARY HYPERTENSION DUE TO LUNG DISEASE: GROUP 3

CHRISTOPHER F. BARNETT, MD, MPH • TERESA DE MARCO, MD

INTRODUCTION
EPIDEMIOLOGY
Prevalence
COPD
Idiopathic Pulmonary Fibrosis
Sleep-Disordered Breathing, Obesity Hypoventilation, and High Altitude
Scleroderma Interstitial Lung Disease
Other Lung Diseases
PATHOLOGIC CHANGES AND PATHOGENESIS
Pulmonary Vascular Remodeling
Pathogenesis
Right Ventricle
Lung Mechanics
CLINICAL PRESENTATION
Symptoms and Signs
B-Type Natriuretic Peptides
Electrocardiography
Chest Radiography
Echocardiography
Computed Tomography
Cardiac Magnetic Resonance Imaging
Right Heart Catheterization
Summary
TREATMENT
Treatments Useful in All Patients With Pulmonary Hypertension Due to Chronic Lung Disease
Treatments That May Be Considered in Selected Patients
Treatment of Decompensated Right Ventricular Failure
KEY POINTS

INTRODUCTION

This chapter focuses on group 3 *pulmonary hypertension* (PH) *due to chronic lung disease* (CLD-PH). This is a common and significant clinical complication of chronic lung disease, and it differs from other types of PH both in causation and therapeutic approach. The current (2019) Updated Clinical Classification of Pulmonary Hypertension (see Chapter 83, Table 83.2) serves to define the terminology used in this chapter and in Chapter 83.[1] Note that the term *pulmonary arterial hypertension* (PAH) refers specifically to diseases in group 1, including idiopathic PAH. PH is used in reference to groups 2, 3, 4, and 5. PAH is covered in Chapter 84, and group 4 PH (chronic thromboembolic PH) is covered in Chapter 86.

The development of PH in patients with chronic lung disease is clinically important because it can lead to subsequent *right ventricular* (RV) failure (previously referred to as *cor pulmonale*[2,3]) and is associated with increased morbidity and mortality. In one large community-based series, CLD-PH was the second most common cause of PH after left heart disease[4] (see Fig. 83.1). PH develops in most types of advanced lung disease. However, patients with COPD and *idiopathic pulmonary fibrosis* (IPF) and sleep-disordered breathing are the focus of this chapter. As in all patients with PH, a thorough and exhaustive diagnostic evaluation is essential to determine the primary cause of PH and to identify comorbid, potentially treatable conditions that might worsen PH and right heart failure. The different groups of PH affect different areas of the pulmonary circulation (Fig. 85.1). Distinguishing between group 3 CLD-PH and group 1 PAH is especially important because these diseases are pathologically and clinically distinct and respond differently to treatment. The best treatment of patients with CLD-PH remains optimal management of the underlying lung disease, correction of hypoxemia, and timely consideration for lung transplantation. Trials in CLD-PH have generally shown that PAH medications lack efficacy and may cause harm; however, early results of a recent trial suggest benefits of inhaled PAH medications in CLD-PH. Due to the need for larger trials to guide the management of CLD-PH, patients diagnosed with CLD-PH should be offered enrollment in clinical trials.

EPIDEMIOLOGY

PREVALENCE

Numerous studies have sought to establish the prevalence of CLD-PH but have suffered from significant limitations, including inconsistent definitions of PH and frequent use of echocardiography rather than right heart catheterization to assess hemodynamics. Additionally, patient cohorts have often been heterogeneous, and comprehensive assessments to exclude other important and common comorbid causes of PH (e.g., chronic thromboembolic PH and left heart disease) were not generally performed. Recommendations from the 2019 Sixth World Symposium on Pulmonary Hypertension incorporate the findings from a large retrospective study which concluded that the upper limit of normal *mean pulmonary artery pressure* (mPAP) in heathy individuals is 20 mm Hg.[5] Adoption of this change in the

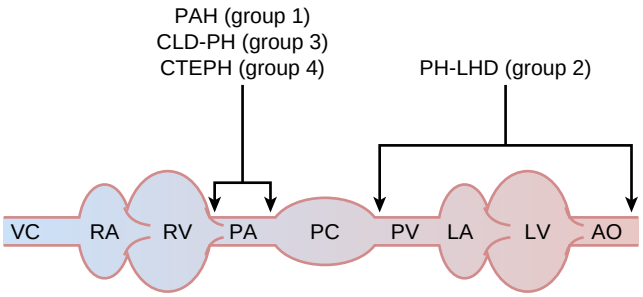

Figure 85.1 Localization of abnormalities in pulmonary hypertension. Pathologic changes that result in *pulmonary hypertension from group 3 chronic lung disease* (CLD-PH) primarily target pulmonary arterioles, the same location as abnormalities in group 1 *pulmonary arterial hypertension* (PAH) and group 4 *chronic thromboembolic pulmonary hypertension* (CTEPH). Abnormalities that result in PH in group 2 *left heart disease* (PH-LHD) are found mostly on the venous side of the pulmonary circulation. AO, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary arteries; PC, pulmonary capillaries; PV, pulmonary veins; RA, right atrium; RV, right ventricle; VC, vena cava.

Table 85.1 Hemodynamic Definitions of Chronic Lung Disease–Pulmonary Hypertension: Recommendations From the Sixth World Symposium on Pulmonary Hypertension

CLD *without* PH: mPAP < 21 mm Hg, or mPAP 21–24 mm Hg with PVR < 3 WU
CLD *with* PH: mPAP 25–34 mm Hg, or mPAP 21–24 mm Hg with PVR ≥ 3 WU
CLD *with severe* PH: mPAP ≥ 35 mm Hg, or mPAP ≥ 25 mm Hg with low cardiac index (<2.0 L/min/m²).

CLD, chronic lung disease; PH, pulmonary hypertension; mPAP, mean pulmonary artery pressure; WU, Wood units, PVR, pulmonary vascular resistance.

From Nathan SD, Barbera JA, Gaine SP, et al. Pulmonary hypertension in chronic lung disease and hypoxia. *Eur Respir J.* 2018;53:1801914.

hemodynamic definition of PH will result in many more patients being classified as having PH[6] (Table 85.1).

COPD

The lung disease most frequently associated with PH is COPD (COPD-PH), accounting for more than 80% of all cases of CLD-PH.[7] However, the estimated prevalence of PH in patients with known COPD varies dramatically, from 2.7–90.8%,[8,9] depending on the definition of PH, whether right heart catheterization or echocardiography is used to establish the diagnosis, and the study population.

The most commonly used definition of PH in studies on COPD-PH, as in other populations, is an mPAP greater than 25 mm Hg, although some studies of CLD-PH have used different cutoff values (e.g., 20 mm Hg). An early study of right heart catheterization in 175 patients with severe COPD showed that 35.4% of patients had an mPAP of 20 mm Hg or greater, and 9.7% had a mPAP greater than 30 mm Hg.[10] In another study, invasive hemodynamic values were assessed in 120 patients with severe airflow obstruction (mean FEV_1 27% of predicted) at the time of enrollment in the National Emphysema Treatment Trial. In this cohort, 90.8% of patients had an mPAP greater than 20 mm Hg, but only 5% had an mPAP greater than 35 mm Hg. Importantly, *pulmonary artery wedge pressure* (PAWP) was

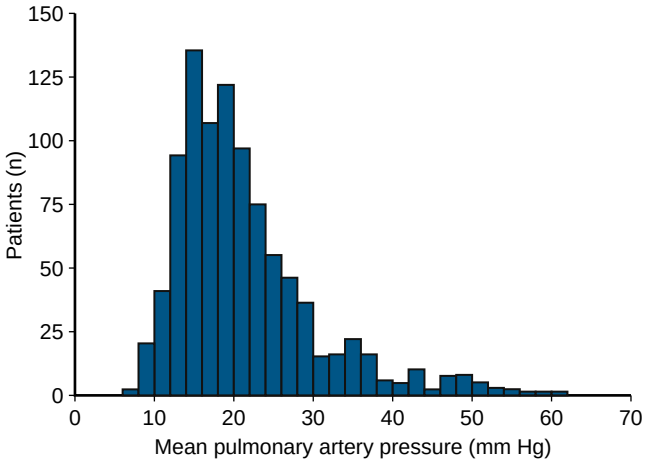

Figure 85.2 Severity of pulmonary hypertension in patients with COPD in a large French cohort. Although elevation in pulmonary artery pressure is common in patients with COPD, severe pulmonary hypertension is unusual. For many of the patients with severe pulmonary hypertension in this cohort, another medical problem such as left heart disease or chronic thromboembolic disease was judged to be the primary cause of pulmonary hypertension. (From Chaouat A, Naeije R, Weitzenblum E. Pulmonary hypertension in COPD. *Eur Respir J.* 2008;32:1371–1385.)

greater than 12 mm Hg in 61.4% of patients and greater than 20 mm Hg in 6.4% of patients, suggesting that left-sided heart failure was an important contributor to PH in this population.[9] To assess the prevalence of PH in an outpatient population with stable COPD, echocardiography was performed in 159 patients to estimate *pulmonary artery systolic pressure* (PASP). Tricuspid regurgitation was adequate to estimate PASP in 105 patients and, of those, 60% had a PASP of 35 mm Hg or greater and were classified as having PH.[11] Patients with PASP of 35 mm Hg or greater were older and had lower FEV_1 and *diffusing capacity for carbon monoxide* (D_{LCO}) values.

In one well-designed study,[8] 998 patients underwent right heart catheterization at a referral center in France as part of an evaluation for chronic respiratory failure; severe PH, defined as mPAP of 40 mm Hg or greater, was diagnosed in 27 patients (2.7%) (Fig. 85.2). Another cause of PH was found in 16 of those patients, resulting in a final diagnosis of PH secondary to COPD in only 11 patients (1.1%). Compared to a control group of patients with COPD, the patients with severe PH had lower D_{LCO} and arterial P_{CO_2} and P_{O_2} values. Patients with severe PH also had lower cardiac indices and higher right atrial pressures, suggesting reduced right ventricular function.

These studies demonstrate that mild PH is common among stable outpatients with COPD. Importantly, more severe hemodynamic abnormalities were observed only in a very small number of patients and, among those patients, other causes of PH were common.

Examining cohorts of patients undergoing evaluation for lung transplantation is useful because they include a relatively homogenous patient population with complete hemodynamic data; however, they represent a cohort with particularly advanced lung disease in whom PH might be expected to be more frequent and more severe. A retrospective study used right heart catheterization data from the Organ Procurement and Transplantation Network

database to study PH in 4930 patients with COPD listed for lung transplantation.[12] The prevalence of mild and moderate PH, defined as an mPAP of 25 mm Hg or greater and less than 35 mm Hg with a PAWP of 15 mm Hg or less, was 30.4%, and the prevalence of severe PH defined as an mPAP of 35 mm Hg or more with a wedge pressure 15 mm Hg or less was 4.0%. A significant number of patients, 17.2%, had an mPAP of 25 mm Hg or more but also had a PAWP greater than 15 mm Hg. Moreover, the PAWP was greater than 15 mm Hg in about 50% of the patients with mPAP of 31 mm Hg or greater, demonstrating that elevated left heart filling pressures (group 2 PH) are common in this population and may contribute significantly to PH. Findings were similar in another study of 409 patients with COPD undergoing evaluation for lung transplantation in Denmark.[13] In this study, 36% of patients had PH with an mPAP of 25 mm Hg or greater and a PAWP of 15 mm Hg or less, and 13% had an mPAP of 25 mm Hg or greater but also had a PAWP greater than 15 mm Hg. Only 6 (1.5%) patients had an mPAP of 40 mm Hg or greater. In this population, PH was associated with the presence of more severe hypoxemia and lower FEV_1 values. In both studies, many patients being evaluated for transplantation had elevations in mPAP; however, there was a low prevalence of severe PH, and a significant proportion of patients had elevated PAWP, which indicates that comorbid group 2 PH is common and may be the primary factor causing PH.

There are limited longitudinal data concerning COPD-PH; however, the progression of PH in these patients appears to be slow.[14] Among patients who are found to have normal PAP at rest, changes in pulmonary hemodynamics are frequently minimal over time. For example, in a group of 61 patients without initial PH, all of whom had arterial hypoxemia, a second right heart catheterization almost 8 years later revealed an average change in mPAP from 15.5 ± 2.4 mm Hg to 19.6 ± 7.0 mm Hg.[15] In a second group of 32 patients who had PH on their first catheterization, there was a nonsignificant rise in mPAP, from 27.7 ± 6.0 mm Hg to 31.0 ± 9.3 mm Hg, after 5 years.[16] An increase of 5 mm Hg or more was seen in approximately one-third of patients and was clearly related to worsening hypoxemia.

In patients with COPD, the presence of PH is clinically important because it is associated with worse exercise tolerance and survival compared to COPD patients without PH. In the retrospective organ procurement database study, *6-minute walk distance* (6MWD) was on average 28 m less in patients with PH compared to those with normal hemodynamics; in addition, mPAP was an independent predictor of a low 6MWD in a multivariate model. In this study, adjusted risk for death on the transplant list was significantly increased in patients with PH (hazard ratio, 1.27).[12] Findings were similar in a study of 362 patients at a single center undergoing transplant evaluation. In multivariate analysis, higher mPAP was associated with a shorter 6MWD, including a reduction of 11 m for every 5 mm Hg increase in mPAP.[17] In the Danish cohort, PH did not affect 6MWD but did affect the survival rate; the survival rate at 5 years was 37% for patients with PH compared to 63% in patients without PH ($P = 0.016$). In this cohort, the presence of PH did not affect outcomes following lung transplantation.[13] Among the 11 patients with severe PH in the French COPD cohort, exertional dyspnea was significantly worse and survival was significantly shorter compared to patients without severe PH.[8] In another study, the effects of PH on survival were assessed in a cohort of 84 patients who underwent hemodynamic evaluation before institution of long-term oxygen therapy. Adjusted 5-year survival rate was 62% for patients with an initial mPAP of 25 mm Hg or less, whereas it was only 36% in the 40 remaining patients who had an initial mPAP higher than 25 mm Hg. In this cohort, initial mPAP was a better prognostic indicator than either the FEV_1, the degree of hypoxemia, or the level of hypercapnia.[18] A study of 101 patients with PH and COPD at a PH referral center came to similar conclusions. Survival at 3 years was 33% in patients with mPAP of 40 mm Hg or greater versus 55% in patients with mPAP of 25 to 39 mm Hg. In a multivariate analysis, age, DL_{CO}, mixed venous oxygen saturation, and World Health Organization functional classification were independent predictors of survival.[19] These findings suggest that even mild PH may have a significant negative impact on exercise tolerance and survival and that the presence of PH may be a more important prognostic factor than the severity of lung disease.

IDIOPATHIC PULMONARY FIBROSIS

Most of the available data regarding *PH associated with IPF* (IPF-PH) come from patients undergoing evaluation for lung transplantation. In a study of 79 patients with IPF referred for lung transplantation who had a right heart catheterization, 32% (25 of 79) had PH documented by an mPAP greater than 25 mm Hg.[20] In another cohort of 124 patients undergoing evaluation for lung transplant at the Cleveland Clinic, 44% (54 of 124) had an mPAP of 25 mm Hg or greater.[21] A study of 101 Japanese patients with IPF who underwent right heart catheterization showed similar results with a prevalence of mPAP greater than 25 mm Hg of 15% (15 of 101).[22] These studies show an overall high rate of IPF-PH in patients with advanced IPF.

The presence of IPF-PH is associated with worsening symptoms, functional impairment, and increased morbidity and mortality.[20,23–25] In a retrospective study of 136 patients with IPF, the median survival of those with estimated PASP of greater than 50 mm Hg by echocardiography was less than 1 year ($P = 0.009$) compared to 4.1 years for patients with mild PH (PASP 36 to 50 mm Hg), and 4.8 years for patients without PH (PASP < 35 mm Hg).[24] The 1-year survival rate in 79 patients undergoing lung transplant evaluation was lower (72%) in those patients with PH compared to IPF patients without PH (94.5%; $P = 0.002$).[20] Furthermore, patients with PH who had lower DL_{CO} values were more likely to require supplemental oxygen, to have shorter 6MWD, and to exhibit a lower arterial oxygen saturation nadir. In one study of 78 patients with IPF-PH, using a cutoff based on a receiver operating curve, the 5-year survival rate was 17% for the group ($n = 24$) with mPAP values greater than 17 mm Hg ($P < 0.001$) and 62% for the group ($n = 37$) with mPAP values less than 17 mm Hg. The relative risk for death was significantly higher at 2.2 for the high-mPAP group.[21] According to an analysis of 2972 patients with advanced IPF listed for lung transplantation between 1995 and 2004, those with PH were 1.6 times

more likely to die after being listed for transplantation compared to those without PH.[25] These data suggest that, similar to patients with COPD-PH, the consequences of IPF-PH are serious and that even mild increases in mPAP are associated with increased mortality.

The presence of pretransplantation PH in patients with IPF may even have a significant effect on posttransplantation outcomes. In a cohort of 126 patients, those who developed primary graft dysfunction had high pretransplantation mPAP values, and each 10 mm Hg increase in mPAP was associated with an increase in the odds of primary graft dysfunction by 1.64.[26]

Combined emphysema and pulmonary fibrosis imparts a greater risk for developing PH and having poorer outcomes. The prevalence of PH in these patients has been described as 30–50%; this group had markedly reduced survival.[27,28] In one retrospective series of 40 patients with combined emphysema and pulmonary fibrosis, elevated mPAP above 40 mm Hg was present in 48% of patients.[29] Patients had severe symptoms, 85% with New York Heart Association functional class III or IV, and an average 6MWD of 244 m. Outcomes in this population were poor. For those with a *pulmonary vascular resistance* (PVR) above the median value, 1-year survival was 48%, whereas for those with a PVR below the median, 1-year survival was 100%.

SLEEP-DISORDERED BREATHING, OBESITY HYPOVENTILATION, AND HIGH ALTITUDE

In patients without parenchymal lung disease, hypoxemia from high altitude, *obstructive sleep apnea* (OSA), and *obesity hypoventilation syndrome* (OHS) are important independent causes of PH by themselves, or they may contribute significantly to PH from other causes.

High altitude affects a large number of individuals globally. Thus, environmental hypoxemia related to altitude may be one of the most common causes of PH worldwide.[30,31]

OSA appears to be an increasingly common cause of PH. In multiple studies of patients with OSA, the prevalence of PH ranges from 20–40%, typically with mild elevation in mPAP (23 to 32 mm Hg).[32] Multiple mechanisms contribute to PH in patients with OSA, including elevated left heart filling pressures (pulmonary venous hypertension), hypoxic pulmonary vasoconstriction, reduced intrinsic vasodilators, and increased vasoconstrictors and inflammatory mediators.[32] Interestingly, this PH may be reversible. One well-designed prospective trial showed that treatment with *continuous positive airway pressure* (CPAP) over 6 months reduced mPAP in patients with OSA.[33] Another more recent study showed improvement in right ventricular function with treatment of OSA.[34]

OHS, which is increasingly common worldwide, also causes PH. The prevalence of mPAP greater than 20 mm Hg among 29 patients with OHS was 59% in a cohort of untreated patients.[35] In another study of 21 patients with OHS treated with noninvasive positive pressure ventilation, the prevalence of mPAP greater than 20 mm Hg was 81%, although only three patients (14%) had severe PH with mPAP greater than 35 mm Hg. In this study, mPAP correlated negatively with use of noninvasive positive pressure ventilation and, by multivariate regression, the presence of PH was an independent predictor of poor physical functioning.[36] The use of CPAP compared to bilevel positive airway pressure treatment for OHS was evaluated in the Pickwick trial.[37] In this short-term trial, bilevel positive airway pressure reduced PASP more than CPAP and only bilevel positive airway pressure reduced left ventricular hypertrophy and improved 6MWD (see also Chapter 137).

SCLERODERMA INTERSTITIAL LUNG DISEASE

Scleroderma interstitial lung disease (SSc-ILD) complicated by PH is a particularly challenging clinical entity. Patients with scleroderma are at high risk of developing group 3 PH from SSc-ILD and also group 1 PAH secondary to connective tissue disease. A recent study found that, in a cohort of patients with SSc-ILD, 31.2% of patients also had PH.[38] Three-year survival after a diagnosis of SSc-ILD was 97%, and survival following a diagnosis of PH was 91%. However, comparison to other previously analyzed cohorts is difficult because the PH cohort included patients with group 1, group 2, and group 3 PH, and patients who were included may have had less severe disease. A retrospective cohort study comparing patients with SSc and group 1 PAH versus SSc group 3 PH found survival in the SSc group 3 PH patients at 1, 2, and 3 years to be 82%, 46%, and 39%, respectively, consistent with a fivefold higher risk of death in the SSc group 3 PH patients.[39]

OTHER LUNG DISEASES

Case reports and small series have described PH as a complication of a variety of other lung diseases, including sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, adult bronchopulmonary dysplasia, and cystic fibrosis. These conditions are discussed in other chapters (see also Chapters 83 and 94). Limited published data suggest that development of PH in all of these conditions is associated with worse outcomes.[40–42]

PATHOLOGIC CHANGES AND PATHOGENESIS

Although the mechanisms underlying the development and progression of PH in patients with lung disease are incompletely understood, they appear to be multifactorial and to vary with the underlying lung disease. Early vascular endothelial injury is likely caused by factors such as hypoxemia and inflammation, leading to endothelial dysfunction and subsequent vascular remodeling. These abnormalities lead to an increase in PVR and a subsequent increase in PAP.

PULMONARY VASCULAR REMODELING

Many of the individual elements of pulmonary vascular remodeling seen in CLD-PH are similar to those seen in PAH. The primary differentiating pathologic feature is the absence of plexiform lesions in CLD-PH.[43] The development of the vascular pathologic features observed in CLD-PH is likely multifactorial.[44,45]

A variety of pathologic vascular changes described in CLD-PH vary with the type of lung disease and overlap significantly with the changes seen in PAH (Fig. 85.3). Knowledge about pathologic changes in CLD-PH comes from autopsy series and studies of explanted lungs at the time of transplant. A characteristic feature often seen in CLD-PH and also seen in PAH is the extension of smooth muscle into small pulmonary arterioles less than 80 μm, which is not found in healthy lungs. This is termed "muscularization" and is characterized by circularly oriented smooth muscle cells between the two layers of elastic lamina.[46] Muscularization may result from hypertrophy and proliferation of existing smooth muscle and from development of new smooth muscle cells. Another common finding in lungs from patients with CLD-PH that overlaps with PAH is proliferation of the intimal layers of the pulmonary arterioles. Inflammation and thrombosis in situ may also be seen.

Pathologic changes unique to CLD-PH are associated with the underlying lung disease. In COPD-PH, destruction of alveoli and concomitant destruction of the associated pulmonary vasculature reduces pulmonary vascular cross-sectional area and increases PVR.[47] In IPF-PH, a unique finding is that vascular changes are seen both in areas of lung fibrosis and in areas of normal lung, though the vascular changes in areas of normal lung are less severe and found in a smaller proportion of vessels. Also, in IPF-PH, much more than in PAH, there are occlusive pathologic changes of pulmonary veins. In general, in IPF-PH, large portions of the pulmonary vascular bed may be destroyed or obliterated from progressive parenchymal fibrosis, inflammation, perivascular fibrosis, and/or thrombotic angiopathy.[48–50]

The severity and extent of structural changes correlate variably with the degree of hemodynamic abnormalities seen in CLD-PH. A recent study compared the structural changes observed in pulmonary arterioles from patients with COPD with and without PH undergoing transplant. Even without PH, patients with COPD frequently had muscularization and medial thickening of the pulmonary arterioles. Severity of pathologic changes worsened as the hemodynamic abnormalities worsened.[51] In another study of tissue from COPD patients who died during the National

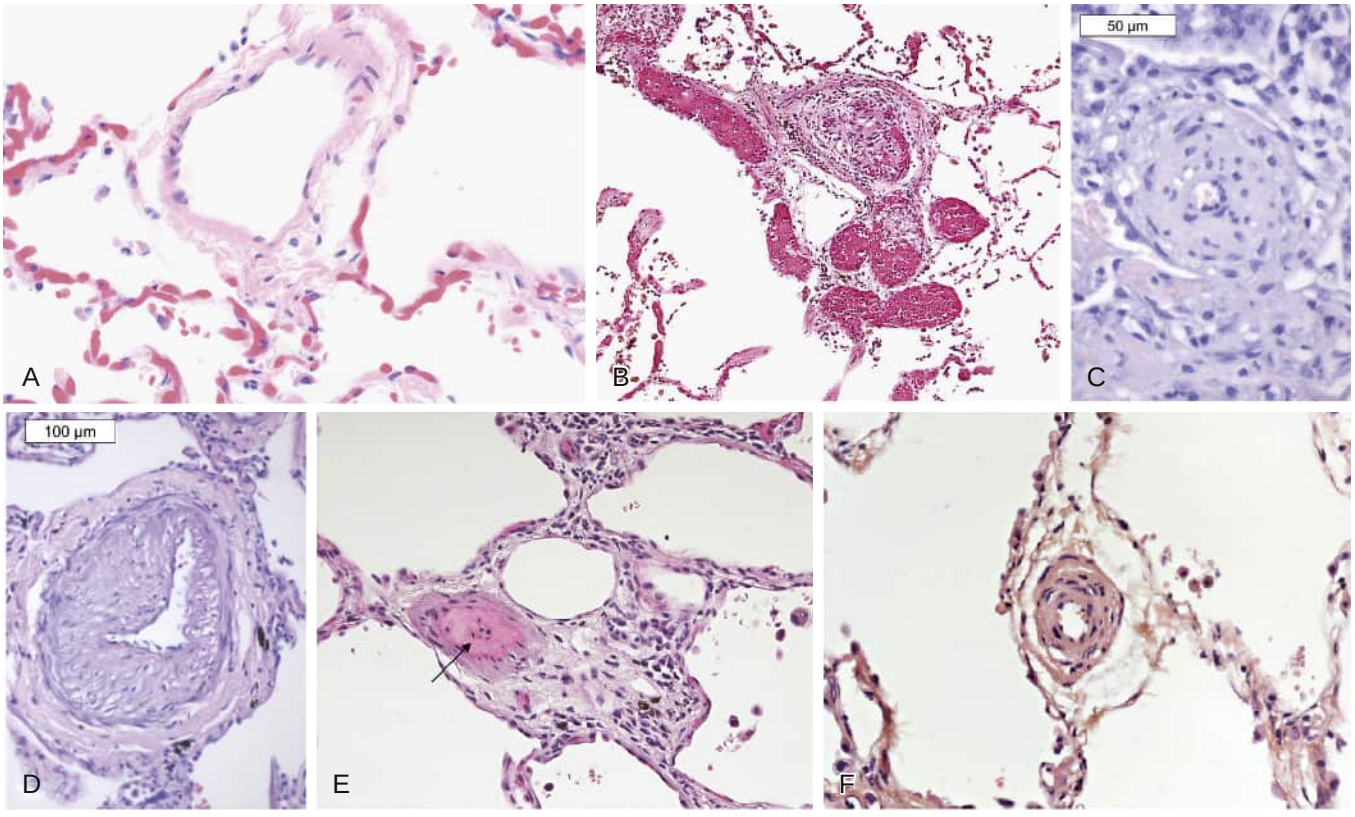

Figure 85.3 Histologic appearance of normal and abnormal pulmonary arterioles. (A) Normal pulmonary arteriole. Characteristic features include a large lumen relative to wall thickness, a single elastic lamina, and the absence of medial smooth muscle. (B) Typical plexiform lesion from a patient with pulmonary arterial hypertension. (C) Pulmonary arteriole from a patient with pulmonary hypertension from COPD showing cellular intimal proliferation in small muscular arteries. (D) Pulmonary arteriole from a patient with pulmonary hypertension from COPD showing medial hypertrophy and concentric laminar intimal fibrosis. (E) Pulmonary arteriole from a patient with pulmonary hypertension from idiopathic pulmonary fibrosis showing vascular intimal fibrosis with luminal obliteration (*arrow*) in a region of interstitial fibrosis and chronic inflammation. (F) Pulmonary arteriole from a patient with pulmonary hypertension from idiopathic pulmonary fibrosis showing muscularization of a small pulmonary arteriole. Institutes of Health Nocturnal Oxygen Therapy Trial, there was no correlation between the histologic appearance of pulmonary arterioles and severity of PH.[52]

Several studies suggest that vascular remodeling in patients with mild COPD without concomitant hypoxemia is a component of early-stage disease as evidenced by increased inflammatory cell density in the adventitia and increased pulmonary artery intimal thickening.[53,54] Furthermore, endothelial lesions have been shown to be present in cigarette smokers without chronic airflow obstruction.[55] These findings suggest that, although the pathologic changes in the pulmonary vasculature predominate, other abnormalities appear to contribute to the development of clinically relevant PH. It is also important to note that pathologic findings are not used clinically in the management of patients with CLD-PH.

PATHOGENESIS

Multiple mechanisms may contribute to the pathogenesis of CLD-PH, including hypoxic pulmonary vasoconstriction, vasoconstrictive neurohormones, and inflammation.

Hypoxic Pulmonary Vasoconstriction

Among all the mechanisms leading to PH in lung disease, the most potent and most important is alveolar hypoxia.[56] *Hypoxic pulmonary vasoconstriction* (HPV) is a normal physiologic response to alveolar hypoxia, first demonstrated in isolated cat lungs[57] and subsequently confirmed in healthy human volunteers[58] (see also Chapters 6 and 10). This effect is unique to the pulmonary circulation. Whereas acute hypoxia in the systemic circulation induces vasodilation, acute hypoxia in the pulmonary circulation causes constriction. The constriction of precapillary pulmonary arterioles effectively shunts blood away from poorly ventilated lung units to preserve optimal ventilation-perfusion matching.[59]

HPV is thought to result from hypoxia-mediated inhibition of voltage-gated potassium channels in pulmonary artery smooth muscle cells. Hypoxia inhibits the outward flow of potassium through these channels, resulting in depolarization of the membrane and entry of calcium, which causes smooth muscle cell contraction and sustained vasoconstriction.[59] When activated, this mechanism results in smooth muscle contraction within seconds of exposure to hypoxia. Smooth muscle contraction is augmented by the activity of RhoA and Rho-associated kinase. Hypoxia signals through the G protein RhoA stimulating Rho-associated kinase to increase phosphorylation of smooth muscle cell myosin light chain and to augment smooth muscle cell contraction, regardless of the level of intracellular calcium.[59]

Even brief periods of hypoxia may result in persistent hemodynamic abnormalities. In six healthy volunteers exposed to 8 hours of hypoxia, there was an increase in PVR, which did not return to normal after 2 hours of normoxia.[60]

Long-term hypoxia–induced structural changes in the pulmonary arterioles were demonstrated in an invasive hemodynamic study of 11 high-altitude natives, which showed that hemodynamics did not normalize even after 2 years at low altitude.[61] Structural changes in the pulmonary vasculature similar to those observed in COPD and IPF patients are present in the lungs of animals and humans exposed to hypoxia. In an autopsy series of tissues from Andean subjects born and living at high altitude who died without cardiac or pulmonary disease, medial hypertrophy of the pulmonary arteries was seen.[31]

The degree of increase in PAP in humans exposed to hypoxia varies widely among individuals from absent to very intense, with a rise to an mPAP of 40 mm Hg in 1–2% of healthy individuals.[62,63] These differences may be due to heritable differences in sensitivity to hypoxia or in pulmonary vascular reactivity, or both. Such differences may help explain why some patients with lung disease develop PH whereas others do not.[64]

Hypoxia is not the sole factor in generating PH.[65] This conclusion is supported by the finding that oxygen therapy in patients with lung disease has an inconsistent effect and does not normalize PAP.[66,67] In addition, hypoxia is not necessary to produce vascular changes; pulmonary vascular structural changes have been observed in patients with mild COPD who do not have hypoxemia (and thus do not have alveolar hypoxia), and structural changes seen in the pulmonary vasculature in patients with IPF are more extensive than can be explained by hypoxia alone.[52]

The development of hypercapnia may be one reason patients with lung disease develop more PH than individuals exposed to environmental hypoxia, such as those living at high altitudes. In patients with COPD-PH, hypoxemia is often accompanied by hypoventilation and hypercapnia, causing acidosis, which worsens HPV and PVR. This is in contrast to high-altitude dwellers such as healthy Andeans who have chronic hypoxia but generally have hyperventilation with resultant hypocapnia. Despite the presence of hypoxia, the high-altitude dwellers generally do not develop PH, suggesting that hypercapnia and acidemia are important contributing elements.

Neurohormones

Neurohormonal abnormalities and increased sympathetic nervous system activation are observed in patients with CLD-PH and contribute to development of hemodynamic abnormalities. Plasma catecholamine levels generally rise in patients with RV failure in a manner comparable to that seen in patients with heart failure secondary to primary myocardial disorders. It is clear that increased sympathetic activity is present with RV failure from CLD-PH, resulting in high plasma levels of circulating catecholamines and stimulation of the renin-angiotensin-aldosterone system.[68] Vasopressin levels have been shown to be higher in patients with RV failure due to COPD-PH than in patients with heart failure not associated with COPD.[69] Because cardiac output is often normal or may even be increased in decompensated RV failure, it is likely that the decrease in *systemic vascular resistance* (SVR) resulting from both hypercapnia and hypoxia leads to a reflex increase in circulating catecholamines and other neural hormones. Increased arterial P_{CO_2} may also directly activate the sympathetic nervous system and worsen pulmonary vascular constriction.

Angiotensin. Angiotensin II is a potent vasoconstrictor of the pulmonary vascular bed. The pulmonary vasculature appears to be more sensitive to the vasoconstrictor effects of angiotensin II than is the systemic vascular bed.[70] This is noteworthy because increased circulating levels of

angiotensin II and aldosterone are found in patients with RV failure secondary to COPD who have hypoxemia and hypercapnia.[71] Activation of the renin-angiotensin-aldosterone systems, together with hypoxemia, is probably an underlying pathophysiologic mechanism responsible for the elevation in PVR observed in patients with decompensated RV failure.

Angiotensin induces a dose-response increase in PVR in normal subjects.[72] Angiotensin II inhibitors have been shown to lower PVR and to be beneficial in patients with CLD-PH, especially in patients with IPF. In healthy human subjects, inhibition of angiotensin-converting enzyme has been demonstrated to attenuate the pulmonary pressor response to HPV.[73] Angiotensin II receptor blockade has resulted in similar reductions in HPV.[74] However, studies performed to date have not clarified a role for angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists in the treatment of CLD-PH.

Endothelin. *Endothelin-1* (ET-1) is a 21–amino acid peptide secreted by vascular endothelial cells in response to stimuli, including pulsatile stretch, sheer stress, neurohormones, cytokines, growth factors, thrombin, and hypoxemia. Endothelin-1 is a potent vasoconstrictor and mitogen. The effects of ET-1 are mediated by both *endothelin A* (ET_A) and *endothelin B* (ET_B) receptors. ET_A is localized on vascular smooth muscle cells, and ET_B is expressed on vascular smooth muscle cells, endothelial cells, and fibroblasts. Activation of ET_B receptors on endothelial cells mediates release of prostacyclin (prostaglandin I_2) and of *nitric oxide* (NO), a pulmonary vasodilator and inhibitor of fibrosis; both mediators exert vasodilatory and antiproliferative effects while also inhibiting ET-1 production by endothelial cells. Furthermore, the pulmonary endothelial ET_B receptors are responsible for the pulmonary clearance of up to 50% of circulating ET-1.[75] Despite these potential benefits of ET_B activation, the dominant effects of ET-1 are those primarily mediated by the ET_A receptor, including vasoconstriction, hyperplasia, hypertrophy, fibrosis, and increased vascular permeability.[76]

Increased ET-1 production has been described in patients with PAH, and both increased ET-1 levels and increased expression of receptors have been shown to be present in plexiform lesions of the lung in patients with PAH.[75,77] Furthermore, high plasma levels of ET-1 correlate with disease severity and adverse prognosis.[77–81] ET-1 concentration is also elevated in the sputum and urine of patients with COPD compared to normal subjects, and urinary levels have been shown to increase further during COPD exacerbations.[82,83] In addition, plasma ET-1 levels are increased in subjects who exhibit exertional and nocturnal hypoxemia.[84,85] In another study, patients with COPD-PH were shown to have elevated transpulmonary ET-1 levels.[86] Increased plasma levels and lung tissue expression of ET-1 have also been identified in patients with IPF with or without PH.[87]

Inflammation

Inflammation has been hypothesized to play a significant role in the development of the vascular changes seen in CLD-PH because increased markers of inflammation and inflammatory mediators have been observed in patients with CLD-PH. However, the exact role of inflammation in CLD-PH remains controversial.[88] Increased numbers of $CD8^+$ T lymphocytes have been observed in the walls of pulmonary vessels of patients with COPD. Furthermore, the presence of these cells was correlated to the enlargement of the intimal layer.[53] Similar findings have been observed in the lungs of smokers without COPD or PH, suggesting that cigarette smoke might induce these inflammatory markers. In another study, elevated serum levels of inflammatory cytokines, including C-reactive protein and tumor necrosis factor-α, were seen in patients with COPD-PH.[89] In patients with IPF-PH, elevated levels of multiple inflammatory mediators have been seen, including thromboxane A_2, tumor necrosis factor-α, platelet-derived growth factor, transforming growth factor-β, and fibroblast growth factor.[66,90,91] Studies of gene expression suggest that inflammatory mediators are overexpressed in patients with IPF-PH.[92] Further studies are needed to determine the causal nature of these changes and whether antagonizing inflammation could be of therapeutic value.

RIGHT VENTRICLE

The pattern of development of RV structural and functional abnormalities is similar in patients with CLD-PH and PAH and is secondary to the increased afterload on the RV resulting from the increase in PVR. RV afterload generally increases slowly in patients with chronic lung disease as PAP and PVR rise, leading to progressive RV hypertrophy, which minimizes wall stress. The RV eventually dilates so that the normal crescent shape of the RV is progressively transformed into a more spherical structure better able to generate an increased stroke work. RV dilation and wall thinning result in increased RV wall stress that, along with increased heart rate, leads to further increases in myocardial oxygen consumption, decreased myocardial perfusion, and RV ischemia. As the RV dilates, severe tricuspid regurgitation may develop, further compromising RV cardiac output and *left ventricle* (LV) filling. RV dilation in the setting of an intact pericardium compromises LV filling by shifting the interventricular septum toward the LV and reducing LV filling and cardiac output.[74] Nevertheless, several studies of end-diastolic pressure-volume relationships suggested well-preserved RV contractility in patients with COPD.[93] The additional presence of acidemia or infection can precipitate RV failure. When chronic hypercapnia with acidosis is present in patients with alveolar hypoventilation, the ability of the RV to increase its work appears to be impaired significantly, and RV end-diastolic pressure increases.

There may be subtle changes before elevations in PAP can be detected. For example, even before the development of significant elevations in PAP, RV hypertrophy and pathologic remodeling has been observed in patients with chronic lung disease. This was studied by echocardiographic and invasive hemodynamic evaluation of the RV in a group of 98 patients with stable moderate to severe COPD and no known heart disease.[94] Compared to 34 healthy controls, patients with COPD but without PH had increased RV wall thickness, RV size, and outflow tract dimension, as well as functional abnormalities assessed by myocardial performance index, RV isovolumic acceleration, and RV strain. In another study of patients with COPD, pulmonary artery compliance was reduced before PVR was significantly elevated, suggesting that decreases in compliance may be an early marker of hemodynamic compromise. In patients with lung disease, it is likely that early destruction of the

pulmonary vascular bed, though not sufficient to increase PVR, significantly reduces pulmonary artery compliance and contributes to early increases in RV afterload and subsequent RV hypertrophy.[95]

This impairment of myocardial contractility in the presence of hypercapnia probably plays a significant role in producing decompensated pulmonary heart disease in response to acute increases in arterial P_{CO_2} associated with exacerbations of COPD and accompanying decreases in alveolar ventilation. The development of RV volume overload with ventricular dilation results in a decreased RV ejection fraction; however, stroke volume tends to be maintained close to the normal range even in decompensated right heart failure.[96,97] With exercise, patients with COPD significantly raise their RV afterload, which causes further increases in RV end-diastolic volume and decreases in ejection fraction. It is likely that this deterioration in hemodynamic performance with exercise is a major factor limiting the exercise capacity of such patients.

LUNG MECHANICS

In healthy individuals, ordinary inspiration causes a small reduction of 3 to 5 cm H_2O in pleural pressure that is adequate to generate a normal tidal volume with only a small transmission of intrathoracic pressure affecting the heart and pulmonary vasculature. Increased stiffness of the chest wall or the lung parenchyma means that patients with obesity or obstructive or restrictive lung diseases must generate more negative pleural pressures to achieve an adequate tidal volume. Additionally, patients with COPD often have lung hyperinflation secondary to airflow obstruction, loss of elastic lung parenchyma, or dynamic hyperinflation. These abnormalities in pulmonary mechanics may contribute significantly to the pathophysiologic features of PH.

Lung hyperinflation affects RV function through changes in RV preload and afterload. Increased lung volumes in diseases such as COPD can passively compress alveolar vessels directly, increasing PVR and RV afterload,[98] and, in some cases, hyperexpanded lungs may even directly compress the heart with negative effects on cardiac performance.[99] Exaggerated swings in intrathoracic pressure such as those seen in patients with OSA can result in increased right-sided venous return, which causes acute RV enlargement and in turn impedes LV filling and cardiac output. At the same time, reductions in intrathoracic pressure increase LV afterload, which may be transmitted backward and result in transient increases in PAP.[100] In patients with acute bronchospasm, echocardiographic studies have shown acute inspiratory RV dilation and simultaneous reduction in LV cavity size that reverse during expiration, resulting in increased PVR from hyperinflation and increased RV wall tension from exaggerated negative pleural pressure. Importantly, the clinical significance of these effects may depend largely on the cardiovascular reserve of the specific patient.[98]

CLINICAL PRESENTATION

A diagnosis of CLD-PH should be considered and an appropriate investigation initiated when the degree of exercise impairment is greater than expected given ventilatory abnormalities and imaging findings or when signs and symptoms of right heart failure are present (Fig. 85.4). At times, the underlying cause of PH may be difficult to establish, and often the cause of PH is multifactorial. As described earlier, one large study showed that 59% of patients with COPD and elevated PAP had another cause of PH, including left heart disease, chronic thromboembolic PH, connective tissue disease, portal hypertension, drug use, and OSA.[7] When evaluating a patient with a new diagnosis of PH, an exhaustive evaluation is required to identify all possible causes of increased PAP (see Chapter 83).[101] The prognosis and treatment of PH vary dramatically with the cause so that a complete and accurate understanding of the underlying cause or causes of PH is required for prognostication and treatment selection.

SYMPTOMS AND SIGNS

The first step in the evaluation of a patient in whom CLD-PH is suspected is a comprehensive history and physical examination to identify any conditions that might cause PH (see Chapter 83, "Clinical Presentation"). In patients already diagnosed with lung disease, it is important that the lung disease be well characterized and that definitive diagnostic studies have been performed and are reviewed. Studies to exclude daytime hypoxemia with exercise and nocturnal hypoxemia secondary to OSA or hypoventilation should be performed. Left-sided heart disease is the most common cause of PH[4] and should always be considered as a potential contributor to PH. Although echocardiography is useful to detect reduced LV ejection fraction and valvular abnormalities, heart failure with preserved ejection fraction can be missed and may be detected only during comprehensive invasive hemodynamic assessment.[9,12]

Mild CLD-PH reflected in small chronic elevations in RV pressure generally causes minimal, if any, clinical, radiologic, or electrocardiographic findings. When moderate or severe CLD-PH develops (mPAP > 35 mm Hg), symptoms are often similar to those associated with the underlying pulmonary disease. Most commonly, these are dyspnea on exertion, chronic cough productive of mucoid sputum, wheezing, and occasional cyanosis. Clubbing of the fingers may be present. In addition to exertional dyspnea and fatigue, some patients experience dizziness or exertional syncope, attributable to the inability to increase cardiac output during exercise in the face of an increased PVR. Furthermore, these patients may have chest pain owing to RV ischemia or stretching of the main pulmonary artery.

When resting PAP is sufficiently elevated, patients may eventually reach a point at which the RV cannot meet the need for increased stroke work without a significant increase in right heart filling pressures. The resultant increase in central venous pressure is associated with developing symptoms of right-sided heart failure, such as peripheral edema, right upper quadrant discomfort, nocturia, and easy fatigability.

On examination, the patient with severe RV failure often appears dyspneic and tachypneic, with prominent use of the accessory muscles. In COPD, pulsus paradoxus may be present, the chest is often hyperinflated, and otherwise mild wheezing may be audible. Sinus tachycardia is often present; atrial and ventricular arrhythmias are

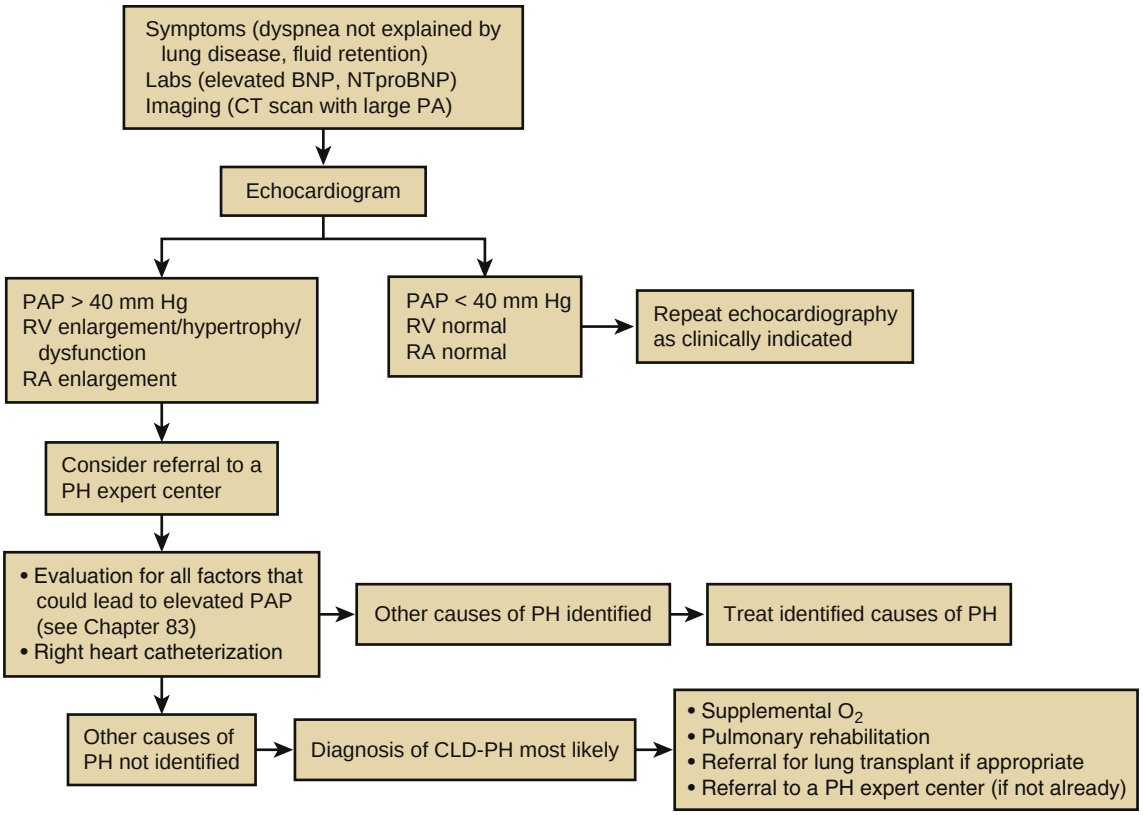

Figure 85.4 Approach to evaluation of patients with chronic lung disease with possible pulmonary hypertension. *Pulmonary hypertension* (PH) should be suspected in patients with *chronic lung disease* (CLD) who have worsening symptoms of dyspnea that cannot be attributed to known lung disease or who develop symptoms or signs of right heart failure, such as fluid retention. Elevated *B-type natriuretic peptide* (BNP) or increased pulmonary artery diameter on *computed tomography* (CT) scan may also suggest the development of PH. An echocardiogram should then be performed to estimate *pulmonary artery pressure* (PAP) and to assess *right ventricular* (RV) structure and function. In patients with elevated PAP or right heart abnormalities, referral to a PH expert center is appropriate. The evaluation proceeds with right heart catheterization to define hemodynamics as well as studies to identify all factors that could cause elevated pulmonary artery pressure, which should then be treated. If no other causes of PH are found, then treatment should be directed at optimization of lung disease, including consideration for lung transplant. It is important to take into consideration the severity of the underlying lung disease as assessed by pulmonary function testing and imaging. If the severity of parenchymal lung disease (i.e., not severe enough to cause hypoxemia) does not explain hemodynamic abnormalities, then a diagnosis of group 1 pulmonary artery hypertension with comorbid lung disease should be considered. NTproBNP, N-terminal pro–B-type natriuretic peptide; PA, pulmonary artery; RA, right atrium.

also common.[102] The cardiac examination is similar to patients with PAH (see Chapter 84). Findings of a parasternal lift, a loud second heart sound, and a right-sided S_3 and S_4 suggest right ventricular enlargement and elevated right ventricular filling pressures. Evidence of fluid retention may include dependent edema and ascites. The liver may be enlarged and tender to palpation and may be pulsatile, reflecting the presence of severe tricuspid regurgitation. Similarly, the neck veins may be distended and, when tricuspid regurgitation is present, show a large *c-v* wave with rapid *y* descent. Signs of volume overload secondary to RV dysfunction must be distinguished from sympathetically mediated renal salt and water retention without RV dysfunction, which can also develop in patients with lung disease.[103]

B-TYPE NATRIURETIC PEPTIDES

Measurement of *B-type natriuretic peptides* (BNPs) may be useful in the assessment of patients with lung disease and possible PH if there are no other reasons for elevated BNP values. In one study, plasma BNP was measured in 176 consecutive patients with a variety of pulmonary diseases[116]; elevated BNP levels identified PH (defined as PASP > 35 mm Hg) with a sensitivity of 0.85 and a specificity of 0.88 and predicted mortality. In both univariate and multivariate analysis, BNP was found to be a risk factor for death independent of pulmonary function impairment or hypoxemia.[116]

ELECTROCARDIOGRAPHY

Findings on the electrocardiogram may suggest the presence of PH; however, they are insensitive and cannot be used to rule out the presence of PH and RV abnormalities. Characteristically, the P wave of the electrocardiogram has a "p pulmonale" pattern with right-axis deviation resulting in an increase in its amplitude in leads II, III, and aVF to more than 2.5 mm (Fig. 85.5). The P wave may also be tall in the right precordial leads. The QRS vector in the frontal plane often shifts to the right and, if lung hyperinflation is present, a low-voltage QRS complex is common. Prominent S waves are seen in leads I, II, and III. An incomplete right bundle-branch block pattern is also frequently observed. When PH is moderate or severe, the more classic findings of RV hypertrophy may dominate the electrocardiogram,

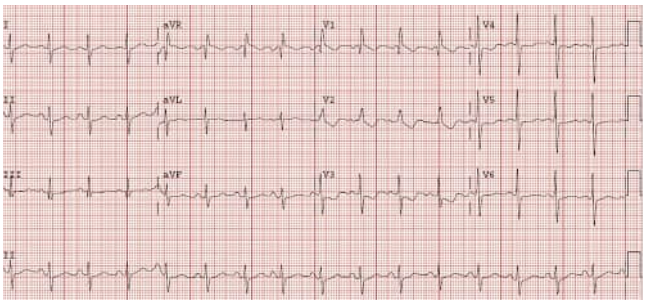

Figure 85.5 Electrocardiogram from a patient with pulmonary hypertension. Findings include a prominent "p pulmonale" and increased R wave voltage in the anterior precordial leads suggestive of right atrial and right ventricular abnormalities.

including tall R waves in V_1 with an R/S ratio of more than 1, and a prominent S wave in V_5 and V_6 with an R/S ratio of less than 1. The presence of electrocardiographic evidence of RV abnormalities in patients with COPD is a poor prognostic sign.[104]

CHEST RADIOGRAPHY

Similar to the ECG, the chest radiograph is insensitive for the detection of PH. There may be enlargement of the main pulmonary artery as well as enlargement of the right and left descending pulmonary arteries. Abrupt tapering of the peripheral vessels may result in disproportionately large central pulmonary arteries and attenuated distal vessels. A right descending pulmonary artery with a diameter greater than 16 mm suggests PH.[105] Enlargement of the RV may be seen on the lateral projection of the chest radiograph as a reduced retrosternal space. If hyperinflation of the lungs is present, the overall diameter of the cardiac silhouette may not be increased, although the heart may have a globular appearance.

The chest radiograph should be carefully evaluated for evidence of left heart failure. Pleural effusions are seldom seen in patients presenting with CLD-PH and right heart failure unless coexisting left ventricular dysfunction and failure are also present.[106] Radiographic findings of pulmonary edema also point to left heart failure as a likely cause of PH. Additionally, a diagnosis of pulmonary veno-occlusive disease should be considered in patients with PH and pleural effusions.

ECHOCARDIOGRAPHY

An echocardiogram should be performed in any patients with a clinical presentation that is suggestive of PH (see Chapter 83). Echocardiography is a useful tool for estimating PAP and evaluating RV structure and function and it can be repeated for serial assessments (see Fig. 83.3, Video 83.1). The echocardiogram is important in assisting the clinician in eliminating various nonpulmonary causes of PH, such as LV systolic dysfunction, aortic or mitral valve disease, and congenital heart disease.

Echocardiographic estimates of PASP are subject to important limitations, especially among patients with parenchymal lung disease. The presence of hyperinflation of the lungs impairs the transmission of ultrasound and can result in suboptimal image quality so that an adequate tricuspid regurgitant jet cannot be measured; in one large series of patients with advanced lung disease, a satisfactory PASP could be estimated in only 44% of patients.[107] The sensitivity and specificity of echocardiography to predict the presence of PH range from 0.79 to 1.0 and from 0.6 to 0.98, respectively.[108] However, when compared to invasive assessment, the echocardiographic estimate of PASP shows only moderate correlation and is often inaccurate.[107,109,110] Therefore, in patients with symptoms or clinical signs that are concerning for PH, right heart catheterization should be considered even if the estimated PASP by echocardiography is normal.

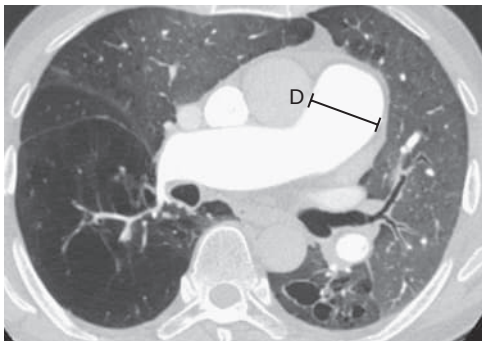

Figure 85.6 Chest computed tomography scan in a patient with interstitial lung disease demonstrating enlargement of the main pulmonary artery. Enlargement of the main pulmonary artery suggests the diagnosis of pulmonary hypertension. D = 36.4 mm, whereas the mean main pulmonary artery diameter in healthy controls is 25.1 ± 2.8 mm.[183]

COMPUTED TOMOGRAPHY

Chest *computed tomography* (CT) is important to evaluate the extent of parenchymal lung disease. It is important that the findings on the CT scan be consistent with the abnormalities detected on PFTs and, if they do not agree, that further investigation be performed to determine the true severity of parenchymal lung disease. Additionally, using this imaging modality, the size of the pulmonary artery can be measured and, in patients with moderate to severe PH, enlargement of the main pulmonary artery or an increased diameter of the pulmonary artery (>29 mm) may be documented (Fig. 85.6). This finding may have prognostic significance and, in a study of 3464 patients with COPD, a pulmonary artery/aorta ratio greater than 1 was associated with future severe COPD exacerbations (odds ratio, 3.44; $P < 0.001$).[111] However, in a study of 65 patients with advanced IPF, main pulmonary artery diameter on chest CT failed to differentiate between those who did or did not have PH diagnosed by right heart catheterization.[112] Other findings, such as dilated right-sided heart chambers on contrast-enhanced CT imaging, are suggestive but not diagnostic of CLD-PH in patients with severe parenchymal lung abnormalities.

CARDIAC MAGNETIC RESONANCE IMAGING

Currently, magnetic resonance imaging is the most accurate method for assessing the characteristics of the RV, including its volume, mass, and systolic function. Additionally,

phase-contrast magnetic resonance imaging has the capability to calculate accurate flow characteristics, including cardiac output, valvular regurgitant fraction, and both right- and left-sided shunt fractions. Magnetic resonance imaging has significant advantages over echocardiography in that it can image in any desired imaging plane, has a large field of view, and is not limited by acoustic windows. Although high cost, relatively long image acquisition time, and lack of widespread availability limit its use compared with echocardiography, cardiac magnetic resonance imaging is increasingly being used as the standard method for evaluating RV structure and function in patients with PH (see also Chapter 83).[113,114]

RIGHT HEART CATHETERIZATION

A discussion about the optimal technique for a right heart catheterization is found in Chapter 83 and applies to patients with CLD-PH. Of particular importance in the hemodynamic assessment of CLD-PH is how to perform pressure measurements, especially measurement of the PAWP in patients who may have large variation in pressure secondary to large swings in intrathoracic pressure during breathing. Incorrect pressure determination could lead to misclassification of the type and the severity of PH. There is no consensus on the best approach to measure pressures during right heart catheterization. It has been recommended that measurements should be made at end-expiration, when gas flow is minimal and transthoracic pressure is zero, to assess hemodynamics without respiratory influence.[115] However, such measurements can be technically challenging; the Sixth World Pulmonary Hypertension Symposium Proceedings suggest that, in CLD-PH, a floating average over several breaths (without a breath hold) should be obtained for measurement of mean pressures, including the PAWP.[6] Regardless of the technique used, it is important to review the hemodynamic tracings carefully and to consider the measurements in the context of the patient's overall clinical picture. Acute vasodilator testing should only be performed in the evaluation of patients with CLD-PH at a PH center to ensure patient safety and appropriate technique (see "Treatment" section).

SUMMARY

There is no single test that can be used to make a diagnosis of CLD-PH. It is important that all of the data described earlier, in particular, a comprehensive assessment of the severity of lung disease, be considered together to determine the most likely etiology of PH in any individual patient. Differentiating group 1 PAH from CLD-PH in a patient with lung disease is a common clinical dilemma that often requires evaluation at a PH specialty center.[117]

TREATMENT

In the vast majority of patients with CLD-PH, optimal treatment of the underlying lung disease according to established guidelines is by far the best approach to managing PH. Comorbidities that worsen PH and are amenable to treatment, such as left-sided heart disease, valvular disease, pulmonary emboli, and sleep-disordered breathing, should also be sought and aggressively treated. Because PH portends a poor prognosis in patients with lung disease, early referral for lung transplantation evaluation is imperative. Although it may be tempting to treat patients who have CLD-PH with therapies proven useful in group 1 PAH, these treatments have not been shown to be useful, and some have been harmful in patients with lung disease. Updated guidelines strongly discourage using treatments for PAH in patients with CLD-PH.[118,119] We recommend consultation at a center of excellence with experience in the evaluation and management of CLD-PH disease before initiation of PAH-specific therapy; if warranted, patients should be enrolled in prospective treatment trials.

Table 85.2 Therapeutic Strategies for Pulmonary Hypertension Due to Chronic Lung Disease

FOR ALL PATIENTS
Treatment of underlying lung disease
Lifestyle modification
Smoking cessation
Sodium restriction
Weight loss
Judicious exercise training
Structured rehabilitation and breathing training programs
Avoidance of overexertion
Avoidance of pregnancy
Avoidance of high altitudes
Supplemental oxygen
Diuretics
Treatment of sleep-disordered breathing and alveolar hypoventilation disorders (CPAP, BPAP, surgery)
Lung transplantation
FOR SELECTED PATIENTS
Lung volume reduction surgery
Phlebotomy
Iron supplementation
PAH-specific therapies (use discouraged except in highly selected circumstances and when managed by a pulmonary hypertension referral center)

BPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure; PAH, pulmonary arterial hypertension.

TREATMENTS USEFUL IN ALL PATIENTS WITH PULMONARY HYPERTENSION DUE TO CHRONIC LUNG DISEASE

In patients with CLD-PH, optimal treatment directed at the specific underlying pulmonary disorder is mandatory and is the subject of most of this textbook. The overall therapeutic strategies for CLD-PH and RV failure are shown in Table 85.2.[120,121]

Lifestyle Modifications

In the management of CLD-PH, diet and lifestyle modifications are crucially important. Smoking cessation is the most important of all preventive lifestyle interventions, especially considering the possible harmful effect of cigarette smoke on the pulmonary vasculature.[54] Other interventions consist of sodium restriction, weight loss, and exercise training to improve functional performance. Structured rehabilitation programs and breathing training have been shown to

be useful.[74,122] Patients with severe PH or RV dysfunction, especially those with a history of syncope, should avoid overexertion, pregnancy, and high altitudes (>1220 m [4000 feet]).

Oxygen

Alveolar hypoxia may make a major contribution to the genesis of CLD-PH, and aggressive treatment with supplemental oxygen to correct hypoxia is central to optimal treatment. Controlled trials evaluating long-term oxygen administration in COPD showed improvement in survival. Oxygen administration may have beneficial effects on hemodynamics,[123,124] RV function,[125] and exercise tolerance.

The effects of oxygen supplementation in CLD-PH have been studied in two major randomized trials. First, in the British Medical Research Council evaluation of long-term home oxygen in chronic hypoxic RV dysfunction, long-term oxygen administration for at least 15 hr/day lessened mortality and appeared to prevent further increases in PAP, compared with no oxygen administration in control patients.[126] Second, in a National Institutes of Health–sponsored study in the United States, continuous oxygen therapy was better than nocturnal therapy alone; furthermore, continuous oxygen lessened the mortality rate at 2 years[127] and decreased PVR in comparison with the group receiving only nocturnal therapy. These findings were confirmed in two more recent studies, both showing stabilization of PAP with long-term oxygen therapy.[128,129] There are other beneficial effects of oxygen therapy, including relief of renal vasoconstriction and improvement in oxygen delivery to critical organs such as the heart and brain.[130]

Based on the results of these studies, it is clear that hypoxemic patients with COPD should receive supplemental oxygen therapy. Additionally, there is evidence that oxygen improves functional class and symptoms in patients with IPF so that, in these patients, maintenance of arterial oxygen saturation at or slightly over 90% at rest and especially with activity has been recommended.[91] It must be remembered, however, that the acute administration of excessive concentrations of oxygen to a patient can have adverse effects on ventilation, particularly in patients with evidence of chronic hypercapnia. Patients given oxygen need to be observed closely when they are initially instructed on the use of this therapy to ensure that arterial oxygen saturation actually increases, but not too high: flow rates of 1 to 3 L/min generally suffice. Further information about the long-term use of oxygen in pulmonary rehabilitation is provided in Chapter 139.

Diuretics

Diuretic therapy to optimize volume status alleviates dyspnea, hepatic congestion, and peripheral edema. Decompression of the RV with diuretics may also improve RV performance by reducing preload and wall stress and reducing tricuspid regurgitation. Judicious diuresis may reduce intrapericardial pressure and potentially attenuate interventricular septal shift toward the LV, resulting in increased LV filling and improved systemic cardiac output.

Treatment of Sleep-Disordered Breathing

Sleep-disordered breathing is common in patients with COPD and can contribute to nocturnal hypoxemia and hypercapnia, leading to increased pulmonary vasoconstriction. As described in Chapter 120, CPAP exerts its beneficial effects by maintaining patency of both upper and lower airways and improving gas exchange. Patients diagnosed with OSA should be treated with CPAP and supplemental oxygen as required; in patients with OSA, CPAP is associated with improved ventricular function and survival and reduced hematocrit level.[131,132] In patients who have nocturnal hypoxemia without evidence of OSA, supplemental oxygen alone may be adequate. In some patients, such as those with obesity-hypoventilation syndrome, bilevel positive airway pressure may be more appropriate (see Chapters 122 and 136).

Lung Transplantation

There is a clear role for lung transplantation in patients with CLD who develop PH.[133] Because development of PH and right heart failure in patients with lung disease portends a poor prognosis and there are no effective medical therapies, timely referral for evaluation for lung transplantation is essential. Early referral to a transplantation center is preferred so that candidacy can be determined and barriers to transplantation can be identified and addressed. Recovery of RV function and good long-term prognosis have been demonstrated in patients following both single- and double-lung transplant for PH.[134,135]

There is conflicting evidence regarding the effects of pretransplantation hemodynamics on posttransplantation mortality in patients with CLD-PH. A retrospective study of 830 patients treated with lung transplant for IPF found that 90-day posttransplantation mortality increased with increasing pretransplant mPAP.[136] Another retrospective study showed that, in COPD patients undergoing lung transplantation, a preoperative echo-estimated PASP of 45 mm Hg or higher was associated with increased intensive care unit length of stay and duration of mechanical ventilation but was not associated with reduced survival.[137] The degree of pretransplantation RV dysfunction is potentially more important than PAP and may be considered by the transplantation team when determining risk and transplantation candidacy and the optimal surgical approach (single or double lung, on-pump or off-pump).[138] In patients with more advanced RV dysfunction, use of mechanical support such as extracorporeal membrane oxygenation during the perioperative period has been used to provide hemodynamic support and permit transplantation in patients with right heart failure[139,140] (see Chapter 138).

TREATMENTS THAT MAY BE CONSIDERED IN SELECTED PATIENTS

Lung Volume Reduction Surgery

The effects of *lung volume reduction surgery* (LVRS) on pulmonary hemodynamics remain controversial. LVRS has been shown to improve symptoms and quality of life in patients with emphysema and may improve pulmonary hemodynamics by improving oxygenation and reducing hyperinflation; by contrast, pulmonary hemodynamics may be worsened by removing or altering the pulmonary vasculature. Results of retrospective studies have shown variable effects of LVRS on hemodynamics; some have shown improvement in RV function[141] and reduction in wedge

pressure,[142] whereas others have found an increase in PAP and PVR.[143,144] The prospective cardiovascular substudy of the National Emphysema Treatment Trial attempted to clarify the hemodynamic effects of LVRS by randomizing 110 patients to either LVRS or medical therapy.[145] Six months after treatment, hemodynamics were similar in both groups, with the exception of a small reduction in wedge pressure in the LVRS group. Based on these results, LVRS is not currently recommended for routine treatment of CLD-PH.

Phlebotomy for Polycythemia

If severe polycythemia is present, phlebotomy may be helpful, although clinicians are frequently reluctant to undertake this type of therapy today. An elevated hematocrit above 40% is known to increase viscosity and PVR (see eFig. 85.1). Phlebotomy in patients with polycythemia and chronic hypoxemia may also improve RV ejection fraction, exercise tolerance, and neuropsychological function.[74] For those with an elevated hematocrit (e.g., above 55%), phlebotomy should be considered and, if the patient benefits, repeated as needed to maintain a lower hematocrit.[146–148]

Iron Supplementation

Experiments in animals and human tissue cells have revealed that the hypoxia-inducible factor family of transcription factors is integral to regulation of the pulmonary vascular response to hypoxia.[149] Hypoxia-inducible factor is primarily regulated by oxygen-dependent proteasomal degradation, a process that is up-regulated or down-regulated based on iron availability. A study in humans showed that intravenous iron infusions into healthy iron-replete volunteers blunted the pulmonary vasoconstrictor response to hypoxia, whereas a reduction in available iron through chelation to those same volunteers enhanced the pulmonary vasoconstrictor response to hypoxia.[150]

In a follow-up study, PAP was assessed by echocardiography in 22 healthy volunteers at sea level.[151] Subjects were then taken to 4340 m for 3 days and treated with either intravenous iron or saline; repeat assessment showed a reduction in PASP in iron-treated patients compared to controls. Another trial evaluated the effects of standard therapy, phlebotomy, followed by iron infusion or saline infusion in 11 patients with chronic mountain sickness.[151] Following phlebotomy, all patients developed iron deficiency with an increase in PASP of 9 mm Hg that did not reverse acutely with intravenous iron treatment. Further randomized trials are needed; however, these studies suggest that evaluation for and correction of iron deficiency in patients with CLD-PH may be beneficial.

Pulmonary Arterial Hypertension–Specific Therapies

Multiple therapies are now available with proven efficacy in the treatment of PAH (see Chapter 84). Elevated PAP in patients with CLD-PH is an appealing target of therapy given the poor outcomes associated with the development of CLD-PH and availability of PAH-specific medications. Acute hemodynamic benefits in CLD-PH have been demonstrated with some of these agents[152,153]; however, adverse effects, including worsening hypoxemia from reversal of physiologic ventilation-perfusion matching and reduction in systemic blood pressure from peripheral vasodilator effects, have been described.[153,154] Randomized studies of IPF patients treated with *endothelin receptor antagonists* (ERAs) and the soluble guanylate cyclase agonist riociguat have resulted in worse outcomes compared to placebo.[155–157]

Current guidelines discourage the use of PAH-specific therapy in CLD-PH patients because of a lack of efficacy and risk for adverse effects.[118,119] However, the INCREASE trial of inhaled treprostinil in ILD-PH, published in early 2021, showed that, compared to placebo, 12 weeks of inhaled treprostinil improved 6MWD, lowered levels of NT-proBNP, and reduced clinical worsening.[157a] This small brief trial is important because it is the first to show a benefit of PAH-specific therapy in CLD-PH. Additional trials will be needed to clarify the effects of this treatment on more consequential long-term outcomes and to show how it should be incorporated into patient management decisions.[157b] This and other PAH-specific therapies might be considered in selected patients with CLD-PH such as those who also have evidence of concomitant group 1 PAH or group 4 chronic thromboembolic PH and to manage right heart failure in CLD-PH patients awaiting lung transplant. If treatment with PAH-specific therapies is considered, we recommend consultation at a PH center of excellence before initiating therapy and, if possible, enrollment in a clinical trial.

Of major concern in patients with CLD-PH is that pharmacologic reversal of HPV with vasodilators may increase pulmonary blood flow to poorly ventilated or nonventilated alveoli and cause arterial P_{O_2} to fall despite a drop in PAP. Ventilation-perfusion mismatching also affects carbon dioxide elimination; therefore minute ventilation may increase to compensate for the retention of carbon dioxide, although arterial P_{O_2} may still fall.[158] Another practical problem limiting the use of pulmonary vasodilators is that very often they also act as systemic vasodilators and cause significant hypotension.

A comprehensive review of the studies of PAH-specific treatment in patients with CLD-PH can be found at ExpertConsult.com.

TREATMENT OF DECOMPENSATED RIGHT VENTRICULAR FAILURE

Management of patients with decompensated RV failure must focus on improvement of the underlying pulmonary disorder.[120] The precipitating event for decompensation in patients with stable chronic right heart failure from either COPD or interstitial lung disease is often an upper respiratory infection. Increased secretions and infection are likely to tip the balance toward further arterial hypoxemia, hypercapnia, and acidemia, which aggravate PH and worsen ventricular contractility, resulting in cardiac decompensation.

Improvement in RV performance is best accomplished not only by correcting acidemia, but also by reducing the afterload of the RV (i.e., reducing mPAP). Correction of arterial hypoxemia through the administration of an increased concentration of oxygen lowers PAP in patients with HPV. Improvement in alveolar ventilation with mechanical or noninvasive positive-pressure ventilation helps eliminate the acute hypercapnia and acidemia that depress myocardial contractility.

Calcium Channel Blockers. Calcium channel blockers are not useful in the treatment of CLD-PH. In a study of 53 patients with COPD and PH, treatment with nifedipine reduced PVR at baseline by 23% at rest and 35% during exercise, but the benefits were no longer seen after an average of 13 months of treatment.[152] Another study randomized 20 patients with COPD and mild PH to either placebo or nifedipine. There were no acute improvements with the first dose of nifedipine, and 18 months later cardiac output was slightly higher in nifedipine-treated patients accompanied by a nonsignificant reduction in arterial Po_2. In another study of felodipine in 13 patients, hemodynamics were improved and gas exchange remained stable at 12 weeks compared to baseline, but exercise tolerance was not improved.[159] Due to the lack of long-term benefits and potential side effects from calcium channel blockers (worsening hypoxemia, systemic hypotension, and peripheral edema), we recommend against attempts to treat CLD-PH with calcium channel blockers.

Endothelin Receptor Antagonists. Three ERAs are approved by the Food and Drug Administration for the treatment of PAH. Bosentan and macitentan are dual ET_A and ET_B receptors, and ambrisentan is a selective ET_A receptor antagonist.[160] Studies of ERAs in lung disease have been designed to evaluate the effects of endothelin blockade on lung fibrosis and have not specifically included patients with CLD-PH.

BUILD 3 (Bosentan Use in Interstitial Lung Disease) was a large, randomized trial of bosentan to reduce the rate of IPF worsening or death. Results of BUILD 3 showed no significant difference in the primary end point of rate of IPF worsening or death in the 407 patients treated with bosentan versus the 209 in the placebo group. Another study evaluated the effects of bosentan on exercise capacity in patients with severe or very severe COPD; at the end of 12 weeks, only 16 of 20 patients randomized to bosentan remained in the treatment group, with the remainder dropping out because of adverse effects.[161] There was no difference in exercise capacity in the bosentan-treated group compared to the placebo group, and, in addition, there was a significant reduction in arterial oxygenation and quality of life in the bosentan-treated patients.

In Artemis-IPF, the largest study of ET_A receptor antagonists in the treatment of IPF, ambrisentan was studied in patients with IPF with minimal lung fibrosis.[155] The study was terminated early because interim analysis suggested a low likelihood of meeting the primary end point. Analysis of data from patients who were enrolled showed that those in the ambrisentan group were more likely than control subjects to experience disease progression (27.4% vs. 17.2% in the placebo group); this end point was primarily driven by higher rates of hospitalization in the ambrisentan group.

The effect of macitentan on forced vital capacity was studied in patients with IPF in the MUSIC trial, in which 178 subjects were randomized to macitentan or placebo. Hemodynamic assessments were not reported in this study. After 12 months there was no difference in change from baseline forced vital capacity, but there was a trend toward a higher rate of worsening of IPF in the macitentan group.[157]

In summary, in patients with lung disease, no benefits to treatment with ERAs have been demonstrated, and the Artemis-IPF and MUSIC studies show ERAs may be harmful in this population. From these findings, we conclude that ERAs should not be used to treat CLD-PH, and further studies of ET_A receptor antagonists in patients with lung disease seem unlikely.

Prostacyclin and Its Analogues. Prostanoids such as epoprostenol are potent pulmonary vasodilators normally synthesized by the pulmonary vascular endothelium, and exogenous prostanoids have a central role in the treatment of PAH.[162] Studies in animals and humans have shown that hypoxemia results in relative prostanoid deficiency[163,164]; however, studies in patients have not found treatment with prostanoids to be uniformly beneficial in CLD-PH.

Intravenous epoprostenol was studied in a small number of patients with respiratory failure secondary to COPD. Those treated with epoprostenol experienced significant reductions in arterial Po_2, most likely from nonselective pulmonary and systemic vasodilation, resulting in a worsening ventilation-perfusion relationship.[165] Several small case series suggest improvements in hemodynamics and right ventricular function of parenteral prostanoids in patients with IPF-PH and with ILD-PH in patients with scleroderma,[166] but these findings have yet to be recapitulated in larger studies. Studies of inhalational prostanoids were performed because it was thought they might cause less nonselective pulmonary vasodilation, preserving ventilation-perfusion relationships and minimizing hypoxemia. Beneficial effects using inhaled prostanoids were shown in several early trials. In one small study, treatment with aerosolized iloprost resulted in preferential pulmonary vasodilation and significant reduction in mPAP and PVR.[167] Another study evaluated the effects of a single dose of inhaled iloprost in 10 patients with COPD-PH and right ventricular abnormalities; patients had a statistically significant improvement of 49.8 m on the 6MWD without a significant change in arterial Po_2 and without adverse hemodynamic effects.[168]

The same beneficial effects of inhaled prostanoids were not seen in a more recent randomized double-blind crossover trial of inhaled iloprost in COPD patients with right heart catheterization–confirmed PH.[169] In this study, placebo, 10 μg, and 20 μg of iloprost were studied in 16 patients during three separate study visits. There was no difference in 6MWD after either dose of iloprost compared to placebo. A significant reduction in arterial So_2 was seen at rest, and a nonsignificant reduction was seen with exercise. The subgroup of 3 participants with right ventricular abnormalities and more severe PAP did have an improvement in exercise tolerance.

More recent trials have utilized inhaled treprostinil, which is delivered via a more user-friendly device and requires less frequent treatments. The INCREASE trial of inhaled treprostinil in ILD-PH demonstrated that after 16 weeks of treatment, the difference between the treprostinil group and the placebo group in the change from baseline in peak 6MWD was 31.1 m ($P < 0.001$).[157a] This trial is important because it is the first to show a benefit of a PAH medication and therapy target elevated PAP in patients in ILD-PH. However, the trial was small and was not designed to evaluate the effects of treatment on long-term outcomes including survival. Additional trials are needed to further

define the role of this therapy in the management of ILD-PH. The PERFECT trial of inhaled treprostinil in COPD-PH is ongoing (ClinicalTrials.gov Identifier: NCT03496623).

Nitric Oxide. NO is produced by the enzyme NO synthase within endothelial cells and activates guanylate cyclase, increasing smooth muscle cell cyclic guanosine monophosphate, which causes pulmonary vasodilation.[170,171] A possible role in the treatment of CLD-PH has been suggested based on data demonstrating that NO reverses HPV in healthy volunteers.[172,173] Similar to inhaled prostanoids, inhaled NO would be expected to cause less nonselective dilation of the pulmonary vasculature and less ventilation-perfusion mismatch than systemic vasodilators. Furthermore, inhaled NO is inactivated before it reaches the systemic circulation so that less systemic hemodynamic effect would be expected. Only limited, conflicting data are available regarding the effects of NO on hypoxemia in advanced COPD; one small study reported a decrease[174] and another no change[175] in arterial Po_2 after inhaled NO. However, because treatment with NO is technically challenging, costly, and associated with a variety of potential adverse effects, clinical use remains impractical at this time.

Phosphodiesterase Type 5 Antagonists. Sildenafil and tadalafil are selective inhibitors of cyclic guanosine monophosphate–specific phosphodiesterase type 5 and cause pulmonary arteriolar smooth muscle cell relaxation and vasodilation. Additionally, sildenafil has antifibrotic activity that has been tested in patients with lung disease.

The acute effects of sildenafil on hemodynamics and oxygenation were studied at rest and with exercise in 20 patients with COPD and mild PH after a single dose of 20 mg or 40 mg of sildenafil.[153] There was a significant 21% reduction in resting mPAP 1 hour after sildenafil that was accompanied by worsening gas exchange with a reduction in arterial Po_2 of 9%. A similar reduction in mPAP was seen during exercise with no significant change in oxygenation; concomitant studies showed that worsening hypoxemia was related to worsening of ventilation-perfusion matching after sildenafil.

Three studies have attempted to address the effects of sildenafil on exercise tolerance in patients with COPD. In the first, sildenafil was administered to 15 COPD patients for 3 months; compared to baseline, there was no difference in the RV stroke volume measured by magnetic resonance imaging or in exercise tolerance measured by cardiopulmonary exercise testing and the 6MWD.[176] In a second study, the effects of sildenafil on exercise capacity were studied in 10 patients in a randomized, double-blind placebo-controlled crossover study.[177] Patients with PH were specifically excluded from this study. After 14 days of sildenafil treatment, there was no difference in exercise capacity, but there was worsening of oxygenation and quality of life with increasing symptoms and adverse events in the sildenafil group. The third study randomized 63 patients with COPD and moderate PH documented by echocardiography to treatment with sildenafil for 3 months during pulmonary rehabilitation; in this study, sildenafil had no effect on exercise capacity or oxygenation.[178]

The acute effects of sildenafil have also been evaluated in patients with interstitial lung disease. Sixteen hospitalized patients with pulmonary fibrosis were treated with inhaled NO and then randomized to receive open-label intravenous epoprostenol (mean dose 8 ng/kg/min) or a single dose of oral sildenafil 50 mg.[154] All three agents reduced the PVR index to a similar extent. However, only inhaled NO and sildenafil reduced the PVR-to-SVR ratio. Intravenous epoprostenol also decreased mean systemic arterial pressure and Po_2 values owing to ventilation-perfusion mismatching. By contrast, during treatment with inhaled NO and sildenafil, ventilation-perfusion matching was maintained. Therefore, among patients in this study, sildenafil exerted a selective pulmonary arterial vasodilatory effect without worsening hypoxemia.

The effects of sildenafil on exercise tolerance in patients with IPF-PH were examined in two studies. In one small open-label study, 14 patients with IPF and mild PH received sildenafil 20 to 50 mg three times daily for 12 weeks.[179] At the end of the study, of the 11 patients who completed the 6MWD, 9 demonstrated an improvement in the mean 6MWD of 49 m (90% confidence interval, 17.5 to 84 m). The second study, STEP-IPF (Sildenafil Trial of Exercise Performance in Idiopathic Pulmonary Fibrosis), was the largest study of sildenafil in patients with IPF to date.[180] In this study, patients with IPF were randomized to either sildenafil ($n = 89$) or placebo ($n = 91$) for 12 weeks of treatment without any assessment for the presence or severity of PH. The primary end point of improvement in 6MWD was not met; however, patients taking sildenafil had improved dyspnea, quality of life, and less deterioration in oxygenation.

Overall, the results of these studies are highly variable but suggest that, in certain patients with lung disease, sildenafil might confer some early hemodynamic and symptomatic improvement, potentially at the expense of worsening ventilation-perfusion matching and worsening oxygenation and without any clear long-term benefits. Further well-designed studies are needed to determine if there is a role for these agents in CLD-PH.

Riociguat. Riociguat is a soluble guanylate cyclase agonist approved by the Food and Drug Administration in 2013 for the treatment of PAH; it was also studied in patients with CLD-PH. In an open-label trial, riociguat was studied in 23 patients with interstitial lung disease who also had PH with an mPAP above 30 mm Hg and no more than mild airflow obstruction. At 12 weeks, there were small but statistically significant improvements in cardiac output, PVR, and SVR compared to baseline. The PVR-to-SVR ratio remained largely unchanged, and the mPAP was increased in some patients, suggestive of an increase in blood flow that may be attributable to reduction in the SVR. There was also statistically significant worsening of oxygenation. The subsequent RISE IIP randomized controlled trial of riociguat versus placebo in patients with idiopathic interstitial pneumonia was terminated early due to increased serious adverse events (37% riociguat group vs. 23% placebo) and mortality and no improvement in the 6MWD in the riociguat group.[156] These findings suggest that riociguat should not be considered in patients with CLD-PH.

In the setting of severe acute RV decompensation with hypoperfusion, intravenous dopamine and dobutamine or milrinone may improve cardiac output, blood pressure, and renal perfusion. Low-dose dopamine infusion (2 to 5 mg/kg/min) can increase cardiac output, reduce PVR, and improve oxygen delivery.[181] Higher infusions of dopamine (10 mg/kg/min) have been shown to increase diaphragmatic blood flow and contraction.[182] Although they are effective in acute decompensated RV failure, the value of these agents in CLD-PH is yet to be determined.

Key Points

- *Pulmonary hypertension* (PH) is present in approximately 25% of patients with *chronic lung disease* (CLD-PH) and is associated with significantly worsened symptoms, functional impairment, and increased morbidity and mortality.
- Mild PH is common among patients with COPD. Severe hemodynamic abnormalities are found in a very small number of patients and, among those patients, other causes of PH are common.
- PH secondary to sleep-disordered breathing may be reversible if it is adequately treated with continuous positive airway pressure or bilevel positive airway pressure.
- The pathogenesis of CLD-PH involves both hypoxic pulmonary vasoconstriction and pulmonary vascular remodeling, which are related to anatomic restriction and/or obliteration of the pulmonary vascular bed from alveolar destruction, fibrosis, inflammation, thrombosis, and the effects of mitogenic mediators specific to the underlying lung disease.
- The diagnostic work-up of patients with CLD-PH should include a comprehensive evaluation to identify any other medical conditions that can elevate pulmonary arterial pressure, including sleep-disordered breathing, left heart disease, and chronic thromboembolic pulmonary hypertension.
- The optimal approach to management of patients with CLD-PH and right heart failure includes aggressive treatment of the underlying lung disease and administration of supplemental oxygen.
- Group 1 PAH-specific treatments, with the exception of inhaled treprostinil, have not shown benefit in patients with CLD-PH and may cause harm.
- Currently, there are no U.S. Food and Drug Administration–approved therapies for the treatment of CLD-PH apart from the administration of oxygen; accordingly, early referral for evaluation of lung transplantation is important and, if specific treatment for PH is warranted, expert consultation before initiating therapy is recommended.

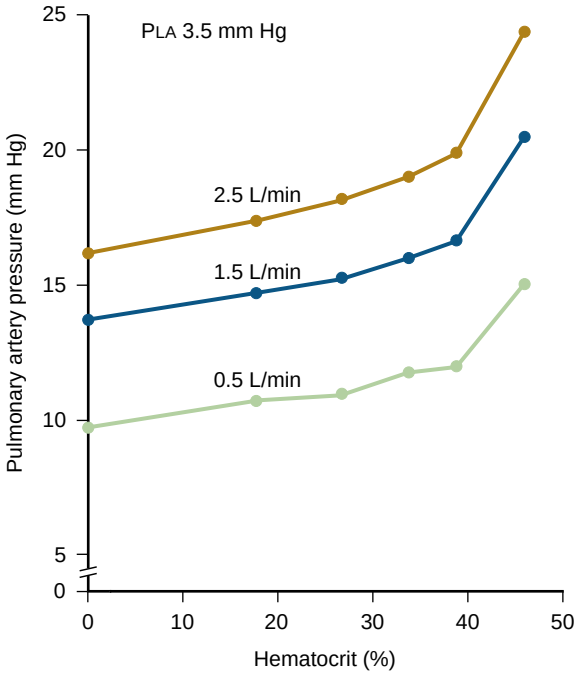
eFIGURE IMAGE GALLERY



eFigure 85.1 Effect of hematocrit on pulmonary artery pressure at three levels of blood flow (0.5, 1.5, and 2.5 L/min). *Left atrial pressure* (Pla) was held constant at 3.5 mm Hg. As the *hematocrit* (Hct) is increased at constant levels of pulmonary flow, pulmonary artery pressure increases, reflecting the higher vascular resistance caused by increased blood viscosity. With an increase in Hct above 40%, the pressure and resistance rise rapidly. (From Murray JF, Karp RB, Nadel JA. Viscosity effects on pressure-flow relations and vascular resistance in dogs' lungs. *J Appl Physiol*. 1969;27:336-341.)

INTRODUCTION

Chronic thromboembolic pulmonary hypertension (CTEPH) is one of the five *World Health Organization* (WHO) classifications of *pulmonary hypertension* (PH). This disease, classified in WHO Group 4, is often under-recognized, and may represent a larger population than *pulmonary arterial hypertension* (PAH), in WHO Group 1. CTEPH is unique among the various forms of PH due to the potential for surgical cure with *pulmonary thromboendarterectomy* (PTE). CTEPH is preceded by an incident PE in approximately 75% of patients. The acute thrombosis is replaced by chronic intravascular scar, which can ultimately lead to PH due to increased flow shunted from the obstructed vasculature through the open vascular beds. This chapter reviews the pathogenesis, epidemiology, diagnostic algorithm, and treatment options for CTEPH.

EPIDEMIOLOGY AND RISK FACTORS

The precise incidence of CTEPH is difficult to establish. In the literature, estimates are either based on small registries in which patients were prospectively followed after acute PE to identify CTEPH or based on the discovery of CTEPH at specialized PAH centers. Given these limitations, current estimates of the incidence of CTEPH after acute PE range from 0.1–8.8% within 2 years of the incident PE.[1]

Based on the incidence of PE in the United States and the natural history learned from well-done prospective follow-up cohorts after acute PE, the expected incidence of CTEPH is much higher than is currently seen. Approximately 300,000 acute pulmonary emboli are diagnosed in the United States annually.[2] In the largest, most rigorous follow-up studies, the observed rate of persistent perfusion defects after 6 months of anticoagulation ranges from 30–50% of all patients with unprovoked PE.[3,4] Persistent perfusion defects are required for the development of CTEPH, although the majority of patients with residual defects do not have resting PH. Approximately 10–15% of patients after acute PE experience dyspnea due to chronic perfusion defects with no evidence of resting PH.[4] Approximately 4% of patients after acute PE developed CTEPH.[5] Based on the incidence of acute PE and a conservative estimate of the rate of persistent perfusion defects and development of CTEPH, approximately 30,000 will have symptomatic dyspnea on exertion and at least 3000 patients per year will be diagnosed with CTEPH. The total number of pulmonary thromboendarterectomies, balloon pulmonary angioplasties, and referrals for medical therapy for CTEPH is much lower than expected by this projected incidence. Furthermore, these estimates of CTEPH incidence do not take into account the approximately 25% of patients who are diagnosed with CTEPH but who do not have a history of a preceding PE.[6]

Some features of the acute PE presentation may increase the likelihood for subsequent CTEPH. A common presenting feature among patients with CTEPH is a delay in diagnosis in which symptoms began more than 2 weeks prior to the onset of anticoagulation.[7] Compared to patients who completely resolved their PE, those with CTEPH had elevated circulating biomarkers, such as heart-type fatty acid binding protein or an *N-terminal pro B-type natriuretic peptide* (NT-proBNP), and more evidence of PH (i.e., massive or submassive presentations of their acute PE) at the time of diagnosis.[8] The presence of an initial right ventricular systolic pressure by a transthoracic echocardiogram of greater than 50 mm Hg at the time of PE diagnosis was associated with a 3.3 times higher odds ratio of PH at 1 year.[9]

Several medical conditions have been associated with the development of CTEPH. Chronic inflammation plays a key

role in the development and persistence of chronic thrombi, and a number of inflammatory conditions, including staphylococcal infection, osteomyelitis, and inflammatory bowel disease, have been linked to increased risk for CTEPH development.[1] DNA from *Staphylococcus* has been isolated from thromboendarterectomy specimens in patients with venoarterial shunts, suggesting a component of chronic infection.[10] Similarly, patients with infected intravascular devices such as pacemakers are associated with increased risk for CTEPH.[11]

Hypothyroidism is seen with increased prevalence in CTEPH patients compared to the general population.[12] The mechanism by which hypothyroidism might mediate CTEPH development has not been delineated, but hypothyroidism is associated with increased risk for *venous thromboembolism* (VTE) development compared to euthyroid controls. Malignancy also is more common in patients with CTEPH than in patients with PAH.[13] Cancer induces a hypercoagulable state associated with increased risk for VTE; certain chemotherapies and high doses of steroids may further amplify this risk. Additionally, many patients with malignancy require chronic intravascular access for chemotherapy infusions; these catheters may lead to small, subclinical PE and have been associated with chronic thromboembolic disease at a distal level.

CTEPH is usually preceded by PE but, interestingly, most of the hypercoagulable states that increase the risk for acute PE are not over-represented in patients with CTEPH (Table 86.1). The notable exceptions are lupus anticoagulant/anticardiolipin antibodies,[14] elevated clotting factor VIII,[15] elevated von Willebrand factor,[16] and certain dysfibrinogenemias[17] (i.e., presence of the fibrinogen Aa chain Ala312 allele[18]), which increase both the risk for acute PE and the persistence of chronic thrombus leading to CTEPH.

PATHOGENESIS

The first step in the pathogenesis of CTEPH is the failure of the initial PE to resolve completely. With anticoagulation, resolution of perfusion defects after acute PE may range from complete restoration of perfusion to long-term persistence of perfusion defects with chronic clot.[19] Several pathways have been implicated in the failure of thrombus resolution. The initial phase of thrombus clearance is dictated by neutrophils and marked by increases in interleukin-1β and transforming growth factor-α.[20] In a rat model of CTEPH, neutropenia leads to failure of thrombus clearance and increased deposition of collagen in the vessel wall.[21] Beyond the first few days after a PE, neutrophils give way to monocytes, which create a fibrotic milieu with elevated levels of vascular endothelial growth factor and transforming growth factor-β, which in turn lead to increased collagen deposition.[22] Over the ensuing weeks, the original fibrin-rich thrombus is remodeled into an intravascular, collagen-rich scar with neovascularization.

Beyond these inflammatory changes that favor thrombus persistence, impaired fibrinolysis has been implicated in thrombus persistence as well. In some cases, patients with CTEPH have fibrin resistant to plasmin-mediated fibrinolysis.[23] This resistance to lysis has been associated with several novel fibrinogen variants that have bulky side chains

Table 86.1 Selected Risk Factors and Univariate Odds Ratios for the Development of Chronic Thromboembolic Pulmonary Hypertension

	Risk Factor	Comparator	OR (95% CI)
Risk factors related to the acute pulmonary embolism	Unprovoked PE[7]	Resolved PE	20.0 (2.7 to >100)
	Massive/submassive PE[65]	IPAH	13.0 ($P = 0.004$)*
	Symptoms >2 weeks prior to PE diagnosis[7]	Resolved PE	7.9 (3.3–19.0)
	RV dysfunction at diagnosis[7]	Resolved PE	4.1 (1.4–12.0)
	Age >60 years[7]	Resolved PE	2.9 (1.2–7.2)
Medical risk factors for CTEPH	VTE history[65]	IPAH	49.0 ($P < 0.001$)*
	Recurrent VTE[66]	IPAH	45.0 (21.0–114.7)
	Splenectomy[66]	IPAH	22.1 (3.0–2824)
	VA shunt[66]	IPAH	19.5 (2.5–2520)
	Prior VTE[66]	IPAH	19.4 (11.7–33.8)
	Thyroid replacement[66]	IPAH	5.4 (2.7–12.2)
	Hypothyroidism[7]	Resolved PE	4.3 (1.4–13.0)
	APS/lupus AC[66]	IPAH	3.3 (1.6–7.5)
	Non–blood group O[65]	IPAH	3.1 ($P < 0.001$)*
	Malignancy[66]	IPAH	2.0 (1.0–4.3)

or post-translational modifications that may obscure the tissue plasminogen activator binding site.[24] The presence of fibrin-rich clot in the pulmonary artery modulates the endothelial and mesenchymal cells, which mediate the formation of an intravascular scar and drive the neoangiogenesis in the residual chronic clot.[25]

The persistence of perfusion defects is necessary, but not sufficient, for the development of CTEPH. Most patients with persistent perfusion defects do not manifest overt resting PH, and what mediates the development of PH is not clear. In vessels obstructed by chronic clot, the distal vascular bed is preserved but the flow is diverted to the unobstructed vascular beds. Over time, this increased flow to the unobstructed vascular beds leads to shear stress on the endothelial walls.[26] Ultimately, the unobstructed vascular bed is remodeled to an appearance similar to that of PAH, with smooth muscle proliferation and endothelial dysfunction.[27] As the pulmonary vasculature remodels, the afterload on the right ventricle increases, culminating in right ventricular remodeling (i.e., dilation, hypertrophy) and, if left untreated, right ventricular failure.

If patients have chronic perfusion defects but no resting PH, they may still be symptomatic due to these defects, a condition called *chronic thromboembolic disease* (CTED). The dyspnea that patients with CTED experience is due either to exercise-induced PH or dead space ventilation.[28] The natural history of CTED and whether these patients would develop overt resting PH in the future is unknown. The management of these patients is somewhat controversial, but many experienced centers offer *pulmonary endarterectomy* (PTE) or *balloon pulmonary angioplasty* (BPA) to selected CTED patients with significant dyspnea and few comorbidities.[29]

DIAGNOSTIC EVALUATION

The key to the diagnosis of CTEPH is having a high index of suspicion for this condition (Fig. 86.1). Most commonly, CTEPH presents in patients with a history of previous PE whose dyspnea did not completely resolve and whose function did not return to baseline. The expectation after a PE should be that the patient returns to the pre-PE level of dyspnea; if there is worsening dyspnea compared to baseline, an investigation should be undertaken to exclude CTEPH as the cause.[30] The other group in whom CTEPH should be considered is patients with unexplained dyspnea, because about 25% of patients with CTEPH do not recall a preceding PE.[6] Finally, all patients who are being evaluated for PAH should be screened for CTEPH prior to initiation of medical therapy.[31]

VENTILATION-PERFUSION SCANNING, ECHOCARDIOGRAPHY, AND EXERCISE TESTING

Ventilation-perfusion (V/Q) scintigraphy and echocardiography are the initial recommended screening tests for CTEPH (Fig. 86.2). V/Q scanning remains the preferred first-line test for CTEPH due to its superior sensitivity compared to *computed tomography pulmonary angiography* (CTPA) (V/Q sensitivity >96% compared to CTPA sensitivity of 51%).[32] The advantage of the high sensitivity of V/Q scanning is that a normal V/Q scan can exclude CTEPH; an abnormal V/Q scan requires further follow-up imaging with either a high-quality CTPA or a conventional angiogram. Transthoracic echocardiography is indicated to assess right ventricular function and estimate right ventricular systolic pressure. However, it is important to note that a normal echocardiogram does not exclude CTEPH as the etiology of the dyspnea. Right heart catheterization should be performed to confirm the diagnosis of PH. (See Chapter 83 for further details regarding the hemodynamic assessment of PH.) Assessment of hemodynamics with exercise can be particularly useful in identifying symptomatic patients with normal resting hemodynamics but an abnormal hemodynamic response to exercise. Cardiopulmonary exercise testing may serve as a complementary tool in assessing symptomatic patients who have a normal resting echocardiogram or right heart catheterization. The hallmark finding in CTED is ventilator inefficiency with elevated dead space ventilation due to pulmonary vascular obstruction.[28] Details regarding the role of cardiopulmonary exercise testing in evaluating dyspnea are described in Chapter 33. Exercise studies have shown that CTEPH patients, when compared to patients with PAH, have higher ventilatory demands at anaerobic threshold and peak exercise, higher minute volume of ventilation/volume of CO_2 exhaled per unit time slope, greater physiologic dead space, and a lower end-tidal CO_2 at anerobic threshold.[33]

Perfusion imaging is performed using ^{99m}Tc-radiolabeled macroaggregated human albumin particles that are injected in a peripheral vein and lodge in precapillary arterioles and capillaries, providing an image of lung perfusion. A ventilation scan is also performed following inhalation of radiolabeled compounds to define lung borders and increase specificity by identifying matching ventilation defects and other pulmonary disorders such as airway obstruction or parenchymal lung disease. Ventilation is usually preserved in segments affected by PE; regional absence of perfusion, when paired with normal ventilation in the same region, defines the V/Q mismatch suggestive of PE. The V/Q scan in CTEPH typically demonstrates one or more segmental or larger mismatched perfusion defects (see Fig. 86.2).[34,35] This is in contrast to the perfusion scan in disorders of the smaller vessels, such as PAH, which typically have a normal or mottled appearance (see eFig. 84.4). Compared to the appearance in acute PE, perfusion defects may be more subtle in CTEPH due to partial recanalization of thromboemboli, resulting in areas of reduced rather than absent perfusion; thus a perfusion scan can under-represent the amount of chronic thromboembolic vascular obstruction.[36] This is why, when there is a suspicion of CTEPH, any degree of abnormality on the V/Q scan is considered sufficient to proceed to further anatomic evaluation.

Although V/Q scanning is a valuable screening test to exclude CTEPH, it cannot distinguish acute from chronic PE. In addition, it cannot distinguish CTEPH from other diseases that can cause mismatched perfusion defects on V/Q imaging, such as pulmonary artery sarcoma, large vessel arteritis, veno-occlusive disease or extrinsic vascular compression from adenopathy, tumor, or fibrosing mediastinitis. For this reason, further radiologic imaging is required to determine the etiology of the perfusion defects.

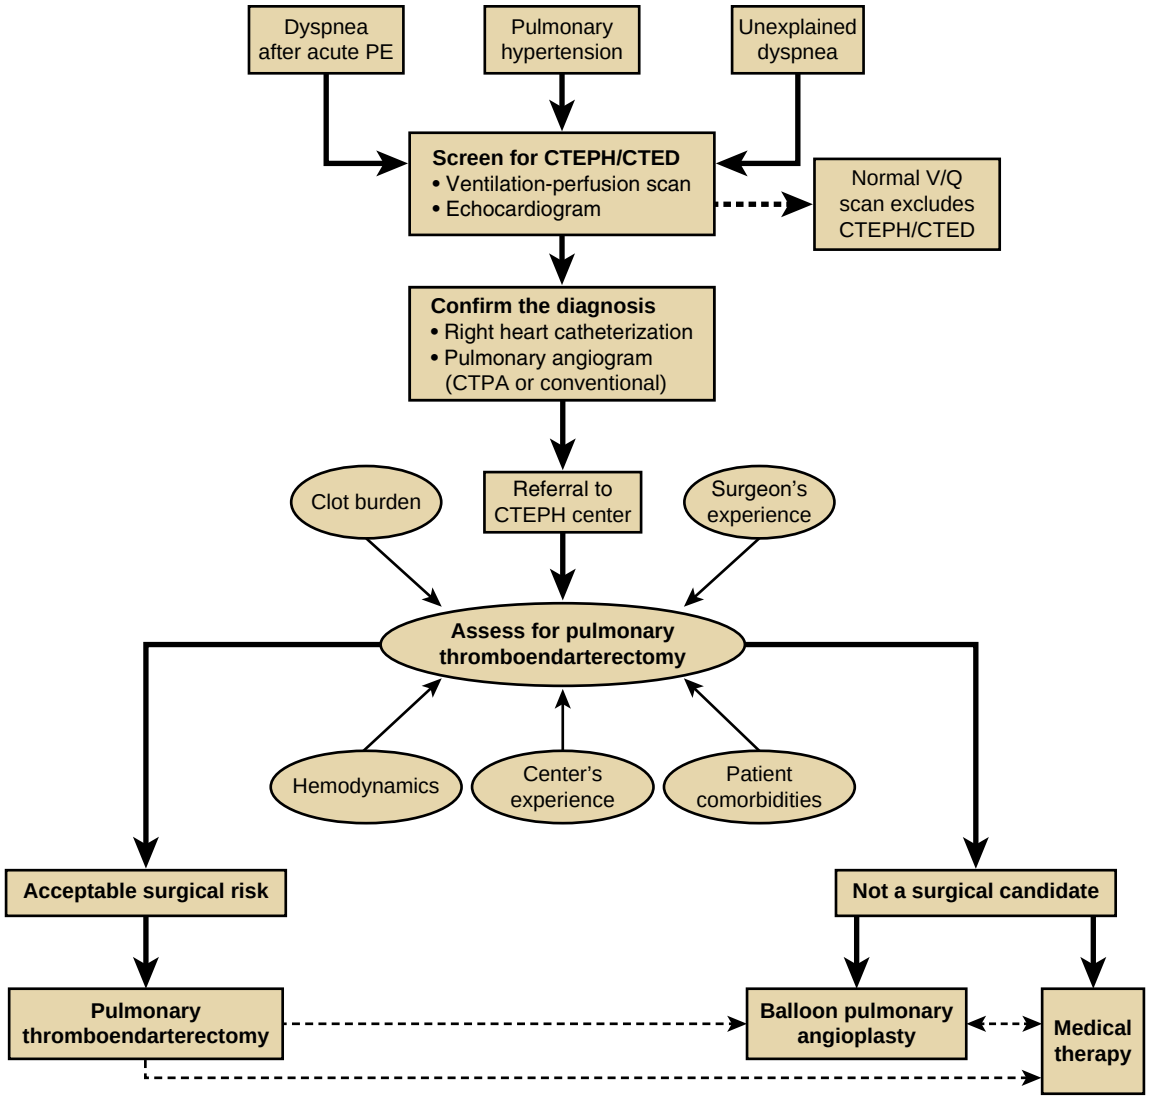

Figure 86.1 Approach to the diagnosis of chronic thromboembolic pulmonary hypertension and determination of operability. Patients with residual dyspnea after acute *pulmonary embolism* (PE), pulmonary hypertension, or unexplained dyspnea should be screened for *chronic thromboembolic pulmonary hypertension* (CTEPH). Initial screening is done with a *ventilation-perfusion* (V/Q) scan (to look for perfusion defects) and an echocardiogram (to screen for resting pulmonary hypertension). The diagnosis of CTEPH is confirmed with right heart catheterization to assess hemodynamics and pulmonary angiography to determine the amount and proximity of the chronic thrombotic material. Once the diagnosis is established, the key is referral to a CTEPH center where both *pulmonary thromboendarterectomy* (PTE) surgery and *balloon pulmonary angioplasty* (BPA) are offered. The first management decision the CTEPH center makes is determining whether the patient is a surgical candidate. Clot burden, location of disease, hemodynamics, comorbidities, and experience of both the surgeon and the center factor into the decision. PTE surgery is offered to all patients with an acceptable risk/benefit ratio because PTE is curative in the majority of patients. In those with residual pulmonary hypertension following PTE, BPA and/or pulmonary hypertension–targeted therapy can be considered. For those deemed not to be surgical candidates (either due to disease that is too distal or to an unacceptable PTE risk/benefit ratio), therapeutic options include BPA, medical therapy, or a combination of both. All patients with CTEPH require lifelong anticoagulation to prevent recurrent thrombosis; CTED, chronic thromboembolic disease.

RADIOLOGIC IMAGING

Digital subtraction angiography has long been considered the gold standard for the diagnostic confirmation and preoperative evaluation of CTEPH (Fig. 86.3). In digital subtraction angiography, an initial "mask" image is taken via fluoroscopy and saved. After contrast is injected, the saved precontrast mask is subtracted from the contrast images. In effect, the background is digitally subtracted, allowing the vessels to be seen clearly. Preferably, both anterior-posterior and lateral images should be obtained in a cine mode; the right and left pulmonary artery should be separately evaluated. Classic digital subtraction angiography findings of CTEPH include pouching defects, webs or bands, intimal irregularities, abrupt vascular narrowing, and complete vascular obstruction.[37] When required, more selective lobar or segmental injections can enhance visualization of more distal segmental and subsegmental arteries, which has recently become more accessible with the advances in more distal endarterectomy and the advent of BPA as a therapeutic option for distal disease. A right heart catheterization can be performed at the same time to determine hemodynamics, which will influence the decision making among PTE, BPA, and medical management. However, expertise in performing and interpreting conventional pulmonary angiography is becoming more limited in many radiologic practices as it is increasingly replaced by noninvasive and easily accessible CTPA.

CTPA findings are often subtle. Chronic thrombi can appear quite different from acute PE and are thus often

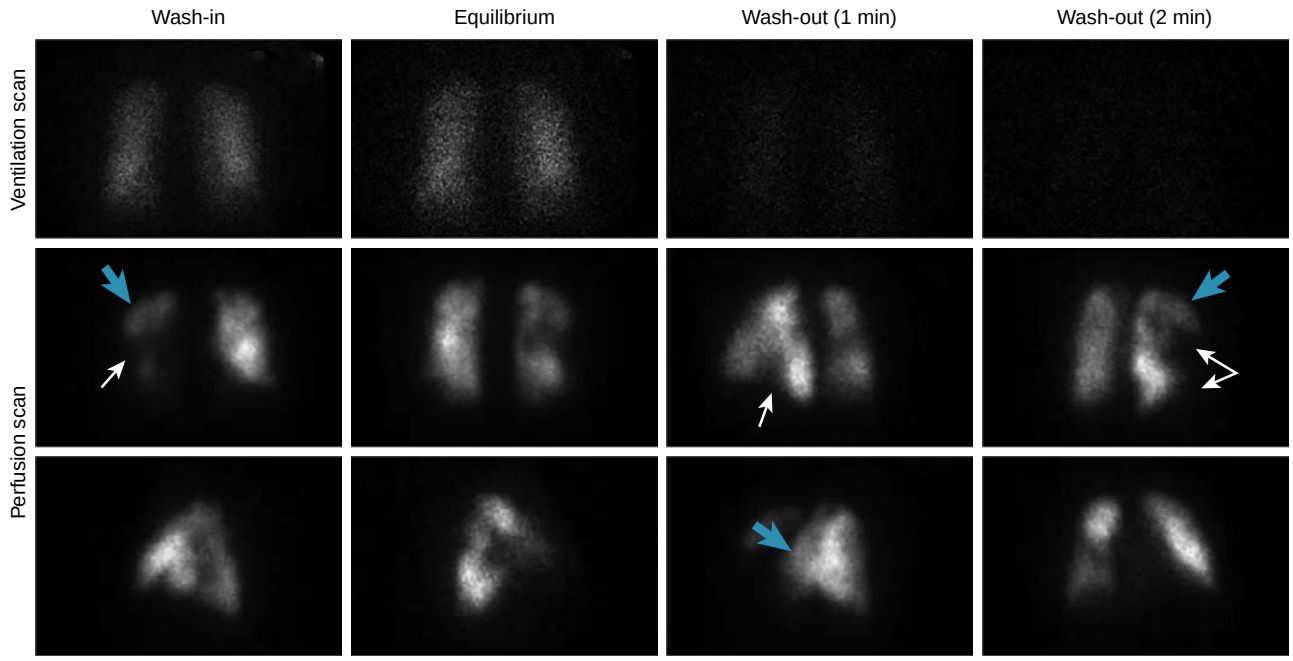

Figure 86.2 Ventilation-perfusion scan. Xenon ventilation scan (posterior view) in a patient with chronic thromboembolic pulmonary hypertension depicted in the top row with wash-in, equilibrium, and wash-out images at 1 and 2 minutes. Perfusion scan images in the bottom two rows demonstrate areas of absent perfusion (*white arrows*) and areas of relative hypoperfusion (*blue arrows*).

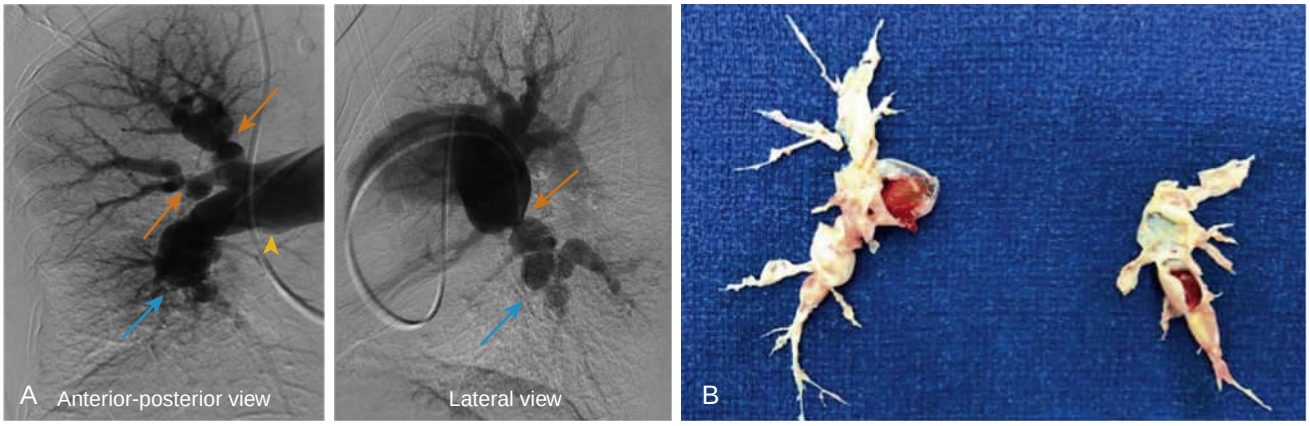

Figure 86.3 Digital subtraction pulmonary angiogram. (A) Right pulmonary digital subtraction angiogram demonstrating luminal irregularities in the distal main pulmonary artery (*arrowhead*), bands with poststenotic dilation (*orange arrows*), and pouch deformity in the right lower lobe (*blue arrow*). (B) Surgical specimen from the same patient.

overlooked, resulting in a delay in diagnosis (Fig. 86.4). Acute PE may appear as central filling defects surrounded by contrast, eccentric filling defects that form acute angles with the artery wall, or complete vessel obstruction associated with normal size or distended vessel caliber. In contrast, chronic emboli can cause complete vessel obstruction with vessel contraction or can cause partial recanalization, forming eccentric defects that form obtuse angles to the arterial wall. Other characteristic features include laminated thrombi that may be calcified, intimal irregularities, and intravascular bands or webs appearing as delicate lines crossing the vessel that may cause stenoses of the vessel. Additional supportive findings include mosaic attenuation of the lung parenchyma, with hyperperfused areas showing more attenuation (possibly even appearing as ground-glass opacities) and areas of hypoperfusion appearing dark. Right ventricular hypertrophy and bronchial artery dilation are other features of CTEPH.[34,35] CTPA can also provide additional ancillary information regarding thoracic abnormalities that may impact surgical candidacy, such as parenchymal lung disease. For example, mechanical interventions such as PTE or BPA should not be pursued if the parenchyma that would be revascularized has significant fibrotic changes. CTPA can also identify alternative diagnoses to CTEPH such as fibrosing mediastinitis, large vessel arteritis, or pulmonary artery sarcoma.

With technological improvements and experience, the sensitivity of CTPA in detecting thromboembolic disease has improved, especially in the setting of more central lobar disease (97–100%), although sensitivity is a bit lower at the segmental level (86–100%).[38–40] However, it must be emphasized that a negative CTPA does not exclude CTEPH, especially in the presence of more distal disease or with an inexperienced reader.[41] In addition, the finding of chronic

Figure 86.5 University of California San Diego classification of pulmonary endarterectomy disease levels. Typical surgical specimens classified based on the most proximal level of obstruction, levels I to IV. (From Madani MM. Surgical treatment of chronic thromboembolic pulmonary hypertension: pulmonary thromboendarterectomy. *Methodist Debakey Cardiovasc J.* 2016;12[4]:213-218.)

clot on CTPA does not alone confirm the diagnosis of CTEPH. A common diagnostic pitfall is the presence of in situ thrombosis, chronic clot seen lining the vessel walls in the massively dilated pulmonary arteries in congenital heart disease with right-to-left shunt and in other forms of advanced PH. In this case, the chronic clot is not causing PH but is a *consequence* of PH. Proposed mechanisms for the formation of thrombus in this setting include shear stress on the vessel wall, endothelial damage, and chronic stasis in the aneurysmal dilated arteries. In situ thrombosis can be distinguished from CTEPH by the absence of mismatched perfusion defects on the V/Q scan, because in situ thrombosis is nonobstructive.[42]

DETERMINING OPERABILITY

Once the diagnosis of CTEPH has been established, patients should be referred to an experienced center capable of PTE and BPA (see Fig. 86.1).[43,44] A multidisciplinary team first determines whether the CTEPH is technically operable, a decision based on the location of the disease and the expertise of the surgeon.[43] Concordance of the amount of surgically accessible disease and the severity of the PH is important; severe PH in the setting of limited accessible disease suggests coexisting small-vessel arteriopathy and less-favorable surgical outcome. The patient's comorbidities, including age, functional status, body habitus, and coexisting medical conditions, must also be evaluated.

PULMONARY THROMBOENDARTERECTOMY

The definitive management of CTEPH is PTE, a surgical procedure that is quite distinct from pulmonary embolectomy performed for acute PE. This invasive surgery entails median sternotomy, cardiopulmonary bypass, deep hypothermia to about 20°C, and then circulatory arrest for multiple intervals of approximately 20 minutes each.[43] While the patient is on circulatory arrest, the surgeon opens the pulmonary artery and identifies the plane between the intima and the media (Video 86.1). Once this plane is found, a true endarterectomy is completed using an eversion technique of the pulmonary artery, and the plane of dissection is continued into each of the subsegmental vessels. The freed specimen is never cut, to allow dissection of long tails into distal vessels beyond the field of view. After completing the endarterectomy on the right pulmonary artery tree, the left pulmonary artery is dissected in a similar fashion.

The surgical specimens removed are classified by the University of California San Diego level (Fig. 86.5).[43] Level I disease refers to proximal disease with the place of dissection beginning in the right or left main pulmonary artery. Level II disease connotes a dissection plane that begins at the level of the lobar pulmonary arteries. Level III and IV are considered distal resections. In Level III disease, the plane of dissection starts in the segmental arteries whereas, in level IV disease, this plane begins at the subsegmental level only. These distal resections are more technically challenging and should be reserved for surgeons and centers with extensive experience with PTE surgery. In the European CTEPH Registry, the overall postoperative mortality was 4.7%.[6] At the most experienced centers, the perioperative mortality is even lower, in the range of 1–2%, despite higher-risk patients and more distal resections.[45]

Immediately after surgery, the hemodynamics are improved, and the expectation is that the *pulmonary vascular resistance* (PVR) should be normalized in the vast majority of patients. The PVR is reduced on average by about 65%. In the International CTEPH

Registry, the mean PVR was reduced from about 800 to 250 dynes•sec•cm^{-5} (normal 100 to 200 dynes•sec•cm^{-5}).[6] This improvement in the hemodynamics is associated with reductions in dyspnea and an improvement in functional ability, as measured by 6-minute walk distance.

There are three immediate potential complications specific to PTE of note: pulmonary hemorrhage, reperfusion lung injury, and residual PH. Due to the delicate nature of the operation on the pulmonary arteries, there is a risk of pulmonary hemorrhage. This happens in less than 5% of patients, but the risk appears to be slightly higher with the more technically challenging distal resections. Pulmonary hemorrhage management ranges from simply withholding anticoagulation to the use of endobronchial blockers to requiring venoarterial or venovenous *extracorporeal membrane oxygenation* (ECMO) life support. The second specific complication of PTE is reperfusion lung injury. The newly endarterectomized arteries become the vessels with the least resistance, and flow preferentially shifts to these vessels and is shunted away from the previously open vascular beds, referred to as *pulmonary vascular steal*.[46] Approximately 20% of patients post-PTE experience an inflammatory, noncardiogenic pulmonary edema resulting in focal opacities in the territory of the newly opened vessels. The high-permeability edema combined with pulmonary vascular steal shunting blood to the edematous lung regions can result in profound hypoxemia with relatively subtle changes on the chest radiograph. The risk of reperfusion lung injury is highest in patients with higher preoperative PVR and right ventricular failure. Treatment is typically supportive but, when more severe, may include steroids or ECMO support.[47]

Although most patients benefit from PTE, residual PH remains a leading cause of morbidity and mortality after surgery. Persistent PH following PTE surgery may be due to inadequate endarterectomy, small vessel arteriopathy, or reversible factors such as hypercarbia, hypoxemia, and/or reperfusion edema. Postoperative residual PH is associated with increased perioperative mortality, although it has improved over time. A study from a single institution showed that patients with a postoperative PVR of greater than 500 dynes•sec•cm^{-5} had a mortality rate of 10.3% compared to those with a postoperative PVR less than 500 dynes•sec•cm^{-5} who had a mortality rate of only 0.9%.[45] Treatment of persistent PH in the immediate perioperative period focuses on minimizing oxygen consumption, reversing hypoxemia and hypercarbia, optimizing right ventricular preload, and providing inotropic support. Systemic administration of pulmonary artery vasodilators is typically avoided in the early postoperative period due to the potential to contribute to systemic hypotension and exacerbate V/Q mismatching and hypoxemia. ECMO may be required in severe cases as a bridge to lung transplant or support during recovery.

Modest residual PH is not uncommon following PTE surgery, but the majority of these patients experience significant functional and symptomatic improvement with no apparent adverse effect on medium-term survival.[48,49] Until recently, no data were available to guide when to evaluate and how to define meaningful residual PH after PTE surgery. A large, single-center cohort of 880 post-PTE patients found only a moderate correlation between the immediate postoperative hemodynamics and those obtained 3 to 6 months after surgery. Longer-term follow-up revealed 51% of the patients had a mean pulmonary artery pressure greater than 25 mm Hg on right heart catheterization at 3 to 6 months post-PTE, but the majority of patients maintained a good functional status over the long term. However, those with a mean pulmonary artery pressure of 30 mm Hg or greater were more likely to have PH therapy initiated and a mean pulmonary artery pressure of 38 mm Hg or greater and PVR of 425 dynes•sec•cm^{-5} or greater at reassessment correlated with a worse long-term survival.[50] Hence, it seems reasonable in most postoperative PTE patients with residual PH to wait at least 3 months and reassess functional status and pulmonary hemodynamics with right heart catheterization before initiating PH-targeted therapy.

Despite these complications, overall outcomes are quite good. Refinements in technique have resulted in the ability to remove more distal disease while also reducing perioperative morbidity and mortality at experienced centers. Long-term studies have demonstrated PTE surgery results in sustained improvement in cardiopulmonary hemodynamics, functional class, and 6-minute walk distance.[6,51–53] Three-year survival is better in those who undergo PTE surgery compared to those who elect against surgery,[54] and postoperative long-term survival rates are 82% at 5 years and 75% at 10 years.[45]

INOPERABLE DISEASE

Even at experienced surgical centers, nearly one-third of patients with CTEPH will be deemed inoperable, for reasons such as distal disease, comorbidities, or PH out of proportion to the surgically accessible clot burden.[6] PH-targeted medical therapy and BPA have potential therapeutic value in these patients.

MEDICAL THERAPY

Lifelong anticoagulation is advised for all CTEPH patients to prevent recurrent thrombosis. The largest and longest experience has been with vitamin K antagonists. Although direct oral anticoagulants have proven to be effective in the treatment of acute VTE, a large prospective study has not yet been done to compare vitamin K antagonists to direct oral anticoagulants in the CTEPH population.[55]

Drugs found to be effective in the treatment of PAH have been used off-label for many years to treat patients with CTEPH who are inoperable or suffer from residual or recurrent PH following PTE surgery. Histologic changes in the distal vascular bed, similar to those seen in PAH patients, have been demonstrated in specimens from CTEPH patients.[27,56,57] CTEPH is not only a macroscopic disease of proximal obstructing chronic thrombi, it is also associated with more distal small-vessel remodeling, which likely explains residual PH in patients who have otherwise undergone a complete endarterectomy. The presence of these small-vessel changes provides the rationale for PH-targeted therapy in patients with inoperable CTEPH and those with residual or recurrent PH. Previous unblinded cohort trials (Table 86.2) have assessed PH-targeted medical therapy in various subpopulations of CTEPH patients using endothelin

Table 86.2 Summary of Key Trials of Pulmonary Hypertension: Targeted Medical Therapy in Inoperable CTEPH

Study	Medication	Study Design	Participants	Primary End Point	Conclusions
CHEST-1[59]	Riociguat	Randomized placebo-controlled trial	261 patients (functional class II–III; 72 with residual PH post-PTE)	Change in 6MWD at 16 weeks	Significant placebo-adjusted mean change by 46 m; improvement in secondary end points including PVR and CI
CTREPH[61]	Treprostinil (subcutaneous)	Randomized trial of low-dose (targeting 3 ng/kg/min) vs. high-dose (targeting 30 ng/kg/min)	105 patients (functional class III–IV, inoperable or residual PH)	Change in 6MWD at 24 weeks	Significant treatment effect (40.7 m) in high-dose group; safe, with most common adverse event being infusion site pain
MERIT[60]	Macitentan	Randomized, placebo-controlled trial	80 patients with inoperable CTEPH	Change in PVR at 16 weeks	Significant treatment effect on PVR; PVR reduced to 73% of baseline
BENEFiT[58]	Bosentan	Randomized, placebo-controlled trial	157 patients with CTEPH (functional class II–VI; 41 with residual PH post-PTE)	Co-primary end points at 16 weeks: change in 6MWD; percent reduction in PVR from baseline	No significant improvement in 6MWT (2.2 m); significant 24% reduction in PVR from baseline
Suntharalingam et al.[67]	Sildenafil	Randomized, placebo-controlled trial	19 patients, all with inoperable CTEPH	Change in 6MWD at 16 weeks	No significant improvement in 6MWT (+17.5 m); PVR reduced 197 dynes • sec • cm^{-5}
Cabrol et al.[68]	Epoprostenol	Retrospective cohort study	27 patients with inoperable CTEPH	Improvements in NYHA class, 6MWT, or hemodynamics	At 3 months, 48% improved NYHA class; 6MWT increased by 66 m; mPAP reduced 5 mm Hg

6MWD, 6-minute walk distance; 6MWT, 6-minute walk test; CI, cardiac index; CTEPH, chronic thromboembolic pulmonary hypertension; mPAP, mean pulmonary arterial pressure; NYHA, New York Heart Association; PH, pulmonary hypertension; PTE, pulmonary thromboendarterectomy; PVR, pulmonary vascular resistance.

receptor antagonists (e.g., bosentan), nitric oxide agonists (e.g., sildenafil), and prostacyclin analogs (e.g., epoprostenol, treprostinil, and iloprost). Each demonstrated measurable pulmonary hemodynamic effects. The first randomized, placebo-controlled trial in inoperable CTEPH was the BENEFIT trial, in which 157 patients were randomized to either bosentan or placebo.[58] After 16 weeks of therapy, there were two co-primary end points: change in PVR and improvement in 6-minute walk distance. After 16 weeks of treatment, bosentan significantly reduced PVR 24% from baseline compared to placebo but failed to improve the 6-minute walk distance.

Riociguat, a soluble guanylate cyclase stimulator acting in the nitric oxide pathway, is the first and currently only U.S. Food and Drug Administration–approved therapy for inoperable CTEPH based on the CHEST-1 trial, which demonstrated both an improvement in functional capabilities (6-minute walk distance) as well as significant gains in secondary pulmonary hemodynamic end points.[59] In the CHEST-1 trial, 261 patients with CTEPH (189 of whom were deemed inoperable) were randomized to 16 weeks of either riociguat (starting at 1 mg and titrated to 2.5 mg or the maximum tolerated dose) or placebo. At 16 weeks, there was a 46-m placebo-adjusted improvement in 6-minute walk distance as well as significant reductions in PVR and levels of NT-proBNP.

In addition to riociguat, there is emerging evidence from randomized controlled trials for the efficacy of both macitentan and subcutaneous treprostinil in selected patients with inoperable CTEPH. In the MERIT trial, macitentan was compared with placebo in reduction of PVR at 16 weeks; there was a significant treatment effect, with macitentan reducing PVR to 73% of baseline.[60] In the CTREPH trial, two doses of subcutaneous treprostinil were compared, a very low dose (3 ng/kg/min) and the typical therapeutic dose (30 ng/kg/min). Patients in the higher-dose group, but not the lower-dose group, experienced a significant improvement in 6-minute walk distance.[61] There are little data about the benefit of combination therapy for inoperable CTEPH, but many providers apply the same principles used in the management of PAH to the management of CTEPH. Furthermore, while many will manage these patients in a similar fashion to PAH, there is not a consensus about the optimal follow-up and goals for treatment of inoperable CTEPH.

BALLOON PULMONARY ANGIOPLASTY

In addition to medical therapy, BPA has emerged as an option for selected patients with inoperable CTEPH or patients with residual PH following PTE surgery. BPA is a percutaneous interventional procedure using telescoping catheters placed in the pulmonary arteries, through which wires and balloons are used to disrupt chronic clot mechanically and relieve pulmonary vascular obstruction (Video 86.2).[62] Initial attempts at BPA for CTEPH were associated with high complication rates (namely hemoptysis and reperfusion edema) and untenably high mortality.[63] Several innovations were made to the technique that brought these complication rates down to an acceptable range. First, BPA now is performed over multiple sessions

to achieve the hemodynamic end points targeted. With the first pass, the balloons are inflated to improve the caliber of the vessel. Opening the lumen to the normal caliber is reserved for later sessions.[64] Second, target lesions are selected to achieve benefit without excessive risk for complications; pouch defects or totally occluded vessels should not be targeted with BPA. Finally, imaging techniques (such as optical coherence tomography or intravascular ultrasound) or pressure wires (which measure the intravascular pressure proximal and distal to an area of stenosis to assess the fractional flow reserve) are used to help choose target lesions and maximize both the safety and efficacy of BPA.[64] Contemporary observational case series from multiple centers worldwide have demonstrated improvement in pulmonary hemodynamics, functional class, and 6-minute walk distance with this approach. As with PTE surgery, BPA should be performed at a center with expertise in the treatment of CTEPH.

Key Points

- About 30% of patients with *pulmonary embolism* (PE) do not have perfusion completely restored despite adequate anticoagulation, and about 4% of all patients with PE will develop *chronic thromboembolic pulmonary hypertension* (CTEPH).
- Identified risk factors for development of CTEPH after acute PE include recurrent PE, history of splenectomy, unprovoked PE, presence of symptoms for more than 2 weeks prior to PE diagnosis, right ventricular dysfunction at the time of PE diagnosis, and hypothyroidism. All patients with PE should be expected to return to their pre-PE baseline; in those who have residual dyspnea, an evaluation for CTEPH should be undertaken.
- Approximately 25% of patients with CTEPH will not have a known prior PE, and CTEPH should be included in the differential for any patient with unexplained dyspnea.
- The *ventilation-perfusion* (V/Q) scan remains the screening test of choice; an abnormal V/Q scan should be followed with an angiogram (either digital subtraction angiography in the catheterization lab or a CT pulmonary angiogram).
- *Pulmonary thromboendarterectomy* (PTE) is the treatment of choice for patients with surgically accessible chronic thromboembolic disease and favorable surgical risks. PTE surgery uses a median sternotomy approach for cardiopulmonary bypass, deep hypothermia to allow circulatory arrest, and a true endarterectomy with removal of pulmonary artery intimal lining with adherent chronic thromboembolic disease.
- For patients with distal, surgically inaccessible disease or in whom risks preclude PTE, options for management include pulmonary hypertension-targeted medical therapy (at this time, only riociguat is U.S. Food and Drug Administration approved for inoperable CTEPH) and balloon pulmonary angioplasty. Lung transplant is an option if all other interventions fail.
- The presence of chronic thromboembolic disease increases the risk for recurrent PE; CTEPH is an indication for indefinite anticoagulation.

INTRODUCTION AND DEFINITIONS

Pulmonary vasculitis is a clinicopathologic term encompassing a wide variety of individual disease entities, all of which share the presence of inflammation and destruction of blood vessels within the lung. More specifically, these disorders are characterized histopathologically by the presence of a variety of types of cellular infiltration within vessel walls, vessel destruction, and ultimately tissue necrosis. Specific clinical features are determined by the site, size, and type of vessel involved, as well as the relative amounts of vessel inflammation, destruction, and tissue necrosis. While simple to define, the recognition, diagnosis, and management of the pulmonary vasculitides are among the most demanding challenges in pulmonary medicine. Protean in their presentation and variable in their clinical evolution, their signs and symptoms fully overlap with pulmonary or systemic infection, adverse medication reaction, other connective tissue diseases, and malignancy. Even in patients with known pulmonary vasculitis, separating clinically active vasculitis from infection, drug toxicity, or some combination thereof will challenge the most astute clinician. Increasing the stakes, all of these diseases impair quality of life, limit functional status, and shorten survival. Even with improvements associated with currently available treatment, the long-term survival among patients with *antineutrophil cytoplasmic antibody* (ANCA)-positive *ANCA-associated vasculitis* (AAV) is shortened—approaching 90% survival at 1 year and 75% survival at 5 years, with a 2.7-fold increase in the standardized mortality ratio compared to the general population.[1] Despite this, the clinician can make the diagnosis, initiate and manage therapy, and minimize complications by keeping some broad concepts in mind.

CLASSIFICATION

The major clinical benefit of classification is to provide a framework that allows for an appreciation of clinically relevant features of disease and the ability to distinguish among specific conditions. The 2012 Revised International Chapel Hill Consensus Conference nomenclature[2] remains broadly accepted and is based on clinicopathologic presentations (Table 87.1). Because it was developed prior to the widespread use of ANCA testing and is not based on disease mechanism or response to therapy, it should be used cautiously to establish a diagnosis or to initiate management. In the near future, the Diagnostic and Classification in Vasculitis Study (a multinational, observational study designed to develop diagnostic criteria and update classification in vasculitis) is likely to replace the Chapel Hill nomenclature. Draft revised criteria for AAV incorporating diagnostic criteria have been proposed (Table 87.2).

Recognizing the variety and complexity of the clinical presentations of these disorders, a broad diagnostic approach is required. A common scheme focuses on clinical manifestations associated with specific vessel size (large, medium, and small). Large vessels are made up of the aorta, its largest branches (e.g., carotid, cerebral, iliac, subclavian, and femoral vessels), and the main pulmonary arteries. Medium vessels are the main visceral arteries (the renal, hepatic, coronary, and mesenteric vessels). Small vessels are the capillaries, venules, and arterioles. In any group of disorders, there is often some overlap, with specific vasculitides that generally affect either the large or small vessels also involving medium-sized arteries, though large and medium vessel vasculitides generally do not involve vessels smaller than arteries.

A second and commonly utilized classification scheme uses ANCA. The identification of these antibodies in the 1980s revolutionized diagnosis and pathogenesis (see

Table 87.1 Classification of Vasculitis[1,125,126]

PRIMARY IDIOPATHIC

Small Vessel

- Granulomatosis with polyangiitis
- Eosinophilic granulomatosis with polyangiitis
- Microscopic polyangiitis
- Idiopathic pauci-immune glomerulonephritis
- Idiopathic capillaritis

Medium Vessel

- Polyarteritis nodosa
- Kawasaki disease

Large Vessel

- Takayasu arteritis
- Giant cell arteritis

PRIMARY IMMUNE COMPLEX-MEDIATED

- Anti-glomerular basement membrane disease (Goodpasture syndrome)
- IgA vasculitis (formerly Henoch-Schönlein purpura)
- Cryoglobulinemic vasculitis
- Hypocomplementemic urticarial vasculitis

SECONDARY

- Classic autoimmune disease
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Anti-phospholipid antibody syndrome
- Infection
- Paraneoplastic
- Drug-induced (e.g., propylthiouracil)
- Inflammatory bowel disease

IgA, immunoglobulin A.

below). The vasculitides that pulmonologists are most likely to encounter, the primary idiopathic small vessel vasculitides, are also AAV. These include *granulomatosis with polyangiitis* (GPA), *eosinophilic granulomatosis with polyangiitis* (EGPA), and *microscopic polyangiitis* (MPA).

A third approach defines the vasculitides by the presence or absence of granulomatous inflammation. Two of the ANCA-associated vasculitides, GPA and EGPA, as well as the large vessel vasculitides, Takayasu arteritis, and giant cell arteritis, are characterized histopathologically by granulomatous inflammation.

Regardless of the classification scheme or diagnostic approach, ultimately the diagnosis of pulmonary vasculitis requires the clinician to recognize both general and specific patterns of clinical, imaging, laboratory, and pathologic features and to determine whether or not the available evidence is adequate to support a specific diagnosis.

EPIDEMIOLOGY

The true overall incidence and prevalence of vasculitis is difficult to gauge, because the available epidemiologic studies contain significant limitations that prevent general applicability. The available data are rarely geographically or ethnically diverse, and the case definitions and data acquisition methodology often vary from study to study. With these caveats in mind, giant cell arteritis remains the most frequently recognized systemic vasculitis in those over the age of 50 yeras, with an annual incidence of 150 to 350 per million persons in those of northern European extraction. Those of non-Caucasian ethnicity appear to be at much lower risk. The primary systemic vasculitides have an overall prevalence estimated at between 90 and 300 per million in European populations.

The annual incidence of all forms of AAV combined ranges from 6 to 32 per million. The epidemiology of the AAV differs among ethnicities in both ANCA specificity and clinical manifestations. GPA is most common in Europe while MPA is more common in East Asia. Among the individual disorders, the annual incidence ranges from 4.9 to 10.5 per million for GPA, 0.5 to 4.2 per million for EGPA, and 2.7 to 11.6 per million for MPA. Their prevalence ranges from 24 to157 per million for GPA, 7 to 38 per million for EGPA, and 0 to 66 per million for MPA. Among the secondary vasculitides, the best data are for *systemic lupus erythematosus* (SLE)-associated vasculitis (incidence of 3.6 per million) and rheumatoid arthritis–associated vasculitis (incidence of 12.5 per million), though the latter incidence appears to have fallen dramatically with the advent of biologic therapy.[3]

NORMAL VASCULAR ANATOMY AND HISTOLOGY

In order to understand the presenting clinical features of the pulmonary vasculitides, it is useful to understand the normal location and histologic characteristics of the arterial and venous blood supplies. The lung has a dual blood supply: the pulmonary and the bronchial circulations. The bronchial arteries arise from the systemic circulation (aorta and intercostal arteries) and form a plexus in the bronchial wall. The bronchial veins associate closely with the bronchial arteries. Neither are commonly affected in vasculitis.

During embryogenesis, the pulmonary arterial system forms in tandem with the branching bronchial buds and is recognized by its close proximity to the corresponding bronchi or bronchiole (Fig. 87.1A). In the normal lung, arteries and adjacent airways (either bronchi or bronchioles) are similarly sized, so significant size differences may be an indication of pathology.[4] The arterial system consists of four components: elastic arteries, muscular arteries, arterioles, and capillaries. The elastic arteries are larger than 0.5 to 1.0 mm in diameter and can be recognized macroscopically. They are composed of an endothelial cell lining layer, a smooth muscle medial layer, and have well-developed, multiple elastic laminae. Muscular arteries are between 100 and 500 μm in diameter, and are composed of an endothelial lining, a smooth muscle media bound by two elastic laminae (inner and outer), and a collagenous adventitia (see Fig. 87.1B). The smooth muscle layer progressively decreases in thickness down to the arterioles, which are defined by the absence of a muscular media and a diameter of less than 100 μm; however, these may become muscularized in a variety of diseased states. The arterioles transition into capillaries, characterized by the presence of a

Table 87.2 Draft classification criteria for the ANCA-associated vasculitides

GPA		EGPA		MPA	
c-ANCA or PR3 antibody	+5	Eosinophil count ≥1 × 10^9/L	+5	p-ANCA or MPO-antibody positive	+6
Bloody nasal discharge, ulcers, crusting, congestion or blockage, or septal defect/ perforation	+3	Obstructive airways diseases	+3	Fibrosis or ILD on chest imaging	+3

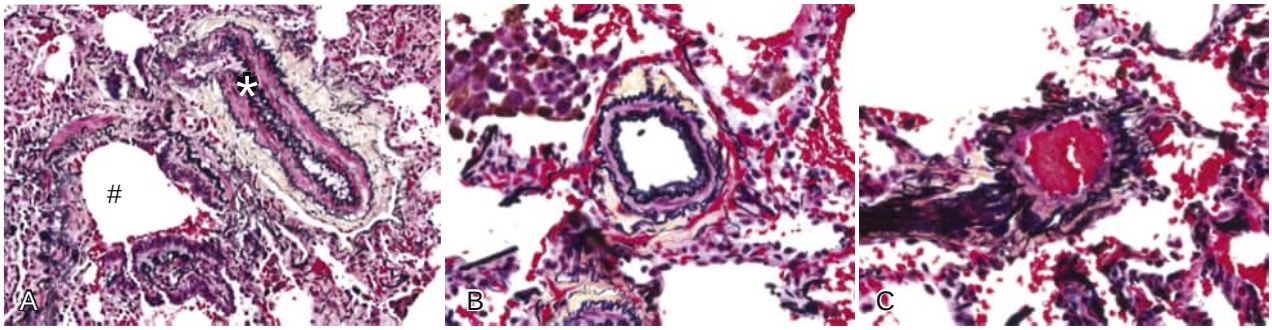

Figure 87.1 Normal appearance of pulmonary artery, small muscular pulmonary artery, and vein. (A) A pulmonary artery (*asterisk*) and bronchiole (#) are shown in close proximity (pentachrome/Movat stain). (B) Muscular pulmonary artery in the peripheral lung showing internal and external elastic lamina in black (pentachrome/Movat stain). (C) Small pulmonary vein in peripheral lung showing one elastic lamina in black (pentachrome/Movat stain).

single layer of endothelial cells and an underlying basement membrane. They form part of the alveolar septa and are the most commonly affected vessels in pulmonary vasculitis. On hematoxylin and eosin stains of surgical lung biopsies, identifying the capillaries may be difficult because a number of cell types including endothelial cells, fibroblasts, and mononuclear cells, are normal occupants of the alveolar septa.

The location of the pulmonary veins in the mature lung is typically within interlobular septa, because the embryonic pulmonary veins form branches that grow into the mesenchyme surrounding the lung buds. Although pulmonary veins can be distinguished from pulmonary arteries by their single elastic lamina (see Fig. 87.1C), in the diseased lung, there can be reduplication of the elastic lamina, causing "arterialization" of the pulmonary veins, and anatomic location may be the only indicator of vessel type.

HISTOPATHOLOGY OF VASCULITIS

Although the diagnosis of vasculitis never relies on histopathology alone, both the general diagnosis and subclassification can often be suggested based on the size and location of the affected vessels (Fig. 87.2). Histopathologic findings common to all the pulmonary vasculitides are inflammatory cell infiltration (inflammation) of the vessel wall with destruction of elastic laminae (in the case of arteries and veins) and often, an accompanying fibrinoid necrosis of the associated tissue. The lining endothelial cells may show abnormalities, with subendothelial inflammation

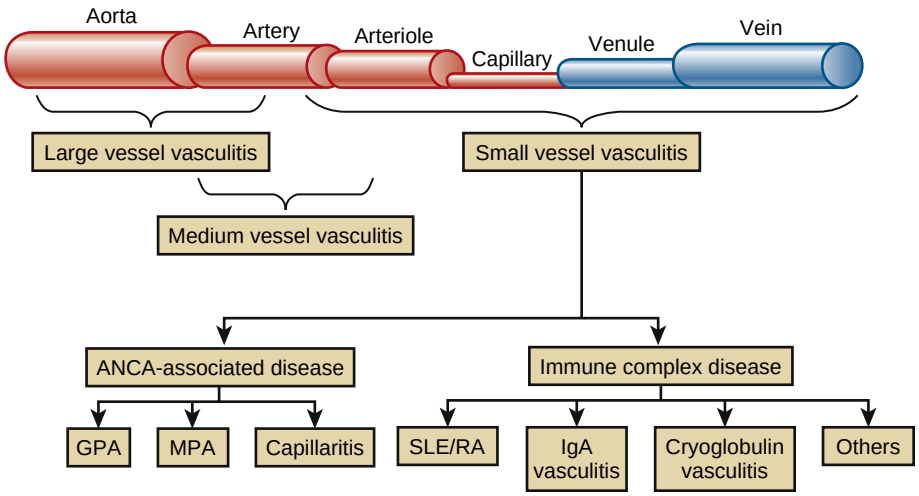

Figure 87.2 Relationship between vessel size and mechanism. The small vessel vasculitides are diagrammed as antineutrophil cytoplasmic antibody–associated disease and immune complex disease. with regenerative/hyperplastic endothelial cells ("endothelialitis"), cellular disruption, and even loss of endothelial cells. The type of inflammation varies widely: neutrophilic, eosinophilic, lymphoplasmacytic, or mixed infiltrates can all be seen. Granulomatous inflammation, consisting of poorly formed granulomas or multinucleated giant cells and/or epithelioid histiocytes, is of particular importance because one classification approach is based on its presence or absence (see above).

The term *capillaritis* is used to describe vasculitic involvement of the capillaries; however, it is often difficult to identify vasculitic involvement on routine hematoxylin and eosin stains, much less to identify the endothelial disruption necessary to make the diagnosis. Therefore, identifying neutrophils and nuclear debris (evidence of cellular apoptosis) within alveolar septal walls is used as an indirect sign.

Beyond the size and type of the affected vessel, changes to the associated lung parenchyma may provide additional clues. For example, a nodular parenchymal opacity is commonly seen in GPA, with microabscesses, necrosis, eosinophilic pneumonia, organizing pneumonia, and/or hemorrhage. The specific pathologic findings associated with each entity are discussed in more detail below.

PATHOGENESIS

Most of the vasculitic syndromes are hypothesized to be the result of immunopathogenic mechanisms responding to antigenic stimuli. Why some patients develop vasculitis, while others do not, is unknown. The etiology is almost assuredly multifactorial, and likely includes genetic predisposition, epigenetic factors, environmental exposures (e.g., drugs, infections, airborne pollutants), and individual immune responses. Genome-wide association studies have found both major histocompatibility complex and non–major histocompatibility complex associations with both an increased and decreased risk of AAV, confirming a genetic contribution to disease development. The strongest associations are with major histocompatibility complex class II genes.[5] Three broadly defined mechanisms have been proposed: pathogenic autoantibody formation with neutrophil activation and endothelial damage, immune complex deposition, and pathogenic lymphocyte responses. For each of these mechanisms, some combination of direct immunologic attack and endothelial and vascular wall response appears responsible for the subsequent clinical and pathologic findings.[6]

A large variety of autoantibodies have been described, including the antiglomerular basement membrane (collagen type IV) antibodies seen in *anti-glomerular basement membrane disease* (anti-GBM disease, formerly called Goodpasture syndrome), antiendothelial cell antibodies, antilaminin antibodies, antiphospholipid (β2-glycoprotein 1) antibodies, and ANCA, among others. Of these, the best-studied mechanism is that proposed for AAV. While the clinical syndrome was described in the 1930s,[7–9] it was not until 1982 that specific autoantibodies, now known as ANCA, were described.[10] ANCA are recognized biomarkers and have pathogenic potential, with considerable in vitro, in vivo, and clinical evidence supporting their pathogenicity. Proinflammatory cytokines generated from a variety of insults result in neutrophil priming and activation, causing them to express antigens (e.g., *proteinase 3* [PR3] and *myeloperoxidase* [MPO]) on their cell surface. ANCA can bind to these cell surface antigens as well as to Fc receptors on the neutrophil, resulting in further neutrophil activation. This over-activation of the neutrophil results in cytokine production, release of reactive oxygen species, lytic enzymes, and neutrophil extracellular traps, all of which can cause extensive endothelial damage through a variety of complex mechanisms. In particular, excessive neutrophil extracellular trap formation and persistence are thought to play key roles. Separately, lymphocyte differentiation and complement activation are also recognized as important. Additional data suggest that ANCA are associated with the severity and persistence of disease activity. These data include the link between the presence of these autoantibodies and the development of systemic vasculitic complications and prognosis, the effectiveness of the anti-CD20 monoclonal antibody rituximab at reducing ANCA titers and controlling disease activity, and the finding that

patients who become ANCA negative appear to be at significantly decreased risk of clinical relapse.

The trigger for initial ANCA production and persistence is an area of active investigation. A role for active infection/inflammation in the disease pathophysiology has been proposed because there is evidence that chronic or concurrent infections can lead to disease exacerbation or relapse.[11–13] ANCA positivity has also been directed against a variety of antigens seen with viral, fungal, bacterial, and protozoal infection, as well as subacute bacterial endocarditis and cystic fibrosis.[14,15] It has been hypothesized that infections may give rise to ANCA through molecular mimicry and may contribute to their persistence through T- and B cell stimulation by microbial superantigens. For example, some patients with AAV have been shown to elaborate antibodies against *lysosome-associated membrane protein-2* (LAMP2) found in neutrophils. The LAMP2 protein bears close homology to the bacterial adhesin FimH protein expressed in gram-negative bacteria, and antibodies against LAMP2 and FimH are capable of producing glomerulonephritis in animal models.[16]

Aberrant lymphocyte responses are hypothesized to contribute to both the granulomatous inflammation seen in GPA and EGPA (T cells) as well as the production of ANCA (B cells). Activated T cells may be found in the peripheral blood of patients with GPA, even when the disease is in remission, and markers of T cell activation appear to correlate with disease activity.[17] Further, there appears to be an increase in Th17-positive T cell populations (believed to promote autoimmunity) and reduced regulatory T cell functionality, suggesting a loss of tolerance.[17–20] Finally, there is increased elaboration of Th1 cytokines in patients with GPA (tumor necrosis factor-α, *interleukin* (IL)-1 and IL-8), whereas there is increased elaboration of interferon-gamma, IL-4, IL-5, and IL-13 in patients with EGPA.[21,22]

Other potential mechanisms for the development of vasculitis include the direct invasion of the vessel wall by infectious organisms (e.g., bacterial, mycobacterial, spirochetal, rickettsial, fungal, viral) leading to an acute, direct inflammatory response as well as deposition of circulating immune complexes in the blood vessel wall. This deposition of immune complexes can lead to complement activation, anaphylatoxin production, and mast cell degranulation. Mast cell degranulation leads to release of vasoactive substances and the anaphylatoxins can act as chemotactic agents for neutrophils, eosinophils, and mononuclear inflammatory cells. The prototypical disease for this mechanism is SLE, in which complexes of nuclear antigens such as DNA, immunoglobulins, and complement proteins lead to vascular injury.[23,24] Other immune complex–mediated vasculitides include rheumatoid vasculitis, IgA vasculitis, and cryoglobulinemic vasculitis.

INITIAL DIAGNOSIS

CLINICAL SCENARIOS SUGGESTIVE OF VASCULITIS

The importance of the initial history in the evaluation of a patient with suspected vasculitis cannot be overemphasized. Symptoms that initially appear of only minor importance and unrelated may need to be explored fully because both vasculitis and its mimics (connective tissue diseases, infection, malignancy, drug toxicity, etc.) present with and evolve through a variety of confusing clinical manifestations. Similarly, a careful physical examination may reveal otherwise asymptomatic disease that suggests the presence of a systemic disorder. In particular, the identification of particular clinical scenarios can suggest the presence of a systemic vasculitis.[25]

Chronic and/or Destructive Upper Airway Lesions

Chronic refractory sinusitis, otitis, and/or subglottic stenosis may be relevant to a diagnosis of vasculitis, particularly when infectious, allergic, traumatic, and anatomic causes have been excluded and/or when soft tissue injury (chronic ulceration) or bone lesions are present.

Chest Imaging Findings of Cavitary or Nodular Disease

While a wide variety of nonspecific findings may be seen on chest imaging in the vasculitides, the presence of nodular or cavitary disease should raise concern. Whereas infection and malignancy are the most common causes of nodular or cavitary opacities, in the correct clinical context, pulmonary vasculitis (particularly an AAV) should be considered. Cavities are found in 35–50% and nodules in 55–70% of patients with GPA.[26,27]

Diffuse Alveolar Hemorrhage (See Chapter 94)

Diffuse alveolar hemorrhage (DAH) refers to the presence of diffuse intra-alveolar bleeding, generally from the alveolar capillaries, and less frequently from the precapillary arterioles and postcapillary venules. Whereas patients classically present with hemoptysis, diffuse alveolar opacities, and a drop in hematocrit, DAH must be considered in all patients with unexplained air space disease. Hemoptysis can be difficult to identify because it is generally only intermittent. Up to one-third of patients with DAH will not present with hemoptysis. The alveolar opacities do not have to be diffuse, and a fall in the hematocrit can be difficult to document. Because of these caveats, DAH should be considered in patients with otherwise unexplained diffuse alveolar opacities, particularly when these opacities are associated with symptoms of a connective tissue disease or new-onset renal insufficiency. While an increase in the diffusion capacity of more than 30% over baseline can be suggestive, it is rare for this information to be available.

DAH is diagnosed by bronchoalveolar lavage. With the bronchoscope in a wedged position, serial aliquots (30 to 60 mL in volume) of sterile saline are instilled and aspirated (for a total volume of 100 to 300 mL). If the serial aliquots of fluid reveal an increasingly hemorrhagic or even a persistently bloody return, the diagnosis of DAH is made. It must be recognized that DAH is not diagnostic of vasculitis. Although differential diagnoses include diseases associated with the histopathologic small vessel vasculitis (including both primary and secondary vasculitides) (Fig. 87.3), DAH can result from both diffuse alveolar damage and bland hemorrhage (eTable 87.1, see also Table 94.1). When DAH is a complication of an AAV, capillaritis is almost always present, though its absence in no way excludes the diagnosis, particularly if treatment has been initiated. When DAH with pathologic pulmonary capillaritis is the only clinical

eTable 87.1 Causes of Diffuse Alveolar Hemorrhage[127,128]

WITH CAPILLARITIS (CLASSIC VASCULITIDES)

Primary idiopathic small vessel vasculitis

- ANCA associated: GPA, EGPA, MPA
- Isolated pauci-immune pulmonary capillaritis

Immune Complex Mediated

- Anti-glomerular basement membrane disease (Goodpasture syndrome)
- IgA vasculitis (formerly Henoch-Schönlein purpura)
- Cryoglobulinemic vasculitis

Secondary Vasculitis

- Defined autoimmune disease
  - Systemic lupus erythematosus
  - Primary anti-phospholipid antibody syndrome
  - Other (e.g., rheumatoid arthritis, scleroderma)
- Hematopoietic stem cell transplantation
- Drug-associated disease (chemotherapeutic agents, diphenylhydantoin)
- Behçet's disease

WITHOUT CAPILLARITIS (BLAND HEMORRHAGE)

Idiopathic pulmonary hemosiderosis
Coagulopathy
Mitral stenosis
Inhalation injury
Drug-associated disease (chemotherapeutic agents, penicillamine, trimellitic anhydride, amiodarone, nitrofurantoin)

ANCA, antineutrophil cytoplasmic antibodies; IgA, immunoglobulin A; EGPA, eosinophilic granulomatosis with polyangiitis; GPA, granulomatosis with polyangiitis; MPA, microscopic polyangiitis.

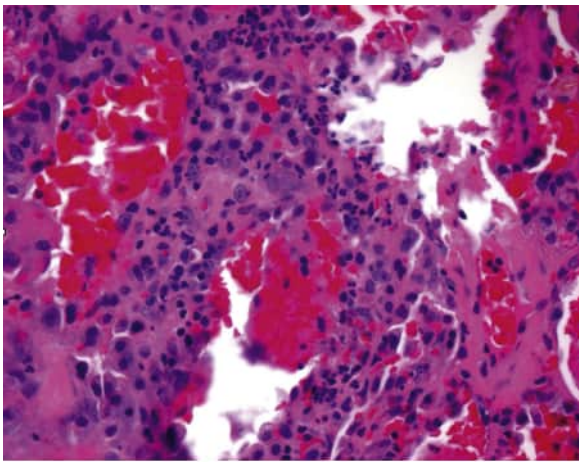

Figure 87.3 Capillaritis. The alveolar septa are disrupted by infiltrates of neutrophils and nuclear debris. The septal borders are indistinct, indicating wall damage.

manifestation of a vasculitis, the term idiopathic pauci-immune pulmonary capillaritis may be used, and this syndrome is classified in the family of primary idiopathic, small vessel vasculitis regardless of ANCA status.

Acute Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is recognized by the identification of an active urinary sediment on urinalysis, including hematuria (especially with dysmorphic red cells), red cell casts, and proteinuria (>500 mg/d) in the setting of a rising blood urea nitrogen and serum creatinine. The microscopic examination of the urine needs to be performed on a fresh urine sample because red cell casts and dysmorphic red cells degenerate within 30 to 60 minutes in a freshly voided sample. Once RPGN is identified, the differential diagnosis includes ANCA-associated vasculitis, idiopathic pauci-immune glomerulonephritis (isolated small vessel renal vasculitis), SLE, anti-GBM disease, postinfectious glomerulonephritis, IgA nephropathy, IgA vasculitis (formerly Henoch-Schönlein purpura), essential cryoglobulinemia, and membranoproliferative glomerulonephritis.[28–31]

Pulmonary-Renal Syndrome

Pulmonary renal syndromes are classically defined as the presence of both DAH and RPGN. However, whenever a destructive airway lesion or chest imaging findings of nodules and/or cavities exist in the setting of renal insufficiency, vasculitis should be considered. When this happens, the primary differential should include AAV, anti-GBM disease, and SLE.

Palpable Purpura

The presence of palpable purpura on physical examination implies a small vessel, cutaneous vasculitis.[32] The most common explanation is a cutaneous (hypersensitivity) vasculitis secondary to a drug reaction; however, AAV, cryoglobulinemia, connective tissue diseases, infections, and malignancy all should be considered. Other evidence of a cutaneous vasculitis, particularly with systemic features, should raise concerns.

Mononeuritis Multiplex

Defined by neuropathic symptoms in two or more independent peripheral nerve distributions, either simultaneously or sequentially, mononeuritis multiplex should raise suspicion for a vasculitis, particularly those disorders that affect the small or medium-sized arteries.[33,34] The underlying vasculitic process affects the vessels supplying the nerves, causing ischemia of the nerves. A variety of central or peripheral nervous system symptoms can be seen, including pain, numbness, paresthesias, weakness, or loss of function (e.g., sudden onset of a foot drop or wrist drop).

Eye Findings

Ocular findings are common in some vasculitides. Approximately one-quarter of patients with giant cell arteritis and GPA will have ocular manifestations as part of their disease. Intermittent or persistent scleritis, retinal vein occlusion, optic neuropathy, or a retro-orbital mass might be seen.

Multisystem Disease

Unusual combinations of signs and symptoms that involve multiple organ systems either simultaneously or over time should raise the possibility of a vasculitis. This requires a high index of suspicion from the clinician because symptoms and/or signs such as constitutional symptoms (e.g., fever of unknown origin), unusual "rashes," migratory polyarthritis, or "chronic sinus disease" may be relevant when the primary clinical presentation is breathlessness, renal failure, or abnormal chest imaging.

SPECIFIC TESTING

Antineutrophil Cytoplasmic Antibodies

ANCAs were initially described in 1959 in patients with chronic inflammation. The first relationship with vasculitis was recognized in 1982, with a pattern of diffuse immunofluorescent staining of ethanol-fixed neutrophils. In 1985, they were identified by *indirect immunofluorescence* (IIF) in a population with GPA, and it was appreciated that they produced a cytoplasmic staining pattern (c-ANCA). Autoantibodies that produce a perinuclear staining pattern (p-ANCA) were then reported in patients with systemic arteritis and glomerulonephritis. These antibodies are closely associated with the small vessel vasculitides of the lung, GPA, EGPA, and MPA. These AAV all involve the small vessels and share a number of clinical features including, when present, pauci-immune, crescentic, and focal necrotizing GN. However, whereas ANCA positivity is common in these disorders, it is by no means universal.

Three staining patterns on IIF are often described, *cytoplasmic* (c-ANCA) (Fig. 87.4A), *perinuclear* (p-ANCA) (see Fig. 87.4B), and *atypical* (a-ANCA). c-ANCA are primarily, but not exclusively, directed against PR3 (in azurophilic granules), while p-ANCA is most commonly directed against MPO (also in azurophilic granules), but they have a wider group of potential intracellular targets. Specific immunoassay testing for PR3 and MPO are now widely available, and a 2016 multicenter *European Vasculitis Study* (EUVAS) Group evaluation demonstrated good diagnostic performance of current antigen-specific immunoassays for ANCA detection in patients with GPA and MPA and,

separately, quite variable results among laboratories in the performance of IIF. Based on this, revised international consensus recommendations are that high-quality immunoassays for PR3-ANCA and MPO-ANCA are the preferred methods for the diagnostic evaluation of patients with AAV, without the categorical need for IIF.

The diagnostic utility of ANCA testing is dependent upon the sensitivity, specificity, and positive predictive value of c-ANCA (or PR3-ANCA) for GPA and p-ANCA (or MPO-ANCA) for MPA and EGPA. When testing is applied indiscriminately, the positive predictive value of the testing declines dramatically. As noted by Mandl et al., the use of clinical guidelines to identify patients with a higher pretest possibility of vasculitis increases the positive predictive value of the tests without reducing sensitivity.[35]

Current consensus guidance provides recommendations for diagnosing AAVs by utilizing high-quality, antigen-specific PR3-ANCA and MPO-ANCA assays as the primary screening method (Fig. 87.5). If results for both PR3-ANCAs and MPO-ANCAs are negative and there is still a strong suspicion of small vessel vasculitis, repeating these assays or using other immunoassays and/or IIF may be helpful to increase sensitivity. It is important to note that a diagnosis of AAV cannot be excluded on the basis of negative PR3-ANCA and MPO-ANCA results; a positive PR3-ANCA and/or MPO-ANCA test contributes to the diagnosis but is not diagnostic by itself. The frequency of ANCA positivity in AAV is noted in Table 87.3.

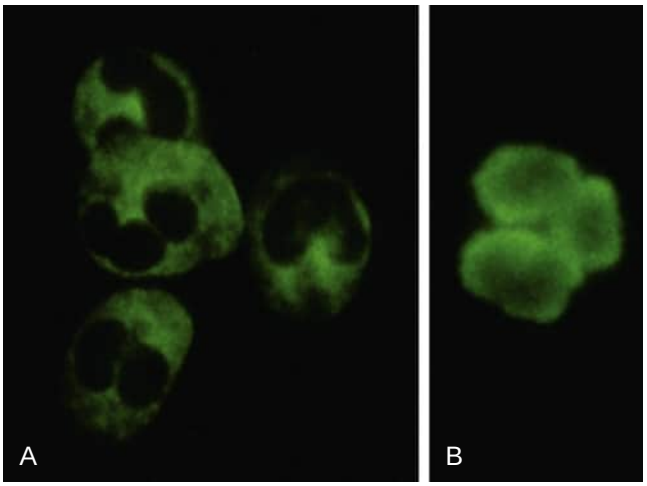

Figure 87.4 Indirect immunofluorescent staining patterns of neutrophils with *antineutrophil cytoplasmic antibodies* (ANCA). Indirect immunofluorescence showing the cytoplasmic pattern of c-ANCA (A) and the perinuclear pattern of p-ANCA (B).

Both the immunoassay for PR3-ANCA and IIF for c-ANCA are quite sensitive in active systemic GPA but less so in limited disease, and even less so for GPA in remission.[36] In the proper clinical setting, with a very high pretest probability of disease, a positive PR3-ANCA may have a sufficient positive predictive value for the diagnosis to obviate the need for tissue biopsy.[37] On the other hand, MPO-ANCA, while generally as specific, is less sensitive due to a wider group of potential intracellular targets, and a negative test may provide no more than supportive evidence of MPA, pauci-immune RPGN, or EGPA.[38] It should be emphasized that the absence of a positive test does not rule out a diagnosis of vasculitis. Indeed, while the concept of ANCA association applies to the patient population as a whole, it must be emphasized that an individual patient may well be ANCA negative and still have what is described as an AAV. In fact, there is a subgroup of ANCA-negative pauci-immune vasculitis, best recognized as renal-limited disease, but assuredly involving the lung as well. In patients who are both PR3-ANCA and MPO-ANCA positive, drug-induced disease should be considered.

Considerable attention has been focused on the utility of ANCA to assess disease activity, particularly the role of rising ANCA titers in predicting relapse.[39,40] Unfortunately there appears to be no clear relationship between antibody titers and disease activity. In a prospective interventional study in which PR3-ANCA levels were routinely obtained, decreasing ANCA titers did not predict time to remission and increasing titers did not predict relapse. Increasing titers were associated with a relapse in only 40% of patients

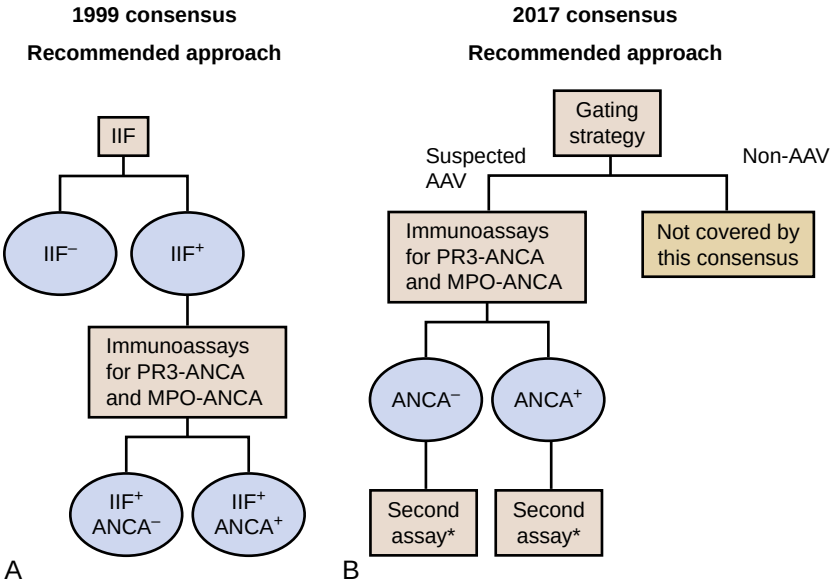

Figure 87.5 Newer recommended algorithm using immunoassays as the first screening method for *granulomatosis with polyangiitis* (GPA) and *microscopic polyangiitis* (MPA). (A) In the 1999 consensus document, the recommended approach for *antineutrophil cytoplasmic antibody* (ANCA) detection was to screen for ANCA by *indirect immunofluorescence* (IIF) and to test for proteinase 3 (PR3)-ANCAs and myeloperoxidase (MPO)-ANCAs in IIF-positive samples; the ideal approach was to perform IIF and immunoassays on all samples (not shown). (B) In the 2017 consensus, the use of high-quality immunoassays is recommended as the preferred first screening method for ANCA detection in patients suspected of having the ANCA-associated vaculitides (AAV), GPA and MPA. IIF is no longer deemed suitable as the first screening test. ANCA detection for non-ANCA-associated vasculitis conditions is not included in this consensus. *A second PR3- and MPO-ANCA or IIF can be considered for negative results in patients with a high clinical suspicion (to increase sensitivity) or in case of low antibody levels (to increase specificity). Take the antibody level into account. (From Bossuyt X, Cohen Tervaert JW, Arimura Y, et al. Position paper: revised 2017 international consensus on testing of ANCAs in granulomatosis with polyangiitis and microscopic polyangiitis. *Nat Rev Rheumatol*. 2017;13[11]:683–692.)

Table 87.3 Clinical Findings in the ANCA-Associated Vasculitides

	GPA	EGPA	MPA
Constitutional	Common. Includes fatigue, malaise, fevers and weight loss.	Common. Weight loss, fatigue, fevers, myalgias and arthralgias.	Very common. Generally precedes renal disease by months.
Pulmonary	70–95% of patients with respiratory symptoms or chest imaging abnormalities. Tracheobronchial and endobronchial disease in 10–50%.	Asthma essentially universal. Patchy, heterogenous radiographic infiltrates in >70%.	10–30% with diffuse alveolar hemorrhage.
Renal	50–90% of patients.	20–50% of patients.	RPGN almost universal.
Upper airway	70–95% of patients. Destructive or ulcerating lesions are suggestive.	Sinusitis, polyposis, and/or rhinitis in ≥70% of patients. Generally not destructive.	5–30%, with sinus disease most common.
Musculoskeletal	Arthralgias, synovitis and myalgias in up to 80%.	Arthralgias and myalgias in up to 50%.	Arthralgias and myalgias in at least 50% of patients.
Eyes	25–60% of patients. Vision-threatening disease including uveitis, ocular ulcers.	<5%	0–30% of patients. May be clinically silent.
Cardiac	5–25% of patients. Conduction delays or other ECG abnormality, systolic or diastolic dysfunction, pericarditis, or coronary artery vasculitis.	30–50% of patients and a major cause of mortality. Conduction delays or other ECG abnormality, systolic or diastolic dysfunction, pericarditis, or coronary artery vasculitis.	10–20%. CHF and pericarditis have been described.
Gastrointestinal	<10%	30–50% of patients and a major cause of morbidity and mortality. Hemorrhage, abdominal pain, infarct or perforated viscus.	35–55% of patients. Findings similar to PAN. Pain, bleeding, and ischemia. Rare visceral aneurysms.
Dermatologic	Up to 60%. Palpable purpura, ulcers, nodules or vesicles.	50–70% purpura, nodules, papules, leukocytoclastic vasculitis with or without eosinophils.	35–60% of patients with purpura common.
Neurologic	Both central and peripheral nervous system involvement.	Mononeuritis multiplex in 50–75%. CNS in 5–40%.	Mononeuritis multiplex in 10–50%.
Chest Imaging	Abnormal in >80%. Alveolar, interstitial or mixed infiltrates, often with nodular and/or cavitary disease.	Infiltrates in >70%. Airways disease common (airway wall thickening, hyperinflation).	Infiltrates in 10–30%. Pleural effusions in 5–20%.
ANCA	ANCA positive > 90% (PR3-ANCA 75%, MPO-ANCA 20%).	ANCA positive in 50% (PR3-ANCA 5%, MPO-ANCA 45%).	ANCA positive in 90% (PR3-ANCA 30%, MPO-ANCA 60%).

ANCA, antineutrophil cytoplasmic antibodies; CHF, congestive heart failure; CNS, central nervous system; ECG, electrocardiography; EGPA, eosinophilic granulomatosis with polyangiitis; GPA, granulomatosis with polyangiitis; MPA, microscopic polyangiitis; MPO, myeloperoxidase; PAN, polyarteritis nodosa; PR3, proteinase 3; RPGN, rapidly progressive glomerulonephritis.
Data from references 26, 31, 42, 44, 47, 62, 64, 66, 72, 81, 84, 123, 129–143, 152.

over a 12-month period. Therefore, the decision to modify therapy in patients with ANCA-associated vasculitis must be a clinical decision based on clinical evidence of disease activity independent of ANCA titers.[36]

Other Laboratory Studies

Cultures of blood and other potentially affected organs (when tissue is obtained) should be performed to exclude infection. Routine laboratory tests (complete blood count with differential, chemistries, liver function tests, blood urea nitrogen, and creatinine) should be obtained, though the findings are generally nonspecific. The erythrocyte sedimentation rate and C-reactive protein are commonly elevated but lack specificity. Urinalysis with microscopy should be performed on a fresh sample in all patients, because proteinuria and microscopic hematuria are common early findings in GPA and MPA. Anti-GBM antibodies should be obtained in all patients with pulmonary hemorrhage or a pulmonary-renal syndrome. Antinuclear antibodies and rheumatoid factor can be positive, although high titers—especially with the presence of disease-specific antibodies (e.g., dsDNA, SS-A/SS-B, anti-RNP, anti-Scl-70, anti-centromere antibodies, anti-Jo1)—favor a connective tissue disease. Immunoglobulin E and circulating eosinophil counts should be obtained when EGPA is being considered.

Chest Imaging

Plain chest radiographs and *computed tomography* (CT) scanning is often abnormal even in the absence of symptoms, and over 80% of patients with GPA and EGPA will have some radiographic abnormalities. Specific findings are best described in GPA and include nodular opacities (Fig. 87.6) and masses, particularly those that cavitate (eFig. 87.1), diffuse ground-glass opacification (eFig. 87.2) (especially when DAH is a possibility), consolidation (eFigs. 87.3 and 87.4), atelectasis, and airway complications such as stenoses (eFig. 87.5) and ulcerations (eFig. 87.6). Pleural involvement is much less common, seen in 10–20% of patients. Effusions are frequently present with pleural

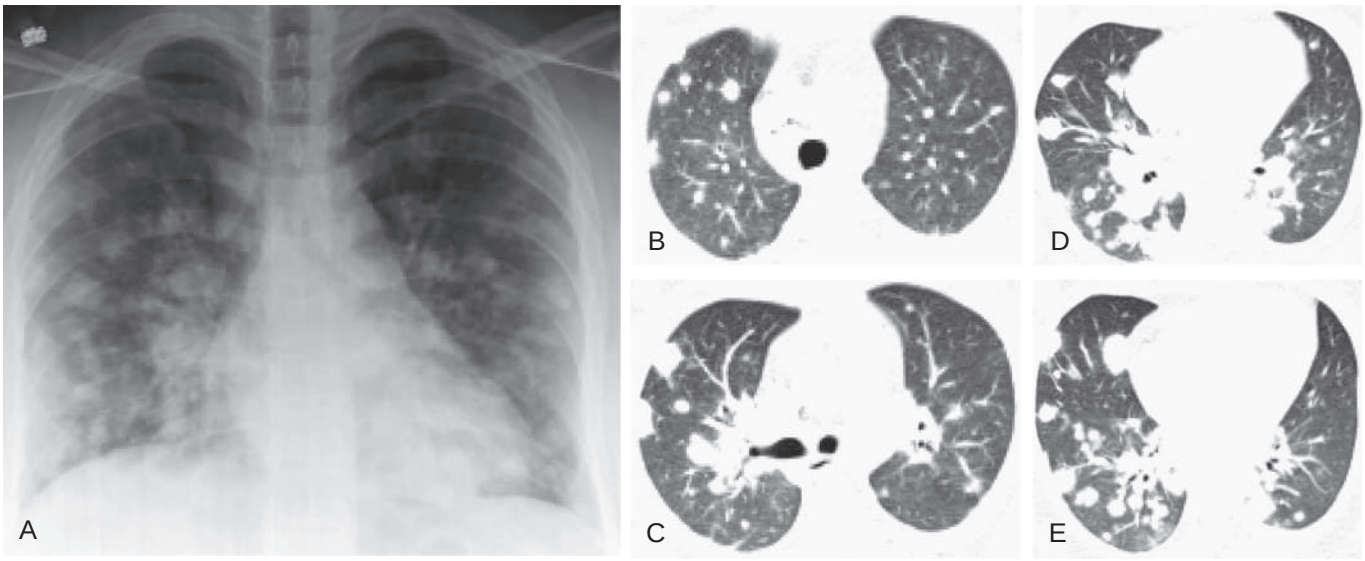

Figure 87.6 Granulomatosis with polyangiitis: nodules. (A) Frontal chest radiograph in a patient with granulomatosis with polyangiitis shows numerous bilateral, variably sized pulmonary nodules. (B–E) Axial chest computed tomography displayed in lung windows confirms the presence of numerous nodules without cavitation. (Courtesy Michael B. Gotway, MD.)

thickening, while nodularity or pneumothorax are quite rare. Adenopathy can be seen (eFig. 87.7) but is not common and is more suggestive of infection or malignancy. [41] Patients with EGPA commonly demonstrate patchy, heterogeneous ground glass opacities or consolidation as well as evidence of airways disease.

Other Imaging Studies

CT imaging of the sinuses (see eFig. 87.6) demonstrates abnormalities in a majority (70–90%) of patients with GPA and EGPA and may help identify destructive or ulcerating disease in patients with GPA. Although both echocardiography and cardiac *magnetic resonance imaging* (MRI) can evaluate for cardiac abnormalities, cardiac MRI is preferred when cardiac involvement is suspected to assess for myocardial inflammation, structure, and function. Although the heart is involved in only 5–15% of patients with GPA, the heart is affected in 30–50% of patients with EGPA and potentially carries a high attributable mortality. Additional imaging or functional studies are determined by the clinical scenario and the signs and symptoms present in the individual patient (e.g., abdominal CT, brain CT/MRI, nerve conduction studies).

Bronchoscopy

Bronchoscopy is primarily used to look for malignancy, infection, stenotic or ulcerative upper airway or endobronchial lesions, pulmonary eosinophilia, and alveolar hemorrhage. Bronchoalveolar lavage should be grossly examined for evidence of alveolar hemorrhage, and sent for culture (bacterial, fungal, and mycobacterial), cytology, and a differential cell count. Transbronchial biopsies may provide important information that helps exclude infection or malignancy; however, they are rarely useful in making a positive diagnosis of vasculitis. When Hoffman et al.[42] performed 59 transbronchial biopsies in 48 patients with GPA, only four provided useful diagnostic features. Schnabel et al.[43] found that transbronchial biopsies supported a diagnosis of GPA in only 2 of 17 patients, while otolaryngologic examination and biopsy of the clinically involved areas of the upper respiratory tract yielded useful information in 13 of 19 GPA patients.

Diagnostic Biopsy. Whereas a confident diagnosis may occasionally be made without tissue, diagnostic tissue biopsy remains necessary for a definitive diagnosis and is recommended when establishing a new diagnosis and for further evaluation of patients suspected of having relapsing vasculitis. Biopsy of the skin or upper airway is generally safe and these sites are easily accessible, but they less commonly yield diagnostic tissue when compared with a needle biopsy of the kidney or a surgical biopsy of the lung. When Hoffman et al.[42] examined 82 open lung biopsies in patients with small vessel vasculitis, diagnostic features were found in 90%. Renal biopsy is often performed to determine the cause of an acute glomerulonephritis. Specific features indicative of vasculitis such as granulomatous inflammation or vascular necrosis are rarely found; however, the presence of focal, segmental necrotizing glomerulonephritis without immune deposits (pauci-immune) strongly suggests a systemic vasculitis.[42,44-46]

The pathologic features of vasculitis often overlap with the pathologic findings seen in other disorders such as necrotizing infections. Separately, some typical histopathologic features that one may expect to see in vasculitis may be absent because of the timing of the biopsy and/or modification of the histology secondary to prior treatment, particularly with corticosteroids. Because of this, it is essential that the surgeon, pulmonologist, and pathologist have a coordinated plan prior to the biopsy. The clinical differential will dictate the appropriate specimens to collect, including fresh tissue for culture and immunofluorescence (the presence of characteristic immunofluorescence patterns, such as IgA deposition in IgA vasculitis, linear IgG deposition in anti-GBM disease, and irregular immunoglobulin and complement deposition in SLE can be diagnostic) as well as for formalin fixation.

SPECIFIC CLINICAL DISORDERS

Because the majority of the vasculitides are systemic disorders, essentially all of them can involve the lung. Pulmonary involvement can range from DAH to cavitary nodules, parenchymal inflammation, pleural disease, vascular aneurysms, and thrombotic and thromboembolic phenomena. A full accounting of each described disorder and their pulmonary manifestations is beyond the scope of this chapter. However, the primary idiopathic small vessel vasculitides deserve special attention.

GRANULOMATOSIS WITH POLYANGIITIS

GPA is the most common of the ANCA-associated small vessel vasculitides, can present at any age (generally 40 to 60 years), and affects the sexes equally. It is clinically recognized by its ability to involve the upper airway (e.g., chronic sinusitis and/or otitis, upper airway ulceration and/or structural deformity, subglottic, tracheal, or endobronchial stenosis), lower respiratory tract (e.g., chest symptoms of cough, chest pain, shortness of breath, hemoptysis, and/or chest imaging abnormalities), and kidney (e.g., glomerulonephritis) (see Table 87.3). However, involvement of all three sites is neither necessary nor common at presentation. For example, even though 80–90% of patients may ultimately develop some renal disease, as few as 40% will have renal involvement at initial presentation.[47–49] Constitutional symptoms, skin, eye, musculoskeletal, peripheral and central nervous system disease, and vascular thrombosis are not rare.[31,47–49]

Chest imaging is abnormal in the majority of patients, with nodular (see Fig. 87.6) or cavitary disease (see eFig. 87.1), or alveolar, mixed, or interstitial opacities (see eFigs. 87.2 through 87.4).[26,27] A positive c-ANCA is seen in 90–95% of those with active systemic disease but in only 60–65% of those with limited disease (disease mostly of the airways, not considered organ- or life-threatening).[39,50–52] The histopathology on surgical lung biopsy is dependent on the stage of the disease and whether there has been prior immunomodulatory treatment. A small and medium-sized vessel necrotizing vasculitis with granulomatous inflammation and parenchymal necrosis, often with a geographic appearance, is characteristic (Fig. 87.7A).[53–57] The pathologic manifestations can be divided into major and minor histologic features. The three major features include (1) lung parenchymal necrosis, either in the form of geographic necrosis or neutrophilic microabscesses; (2) vasculitis (generally involving small to medium-sized arteries, but also veins and capillaries) (see Fig. 87.7B–C); and (3) granulomatous inflammation (see Fig. 87.7D). Although the inflammation in GPA is typically described as granulomatous, it is often mixed and includes granulomas, giant cells, neutrophils, lymphocytes, plasma cells, histiocytes, and eosinophils. The minor histologic criteria include organizing pneumonia (70% of cases), DAH (10% of cases), eosinophilia, and bronchocentric granulomatosis (1% of cases).[53,58] The earlier the biopsy is performed, the more likely it is that some of the classic histologic findings will be absent. With prior treatment, there may be no significant cellular inflammatory infiltrates and the only histopathologic clue may be scarring of arteries and/or airways.[59] A distinctive, but uncommon, histologic appearance is isolated capillaritis (see Fig. 87.3).

With current therapy, there is a 5-year survival rate of 74–91%, with a significant improvement noted over the past 25 years. The mortality risk of patients diagnosed from 1997–2004 and those diagnosed from 2005–12 has declined from a hazard ratio of 5.6 to 2.3, though the increased mortality risk persists beyond 5 years. Overall, there was excess mortality due to cardiovascular disease but not cancer. So, while it is commonly assumed that active vasculitis itself accounts for all the excess mortality, the actual cause of death can result from a variety of causes including cardiac disease, thromboembolic disease, infection, renal failure, malignancy, and drug toxicity.[60] Historically, a leading cause of death among patients with AAV is infection, which is linked to the intensity of immunosuppression, particularly cyclophosphamide. Poor outcomes correlate with advanced age; *lack* of ear, nose and throat involvement; more severe renal impairment; pulmonary involvement (particularly with alveolar hemorrhage); cardiac involvement; and high-level PR3-ANCA positivity.[61]

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (see Chapter 96)

EGPA is a specific ANCA-associated small vessel vasculitis clinically distinct from GPA and MPA (see Table 87.3). EGPA affects adults of all ages, and both sexes equally. Its presentation often overlaps with the eosinophilic lung diseases (chronic eosinophilic pneumonia, allergic

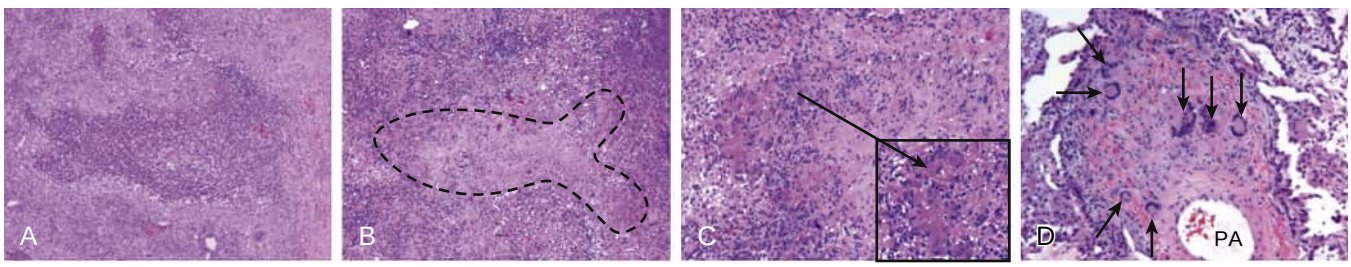

Figure 87.7 Granulomatosis with polyangiitis. (A) Irregular outlines of geographic necrosis are typical of the parenchymal necrosis found in granulomatosis with polyangiitis. (B) Low-power view of a branching vessel (*dashed line*) demonstrating necrotizing vasculitis (hematoxylin and eosin). (C) Higher power views of same vessel shown in part B. bronchopulmonary mycosis, drug reactions, hypereosinophilic syndrome, parasitic infection, asthma/atopic disease), and difficult to control asthma/atopy.

The syndrome has a triad of (1) asthma, (2) hypereosinophilia, and (3) necrotizing vasculitis that classically has a three-phase presentation with the initial presence of atopy/rhinitis/sinusitis/asthma, followed by an eosinophilia, and finally a vasculitic phase. However, the three phases may not happen sequentially, and the asthma may even postdate the vasculitis. Asthma is essentially universally found and, whereas EGPA may present with any degree of asthma severity and duration, severe (steroid-requiring) asthma is common. Patients may have the airways disease for 7 to 10 years prior to the diagnosis of vasculitis. The upper airway is commonly involved with chronic rhinitis and sinusitis (with or without nasal polyposis) as well as laryngeal involvement, although generally without any of the destructive features associated with GPA and therefore not as characteristic.

Chest imaging is abnormal in more than two-thirds of patients. Most commonly, waxing and waning parenchymal opacities (ground-glass attenuation and consolidation) (eFig. 87.8) and less commonly nodules, are seen on CT imaging of the chest. Pleural effusions can be seen in 10%. In contrast to GPA and MPA, pulmonary hemorrhage and glomerulonephritis are much less common.[62–66] Significant neurologic, cardiac (conduction abnormalities, systolic or diastolic dysfunction, intracavitary thrombus, pericarditis), or gastrointestinal disease (perforation, ischemia, bleeding) are dreaded, but well-recognized, complications. ANCA is positive in a perinuclear IIF pattern (p-ANCA) in 30–70%, with peripheral eosinophilia (absolute eosinophil count >1500/μL) almost universal at some point in the course.

Recently, it has been recognized that patients with EGPA segregate into two distinct clinical phenotypes. One subset is characterized by a greater incidence of neurologic, renal, gastrointestinal, and cutaneous involvement and is more commonly ANCA- or MPO-positive (i.e., shares a high degree of overlapping features with GPA and MPA). The other subset typically shares features with the hypereosinophilic syndromes, namely cardiac manifestations, migratory lung opacities (eosinophilic pneumonia), and an ANCA-negative/MPO-negative serologic profile.[66–68] These subgroups may have differing underlying genetic predispositions. Both ANCA-positive and ANCA-negative groups carry variants in Th2 response, eosinophil proliferation, and eosinophil survival genes; however, the ANCA-positive group is strongly associated with variants in HLA, suggesting a role for HLA class II–associated autoimmunity, while the ANCA-negative patients show variants in interferon regulatory factor-1/IL-5 and a gastrointestinal and bronchial mucosal/barrier protein, suggesting abnormal mucosal function in the lung and gastrointestinal tract.

Pathologically, patients with EGPA will demonstrate both a necrotizing, small vessel vasculitis and an eosinophil rich cellular infiltrate.[69,70] The diagnostic findings on lung biopsy include eosinophilic pneumonia, necrotizing vasculitis, and granulomatous inflammation (Fig. 87.8A–B). The vasculitis consists of artery, vein, or capillary wall infiltration by lymphocytes and eosinophils. The granulomas often show central areas of necrosis with abundant necrotic eosinophils, surrounded by palisaded histiocytes and multinucleated giant cells. Findings highly suggestive of EGPA include eosinophilic pneumonia and parenchymal necrosis.[70]

Mortality is generally due to cardiac complications (up to half of EGPA-related deaths), gastrointestinal complications, or status asthmaticus and respiratory failure.[62,63,71] While mortality rates of up to 40% were described in the 1970s, more recent data suggest that, when adequately treated, patients may have a normal lifespan.[72] A recent single center study demonstrated that a comprehensive vasculitis center–based management strategy of patients with EGPA without heart failure had a survival rate no different than a matched general population.[73] Overall 5-year survival rates have been estimated at 60–97%.[61]

In the late 1990s, an association between the use of leukotriene inhibitors and EGPA had been suggested in

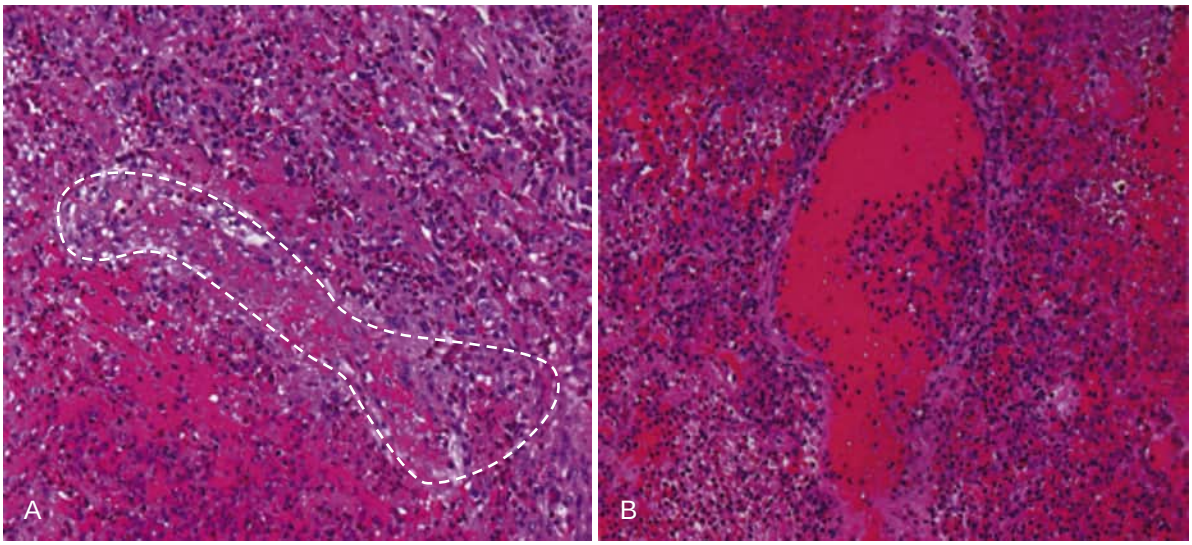

Figure 87.8 Eosinophilic granulomatosis with polyangiitis. (A) Outline (*dashed line*) of a destroyed vessel. Note the marked eosinophilic infiltration. (B) A small vein showing destruction of its wall by eosinophils. There is an accompanying eosinophilic pneumonia characterized by numerous clusters of eosinophils within the air spaces. Hemorrhage is also present.

a number of case reports and case series.[74,75] This led to the concern that leukotriene inhibitors may help promote the biologic conversion of severe asthma/atopic disease to EGPA.[76] However, analyses of postmarketing surveillance data and a number of patient cohorts over the mid-2000s argued against this relationship, and hypothesized that these excess cases were due to either reporting bias or to the unmasking of EGPA precipitated by withdrawal of corticosteroids in patients with improved control of their asthma.[72,77–79] However, in 2010, an analysis of the Food and Drug Administration Adverse Event Reporting Database found that only 36% of cases of EGPA in patients treated with leukotriene inhibitors had preexisting clinical evidence suggesting possible EGPA or an associated tapering of the patient's corticosteroids, hence, the majority of cases of EGPA associated with leukotriene antagonists could not otherwise be explained.[80] Similar findings were identified in the United Kingdom's Committee on Safety of Medicines "yellow card" scheme. As such, the pendulum has swung back towards favoring a very small but potentially real relationship between the use of leukotriene antagonists and the development of EGPA.

MICROSCOPIC POLYANGIITIS

MPA is an ANCA-associated small vessel vasculitis generally heralded by weeks to months or longer of profound constitutional symptoms (fever, asthenia, fatigue, malaise, myalgias, arthralgias) followed by the development of renal disease, generally RPGN (see Table 87.3). MPA is more common in men, with an average age of onset in the sixth decade. Its clinical manifestations overlap with those of polyarteritis nodosa, explaining the decades of confusion over their relationship. The glomerulonephritis is essentially universal, whereas the lungs are involved in a minority of patients (10–30%).[81–83] In patients who develop lung disease, DAH/capillaritis is the most common manifestation (eFig. 87.9). Pulmonary fibrosis is uncommon but associated with a high mortality rate. The skin is involved in over half of patients, most commonly with purpura. The peripheral nervous system (most commonly with mononeuritis multiplex) is involved more frequently than the central nervous system, and the gastrointestinal tract can be involved, with bleeding and ischemia.[84] MPO-ANCA and a perinuclear pattern on IIF is positive in 50–75%. Pathologically, a focal, segmental necrotizing vasculitis and a mixed inflammatory infiltrate without granulomata are seen. Pathologically, this vasculitis affects venules, capillaries, and arterioles. Neutrophilic capillaritis (see Fig. 87.3) is the classic histologic finding in the lung, with pulmonary alveolar hemorrhage and hemosiderin-laden macrophages (Fig. 87.9). As the lesions heal, plugs of organizing pneumonia may fill air spaces, resulting in an organizing pneumonia–like pattern. Unlike the other small vessel vasculitides, MPA lacks granulomatous inflammation. The overall 5-year survival rate has been estimated to be approximately 45–76%, with higher mortality rates in those greater than 65 years old or those with significant renal impairment.[61] Relapses after successful induction therapy are common (25–33%)[81] but usually less severe and responsive to therapy.

SMALL VESSEL VASCULITIS RELATED TO IMMUNE COMPLEXES

There are a number of small vessel vasculitides that involve the lung and are pathophysiologically defined by the deposition of

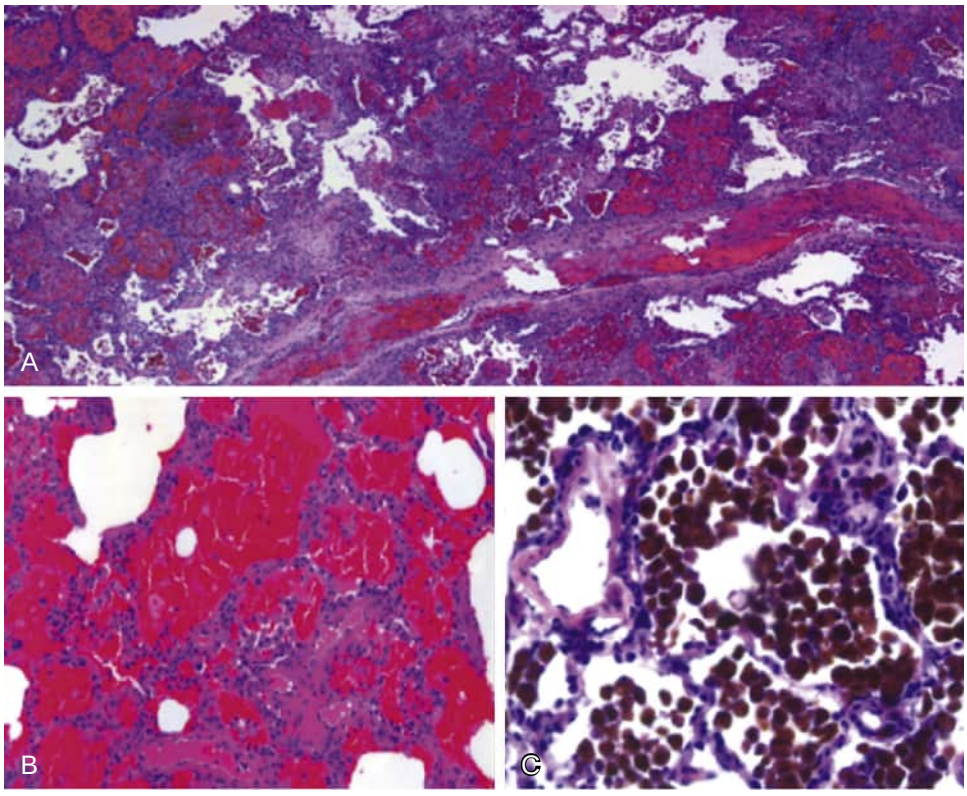

Figure 87.9 Microscopic polyangiitis. (A) Low-power view of diffuse alveolar hemorrhage. The air spaces are filled with red blood cells and the alveolar septa show concomitant inflammatory thickening. (B) Alveolar hemorrhage demonstrating the smudged, homogeneous appearance of the disrupted red blood cells in the air spaces. Occasional hemosiderin-laden macrophages can be seen in the center. (C) Hemosiderin-laden macrophages within the air spaces indicating chronic alveolar hemorrhage.

immunoglobulins and/or complement in the wall of the small vessels. These include *anti-glomerular basement membrane disease* (anti-GBM disease), hypocomplementemic (anti-C1q) urticarial vasculitis, cryoglobulinemic vasculitis, and IgA vasculitis. All are quite rare, variably affect the lung, frequently involve the kidney, and can be identified by the presence of specific circulating antibodies and pathologic findings.

Anti-GBM disease is a rare, small vessel vasculitis that results from antibodies that target domains on the alpha-3 chain of type IV collagen. Because these chains are most highly expressed in the glomerulus and the alveolar basement membrane, immune complex deposition in the small vessels of the kidney and lung define the clinical manifestations. It is a classic pulmonary-renal syndrome, presenting with RPGN and alveolar hemorrhage. Once alveolar hemorrhage and RPGN are identified, the differential includes ANCA-associated vasculitis, anti-GBM disease, IgA vasculitis, cryoglobulinemic vasculitis, and SLE. Up to 50% of patients with anti-GBM disease will also have positive ANCA; even in patients with known anti-GBM disease, ANCA should be measured because the antibodies are associated with clinical manifestations and outcome. Whereas renal disease is almost universal, lung disease is present in up to 60% of patients. The pulmonary presentation is generally that of alveolar hemorrhage, with cough, dyspnea, and sometimes, but not always, hemoptysis. Chest imaging is abnormal with diffuse ground-glass opacities with occasional consolidation. Active hemorrhage may be associated with an increased diffusing capacity for carbon monoxide. Treatment is with plasmapheresis (to remove circulating antibodies) and immunomodulatory therapy (to decrease new antibody production), generally a combination of glucocorticoids and cyclophosphamide. Alternatives to cyclophosphamide include mycophenolate mofetil and rituximab. A response to therapy is measured by serum creatinine, urine output, and hemoglobin. Outcome is generally dictated by renal disease. Monitoring anti-GBM antibodies is common, and they should become undetectable with efficacious treatment.

Hypocomplementemic urticarial vasculitis is clinically characterized by the presence of obstructive airways disease, urticaria, arthralgia/arthritis, glomerulonephritis, low complement levels, and anti-C1q antibodies. Treatment is based upon disease severity and generally includes glucocorticoids. Cryoglobulinemic vasculitis (mixed, types II/III) is most often secondary to hepatitis C infection or an underlying connective tissue disease. Symptomatic respiratory involvement is rare, but when present includes cough and dyspnea associated with airflow limitation. Pulmonary hemorrhage is exceedingly rare. Treatment depends upon the underlying cause and disease severity. Both glucocorticoids and rituximab have been used. IgA vasculitis is a systemic vasculitis with deposition of IgA1 predominant immune complexes affecting mostly the small vessels. Skin (palpable purpura), gastrointestinal (pain), joint (arthralgia/arthritis), and renal disease are the classic presenting tetrad. Lung involvement is rare.

TREATMENT

GENERAL PRINCIPLES

Therapy of the pulmonary vasculitides, particularly the AAV, generally involves aggressive immunomodulation with varying combinations of cytotoxic agents, biologic agents, and corticosteroids. Most treatment approaches have been defined using GPA as the most common of the AAV, though treatment of MPA is similar. EGPA is somewhat unique given the prominence of eosinophils in the pathophysiology and the availability of eosinophil-specific therapy. Given the risks associated with therapy, the intensity of immunosuppression should be titrated to the severity of the disease, therefore the choice, dose, and duration of therapy is not driven by the clinical diagnosis alone, but rather by the combination of the diagnosis and its severity. The goal is disease control while minimizing the risk of treatment-related adverse events.

A variety of disease severity and activity scoring systems have been utilized. The French Vasculitis Study Group has validated the *five-factor score* (FFS) in EGPA and subsequently across the AAV.[85] The FFS is calculated by adding 1 point for the presence of each of the following: (1) renal insufficiency, (2) clinically significant gastrointestinal disease, (3) cardiac symptoms, (4) the *absence* of upper airway (ear, nose, and throat) involvement (because involvement may define a more limited phenotype), and (5) age 65 years or older. Five-year mortality rates for scores of 0, 1, and 2 or greater are 9%, 21%, and 40%, respectively.[85]

More recently and conveniently, disease severity has been divided into two groups: non–organ-threatening disease and organ- or life-threatening disease (including the specific subset of rapidly progressive renal failure or pulmonary hemorrhage) (Table 87.4). Non–organ-threatening disease may have a variety of signs or symptoms such as rhinosinusitis without bone or cartilage involvement or hearing loss, exanthem without ulceration, or pulmonary nodules with hemoptysis, but it does not have evidence of active renal disease (i.e., an abnormal serum creatinine, proteinuria or red cell casts on urinalysis), cardiac disease (i.e., pericarditis or myocarditis), central or peripheral neurologic involvement (i.e., cerebral vasculitis, meningeal disease, progressive neuropathy), gastrointestinal bleeding (with or without mesenteric involvement), or orbital pseudotumor. In contrast, organ- or life-threatening disease includes rapidly progressive renal disease, pulmonary hemorrhage, pulmonary cavitary disease, motor neuropathy, and cardiac involvement among a variety of others.

Ongoing monitoring of disease activity and persistent damage is also important. Complete remission does not mean all evidence of disease activity must fully resolve, because there may be irreversible injury due to vasculitis, even early in the disease, and other potential causes (e.g., infection) may be responsible for some manifestations of disease. For example, nasal ulcers and other upper airways signs and symptoms are unlikely to respond rapidly to therapy and are not considered resistant or refractory disease. To improve interobserver reliability and to make disease activity and vasculitic damage scoring more objective, reliable, and reproducible, specific instruments have been developed. The Birmingham Vasculitis Activity Score (version 3.0) is an inventory of signs, symptoms, and laboratory findings associated with AAV that is commonly used in clinical trials to grade and quantify vasculitic disease activity objectively.[86] The instrument quantifies the history, examination, review of systems, and routine laboratories obtained by the bedside clinician caring for the patient. The Vasculitis Damage Index similarly quantifies vasculitic

Table 87.4 Disease Severity and Proposed Treatment Options for Induction and Maintenance

Disease Class	Treatment Options for Induction
New non–organ-threatening disease	Methotrexate + glucocorticoids *or* Rituximab + glucocorticoids *or* Cyclophosphamide + glucocorticoids
New organ- or life-threatening disease	Cyclophosphamide + glucocorticoids *or* Rituximab + glucocorticoids
Major relapse of organ-threatening or life-threatening disease	Rituximab + glucocorticoids *or* Cyclophosphamide + glucocorticoids
RPGN with serum creatinine >500 mmol/L (5.7 mg/dL) *or* Diffuse alveolar hemorrhage	Consider plasma exchange *plus* Cyclophosphamide (or rituximab) + glucocorticoids
Refractory disease	Referral to a center with specialized expertise in the management of vasculitis when feasible. Switch from cyclophosphamide to rituximab or from rituximab to cyclophosphamide.
Maintenance of remission for a minimum of 24 months	Azathioprine ± low-dose glucocorticoids *or* Methotrexate ± low-dose glucocorticoids *or* Rituximab ± low-dose glucocorticoids

RPGN, rapidly progressive glomerulonephritis.
Data from references 90–92, 98, 99, 111, 113, 116, 131, 144–151, 153.

damage.[87] Both of these instruments are well validated and commonly used in the conduct of clinical trials.

Similar to cancer therapy, treatment is divided into two phases, an initial remission-induction phase to control active disease and a maintenance phase to maintain disease remission while lowering treatment-related risk. Regardless of the phase of therapy, both disease-specific and drug-specific monitoring is required and should focus on the early identification of disease activity and adverse events (e.g., infection and drug toxicity). Clinicians should be familiar with the common toxicities associated with each drug utilized and have a standard protocol to monitor for potential treatment-related adverse effects during both remission-induction and maintenance therapy. Not to be forgotten, oxygen therapy (when needed), the treatment of comorbid disease, appropriate vaccinations, *Pneumocystis jirovecii* prophylaxis (as appropriate), physical and occupational therapy, a regular exercise regimen to maintain conditioning, proper nutrition along with achieving and maintaining ideal body weight, proper sleep hygiene, supporting bone health, and psychosocial support should be provided because they reduce morbidity associated with these diseases.

INDUCTION OF REMISSION

Fauci's early studies[48] of cyclophosphamide plus corticosteroids dramatically changed the field of vasculitis therapy. The combination of oral cyclophosphamide plus oral corticosteroids in this initial study yielded a remission rate of greater than 90%. Prior to the advent of this regimen, the prognosis for patients with AAV was uniformly poor, with 5-year mortality rates as high as 85%.

Glucocorticoids have been the mainstay of treatment for the vasculitides, while their adverse effects have been a primary driver of the early study of the addition of cyclophosphamide. There is general disagreement among experts regarding the appropriate dosing and tapering regimens in the treatment of AAV. Pulse methylprednisolone (7 to 15 mg/kg to a maximum dose of 500 to 1000 mg/day) for 3 days is often recommended for those with severe pulmonary disease and/or necrotizing or crescentic glomerulonephritis, but whether it should be used in those with less severe disease is unknown. After initial pulse intravenous therapy, oral prednisone therapy of 1 mg/kg per day, to a maximum of 80 mg/day, is generally started. The tapering regimen is then dictated by clinical response with a goal of 20 mg/day or less by the end of 2 months. The use of glucocorticoids beyond 6 months may be associated with a significantly higher incidence of infections. The results of the recent PEXIVAS trial suggest that standard induction with pulse methylprednisolone followed by oral doses less than 60% of standard dose is noninferior in terms of all-cause mortality or end-stage kidney disease. This more rapid tapering of therapy, starting in the second week of therapy, is likely to become standard.

In an attempt to reduce the side effects and toxicity associated with oral cyclophosphamide induction therapy while preserving high rates of disease remission, a number of clinical trials have been performed looking at alternative regimens. Pulsed intravenous cyclophosphamide has been compared head-to-head with oral cyclophosphamide in the EUVAS-sponsored CYCLOPS trial (daily oral versus pulse cyclophosphamide for renal vasculitis).[88–90] While the investigators found that intravenous cyclophosphamide was as effective as oral cyclophosphamide at inducing disease remission and was associated with fewer side effects, long-term follow-up data found that the risk of relapse was higher (29.5% vs. 20.8%).[90,91] On the other hand, no significant differences were found between the two groups in regard to survival, renal function, or adverse events. The EUVAS sponsored Methotrexate versus Cyclophosphamide for "Early Systemic Disease" trial showed oral methotrexate to be as efficacious as oral cyclophosphamide in the induction of disease remission at 6 months (84% vs. 83%), albeit with a longer time to remission (5.2 months vs. 3.2 months).[92–94] The methotrexate side effect profile was also more favorable, though the rate of relapse in this group was also higher (74% vs. 42%).[95] The EUVAS study group has also shown that *mycophenolate mofetil* (MMF) was noninferior to cyclophosphamide for remission induction in AAV, but resulted in a higher relapse rate. One hundred forty newly diagnosed patients were randomly assigned to MMF or pulsed cyclophosphamide. All patients received the same oral glucocorticoid regimen and were switched to azathioprine following remission. Noninferiority was demonstrated for the primary remission end point, 67% in the MMF group and 61% in the cyclophosphamide group. There were more relapses in the MMF group (33%) than in the cyclophosphamide group (19%). In MPO-ANCA patients, disease relapsed in 12% of the cyclophosphamide group and

in 15% of the MMF group. In PR3-ANCA patients, disease relapsed in 24% of the cyclophosphamide group and in 48% of the MMF group. Serious infections were similar between groups (26% MMF group, 17% cyclophosphamide group).

Because B cells have also been implicated in the pathogenesis of AAV, the anti-CD20 monoclonal antibody rituximab was tested and has been shown to be a safe and effective therapy. After a number of promising case series, two large randomized, multicenter controlled clinical trials were performed comparing rituximab to cyclophosphamide for the induction of disease remission.[96,97] The RAVE trial compared rituximab to daily oral cyclophosphamide. In this study, rituximab was shown to be noninferior to cyclophosphamide as measured by the primary end point of disease remission plus successful tapering of corticosteroids at 6 months.[98] Subgroup analysis found no difference in efficacy for the treatment of alveolar hemorrhage and that rituximab may be superior for the treatment of relapsing disease. No differences were noted in the rate of adverse events. Similar findings were found in the RITUXVAS trial in which rates of sustained remission, median time to remission, and adverse events were similar between the two treatment groups.[99]

In Non–Organ-Threatening Disease

Patients with non–organ-threatening disease may have a variety of signs or symptoms but do not have evidence of active renal or cardiac disease, central or peripheral neurologic involvement, gastrointestinal bleeding, or orbital pseudotumor. For this group of patients with comparatively mild disease, glucocorticoids in combination with methotrexate, cyclophosphamide, rituximab, and MMF have all been evaluated. Current recommendations suggest the combination of glucocorticoids and methotrexate as first-line therapy with the combination of glucocorticoids with rituximab for those patients with contraindications to the use of, or intolerant to, methotrexate. For patients unresponsive to methotrexate or who progress despite an initial response, cyclophosphamide or rituximab should be considered.

In Organ-Threatening or Life-Threatening Disease

Organ- or life-threatening disease will manifest with active renal disease (i.e., an abnormal serum creatinine, proteinuria or red cell casts on urinalysis), cardiac disease (i.e., pericarditis, myocarditis, cardiomyopathy), central or peripheral neurologic involvement (i.e., cerebral vasculitis, progressive neuropathy), pulmonary involvement with aggressive cavitary disease or DAH, and gastrointestinal bleeding or orbital pseudotumor, among others. In this group of patients, aggressive immunomodulation with the combination of either glucocorticoids plus cyclophosphamide or glucocorticoids plus rituximab is indicated.

In Rapidly Progressive Renal Failure, DAH

Plasma exchange (PEX) has been considered a reasonable treatment option for patients with rapidly progressive renal failure in the setting of new or relapsing disease or DAH. This approach was based on data from the MEPEX trial in a cohort of patients with severe renal disease. In this small study, the addition of plasma exchange therapy to the standard cyclophosphamide plus corticosteroid regimen was found to be superior to high-dose, pulsed intravenous steroids as measured by dialysis-free survival (69% vs. 49%).[100–106] Based upon a 20-patient case series and number of case reports, this strategy was also thought to be effective for the treatment of DAH.[105] However, the recently published PEXIVAS trial changes this thinking. In this trial, PEX and two regimens of oral glucocorticoids were tested in patients with severe ANCA-associated vasculitis (defined by renal disease or DAH). Patients underwent either PEX (seven plasma exchanges within 14 days after randomization) or no PEX. Among patients with severe ANCA-associated vasculitis, the use of PEX did not reduce the incidence of death or end-stage kidney disease. In addition, the reduced-dose regimen of glucocorticoids was noninferior to a standard-dose regimen. In the reduced-dose group, oral glucocorticoids were reduced by approximately 50% at the start of the second week. The dose in the standard-dose group was tapered more gradually, starting in week 3. At 6 months, the cumulative dose of glucocorticoids in the reduced-dose group was less than 60% of that in the standard-dose group.

Additional therapies described at the case report level for patients with unresponsive DAH include activated human factor VII to control ongoing, refractory hemorrhage in patients with respiratory failure[107,108] and extracorporeal membrane oxygenation, which has been used to treat refractory hypoxemic respiratory failure in patients with severe hemorrhage until other interventions have had a chance to work.[109]

After Relapse of Organ- or Life-Threatening Disease

Historically, up to 50% of patients with an ANCA-associated vasculitis have suffered at least one relapse despite active treatment. Relapses are more common among patients with GPA (40–65%) and less common among patients with EGPA (15–25%).[57,110] The features of clinical deterioration during a relapse may be similar to the patient's original presentation or may present with novel symptoms and signs and in previously unaffected organs.

For a major relapse of organ- or life-threatening disease in AAV, it is recommended that treatment be approached as if the disease were newly diagnosed, with a combination of glucocorticoids and either cyclophosphamide or rituximab. Given the risks associated with cumulative doses of cyclophosphamide, rituximab may be the preferred choice.

In Refractory Disease

According to European League Against Rheumatism definitions, refractory disease is persistent or increased disease activity in acute AAV after 4 weeks of treatment with standard therapy or a lack of response (defined as <50% reduction in the activity score of the Birmingham Vasculitis Activity Score) after 6 weeks of treatment. Chronic, persistent disease is defined as the presence of at least one major or three minor items on the disease activity score after greater than 12 weeks of treatment. Questions to be asked prior to the diagnosis of refractory disease include: Is the diagnosis correct? Has the correct treatment been given? Is the disease actually active? and Is the measured activity due to AAV or due to infection, drug toxicity, malignancy, or other comorbidity?

For patients with refractory disease, it is recommended that therapy be switched from cyclophosphamide to rituximab or from rituximab to cyclophosphamide. In particular, for patients who are PR3-ANCA positive, rituximab may be a better choice. Other considerations include intravenous immunoglobulin and antithymocyte globulin.[111] Patients with presumed refractory disease should be cared for in centers with specialized expertise in the management of vasculitis when feasible.

MAINTENANCE

Maintenance therapy is designed to control the disease while reducing the risk or severity of medication-related adverse effects. Options during this phase of treatment include azathioprine, rituximab, methotrexate, and MMF.[92,93,112–115] The choice may be informed by initial induction regimen and ANCA status. In patients with GPA or MPA in remission, azathioprine and methotrexate appear to have similar efficacy. Among patients who are PR3-ANCA positive, rituximab may be superior to both of these. As with all therapy, any of these agents must be introduced with drug-specific monitoring to identify adverse effects as early as possible. In particular, persistent unexplained hematuria in patients with prior exposure to cyclophosphamide should be investigated and serum immunoglobulins should be tested prior to each course of rituximab and in those with recurrent infection.

The timing of transition from the induction to maintenance therapy had been a subject of debate with one school of thought arguing that patients should be treated until there was clinical evidence of response and another school of thought arguing that they should have defined courses of therapy to "consolidate" the induction of remission. Transitions determined by clinical evidence of response tend to be earlier than those determined by fixed courses of therapy. The results of a European Vasculitis Study Group trial demonstrated that patients with active generalized vasculitis may be transitioned from oral cyclophosphamide to azathioprine at the time of clinical remission (using defined criteria; generally within 3 to 6 months). Patients in the clinically determined (early) transition group demonstrated no increase in the rate of relapse, disease activity scores, or change in renal function, suggesting that this approach is as safe and effective as fixed-course therapy.[116]

Maintenance therapy should continue for at least 24 months following the induction of remission.[117] The EUVAS-sponsored REMAIN trial prospectively compared two different durations of maintenance immunosuppressive therapy for the prevention of relapse in AAV. After cyclophosphamide/prednisolone-based induction followed by azathioprine/prednisolone maintenance therapy, patients were randomized (1:1) to receive continued azathioprine/prednisolone to 48 months from diagnosis (continuation group) or to withdraw azathioprine/prednisolone by 24 months (withdrawal group). The primary end point was relapse, from randomization to 48 months from diagnosis. It was found that prolonged remission-maintenance therapy with azathioprine/prednisolone beyond 24 months after diagnosis reduced relapse risk out to 48 months and improved renal function. This study supports the use of prolonged maintenance therapy to minimize the risk of relapse.

Another point of controversy has been the optimal dosage and duration of the corticosteroid component of the treatment regimen. While there is general agreement that "high-dose" corticosteroids should be introduced in patients with active disease as part of their induction therapy (e.g., 1 mg/kg/day of oral prednisone or equivalent), and that this should be "slowly tapered" (e.g., 3 months) towards a "low" maintenance dose (e.g., 5 to 10 mg of oral prednisone per day or equivalent), there is no validated, widely accepted corticosteroid protocol. However, the recent PEXIVAS study showed that a reduced dose approach with an early taper starting in week 2 is noninferior to the higher, "standard dose" taper. Whether the corticosteroids should be tapered off or remain at a low dose for a prolonged period of time remains controversial, with advocates on both sides of the argument. That said, a meta-analysis of 13 large clinical trials has suggested that patients maintained on some dose (i.e., "non-zero") of corticosteroids have a lower rate of disease relapse than patients who are weaned entirely off (14% vs. 43%). Still, this has not been replicated in a well-designed, prospective clinical trial and even low-dose corticosteroids carry a risk of adverse side effects.

Finally, trimethoprim/sulfamethoxazole[13,118] may have an adjunctive (but not sole) role in the management of AAV and reduces the risk of relapse in GPA.[12,119] Studies have demonstrated a reduced frequency of disease relapse in patients who are maintained on trimethoprim/sulfamethoxazole compared to those without,[118] with additional work suggesting that this is related to *Staphylococcus aureus* nasal carriage.[12,119] For those with nasal *S. aureus*, mupirocin may be considered. Regardless, trimethoprim/sulfamethoxazole should be considered for *P. jirovecii* prophylaxis in patients maintained on cyclophosphamide or other aggressive immunosuppression regimens barring a sulfa allergy or other contraindication.

SPECIFIC TREATMENT ISSUES IN EGPA

While grouped with the AAV, EGPA is unique in that eosinophils are recognized as pathophysiologically important and responsible for multiple clinically relevant features of the disease. With the availability of specific anti-eosinophilic biologic therapy, the treatment of EGPA (particularly more severe disease) often includes one of these newer agents.

Similar to the other AAV, therapy depends upon underlying disease severity, which can be scored using the FFS (see above). Glucocorticoids alone are the usual remission induction therapy for EGPA, generally at doses of 0.5 to 1.0 mg/kg. More severe disease may be treated with intravenous pulse methylprednisolone. In patients with mild disease, remission rates above 90% have been described using glucocorticoid therapy alone. Once remission is achieved, a glucocorticoid taper is planned for 12 to 18 months, though the majority may need prolonged, low-dose steroids.

Additional immunomodulatory therapy is generally reserved for patients with more severe disease, refractory disease, or disease that continues to flare with steroid tapers. Cyclophosphamide is the preferred choice, particularly for patients with an FFS score of 2 or more, with cardiac or central nervous system involvement, and with a positive ANCA. Cyclophosphamide is associated with improved survival in severe EGPA patients with a higher FFS. In those with milder disease who need additional therapy, methotrexate or azathioprine are recommended.

Large retrospective studies suggested the efficacy of azathioprine as maintenance therapy, though a randomized controlled trial (CHUSPAN2) for nonsevere vasculitides, including an EGPA subset ($n = 51$), showed that azathioprine was not superior to placebo in preventing relapse. Ultimately, the role of long-term azathioprine maintenance therapy for EGPA is still unclear. Other maintenance therapy has included methotrexate and leflunomide.

Mepolizumab, a humanized monoclonal antibody against IL-5 (a cytokine with major effects on eosinophil differentiation and survival), has also been studied in EGPA. MIRRA was a randomized placebo-controlled trial of mepolizumab in addition to standard care, in relapsing or refractory EGPA patients. Mepolizumab was associated with more weeks of remission than placebo (28% vs. 3% of the participants had ≥24 weeks of accrued remission; $P < 0.001$) and a higher percentage of participants in remission at both week 36 and week 48 (32% vs. 3%; $P < 0.001$). Minimal adverse effects were noted. However, it also appears that mepolizumab alone or with less than 5 mg/day of prednisolone does not maintain remission in the majority of patients. Mepolizumab is considered a good choice in EGPA, especially in patients whose disease is not controlled with glucocorticoids alone, have a low FFS, and in ANCA-negative EGPA patients. Reslizumab, another anti-IL-5 monoclonal antibody, and benralizumab, an anti-IL-5 receptor monoclonal antibody, are now being investigated for EGPA.

Rituximab has also been evaluated for treatment of EGPA. A recent retrospective review of EGPA patients who received rituximab for mostly refractory EGPA or in whom cyclophosphamide was contraindicated were reviewed. In this population, rituximab led to improvement (response and partial response with a reduction in prednisolone requirement) in 76.8% of patients at 6 months, 82.8% at 12 months, and 93.2% by 24 months, while there were relapses (particularly asthma and ENT) in 54% by 24 months. The ANCA-positive subset appeared to have a more sustained response on isolated asthma/ENT exacerbations. Currently, there are two randomized placebo-controlled trials (REOVAS and MAINRITSEG) evaluating the efficacy of rituximab as remission induction therapy compared to cyclophosphamide and as remission maintenance therapy compared to azathioprine, respectively.

Additional therapies have been evaluated including, interferon-α and the anti–immunoglobulin E monoclonal antibody, omalizumab. It has shown effectiveness for asthma in EGPA patients. Intravenous immunoglobulin has been approved for refractory EGPA in Japan since 2010. The underlying asthma is often difficult to control and should be managed using standard guidelines.

MONITORING FOR COMPLICATIONS

Monitoring for complications is mandatory in order to minimize the morbidity and mortality of both the disease and its treatment. When there is clinical deterioration, infection, drug toxicity, disease relapse, thromboembolic disease, and disease processes unrelated to the underlying vasculitis[120] should all be considered (Table 87.5).

Infection is the leading cause of morbidity and mortality in patients with vasculitis. Infection may present with atypical clinical features or atypical organisms and is frequently difficult to separate from disease activity. Infection may also contribute to triggering or increasing disease activity, and the immune dysfunction associated with disease activity appears to place patients at increased risk for infection, so that infections may accompany disease flares. Ultimately, infection accounts for 13–48% of deaths in patients with vasculitis.[2,121,122] Combining high-dose glucocorticoids with cytotoxic or rituximab therapy puts patients at especially high risk for infection. Measuring immunoglobulins (particularly IgG and IgM) in those on active rituximab therapy as well as those with recurrent infection is recommended, because profound hypogammaglobulinemia increases infection risk.

Drug toxicity is also common. In GPA patients treated with cyclophosphamide, cystitis is described in up to 12%, myelodysplastic syndrome in 8%, and solid malignancy in 5%.[123] Ultimately, the bedside clinician must be familiar with the adverse effects associated with the therapies used and have a system in place for the monitoring of cytotoxic/immunosuppressive therapies to identify toxicity as early as possible. Evidence-based clinical practice guidelines have been developed by the American College of Chest Physicians to assist with monitoring practices.[124]

Thromboembolic disease is an under-recognized complication of vasculitis, particularly of GPA. Patients with GPA have the same rate of venous thromboembolism as patients with a known prior history of venous thromboembolism, 7.0 events per 100 person years. As such, venous thromboembolism must also be considered in the differential diagnosis of a patient with new chest or lower extremity symptoms. The rate of venous thromboembolism in MPA and EGPA has yet to be defined.

Table 87.5 Common Complications in the Management of Vasculitides

Common Complications	Potential Interventions
■ Infection ■ Drug toxicity ■ Disease recurrence or relapse ■ Comorbid disease ■ Osteoporosis ■ Venous thromboembolism ■ Deconditioning ■ Psychosocial distress	■ Pneumocystis prophylaxis ■ Vaccination ■ Tailor treatment intensity to disease severity ■ Drug-specific standardized monitoring ■ Disease-specific monitoring, as appropriate for specific disease ■ Bone mineral testing and prophylaxis as appropriate for corticosteroid dose ■ Physical therapy, occupational therapy, routine aerobic exercise, nutrition ■ Patient support groups

Key Points

- Pulmonary vasculitis describes a variety of disorders characterized by their ability to cause vascular inflammation, destruction, and tissue necrosis in the lung.
- The presentation, clinical features, and evaluation overlap with more common disorders including infection, other characterized autoimmune disorders, and drug toxicity.

- A confident diagnosis may occasionally be made without tissue biopsy; however, diagnostic biopsy remains necessary for a definitive diagnosis and is generally recommended when establishing a new diagnosis and for further evaluation of patients suspected of relapse.
- The antineutrophil cytoplasmic antibody–associated vasculitides—granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis, and microscopic polyangiitis—are the most commonly encountered pulmonary vasculitides.
- A large number of high-quality randomized, controlled therapeutic trials have defined evidence-based treatment recommendations and generally allow for confidence in initial therapy.
- Because most treatment approaches involve aggressive immunosuppression, treatment-related complications are common and can be severe. Common complications that arise during the course of disease include infection, adverse drug reactions, disease relapse, comorbid disease, and venous thromboembolism.

KEY POINTS

INTRODUCTION

Pulmonary vascular anomalies are a diverse group of blood vessel anomalies that can lead to pulmonary hemorrhage and/or other complications, such as shunting. The anomalies are often rare and can be congenital, inherited, or acquired. The most common and well characterized are the pulmonary arteriovenous malformations, whereas sequestrations, pulmonary arterial aneurysms, venous varices, and anomalies of systemic supply are more rare. These typical anomalies are described, including their imaging and clinical presentations, as well as treatment, as relevant.

PULMONARY ARTERIOVENOUS MALFORMATIONS

DEFINITION AND EPIDEMIOLOGY

Pulmonary arteriovenous malformations (PAVMs) consist of a direct pulmonary artery to pulmonary vein connection, with resulting right-to-left shunting. These most frequently arise as a complication of *hereditary hemorrhagic telangiectasia* (HHT). In fact, as HHT has become more recognized and diagnosed and genetic testing has become available, the proportion of PAVMs reported to be associated with HHT has risen steadily from 30–90%.[1-5] Most other cases are *idiopathic*[6] and presumed to be congenital. Other causes,[7] as described remotely in the literature, are exceedingly rare and may have represented unrecognized HHT, with the detection of PAVMs in these cases predating the diagnosis of HHT. The prevalence of PAVMs has been previously estimated at 38 in 100,000 based on a lung cancer *computed tomography* (CT) screening study,[8] although this rate has not been confirmed in other studies and may be an overestimate because not all cases were confirmed.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

HHT is an autosomal dominant disorder with an estimated prevalence of 10 to 20 per 100,000 HHT is characterized by the presence of malformations with direct artery-to-vein connection. The larger lesions, arteriovenous malformations, typically are found in the lungs of 40–50% of HHT patients.[9] Arteriovenous malformations are also present in the brain in approximately 10%, in the pancreas in 15%, and rarely in other organs (small bowel in 5%, kidney in 1%, and spine in 1%). Smaller shunting lesions, or telangiectasias, can be seen typically on the nasal mucosa, oral mucosa, and skin of the face and hands, with multiple lesions noted in 90% of adults older than 50 years. Telangiectasia also develops in the liver in 75% and gastrointestinal tract in 30%.

The genetics of HHT have been largely elucidated over the past 30 years. In studies of patients from several countries, 80% of families were found to have a pathogenic mutation in either the *ENG* (endoglin) gene, the *ACVRL1* (activin receptor-like kinase 1) gene[10-12] or the *SMAD4* gene.[13,14] All three genes are members of the transforming growth factor-β signaling pathway. Depending on the locations worldwide, the distribution of genotype varies widely, with a predominance of endoglin families in the United States,[12,15] a predominance of *ACVRL1* families in France and Italy,[9] and roughly equal proportion in Canada and the Netherlands.[16]

Approximately 40% of HHT patients have PAVMs,[17,18] and PAVMs are significantly more frequent among HHT patients with an endoglin mutation compared to those with a mutation of *ACVRL1*.[9,15,16,19,20] However, patients with mutations in *ACVRL1* or *SMAD4* genes also have PAVMs, and therefore screening recommendations for PAVMs in HHT have not been limited to endoglin families.[21] The International HHT Guidelines recommend screening all HHT patients for PAVMs,[21] given the risk of debilitating and life-threatening complications from untreated PAVMs and the availability of low-risk preventative treatment.

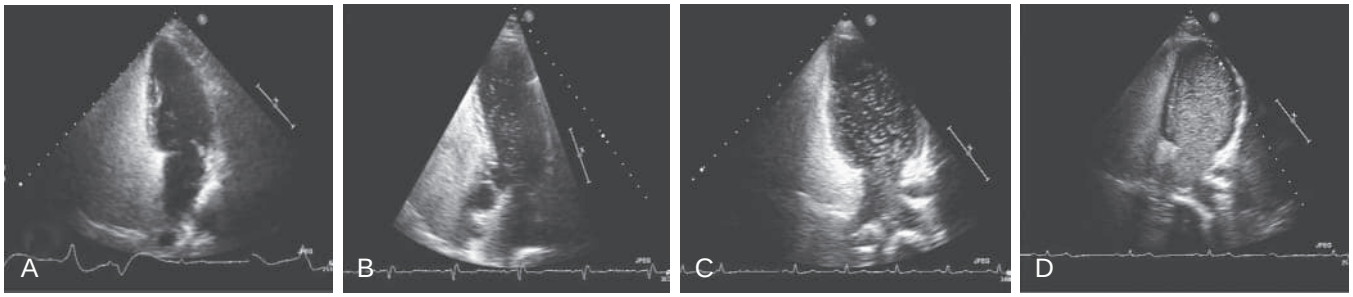

Figure 88.1 Contrast echocardiography showing different grades of left ventricular opacification. The grades shown are minimal (A), moderate (B), extensive (C), and extensive with endocardial definition (D). The likelihood of detecting a pulmonary arteriovenous malformation on chest computed tomography increases with higher grades of abnormality. (From Parra JA, Bueno J, Zarauza J, et al: Graded contrast echocardiography in pulmonary arteriovenous malformations. *Eur Respir J.* 2010;35:1281-1285. Courtesy the European Respiratory Society.)

CLINICAL PRESENTATION

PAVMs are often asymptomatic until they present with neurologic or hemorrhagic complications. At the usual time of diagnosis of PAVM, typical patients are in their 40s and have already had a stroke or transient ischemic attack (30%), cerebral abscess (10%), massive hemoptysis (10%), or spontaneous hemothorax (10%). Only 10% of PAVM patients present with classical features such as cyanosis, clubbing, and pulmonary bruit. Approximately 50% of patients with PAVMs experience exertional dyspnea,[22,23] but this is nonspecific and often unrecognized. In other words, patients with PAVMs are at risk of debilitating and life-threatening complications and often have no warning symptoms.[24,25]

PAVMs occasionally come to attention when a "nodule" is discovered on chest radiograph or CT. This is often how idiopathic PAVMs are first detected, though their clinical presentations are similar to HHT-related PAVMs,[6] and neurologic complications can also be the first presentation of an idiopathic PAVM.[26]

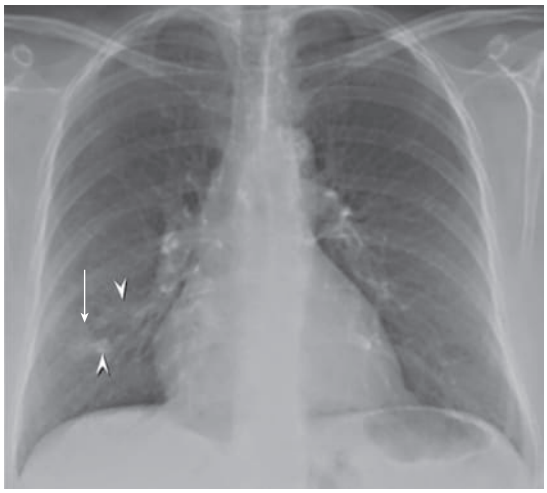

Figure 88.2 Pulmonary arteriovenous malformation. Chest radiograph shows a large lobulated pulmonary arteriovenous malformation (*arrow*). Note the serpiginous-appearing vessels (*arrowheads*) faintly seen leading toward the malformation.

SCREENING AND DIAGNOSIS

Transthoracic contrast echocardiography, using agitated saline, has emerged as the first-line screening test of choice[21] for PAVMs, given its high sensitivity of 93–97%[23,27,28] as well as its accessibility and low risk to patients. Grading of right-to-left shunt on contrast echocardiography predicts the presence of PAVM and guides the next steps for diagnostic confirmation[29,30] (Fig. 88.1). Chest radiography is not sensitive for detecting PAVMs, even in experienced hands,[23] though larger lesions can be detected (Fig. 88.2). Measurement of right-to-left pulmonary shunt fraction while breathing 100% oxygen also has a low sensitivity, detecting only approximately 50% of patients with right-to-left shunt found on contrast echocardiography; even large right-to-left shunts on contrast echocardiography could be missed on shunt testing.[31] Positional oximetry, in an attempt to detect orthodeoxia (i.e., a fall in oxygen saturation of 2% or more upon standing, as evidence of the redistribution of blood flow to the base where PAVMs are more common), had even lower sensitivity.[22] Of the patients with PAVMs in this prospective study, only 29% (n = 79) demonstrated orthodeoxia, and none described platypnea (i.e., dyspnea on standing).

The recommended diagnostic confirmatory test is chest CT[21] (Fig. 88.3A–B; see also eFig. 20.18A), which demonstrates a fistulous lesion with a feeding artery, aneurysm, and draining vein. Lesions are often multiple and peripheral in location. Varied protocols are used, with contrast-enhanced CT angiogram the most reliably sensitive and specific across centers of variable experience. However, many experienced centers routinely use non-contrast low-dose protocols[32] to minimize radiation and contrast risk for patients.[33] Pulmonary catheter angiography is rarely required for diagnosis given the current high resolution of CT imaging, but it is typically performed at the time of treatment (Fig. 88.4A, Videos 88.1 to 88.3; also see eFig. 20.18B). Contrast-enhanced magnetic resonance imaging has also been described for screening and confirmation of PAVMs[34] in HHT, but its operating characteristics are less well studied and access remains more limited.

TREATMENT

Transcatheter embolization is the treatment of choice for PAVMs, given its high success rate and low complication rate.[2,35] Embolization is recommended for all PAVMs, regardless of symptoms, with the goal of preventing

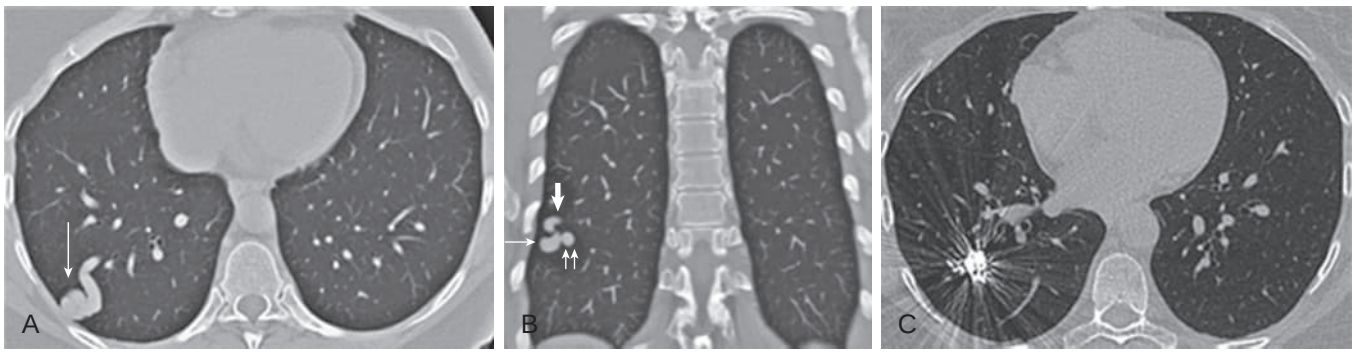

Figure 88.3 Pulmonary arteriovenous malformation before and after embolization. Axial (A) unenhanced and coronal (B) computed tomography with maximum intensity projection shows the lobulated pulmonary arteriovenous malformation (*thin arrow*), feeding artery (*double arrow*), and draining pulmonary vein (*thick arrow*). (C) One year after embolization, axial unenhanced computed tomography shows complete involution of the aneurysmal segment, with streak artifact from the embolic material.

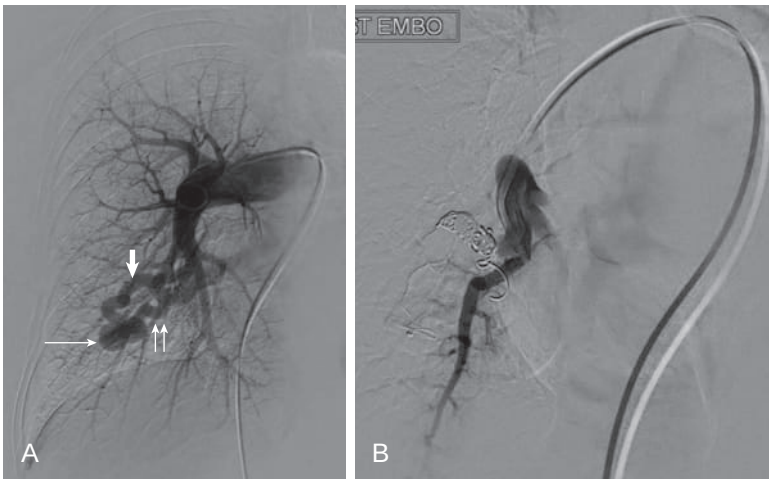

Figure 88.4 Pulmonary arteriovenous malformation before and after embolization. Catheter angiogram before (A) and after embolization (B) shows the lobulated pulmonary arteriovenous malformation (*thin arrow*), feeding artery (*double arrow*), and draining pulmonary vein (*thick arrow*). Postembolization, the lobulated aneurysm and draining vein are no longer visible.

neurologic and hemorrhagic complications.[21,36] Typically, embolization (see Fig. 88.4B, Video 88.1B) is performed with coils or Amplatzer vascular plugs,[2,37-40] with the patient under sedation and with local anesthesia of the femoral vein access site. The decision to treat a PAVM is based on the diameter of the feeding artery, generally at 3 mm or greater, although targeting PAVMs with a feeding artery of 2 to 3 mm may also be appropriate. Embolization is generally well tolerated and is often done as an outpatient procedure, with the most common complication being postembolization pleuritic chest pain in approximately 30%. The pain is usually self-limited, lasting an average of 7 to 10 days, and is treated with nonsteroidal anti-inflammatory drugs as needed. Other complications are rare in experienced centers, including hemoptysis (5%), device migration into the systemic circulation (1%), and very rare (<1%) reports of complication by angina pectoris, transient ischemic attack, or stroke.[41] Embolization device migration through a PAVM (paradoxical device embolization) is a complication at the time of embolization, but not after. The migrated device can usually be retrieved with a catheter by the interventional radiologist during the same procedure. The published series of PAVM outcomes are all from experienced centers; outcomes may be less favorable from inexperienced centers because of the rarity of the disease.

Long-term follow-up after embolization is recommended to ensure ongoing occlusion of the embolized PAVMs and also to follow growth of untreated small PAVMs. The reported long-term PAVM reperfusion rate after embolization ranges from 7–30%[35,37,42] and is generally via recanalization of the embolized feeding artery, and less frequently through a previously unrecognized additional feeding artery. Reperfused PAVMs are typically retreated with embolization with outcomes similar to the initial embolization.[43,44] Clinical follow-up after embolization is typically performed initially at 1 to 2 months after the procedure, with the goal of early confirmation of success of the procedure. On chest radiograph, visible involution of the aneurysmal sac and/or draining vein distal to the embolization material is reassuring, as is improvement in arterial P_{O_2} (room air and/or on 100% oxygen where available). HHT Guidelines[21] recommend that PAVMs should then be reassessed at 1 year postembolization with unenhanced chest CT to confirm involution of the aneurysm and of the draining vein of the embolized PAVMs (Fig. 88.3C). If there is not sufficient involution (<50%), reperfusion is suspected and retreatment should be considered. Further follow-up after initial confirmatory CT should be performed every 3 years with unenhanced chest CT using a low-dose protocol as feasible.

PAVM precautions should be recommended for all patients, even after treatment. These include antibiotic prophylaxis for bacteremic procedures, an air-eliminating intravenous filter when there is intravenous access, and

Downloaded for Time Ceal (jinzh 2021. For personal use only. No

avoidance of scuba diving.[21,45] The rationale for antibiotic prophylaxis is the high rate of brain abscess in these patients[2,24,46] and the presumed mechanism of paradoxical embolization of biofilms of bacteria through pulmonary shunting vessels. The air-eliminating filter is perhaps an overly cautious precaution but is easily administered, with the goal of preventing transient ischemic attack from iatrogenic paradoxical air embolism. Finally, scuba diving should be avoided based on the evidence that decompression from any depth, even within recommended limits, leads to nucleation of circulating nitrogen bubbles[47] that may lead to transient ischemic attack in a diver with PAVM[48] (see Chapter 107).

PULMONARY SEQUESTRATION

Pulmonary sequestration, also called bronchopulmonary sequestration, is a condition with aberrant lung tissue that has no normal connection to the bronchial tree or with the pulmonary arteries and is supplied by a systemic artery. This condition was first described in 1946 by Pryce,[49] who divided this condition into intralobar and extralobar types. In intralobar sequestration, the aberrant tissue is contained within the normal lung; in extralobar sequestration, the aberrant tissue is contained within its own pleural lining. Pulmonary sequestration usually is a congenital abnormality secondary to failure of obliteration of one of the systemic arterial connections to the base of the developing fetal lung, although intralobar sequestration may possibly also be acquired from chronic infection.[50]

INTRALOBAR

Intralobar sequestration is the more common variety and accounts for 75–85% of cases, frequently presenting in adult life as an abnormality detected on imaging or as a cause of recurrent pneumonia. It is usually seen in the lower lobes in the posterior basal segment, more frequently on the left side. In a subset of patients, the intralobar sequestration is associated with partial anomalous venous return, called scimitar syndrome; in this setting, right-sided lesions are more common.[51]

Imaging

Imaging appearances are varied, with two major patterns described depending on the degree of aeration and presence or absence of associated infection. Some of these appear as a solid water-density mass or an area of consolidation; others present as an air-containing single or multicystic lesion. Air likely enters the sequestrated tissue from the surrounding parenchyma through collateral ventilation. With underlying infection, an air-fluid level may be seen on radiograph or cross-sectional imaging. Enhanced CT (Fig. 88.5; also see eFig. 20.21) or magnetic resonance imaging shows the abnormal systemic artery in the majority of these cases. CT also demonstrates the architecture of the sequestrated lung. In some cases, the systemic artery is not seen on cross-sectional imaging and catheter angiography may be required for diagnosis.

EXTRALOBAR

Extralobal sequestration is less common and is seen in 15–25% of cases. It typically manifests in early infancy or in the newborn. The sequestrated segment is most often seen in the left hemithorax between the lower lobe and the diaphragm, although it can be found in the mediastinum, within the diaphragm, or below the diaphragm. Associated congenital anomalies are more frequent with extralobar than with intralobar sequestrations. These happen in approximately 50–60% of patients and may include congenital diaphragmatic hernia, congenital cystic adenomatoid malformation, vertebral defects, congenital heart disease, tracheoesophageal fistula, pulmonary hypoplasia, bronchogenic cyst, and congenital megacolon.

Imaging

Chest radiography shows a well-defined homogenous area of increased opacity in the lower chest silhouetting the posterior medial hemidiaphragm. The diagnosis is usually made on cross-sectional imaging with demonstration of the anomalous feeding artery and draining vein. Usually there is no air bronchogram. Extralobar sequestration may be identified in the mediastinum, pericardium, upper chest, and rarely subdiaphragmatic areas. Communication with the stomach or esophagus has been described and may be demonstrated on an upper gastrointestinal contrast study.

Routine prenatal imaging studies have led to the diagnosis in utero. Ultrasound is useful in the neonatal infant, where typical findings of a uniformly echogenic mass with a hyperechoic rim are demonstrated. Duplex scanning may demonstrate the aberrant arterial and venous connections. On CT,

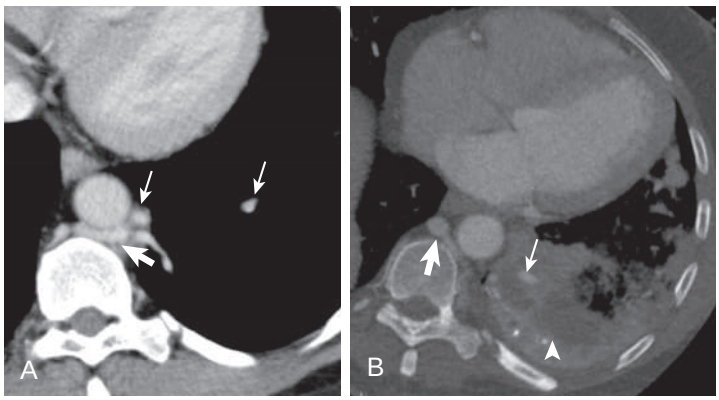

Figure 88.5 Intralobar sequestration. (A) Asymptomatic patient. (B) Symptomatic patient with consolidation (*arrowhead*), a complication of sequestration. *Thin arrows* show the systemic artery arising from the aorta, and the *thick arrows* show the venous drainage.

the extralobar sequestration presents as a homogenous, well-defined mass with soft tissue attenuation (Fig. 88.6), occasionally accompanied by emphysema in the adjacent lung.

TREATMENT

Surgery, usually requiring lobectomy or segmentectomy, is the treatment of choice.[52] Approximately half of adults diagnosed with pulmonary sequestration are asymptomatic. In patients with hemoptysis,[53] selective systemic artery embolization can be helpful preoperatively to decrease intraoperative bleeding.[54] Perinatal management of pulmonary sequestration is typically performed in a hospital environment equipped to provide resuscitation and appropriate treatment for pulmonary hypoplasia.

PULMONARY VEIN VARIX

Pulmonary vein varix (PVV) is defined as focal dilation of a pulmonary vein without an anomalous arterial connection.[55] This condition may be either congenital or acquired. The acquired subtype may be secondary to trauma or increased pulmonary vein pressure resulting from mitral regurgitation, aortic dilation, congenital heart diseases, cirrhosis, or emphysema. When secondary to mitral regurgitation, the right inferior pulmonary vein is most commonly affected, probably due to the direction of the jet, and the dilation may regress after repair of the mitral valve.

CLINICAL PRESENTATION

PVVs are almost always asymptomatic and detected incidentally on imaging. Hemoptysis secondary to rupture or systemic embolization secondary to thrombosis is very rare.[55] PVVs are very rarely clinically significant, but they often require diagnostic imaging to confirm the diagnosis and differentiate the PVV from a PAVM.

IMAGING

Chest radiographs may show a well-defined nodular opacity without calcification or a tortuous tubular structure close to the hilum. As such, the PVV may be mistaken for mediastinal adenopathy.[56] This condition is usually diagnosed on CT (Fig. 88.7) and magnetic resonance imaging.[55-57] If performed, conventional catheter angiography demonstrates a normal pulmonary artery with the tortuous pulmonary varix opacifying at the same rate as normal pulmonary veins, with the varix draining into the left atrium with no left-to-right shunt (Fig. 88.8 and eFig. 88.1, Video 88.4). Although it opacifies at the same time as other veins, the varix usually drains later than normal pulmonary veins.

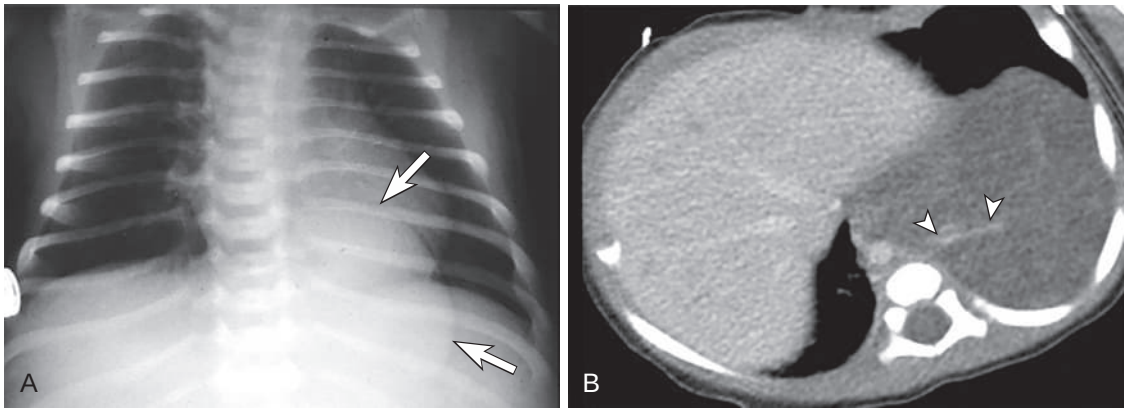

Figure 88.6 Extralobar sequestration. (A) Frontal chest radiograph shows a mass (*arrows*) at the medial left base. (B) Axial enhanced computed tomography shows a homogeneous soft tissue mass in the left posteromedial thorax. Note anomalous systemic artery (*arrowheads*), derived from the descending thoracic aorta, supplying the mass. (Courtesy Michael B. Gotway, MD.)

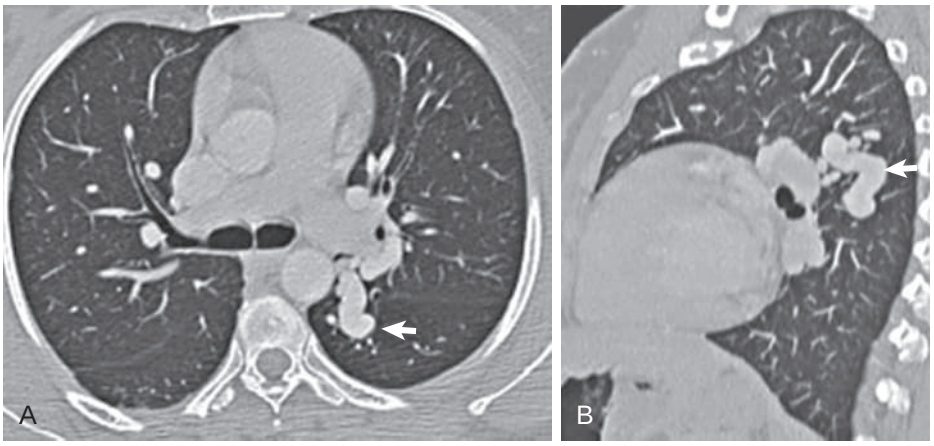

Figure 88.7 Pulmonary vein varix. Axial (A) and sagittal (B) computed tomography shows a varix of a pulmonary vein (*arrow*). It is a dilated tortuous channel draining the left upper lobe via the inferior left pulmonary vein.

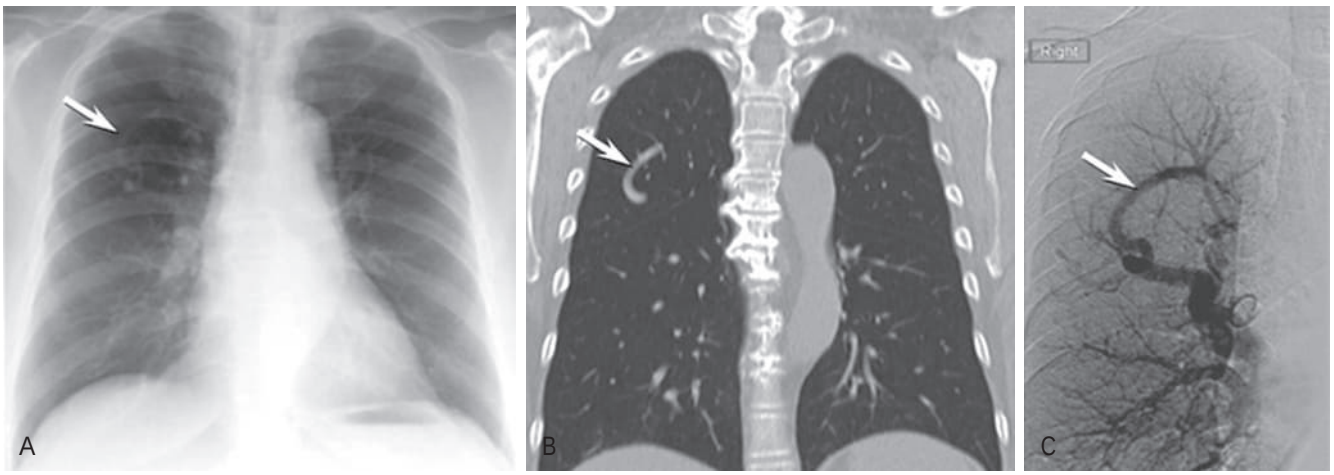

Figure 88.8 Pulmonary vein varix. (A) Frontal chest radiograph, (B) coronal computed tomography, and (C) conventional catheter pulmonary angiogram in the pulmonary venous phase demonstrate a dilated vascular structure. Curvilinear opacity in the right upper lobe with no arterial connection and no shunting is in keeping with pulmonary vein varix.

TREATMENT

Most cases are asymptomatic, considered benign, and require no specific treatment. Rare symptomatic patients may require surgical resection.[56,57]

PULMONARY ARTERY ANEURYSM

Pulmonary artery aneurysm (PAA) is defined by a dilation of the pulmonary artery to at least 1.5 times the normal diameter, involving all three layers of the vessel wall. PAA is an uncommon finding, with an estimated prevalence of 1 in 14,000.[58,59] When fewer than three layers are involved, it is defined as a pseudoaneurysm and is associated with a higher incidence of rupture.[60] Spontaneous dissection or rupture of PAA is rare, although it is described as a complication of catheterization. PAA can be a feature of a broad range of diseases, as detailed in Table 88.1.[61,62]

CLINICAL PRESENTATION

Patients with PAA are typically asymptomatic, and the diagnosis is made incidentally on imaging. Rarely, patients present with hemoptysis.

IMAGING

Chest radiographs have limited value in diagnosis but may demonstrate hilar enlargement or a lung nodule. Cross-sectional imaging, typically CT, is the imaging modality of choice and demonstrates focal pulmonary artery dilation (Figs. 88.9 and 88.10A). Associated mural calcification suggests chronic pulmonary hypertension or calcified intramural thrombus. There may be pulmonary artery wall thickening if the underlying condition is vasculitis. Ground-glass opacities in the adjacent parenchyma suggest associated pulmonary hemorrhage. Other parenchymal changes, including scarring, bronchiectasis, and granulomas, can indicate underlying lung disease. Conventional catheter angiography is generally not required for diagnosis but typically is performed if endovascular treatment is planned (see Figs. 88.10B–C and 88.11).

Table 88.1 Etiology of Pulmonary Artery Aneurysm

VASCULAR
▪ Pulmonary arterial hypertension
▪ Pulmonary valvular or post–valvular stenosis and regurgitation
▪ Cystic medial degeneration
INFECTIOUS
▪ Tuberculosis (Rasmussen aneurysm)
▪ Syphilis
▪ Mycotic (intravenous drug users); may be multiple
TRAUMATIC
▪ Penetrating or blunt thoracic trauma
▪ Iatrogenic, following chest tube insertion and most commonly from Swan-Ganz catheters
AUTOIMMUNE/VASCULITIS
▪ Behçet disease and its variant Hughes-Stovin syndrome; usually multiple
▪ Giant cell arteritis
IDIOPATHIC
CONGENITAL
▪ Left-to-right shunts, most commonly patent ductus arteriosus

TREATMENT

Routine treatment usually involves management of the underlying cause. PAA associated with vasculitis may regress with immunosuppressive treatment. If the patient presents with hemoptysis, emergency management includes airway stabilization followed by endovascular treatment, usually embolization (Figs. 88.10C and 88.11B). Central or large PAA may need surgical treatment, including excision and patch angioplasty. Endovascular management, including use of stent grafting, has been described.

ANOMALIES OF SYSTEMIC ARTERIAL SUPPLY

Systemic arterialization of the lung without bronchopulmonary sequestration is a rare form of anomalous systemic arterial supply[63] to the lung. It is characterized

by an aberrant systemic arterial branch arising from the descending thoracic aorta and, less commonly, from the upper abdominal aorta or its branches, with a normal bronchial system (i.e., pseudosequestration). The etiology[64] of this anomaly is considered to be a persistent remnant of the embryonic connection between the aorta and the pulmonary parenchyma. The normal lung can be supplied either by an entirely systemic arterial source or by both systemic plus pulmonary arterial sources (dual supply). Anomalous systemic arterial supply may also be seen in patients with chronic pulmonary parenchymal inflammation.[65] In these patients, in addition to hypertrophy of the preexisting connection[66] between the bronchial and pulmonary arteries (eFig. 88.2), transpleural systemic to pulmonary artery anastomoses develop, especially in the presence of pleural adhesions (Fig. 88.12).

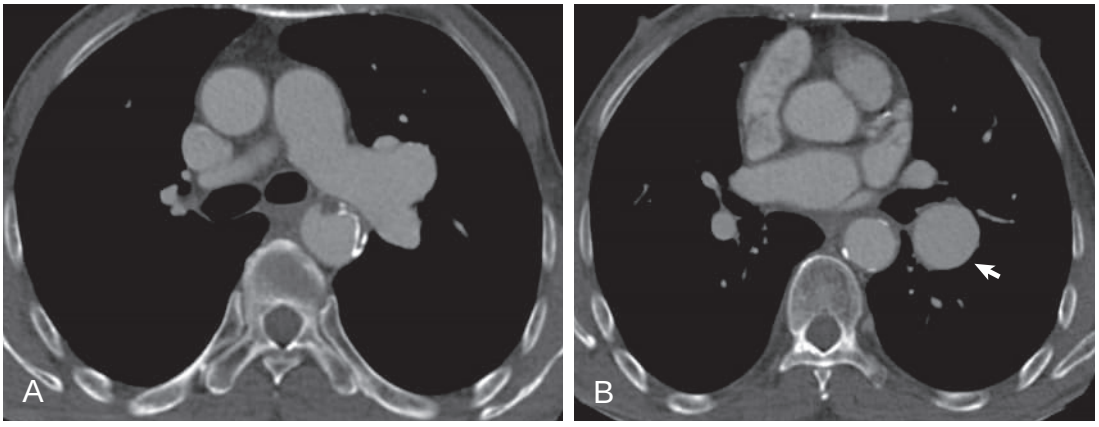

Figure 88.9 Pulmonary artery aneurysm. Axial computed tomography at the level of left hilum (A) and at the left atrial appendage level (B) shows aneurysmal dilation of the left pulmonary artery (*arrow*) in a patient with pulmonic stenosis.

Figure 88.10 Pseudoaneurysm (Rasmussen aneurysm). (A) Axial enhanced computed tomography shows a pseudoaneurysm (*arrow*) arising from an upper lobar branch of the left pulmonary artery, bulging into a large cavity. (B–C) Catheter angiogram confirms the pseudoaneurysm (*arrow*, B), which was occluded using several coils.

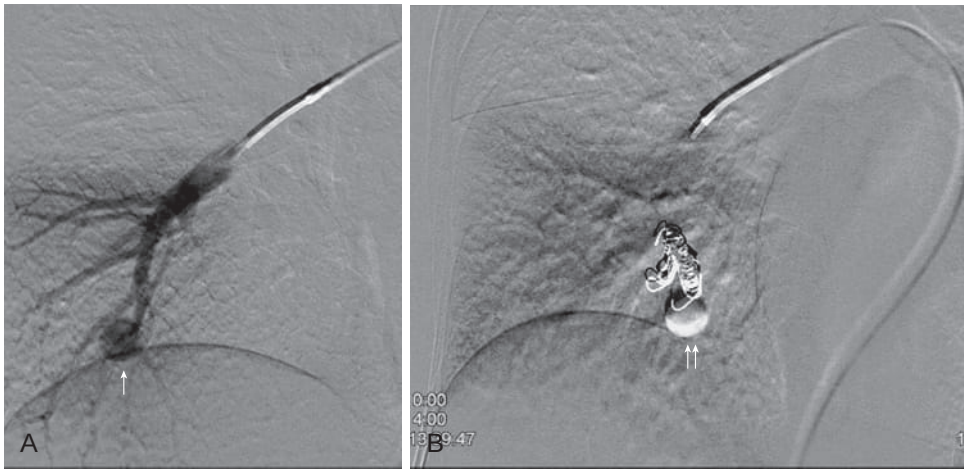

Figure 88.11 Pulmonary artery aneurysm. Catheter pulmonary angiogram shows a pulmonary artery aneurysm (*arrow*) that was embolized using coils. Note the stagnant pool of contrast in the sac (*double arrows*).

Figure 88.12 Systemic arterial supply. Selective bronchial angiogram in a patient with remote tuberculosis and aspergilloma presenting with hemoptysis. Note extensive parenchymal vascularity with hypertrophied right bronchial artery (*thick arrow*) and very prominent pulmonary artery shunting (*thin arrow*).

CLINICAL PRESENTATION

Most patients are asymptomatic and the anomaly is noted incidentally on imaging. When symptomatic, the typical presentation is massive hemoptysis and, less frequently, hemothorax. The proposed explanation for the hemoptysis is the higher pressure of systemic circulation generated in the abnormally perfused segments, resulting in intra-alveolar hemorrhage. Rarely, patients may present with dyspnea, a bruit over the chest, or cardiac symptoms related to left-to-right shunting. These lesions are not typically associated with right-to-left shunting and its related complications.

IMAGING

Chest radiographs may demonstrate tortuous vessels, but only when the anomalous systemic arterial supply vessel is large in caliber. CT is the most common imaging modality and can confirm the diagnosis and the specific vascular anatomy (see Figs. 88.13A and 88.14). Catheter angiography may be needed for confirmation (Figs. 88.13B–C and eFig. 88.3, Video 88.5). Anomalous systemic arterial supply

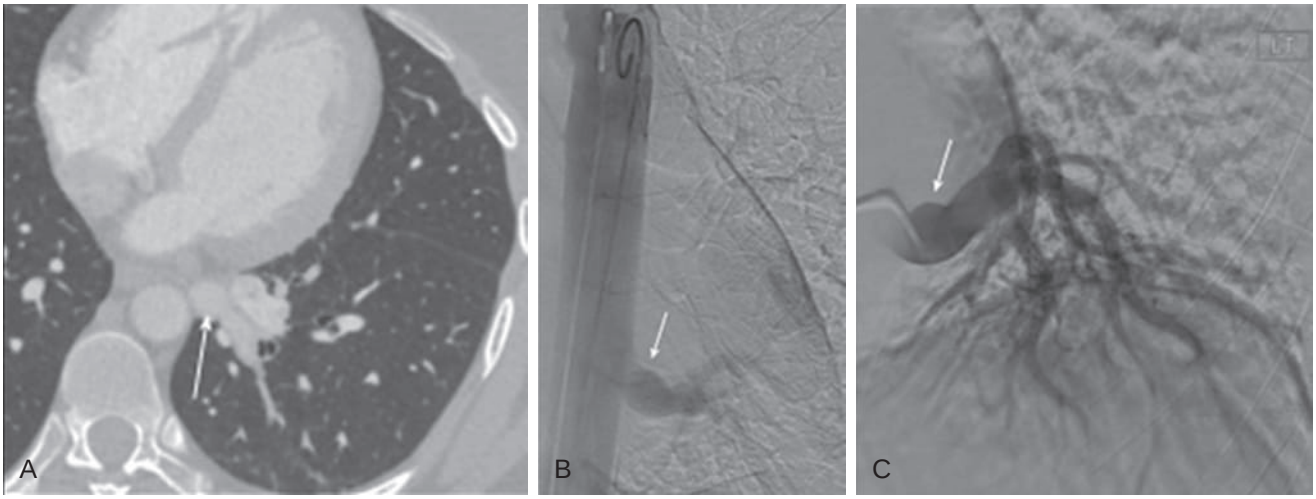

Figure 88.13 Systemic arterial supply to the left lower lobe. (A) Axial contrast-enhanced computed tomography shows an aberrant artery (*arrow*) arising from the descending thoracic aorta with normal bronchial tree. (B) Flush descending thoracic catheter angiogram and (C) selective angiogram show the aberrant artery arising from the aorta (*arrow*) and supplying the lung parenchyma.

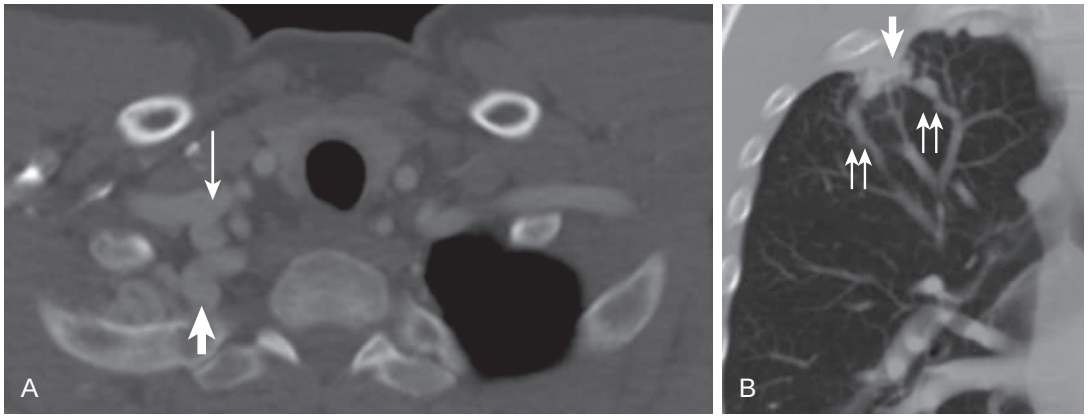

Figure 88.14 Systemic arterial supply. Contrast-enhanced axial (A) and coronal (B) computed tomography shows the right subclavian artery (*thin arrow*) and, from it, an anomalous systemic branch (*thick arrow*) drains into the pulmonary artery branch (*double arrows*).

can mimic a PAVM, although the anatomy can usually be clarified on CT. When pulmonary arterial supply is suspected, contrast echocardiography (as described above) can be helpful in ruling out right-to-left shunting. Echocardiography can also be helpful in ruling out pulmonary hypertension and associated cardiac anomalies.

In cases of massive hemoptysis, CT may help localize the site of bleeding and may also identify the underlying cause, as well as the presence of hypertrophic bronchial or systemic arteries supplying the parenchyma.[67]

TREATMENT

Asymptomatic systemic (bronchial) to pulmonary artery shunt rarely requires treatment. Surgical or endovascular treatment has been used in symptomatic cases. Usual indications for treatment include hemoptysis, heart failure, and high-flow pulmonary hypertension. Angiography with embolization of the abnormal vessels is the preferred method of management.[68,69] Although rare, inadvertent spinal artery embolization resulting in transverse myelitis is a potential serious complication, typically when there is an unrecognized spinal artery arising from the intercostal or bronchial arteries. In 80–90% of cases, control of hemoptysis is achieved with embolization, with 20% rebleeding in the first 6 months and another 50% on longer follow-up.[70] Although this procedure is not curative and there is always a risk for further bleeding, embolization can be repeated several times if needed. Surgery is reserved for selective cases, such as mycetoma, and may involve segmentectomy, lobectomy, or pneumonectomy.[71]

Key Points

- Pulmonary vascular anomalies are diverse, but can lead to massive hemoptysis or specific complications related to shunting.
- *Pulmonary arteriovenous malformation* (PAVM) is the most common anomaly, and the vast majority are due to underlying hereditary hemorrhagic telangiectasia.
- PAVM often presents with complications of the right-to-left shunting of blood, including stroke, transient ischemic attack, or brain abscess; in addition, it may present with massive hemoptysis or spontaneous hemothorax.
- Transthoracic contrast echocardiography is the first-line screening test for PAVM, with chest computed tomography recommended for confirmation.
- Transcatheter embolization is the treatment of choice for PAVM. Patients should be followed for reperfusion of PAVM, which is seen in up to 30% of cases. Even after treatment, precautions include antibiotic prophylaxis, air-eliminating intravenous filters for intravenous catheters, and avoidance of scuba diving.
- Less common causes of pulmonary vascular anomaly include pulmonary sequestration (intralobar and extralobar), pulmonary vein varix, and systemic arterial supply to the lung.

INTRODUCTION

This first chapter in the section on infiltrative and interstitial lung diseases is focused on *idiopathic pulmonary fibrosis* (IPF), a disease characterized by progressive parenchymal fibrosis of unknown cause. The term *interstitial lung disease* (ILD) refers to a heterogeneous group of diffuse parenchymal infiltrative disorders that impair the gas exchange function of the lung by disrupting the alveolar walls. In many ILDs, lung regeneration fails and interstitial fibrosis resulting from fibroblastic proliferation and excessive collagen deposition is the dominant pathologic process as a reparative response to injury of the gas-exchanging units. However, nonfibrotic processes can also cause ILDs by abnormal infiltration of the lung parenchyma (interstitium and/or alveolar spaces) by cells (e.g., eosinophils, histiocytes) or substances (e.g., amyloid). Thus ILDs comprise a broad spectrum of disorders of varying etiology with some similarities in clinical, imaging, physiologic, and pathologic features. In most ILDs, the pathologic involvement is not restricted to the "interstitium" (i.e., the anatomic space between the basement membranes of the alveolar epithelium and capillary). Some develop from identifiable causes or arise in the context of systemic diseases, such as connective tissue disease, whereas others remain idiopathic.

The exact prevalence and incidence of ILDs are unknown. Studies suggest a prevalence of 81 in 100,000 for men compared with 67 in 100,000 for women.[1,2] Similarly, the overall incidence of ILD is slightly higher in men (32 per 100,000 annually) than in women (26 per 100,000 annually) and increases with age. In the United States, the mortality rate from ILDs increased twofold from 1980 to 2014.[3]

Classification of ILDs can be based on several parameters including etiology, clinical features, histopathology, or pattern of radiologic abnormalities. A classification of ILDs based on the presence or absence of an identifiable cause (including underlying systemic disease) is likely the most practical option for clinicians and is shown in Table 89.1.[4] Alternative methods of classifying ILDs based on clinical, histopathologic, or radiologic parameters are less clinically useful because similar features can result from different ILDs (see Table 90.2). For example,

Table 89.1 Classification of Interstitial Lung Diseases

Known Cause	Unknown Cause
Connective tissue disease-related ILDs Environmental and occupational ILDs Drug- and radiation-related ILDs Smoking-related ILDs Rare forms (lymphangioleiomyomatosis, pulmonary alveolar proteinosis, amyloidosis, alveolar microlithiasis, heritable disorders, etc.)	Idiopathic pulmonary fibrosis and other IIPs Sarcoidosis Idiopathic eosinophilic pneumonias Vasculitis Rare forms (IgG4-related disease, Erdheim-Chester disease, etc.)

Ig, immunoglobulin G; IIP, Idiopathic interstitial pneumonia; ILD, interstitial lung disease.

the histopathologic pattern of *usual interstitial pneumonia* (UIP), a hallmark of IPF, can be seen in other ILDs such as chronic hypersensitivity pneumonitis, drug-induced ILD, connective tissue disease–associated ILD, and asbestosis. In other words, multiple clinical entities may result in similar histologic appearances.

A specific diagnosis can be made in many patients presenting with ILD based on the results of a careful history, physical examination, laboratory tests, and imaging findings.[4,5] Although the diagnosis of ILD due to occupational exposure, a medication, or a connective tissue disease may be obvious, idiopathic ILDs can be more difficult to diagnose using clinico-radiologic parameters alone. Bronchoscopy with *bronchoalveolar lavage* (BAL) and transbronchial biopsy can be useful in the diagnosis of some ILDs.[6] In some cases, surgical lung biopsy (thoracoscopic or open) may be required for a definitive diagnosis.[7-9] The goal of the diagnostic evaluation is to determine the cause or underlying disease whenever possible or, if not, at least a working diagnosis that allows reasonable prognostication and a management plan for the individual patient.

APPROACH TO PATIENTS WITH SUSPECTED INTERSTITIAL LUNG DISEASE

The hallmarks of an ILD are progressive dyspnea and cough, abnormal chest imaging, and impaired pulmonary function results.[4,5] The initial evaluation of a patient with suspected ILD is focused on confirming the presence of ILD, gauging the tempo of the process (duration of symptoms), and obtaining clues as to the underlying cause.[4] This is performed by assessment of demographics and findings gathered from history taking, physical examination, chest imaging, and laboratory tests. It should be noted that 5–10% of symptomatic patients eventually diagnosed as having ILD have normal chest radiographs at the time of presentation. There are also dyspneic patients with or without abnormal chest radiographs in whom routine pulmonary function tests (flows, volumes, and diffusing capacity) are normal. Some patients with ILD (e.g., sarcoidosis) on chest imaging may have no associated symptoms or pulmonary function abnormalities.

CLINICAL ASSESSMENT

Taking a careful history is of paramount importance in identifying the clinical manifestations and their temporal evolution as well as potential cause for the lung disease including exogenous agents and hereditary disorders. Persistent cough and progressively worsening exertional dyspnea are common presenting symptoms but are nonspecific and can be a feature of many pulmonary and nonpulmonary disorders. The presence of extrapulmonary symptoms may lead to the diagnosis of connective tissue disease–associated ILD. Symptoms of *gastroesophageal reflux* (GER) may suggest aspiration-related ILD.[10,11]

There are some clinical presentations characteristic of certain ILDs. For example, spontaneous pneumothorax can be the presenting manifestation or *pulmonary Langerhans cell histiocytosis* (PLCH) (see Chapter 95) or lymphangioleiomyomatosis (tuberous sclerosis–related or sporadic forms) (see Chapter 97). Hemoptysis is typical for the diffuse alveolar hemorrhage syndromes (see Chapter 94).

Symptoms in many patients with ILDs are present for months to years (i.e., chronic) and progress at varying rates. However, some ILDs are acute (days to several weeks) in presentation and often misdiagnosed as community-acquired or atypical pneumonia. Examples of acute ILDs include acute interstitial pneumonia (Hamman-Rich syndrome) (see Chapter 90), acute eosinophilic pneumonia, diffuse alveolar hemorrhage syndromes, and acute presentations (acute exacerbation) of IPF, hypersensitivity pneumonitis, drug-related ILDs, cryptogenic organizing pneumonia, and connective tissue disease–associated ILD.

Eliciting a history of tobacco use as well as of electronic cigarettes is important. Most adults presenting with PLCH, respiratory bronchiolitis, or desquamative interstitial pneumonia are smokers.[12,13] Smoking is a risk factor for rheumatoid arthritis-related ILD.[13] A subset of acute eosinophilic pneumonia is smoking-related.[14] Conversely, hypersensitivity pneumonitis infrequently appears in the active smoker.[15]

The occupational and environmental history is of obvious importance. It should be thorough and detailed because a long latency period (e.g., asbestosis) may occasionally exist between exposure and the appearance of clinical impairment and disability. Hypersensitivity pneumonitis (see Chapter 91) can manifest either as recurrent acute or subacute pneumonitis or as an insidious chronic form with slowly progressive dyspnea.

A review of the medications used in the recent and distant past is important. Uncommonly, lung disease may appear weeks to years after the drug has been discontinued (see Chapter 99). The medication history should include over-the-counter medications. For example, the nocturnal use of oily nose drops or use of mineral oil as a laxative should lead to the consideration of exogenous lipoid pneumonia.[16]

Family history is relevant for recognizing ILDs related to hereditary disorders such as tuberous sclerosis, and neurofibromatosis. Familial associations have also been identified in cases of IPF (see "Familial Pulmonary Fibrosis" later) and sarcoidosis.[17] Niemann-Pick disease, Gaucher disease, and Hermansky-Pudlak syndrome are inherited in an autosomal recessive fashion.[18]

There are ILDs with a sex predilection. Sporadic lymphangioleiomyomatosis arises almost exclusively in women. In addition, many connective tissue diseases (see Chapter 92) more commonly affect women. Occupation-related pneumoconioses are more likely in men. However, transmission of inorganic dust, either from clothes or by living in the vicinity of a manufacturing or mining facility, has resulted in asbestosis and chronic beryllium disease in women, children, and men not employed in the industry. IPF is usually encountered in middle-aged to elderly subjects and is unusual in those younger than 50 years, while sarcoidosis is typically seen in younger patients.

The most common physical finding in patients with ILD is bibasilar inspiratory crackles. For example, nearly all patients with IPF will manifest this finding. Crackles are less likely in granulomatous diseases such as sarcoidosis. Clubbing of the digits, which in most cases indicates advanced fibrotic disease, is a common finding in patients with IPF. However, the new appearance of digital clubbing in a patient with an established case of ILD could indicate an underlying bronchogenic carcinoma. With advanced fibrosis causing chronic hypoxemia, clinical signs of pulmonary hypertension and right heart dysfunction appear. Attention to extrapulmonary physical findings such as skin lesions or cardiac findings may lead to a specific diagnosis.

CHEST IMAGING

Although standard chest radiography is not as sensitive for detection of ILD as the *high-resolution computed tomography* (HRCT) scan, it is the logical starting point and the initial way of identifying and defining disease. Chest radiography allows for the initial assessment of pattern and distribution of parenchymal abnormalities and associated features such as pleural effusion or mediastinal lymphadenopathy. The predominant type of parenchymal abnormalities can be categorized as reticular or linear, nodular (small nodules), combination of linear opacities and nodules ("reticulonodular" opacities), consolidation (characterized by confluent opacities with ill-defined outer borders, air bronchograms, and obliteration or silhouetting of normal structures such as the diaphragm, heart, and intrapulmonary blood vessels), ground-glass (hazy increased opacity in which pulmonary vessels are visible but indistinct), and cystic. Linear or reticular interstitial changes are seen in most ILDs, including IPF, and are generally more prominent in the lower lung zones (Fig. 89.1).

Aside from the dominant pattern of parenchymal abnormalities, the distribution and associated findings may provide clues as to the diagnosis. For example, some ILDs characteristically present with radiographic changes that are more prominent in the upper lung zones.[4,19,20] These ILDs include sarcoidosis, PLCH, silicosis, coal worker's pneumoconiosis, and carmustine-induced pulmonary fibrosis.[4,20] Pneumothorax is often the presenting manifestation of PLCH or lymphangioleiomyomatosis. Calcified pleural plaques in a patient with interstitial opacities is indicative of asbestos-related lung disease. Pleural thickening and pleural effusion may complicate the course of the connective tissue–associated ILDs.

In patients with suspected ILD, HRCT of the chest (see Chapter 20) is more sensitive than chest radiography and enables better visualization of parenchymal details, their distribution, and associated findings (e.g., mediastinal lymphadenopathy).[4,21,22] In some ILDs, the clinical context and characteristic features seen on HRCT may be sufficient to establish a diagnosis without the need for a lung biopsy. For example, the presence of rounded, thin-walled cysts diffusely throughout both lungs in a woman with tuberous sclerosis complex is diagnostic of lymphangioleiomyomatosis and histopathologic confirmation is not necessary.

Figure 89.1 Frontal chest radiograph in a patient with idiopathic pulmonary fibrosis. Peripheral basal predominant reticulation is seen consistent with fibrotic lung disease. Note diminished lung volumes. (Courtesy Michael B. Gotway, MD.)

PULMONARY FUNCTION TESTING

Assessment of ventilatory function and the mechanical properties of the lungs, as well as gas exchange, particularly during exercise, are vital components of the initial evaluation of patients with suspected ILD (see Chapters 31–33). Although limited in diagnostic usefulness, the pulmonary function results are an important component of assessing the severity of ILD. In addition, serial measurements of function enable the physician to determine progression of the disease and the response to therapeutic interventions.

Most patients with ILDs manifest a restrictive pulmonary impairment with a reduced *diffusion capacity for carbon monoxide* ($D_{L_{CO}}$). In most patients, gas exchange is disturbed during exertion, even in those with normal gas exchange at rest. In early or mild ILD, however, pulmonary function results may be entirely normal. Obstructive pattern of impairment is commonly seen in some ILDs, including PLCH, lymphangioleiomyomatosis, sarcoidosis, and ILD superimposed on preexisting COPD/emphysema.

LABORATORY TESTS

Laboratory tests performed in patients with suspected ILD generally include a complete blood count with differential leukocyte counts, metabolic panel, and urinalysis. Anemia is frequently seen in patients with diffuse alveolar hemorrhage syndromes. Peripheral eosinophilia raises suspicion for eosinophilic pneumonias or drug reactions.

Hypercalcemia is often seen in patients with sarcoidosis. Abnormal urinary sediment suggests possible pulmonary-renal syndrome such as systemic vasculitis.

Serologic testing for connective tissue disease, vasculitis, or hypersensitivity pneumonitis may be useful depending on the clinical context and imaging findings. Serologic results should be interpreted judiciously. For example, elevated serum precipitins to certain environmental fungi indicate exposure and sensitization but do not confirm the diagnosis of hypersensitivity pneumonitis. Similarly, positive autoimmune serologic results need to be correlated to the clinical context to decipher their relevance.

BRONCHOALVEOLAR LAVAGE

BAL is a technique used to sample the distal airways via the instillation of sterile saline through a wedged fiberoptic bronchoscope (see Chapter 26). After aspiration, the contents, which are thought to represent the cellular, immunologic, and biochemical milieu of the alveolar structures, can be analyzed. The results of BAL for the evaluation of ILD have been difficult to interpret because of the prior lack of standardized techniques for both the performance of the procedure and the subsequent analysis of the data.[23-25] Furthermore, in some of the earlier studies, correlative data between BAL and lung biopsies were not obtained. Often, the treatment or smoking status of the patient was not considered.[26]

BAL can be a useful tool in evaluation of ILDs depending on the clinical context.[25] Cytologic analysis of BAL fluid can be diagnostic for malignancies and infections that mimic ILD in presentation. The finding of cloudy BAL fluid containing numerous periodic acid-Schiff–positive lipoproteinaceous bodies is seen in pulmonary alveolar proteinosis. Increased number of Langerhans cells (>5%) in BAL fluid supports the diagnosis of PLCH.[25,27] In cases of diffuse alveolar hemorrhage, red blood cells and hemosiderin-laden macrophages dominate the BAL specimen.

The differential cell profile in BAL has limited value in diagnosing specific ILDs.[25] For example, BAL lymphocytosis (>15% lymphocytes) predominates in some ILDs including sarcoidosis and hypersensitivity pneumonitis but can also be seen in many other entities including lymphocytic interstitial pneumonia, cryptogenic organizing pneumonia, pulmonary lymphoma, chronic beryllium disease, and some drug-induced or connective tissue disease–related ILDs.[25] An eosinophil level in BAL of 25% or more (normal, <2%) suggests eosinophilic pneumonia.

Other attempted applications of BAL in ILDs have included assessment of disease activity, therapeutic responsiveness, and prognosis. For example, some studies have correlated BAL lymphocytosis with a cellular histology (as opposed to fibrosis) and an improved response to treatment.[23-26] However, more recent data indicate that BAL cellular analysis has very limited value in predicting response to therapy or prognosis.[25]

LUNG BIOPSY

The final step in the evaluation of a patient with ILD is to decide whether histologic evaluation is necessary for diagnosis. As previously noted, the diagnosis of connective tissue, occupational, or drug-related ILD is often obvious after a careful history has been taken. In cases of idiopathic ILDs (see Table 89.1), the diagnosis may not be easily reached. If the clinical, imaging, and laboratory results are inconclusive, lung histopathology may be needed to reach a specific ILD diagnosis (see Table 90.3).

Transbronchial biopsy (see Chapter 26) has traditionally been performed using forceps via flexible bronchoscope and yields specimens that measure in the range of 2 to 3 mm in diameter. This procedure is relatively safe and often diagnostic in certain ILDs including sarcoidosis, diffuse malignancy, pulmonary alveolar proteinosis, and eosinophilic pneumonias.[6] Other entities, such as IPF, are less frequently confirmed by this procedure.

In recent years, a new method of bronchoscopic lung biopsy has emerged. Transbronchial cryobiopsy employs a cryoprobe and has the advantage of yielding larger specimens (≥5 mm) with less crush artifact.[28-30] However, this procedure is associated with a higher rate of bleeding and pneumothorax compared to forceps biopsy. Although the role of transbronchial cryobiopsy in the evaluation of ILD remains to be clarified, it seems likely that the use of this procedure will expand in the coming years.

The definitive method of obtaining lung tissue in the diagnostic evaluation of ILD is surgical lung biopsy, more commonly performed via video-assisted thoracoscopic surgery than thoracotomy.[4,5,31-33] However, the use of surgical lung biopsy for evaluation of ILD has been declining in recent years, in part due to concerns regarding associated morbidity and mortality.[34,35] The benefits and risks of surgical lung biopsy need to be weighed in individual patients with consideration of their personal preferences in reaching a decision regarding this procedure.

IDIOPATHIC PULMONARY FIBROSIS

Among ILDs, there is a subset of disorders referred to as *idiopathic interstitial pneumonias* (IIPs) (see Chapter 90) that comprise a heterogeneous group of diffuse parenchymal lung diseases characterized by varying patterns of inflammation and fibrosis.[32,36] Although each IIP manifests characteristic histopathology, it is crucial to be aware that the histologic pattern underlying these IIPs can also be encountered in subjects with known causes for their lung disease (e.g., connective tissue diseases, smoking, drugs). Thus the UIP pattern can be seen not only in patients with IPF but also in patients with rheumatoid arthritis (i.e., rheumatoid arthritis–related ILD (see Table 90.4).[36,37] Some interstitial pneumonia patterns are more specific with respect to etiology. For example, respiratory bronchiolitis–associated ILD in most patients is caused by smoking.[32]

IPF is the most common form of IIP and accounts for 20–30% of ILDs.[2,38,39] It is associated with characteristic clinical, radiographic, physiologic, and pathologic manifestations but is also a diagnosis of exclusion.[33,40,41] Epidemiologic studies indicate steadily increasing mortality from IPF worldwide.[42]

Figure 89.2 Usual interstitial pneumonia pattern often shows a striking subpleural distribution. This low-power photomicrograph is from an area without the usual remodeling of the lung architecture with cystic (honeycomb) changes. The visceral pleura is at the bottom of the image. (Courtesy Thomas V. Colby, MD, Mayo Clinic, Scottsdale, AZ.)

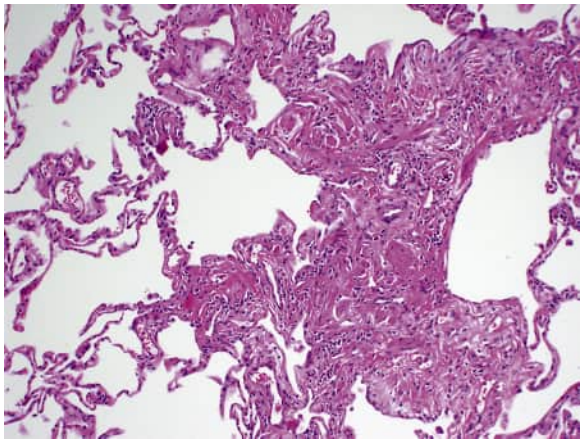

Figure 89.3 Photomicrograph of usual interstitial pneumonia. Residual lymphoplasmacytic inflammation and collagen deposition are seen broadening alveolar walls. (×10 original magnification.)

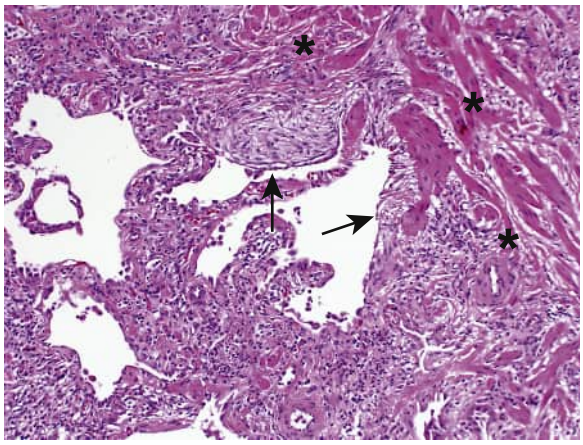

Figure 89.4 Photomicrograph of usual interstitial pneumonia. Two fibroblastic foci of loose organizing connective tissue *(arrows)* are seen adjacent to an area of dense fibrosis *(asterisks).* (Courtesy Thomas V. Colby, MD, Mayo Clinic, Scottsdale, AZ.)

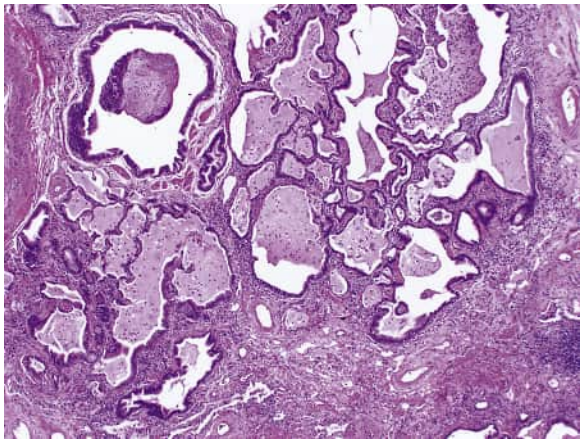

Figure 89.5 Photomicrograph of honeycomb lung in idiopathic pulmonary fibrosis. There is total disruption of the lung architecture by bands of fibrous tissue forming cystic spaces. The spaces are lined by metaplastic epithelium. (×10 original magnification.)

EPIDEMIOLOGY

The incidence and prevalence of IPF are not fully defined. A systematic review analyzing data from population-based studies in 1968 to 2012 estimated an incidence range of 3 to 9 cases per 100,000 per year for Europe and North America.[43] In a study using "narrow" case-finding criteria, the incidence of IPF in the United States was estimated to range from 0.4 to 27 per 100,000 persons; comparable figures for prevalence were 0.8 to 65 per 100,000 persons.[39] Both the incidence and the prevalence of IPF increase markedly with age, particularly over 75 years.[39]

GROSS APPEARANCE AND HISTOPATHOLOGY

The gross appearance of the lungs in IPF reveals a distinctive nodular pleural surface, sometimes resembling cirrhosis of the liver, due to contraction of the fibrotic septa. Cut sections show scarring and often abnormal cystic regions of honeycombing, typically with a lower lung zone and subpleural distribution. The histopathologic pattern seen in IPF is UIP. UIP is characterized by a pattern quite distinguishable even on low-power magnification because of its characteristic heterogeneous, predominantly subpleural and paraseptal distribution (Fig. 89.2). This striking heterogeneity is characterized by the presence of regions of residual normal or nearly normal lung tissue interspersed among extensively scarred parenchyma, which may show microscopic (i.e., not obvious grossly) honeycombing characterized by enlarged air spaces lined by bronchiolar epithelium, often filled with mucin and variable numbers of acute inflammatory cells. Abutting more densely (i.e., older) scarred areas of lung, one finds discrete active (i.e., more recent) proliferations of fibroblasts and myofibroblasts (Figs. 89.3 to 89.5).[33,36,37] These discrete areas of fibroblastic proliferation have been termed *fibroblastic foci* and are essential to the histopathologic diagnosis of UIP[37] (see Fig. 89.4), and are a reflection of active and ongoing fibroplasia. Fibroblastic foci are composed of small convex or dome-shaped collections of spindle-shaped fibroblasts and

myofibroblasts within myxoid stroma, covered by hyperplastic alveolar lining cells. Generally, interstitial chronic inflammation away from foci of honeycombing is minimal in UIP; if chronic interstitial inflammation is present in significant amounts, the diagnosis of IPF should be reconsidered and other causes of a UIP pattern such as chronic HP and collagen vascular disease should be considered. However, chronic inflammation, lymphoid aggregates with germinal centers, and even acute inflammation may be prominent around honeycomb areas, likely related to poor clearance from the areas of scarred lung.[37]

ETIOLOGIC FACTORS AND PATHOGENIC MECHANISMS

A widely held hypothesis is that IPF develops in susceptible individuals following some unknown stimulus that initiates an uncontrolled epithelial-driven cascade of events that evolve to the fibrotic process.[44] Several potential risk factors for the development of IPF have been identified. Smoking presents the most significant association with IPF, particularly for individuals who were ever smokers, with odds ratios varying from 1.6 to 9.4.[45] The same association has been found in familial pulmonary fibrosis.[46] Some occupational and environmental exposures—primarily to wood and metal dusts—have also shown increased association with IPF.[45] The presence of Epstein-Barr virus found in some patients has led to speculation that chronic viral infection might play a role in the etiology of IPF,[47] but this virus has also been found in other fibrotic lung diseases, as well as in many controls. The lungs of patients with IPF have higher bacterial loads and substantial differences in the composition and diversity of their microbiota compared with control subjects. However, the role of bacteria in the development and/or progression of IPF remains unclear.[48] A higher incidence of GER has been found in patients with IPF.[49] GER is frequent, however, in the normal population, as well as in patients with other advanced lung diseases, including cystic fibrosis, COPD, and fibrosis associated with scleroderma.[50]

The role of host genetic factors and their interactions with environmental factors leading to IPF is being elucidated. The first gene association revealed that a common polymorphism in the promoter region of the *MUC5B* gene increased the risk for sporadic IPF as well as familial pulmonary fibrosis, although the link with disease pathogenesis is unclear.[51,52] Paradoxically, it has been suggested that this polymorphism in *MUC5B* may be associated with improved survival.[53]

After this discovery, several large genome-wide association studies have revealed and confirmed a number of gene variants as risk factors, including in *MUC5B*, components of telomerase (telomerase reverse transcriptase, telomerase *ribonucleic acid* [RNA]), desmoplakin, and toll interacting protein, indicating that genes involved in host defense, epithelial integrity, DNA repair, and senescence increase the risk of developing the disease.[54-57]

One of the intriguing observations regarding IPF is that the disease is clearly associated with aging; it usually appears in individuals older than 50 years, reaching a peak in subjects of 60 to 65 years old.[44] Actually, most of the hallmarks that characterize the aging process have been identified in IPF lungs, including abnormal shortening of telomeres, genomic instability, mitochondrial dysfunction, increased oxidative stress, loss of proteostasis (i.e., homeostasis of proteins in the cell), and cellular senescence, supporting the notion that aging is a driving force of the disease.[58,59] These alterations have been revealed primarily in epithelial cells. For example, severely short telomeres, dysmorphic and dysfunctional mitochondria, and accumulation of damaged DNA have been found in alveolar epithelial cells, indicating that these cells may be the main culprit in this pathologic process.[58-61] Telomeres play a central role in cell fate and aging by adjusting the cellular response to stress and growth stimulation on the basis of previous cell divisions and DNA damage; their shortening has been associated with aging and several diseases.[62]

An important advance in our understanding of ILD has been the recognition that UIP appears to be a distinct pathophysiologic entity characterized by minimal inflammation and chronic fibroproliferation due to abnormal parenchymal wound healing.[63] This paradigm suggests that the pathologic process of UIP is the result of persistent remodeling (abnormal wound healing) of the lung parenchyma. Multiple "microinjuries" damage and activate alveolar epithelial cells, which in turn provoke a profibrotic microenvironment.[58,63] Single-cell RNA sequencing has identified unique differentiation states and gene expression patterns of epithelial cells in this disease with the up-regulation of several profibrotic pathways including HIPPO/YAP, TGF-β, and PI3K/AKT signaling pathways.[64] Accordingly, alveolar epithelial cells secrete growth factors and induce migration and proliferation of fibroblasts and differentiation into myofibroblasts. Aggregates of subepithelial fibroblasts-myofibroblasts (fibroblastic foci) and alveolar epithelial cells produce matrix-metalloproteinases 2 and 9 that may increase basement membrane disruption and allow fibroblast-myofibroblast migration into the alveolar spaces. In addition, alveolar epithelial cells induce an antifibrinolytic environment in the alveolar spaces, enhancing wound clot formation. Current evidence suggests that the epithelial assembly of the tissue factor complex (TF/FVIIa/FX) leading to factor X activation is the predominant mechanism by which the coagulation cascade is locally activated in the lungs of patients with pulmonary fibrosis.[64] Both intra-alveolar and interstitial myofibroblasts secrete extracellular matrix proteins, mainly collagens. Matrix stiffness and mechanical forces play critical roles in the progression of IPF contributing to the direct activation of myofibroblasts through mechanotransduction signaling pathways, and by integrin-mediated activation of latent TGF-β1.[65,66]

Signals responsible for myofibroblast apoptosis seem to be absent or delayed in UIP, increasing cell survival.[67] In addition to extracellular matrix proteins, these myofibroblasts produce angiotensinogen and hydrogen peroxide, which have been implicated in alveolar epithelial cell death, further impairing reepithelialization.[68,69] Although the molecular mechanisms that lead to end-stage pulmonary fibrosis are poorly understood, data support this "abnormal wound healing" hypothesis in UIP. At least in part, the abnormal communication between alveolar epithelial cells and myofibroblasts may be provoked by an aberrant recapitulation of embryologic programs.[59,70-72]

FAMILIAL PULMONARY FIBROSIS

While most cases of IPF are sporadic, pulmonary fibrosis in two or more first-degree relatives within the same biologic family may account for 2–20% of the cases overall.[73] Importantly, *familial pulmonary fibrosis* (FPF) has been associated with multiple pathologic subsets of idiopathic interstitial pneumonias (e.g., UIP [the most frequent in adults], *nonspecific interstitial pneumonia* [NSIP], and unclassifiable lung fibrosis), as well as to nonidiopathic interstitial pneumonias such as hypersensitivity pneumonitis, and connective tissue disease–related interstitial fibrosis. Moreover, discordant forms of interstitial lung disease have been found in affected individuals from 50–80% of studied families.[46,74]

The clinical, radiographic, physiologic, and morphologic manifestations of familial IPF/UIP are indistinguishable from the sporadic form of the disease, although those associated with mutations affecting telomere biology tend to present it at a younger age.[75] Geographic clustering of patients with familial IPF has been noted, suggesting a "recent founder effect," the nonrandom genetic sampling when a population derives from a small number of individuals.[76,77]

Several rare variants (defined as those with minor allele frequency of <0.1%) have been found associated with FPF. However, at present, only around 30% of the mutations associated with FPF have been identified. The most frequent gene mutations identified so far are those related to telomere biology and include rare variants in telomerase reverse transcriptase, human telomerase RNA component, dyskerin, telomere interacting factor 2, regulator of telomere elongation helicase, and nuclear assembly factor 1.[78-82] Pathogenic variants in these genes are associated with extremely short age-adjusted telomere length that may result in apoptosis or senescence.

Familial studies have also identified FPF-associated variants related to the integrity and function of alveolar epithelial cells such as genes encoding surfactant protein C and A *(SFTPC, SFTPA1, SFTPA2),* ATP-binding cassette-type 3, and thyroid transcription factor 1.[83] In general, these mutations lead to accumulation of misfolded protein resulting in increased endoplasmic reticulum stress and activation of the unfolded protein response. As mentioned for telomere-related genes, the presence of different pathologic diagnoses is also observed in patients with mutations in surfactant proteins genes. Thus NSIP, DIP, and other histopathologic disorders have been diagnosed in affected relatives sharing the same mutation, suggesting that these diseases may represent pleiotropic manifestations of the same central pathogenesis.[83-85]

Most FPF patients appear to have an autosomal dominant inheritance pattern with incomplete penetrance, indicating a significant role for rare gene variants of large effect. Evidence of aggregation of disease was highly significant among sibling pairs, and 20 pedigrees demonstrated vertical transmission, consistent with autosomal dominant inheritance.[46] Certainly, environmental factors also play a role and, for example, in one study of FPF it was found that older age, male gender, and having ever smoked cigarettes were associated with the development of IIP.[46]

CLINICAL FEATURES

IPF is generally a disease of middle-aged or older subjects, most commonly encountered in those between 60 and 75 years of age. Patients with familial pulmonary fibrosis tend to present at a younger age, as already described; otherwise, it is quite uncommon for a patient to present before the age of 40 years.[46,86,87] The typical patient presents with the insidious onset of exertional breathlessness and a persistent nonproductive cough. In some patients, cough can be debilitating. Constitutional symptoms are uncommon, but weight loss, fever, fatigue, myalgias, or arthralgia is occasionally present. Although some patients may present with only a nonproductive cough, all patients experience dyspnea with exertion as the disease progresses. Most patients have these symptoms for months to years before definitive evaluation leading to diagnosis, usually around 12 to 30 months.[88,89,89a]

The physical examination is rarely normal. Most patients have bibasilar late inspiratory fine crackles (Velcro crackles) on chest auscultation. Clubbing of the fingers is seen in 40–75% of patients and is a finding late in the disease course. Cardiac examination is usually normal except in the later stage of the disease, when findings of pulmonary hypertension (e.g., augmented P2, right-sided lift, tricuspid regurgitation, and S3 gallop) and right heart dysfunction may become evident. Similarly, cyanosis is a late manifestation indicating advanced disease. Spontaneous pneumomediastinum or pneumothorax happens rarely.

BLOOD AND SEROLOGIC STUDIES

In the diagnostic evaluation of patients with suspected IPF, laboratory tests are used to exclude other diagnostic possibilities rather than to confirm the suspected diagnosis. These other diagnostic entities include connective tissue disease–related interstitial lung disease, chronic hypersensitivity pneumonitis, and vasculitis-associated pulmonary fibrosis. Thus serologic testing relevant to these disorders is frequently sought.

It is not uncommon for such screening serologic studies for autoimmune diseases and hypersensitivity pneumonitis to yield positive results. However, positive serologic results do not necessarily confirm a diagnosis and need to be interpreted in the context of presenting clinico-radiologic findings (see Chapters 91 and 92). An elevated erythrocyte sedimentation rate, positive low-level antinuclear antibodies titer, and elevated rheumatoid factor have been identified in some patients with IPF.[90,91] The hemoglobin level, leukocyte and differential counts, and metabolic panel are usually normal.

CHEST IMAGING

Chest Radiography

The typical finding in patients with IPF is peripheral reticular opacities with a netlike appearance of linear or curvilinear densities, with predominance at the lung bases (Fig. 89.1). A coarse reticular pattern or multiple cystic or honeycombed areas (i.e., coarse reticular pattern with cystic translucencies measuring 0.3 to 1 cm in diameter, best seen in the lower and peripheral lung zones) are radiographic

Figure 89.6 Frontal chest radiograph showing characteristic features of honeycomb lung. A network of 2- to 3-mm cystic spaces is distributed throughout the lung fields. This patient with end-stage idiopathic pulmonary fibrosis also had pulmonary hypertension and was receiving oxygen through a transtracheal catheter.

Figure 89.7 Advanced idiopathic pulmonary fibrosis. High-resolution computed tomographic image shows extensive honeycomb changes.

findings that correlate with advanced fibrotic disease and poor prognosis (see Figs. 89.1 and 89.6). Reduced lung volumes are usually evident unless there is associated obstructive airway disease, as can be seen in smokers.

Pleural abnormalities are uncommon in IPF; their presence should suggest another diagnosis, such as connective tissue disease (especially rheumatoid arthritis or systemic lupus erythematosus), mitral valve disease, congestive heart failure, asbestos-related lung disease, infection, drug-induced lung disease, or lymphangitic carcinomatosis.

High-Resolution Computed Tomography

CT plays a major role in the evaluation of ILDs, including IPF.[33,40,41,92,93] HRCT is useful in the differentiation of IPF from other ILDs and the determination of the extent and severity of disease.

HRCT findings in IPF include a predominantly peripheral (subpleural) and basal distribution of the interstitial opacities.[33,40] This involvement is patchy, with areas of reticulation intermingled with areas of normal tissue, often associated with traction bronchiectasis and cystic spaces 3 to 5 mm in diameter that share walls and frequently stack on one another in several layers (i.e., honeycombing; Fig. 89.7).[40,92] Early disease may manifest as mainly patchy subpleural reticular opacities without discernible honeycombing (eFig. 89.1).[40,92] The predominantly basal nature of these abnormalities is readily appreciated with reconstructed coronal imaging (eFig. 89.2). The presence of honeycomb cysts in a bibasilar subpleural distribution is a key finding in achieving a radiologic diagnosis of IPF (eFig. 89.3). Ground-glass opacities are common but of mild severity and characteristically much less extensive than the reticular opacities.

A typical or definite UIP pattern is characterized by the combination of findings that include the *presence* of a reticular pattern with associated traction bronchiectasis, honeycombing, basal and subpleural dominant distribution with the *absence* of features that suggests an alternative diagnosis.[33,40] An alternative diagnosis would be considered if findings include extensive consolidation or ground-glass opacities, extensive mosaic attenuation with air trapping on expiratory views, diffuse nodules or cysts, pleural plaques, predominant distribution involving the upper, mid or peribronchovascular lung zones. For the diagnosis of definite UIP, the presence of honeycombing is key. If the CT demonstrates all the aforementioned features except for honeycombing, it is classified as "probable" UIP pattern.[33,40]

In some patients, radiologic features of lower lobe pulmonary fibrosis may be combined with significant upper lobe emphysema and is referred to as *combined pulmonary fibrosis and emphysema* syndrome (Fig. 89.8, eFig. 89.4, Video 89.1,).[94-96] Patients with this entity have a smoking history and are more commonly men with a mean age of 65 years. These patients manifest relatively preserved lung volumes but marked reductions in D_{LCO} on pulmonary function testing. These patients with IPF and coexisting emphysema are more likely to require long-term oxygen therapy due to severe gas exchange impairment, to develop pulmonary hypertension, and to have a worse outcome than those without emphysema.[94,97]

Other Imaging Techniques

Magnetic resonance imaging (MRI) provides inferior resolution of lung parenchyma compared to HRCT but has several advantages, including the lack of ionizing radiation and the ability to identify tissue characteristics at a nuclear level that may allow for novel assessments of lung function and microstructure.[98,99] Although MRI is not ready for use in clinical practice, MRI may eventually find a role in differentiating between inflammation and fibrotic changes in ILDs.

Functional imaging using *^{18}F-fluorodeoxyglucose* (FDG) positron emission tomography scans may have a role in IPF.[100-102] In general, the lungs of patients with IPF appear to show increased FDG uptake. Higher scores of FDG uptake in the lung seemed to correlate with severity of disease and predict worse progression-free survival.[102] Some studies have suggested that cis-4-^{18}F-fluoro-L-proline may be a reliable marker for fibrosis formation. This radioligand has been tested in patients with IPF who manifested disappointingly low pulmonary uptake, perhaps because of the slow

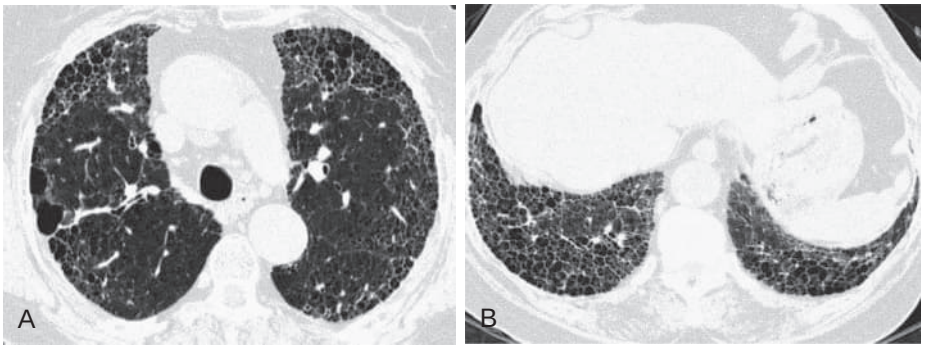

Figure 89.8 Combined pulmonary fibrosis and emphysema. Computed tomographic images from a 69-year-old woman with a 12-month history of worsening cough and dyspnea. She was a current heavy smoker. (A) Upper zones of the lungs show emphysema and mild patchy peripheral reticular opacities. (B) Lower zones of the lungs show emphysema and architectural distortion with patchy peripheral reticular opacities and extensive honeycombing lesions.

nature of fibrogenesis or the low doses of agent that must be used; as a result, this technique did not seem suitable for assessing the activity of fibrogenesis.[103]

PULMONARY FUNCTION TESTS

In most cases, IPF is associated with a restrictive pattern of pulmonary impairment with a decreased D_{LCO}. Early in the disease process, the lung volumes may be normal. As mentioned previously, smokers with emphysema who develop IPF can also manifest normal or near-normal lung volumes, even in advanced disease.[94-96] The decrease in D_{LCO} results from both a loss of the pulmonary capillary volume and the presence of ventilation-perfusion abnormalities. Resting arterial blood gases are often abnormal, revealing hypoxemia and respiratory alkalosis. The major cause of resting hypoxemia is ventilation-perfusion mismatching. With exercise, the alveolar-arterial P_{O_2} difference widens, and the arterial P_{O_2} and oxygen saturation fall. During maximal exercise, 20–30% of the exercise-induced widening of the alveolar-arterial P_{O_2} difference may be caused by a limitation of diffusion.

In patients with IPF, a significant correlation has been reported between the *6-minute walk distance* (6MWD) test and D_{LCO}, as well as maximal oxygen consumption; the 6MWD is a strong predictor of mortality.[104,105] The 6MWD test is difficult to perform in patients with advanced lung disease, however, and variability is common.

DIAGNOSIS

The diagnosis of IPF is achieved by establishing the presence of UIP by HRCT or lung biopsy in the absence of an identifiable cause, in other words, by establishing the diagnosis of idiopathic UIP.[33,40] Although surgical lung biopsy has been considered the most definitive method of obtaining diagnostic lung specimens, it should again be noted that the histopathologic findings of UIP can be seen in patients with non-IPF ILDs such as chronic hypersensitivity pneumonitis and connective tissue disease–related ILDs.[105a] Thus the clinical and HRCT features must be compatible with the diagnosis of IPF and not include findings inconsistent with this diagnosis, such as diffuse mosaic attenuation or upper lung predominance of abnormalities depicted on HRCT.

If HRCT findings represent typical/definite UIP (reticular opacities, honeycombing, and traction bronchiectasis with subpleural/basal predominant distribution) or probable UIP (reticular opacities, and traction bronchiectasis with subpleural/basal predominant distribution but without honeycombing) pattern, the diagnosis of IPF can be made without histopathologic confirmation in the presence of appropriate clinical context (i.e., age >60 years, absence of significant inhalational or medication exposure, no evidence of connective tissue disease).[40,106-109] Overall, approximately half of patients with IPF can be diagnosed without lung biopsy,[33,110-115] but this number may increase as radiologic criteria are refined.

When the findings on the HRCT study combined with clinical and laboratory features do not yield a clear diagnosis of IPF or another disorder, histopathology obtained by lung biopsy may be needed. Transbronchial lung biopsy is unlikely to yield the amount of lung tissue needed to recognize the features of UIP. However, recent reports suggest transbronchial cryobiopsy may be more informative in such patients, but requires validation and is not currently recommended by international guidelines.[28,30] In addition, molecular classifiers are becoming available that may allow a confident diagnosis of UIP on bronchoscopic biopsy specimens.[116] Surgical lung biopsy (thoracoscopic or open) is the most reliable method of obtaining adequate tissue to identify the underlying histopathologic pattern. As previously described, however, surgical lung biopsy is associated with increased in-hospital mortality.[34] Age and comorbidity are main risk factors for in-hospital mortality related to surgical lung biopsy, but a provisional diagnosis of IPF also increases this risk.[34]

Because the diagnosis of IPF requires correlation of clinical, radiologic, and sometimes histopathologic findings, a multidisciplinary discussion among clinicians, radiologists, and pathologists improves interobserver agreement and enhances diagnostic specificity.[117] As previously discussed, the presence of UIP alone, whether by HRCT or lung biopsy, does not automatically translate to the diagnosis of IPF.

THERAPEUTIC APPROACH

IPF is a progressive and fatal disorder without spontaneous remission and, until the recent introduction of antifibrotic therapy, no therapy had been shown to be effective.[118] Nonetheless, IPF remains a progressive lung disease in most patients even in the era of antifibrotic therapy. Thus it is essential that the prognostic aspects, management options, and goals of care be thoughtfully discussed with patients and family members, taking into account their individual contexts, values, and preferences. This discussion should

include advanced care planning to avoid treatments such as mechanical ventilation that may be unwanted by patients.

Era Before Antifibrotic Therapy

Although corticosteroids alone were the mainstay for the treatment of IPF for many years, there was never any randomized, placebo-controlled study to support their use.[119,120] The use of anti-inflammatory therapies in this disease was based on the earlier concept that a chronic inflammatory infiltrate led to progressive extracellular matrix deposition. However, the response to corticosteroid treatment in IPF has been almost uniformly poor.[121] In addition, significant complications can result from corticosteroid therapy, affecting the quality of life.

Because of the poor responsiveness of IPF to corticosteroids, various immunomodulatory agents (alone or in combination with corticosteroids) were tried and suggested possible benefit.[122-125] Combination therapy with prednisone, azathioprine, and *N-acetylcysteine* (NAC) was suggested for patients with mild to moderate disease and seemed to be associated with preserved *forced vital capacity* (FVC) and D_{LCO} when compared to standard therapy of prednisone plus azathioprine after approximately 1 year of follow-up.[126] However, in a subsequent study, this combination therapy (prednisone, azathioprine, and NAC) was shown to be associated with an increased rate of death and hospitalizations compared with placebo.[127] The comparison of NAC alone versus placebo also yielded negative results with no significant benefit in preventing FVC decline in patients with IPF with mild-to-moderate impairment in lung function.[128] A subsequent study suggested that toll interacting protein polymorphisms may influence the response to NAC in patients with IPF.[129]

A number of other immunosuppressive or putative antifibrotic agents have been reported in individual cases or in small groups of patients with IPF but lack evidence to support their efficacy. These agents include colchicine,[130-132] penicillamine,[132] captopril,[133] and etanercept.[134] Based on positive results from in vitro studies, animal experiments,[135] and a preliminary open, randomized trial,[136] interferon γ-1b in IPF was investigated in two large, controlled trials but yielded no difference in the primary end point (progression-free survival) or in secondary end points compared to placebo.[137-139] Similarly, bosentan, a dual endothelin-1 receptor antagonist (ET_A and ET_B), was investigated in two large, randomized, multinational, double-blind, placebo-controlled trials in patients with IPF but failed to demonstrate a benefit in primary end points (time to worsening or death) or other end points, including health-related quality of life or dyspnea.[140,141] Other agents that have failed to show efficacy in clinical trials include imatinib, a competitive tyrosine-kinase inhibitor capable of blocking the TGF-β pathway,[142] and anticoagulant therapy with warfarin.[143]

Current Era

On the basis of accumulating knowledge about the pathogenic mechanisms involved in IPF, newer antifibrotic agents have been developed and tested in patients with IPF.

Pirfenidone. Pirfenidone (5-methyl-1-phenyl-2-[1H]-pyridone) is a novel antifibrotic agent that inhibits the progression of fibrosis in animal models. Several clinical trials showed promise in stabilizing lung function and reducing the number of patients with IPF who experienced acute exacerbation.[144,145] In a randomized clinical trial from Japan, the high-dose pirfenidone group had better progression-free survival than the placebo group.[146] Two international randomized clinical trials of pirfenidone enrolled 435 and 344 IPF patients, respectively.[147] In one of these trials, pirfenidone achieved the primary end point of reducing decline from baseline in percent-predicted FVC. The second trial did not meet this primary end point. A subsequent phase III randomized, double-blind, placebo-controlled trial evaluating pirfenidone in patients with IPF observed reduced disease progression as reflected by lung volume, exercise tolerance, and progression-free survival.[148]

As a result of these positive trials, pirfenidone is approved for the treatment of IPF in the United States, Canada, Europe, Japan, and many other countries. The usual dosing is 267 mg 3 times daily by mouth, which is increased weekly to 801 mg 3 times daily by the third week. The main adverse effects are gastrointestinal and hepatic; patients often develop a photosensitivity skin rash.

Nintedanib. Nintedanib (BIBF-1120) is a tyrosine kinase inhibitor that targets the platelet-derived growth factor receptor, vascular endothelial growth factor receptors, and fibroblast growth factor receptors.[149] A 12-month, randomized, double-blind, placebo-controlled, phase II trial with 432 IPF patients included four groups assigned to different doses of nintedanib.[150] The primary end point was the annual rate of decline in FVC. A trend toward a reduced decline of lung function with fewer acute exacerbations and preserved quality of life was associated with the highest-dose (150 mg twice daily) regimen. In two subsequent replicate phase III, multinational, randomized, placebo-controlled, parallel-group trials (INPULSIS-1 and INPULSIS-2), nintedanib slowed disease progression by significantly reducing the rate of decline in FVC.[151]

As a result of these data, nintedanib has been approved for the treatment of IPF in the United States, Canada, Europe, Japan, and many other countries. The usual dosing of nintedanib is 150 mg by mouth twice a day. The main adverse effects are gastrointestinal and hepatic.

In sum, both pirfenidone and nintedanib reduce the rate of FVC decline by approximately 50% over 1 year of treatment in patients with IPF. Pooled data analyses and post hoc analyses suggest these drugs may improve quality of life, reduce the rate of hospitalizations and acute exacerbations, and prolong survival.[152-156] A recent real-world retrospective cohort analysis using a large insurance database suggested the use of these medications reduced risk of all-cause mortality (hazard ratio 0.77) for up to 2 years with no significant difference between the two drugs.[157] Studies to date suggest the adverse effects of these medications are manageable for the majority of patients with a reasonable long-term tolerability profile.[155,158,159] Combination therapy with both pirfenidone and nintedanib is being explored.[160]

There are additional pharmaceutical agents currently being investigated as potential therapies for IPF. A phase II study of recombinant human pentraxin 2, an inhibitor

of monocyte differentiation into profibrotic fibrocytes and TGF-β1 production, has shown some early promising results in slowing the decline of lung function in patients with IPF.[161] GLPG1690 (Galapagos), a potent inhibitor of autotaxin, an enzyme thought to play a role in fibrogenesis, is currently undergoing clinical trials.[162]

Lung Transplantation (see Chapter 140)

Since the late 1980s, lung transplantation has been used for the management of a wide range of severe lung disorders with progressive impairment unresponsive to pharmacologic treatment, with evidence supporting an improved quality of life and survival benefit.[163-165]

Given the scarcity of donors, along with the age considerations and comorbidities seen in IPF patients, transplantation is indicated only in carefully selected patients. The International Society for Heart and Lung Transplantation has published updated guidelines for the selection of IPF patients who should be considered potential transplant candidates.[166] Early referral for consideration of transplant is highly desirable, particularly for those who have progressive disease (including oxygen desaturation at rest or with exercise). It allows an orderly process for assessment, management of issues of concern, and patient education before active listing. Extracorporeal membrane oxygenation may be an option for selected patients who have developed acute respiratory failure and are candidates for lung transplantation.[167]

According to the 2012 International Society for Heart and Lung Transplantation/United Network of Organ Sharing International Registry, the 1- and 5-year survival rates following lung transplantation for IPF were 84% and 48%, respectively.[168] Telomere length less than the tenth percentile may be associated with worse survival and shorter time to onset of chronic lung allograft dysfunction.[169] Survival after lung transplantation for IPF appears to be worse than for other indications, and some studies have suggested that survival may be improved by double-lung transplant.[170] However, a study using registry data showed no difference between patients who had single- and double-lung transplant when adjusted for baseline differences.[171]

MANAGEMENT OF COMORBIDITIES AND PALLIATIVE CARE

The clinical course and management of patients with IPF may be complicated by comorbidities. These include GER disease, pulmonary hypertension, sleep-related breathing disorder, lung cancer, and other issues.

Gastroesophageal Reflux

Although GER is common in patients with IPF, it is not clear how aggressively to pursue this diagnosis and to treat GER in patients with IPF.[172-175] There is some evidence suggesting a clinical benefit in those patients with IPF treated with proton-pump inhibitors or histamine 2 receptor blockers.[49,176-178] However, other studies have cast doubt on the beneficial effects of antacid therapy in IPF.[173,179-182] A randomized, controlled trial (n = 58) assessed the effect of laparoscopic antireflux surgery in patients with IPF and abnormal acid GER and found a lower rate of acute exacerbation, respiratory-related hospitalization, and death in the surgery group (n = 29), but the difference was not statistically significant compared to the nonsurgery group (n = 29) in this small study.[182a] It is unknown if other measures used in the management of GER, such as lifestyle modifications (e.g., small meals, avoidance of certain foods and alcohol), and other pharmaceutical interventions (e.g., prokinetics) have a role in the treatment of patients with IPF.[178,183]

Pulmonary Hypertension

Pulmonary hypertension due to IPF (PH-IPF) is relatively common (32–85% of patients) and may contribute substantially to functional status, quality of life, morbidity, and mortality (see Chapter 85).[184-189] As previously described, patients with combined pulmonary fibrosis and emphysema syndrome are at increased risk for the development of PH.

The most appropriate method to detect PH noninvasively is transthoracic (Doppler) echocardiography. However, echocardiography may be inaccurate in estimating pulmonary arterial systolic pressure in patients with ILD.[190,191] Right heart catheterization is the gold standard for the hemodynamic evaluation of the pulmonary circulation and the diagnosis of PH. Abnormalities in gas exchange and exercise capacity seem to have a significant association with PH-IPF. Thus exaggerated exercise-related oxygen desaturation and out-of-proportion reduction of D_{LCO} should raise suspicion of PH.[184,189] Brain natriuretic peptide concentration may also be helpful in predicting the presence of moderate to severe PH in patients with IPF.[192,193] In addition, a ratio of the main pulmonary artery to ascending aorta diameter greater than 1 on chest CT images also raises the suspicion for PH.[194,195]

Supplemental oxygen is the most obvious choice for prevention or treatment of PH; however, there are no data supporting favorable effects of oxygen on survival in PH-IPF. Vasoactive agents are being studied, but one must recognize that decreased physiologic vasoconstriction in low ventilation-perfusion lung units may worsen shunt and hypoxemia in IPF.[187,189,196] To date, pulmonary vasoactive agents, including ET-1 receptor antagonists, prostacyclin (prostaglandin I_2) analogs, and phosphodiesterase-5 inhibitors, have been associated with short-term functional improvement in some studies, but long-term benefits including improved survival have not been demonstrated.[196-201]

Sleep-Related Issues

Many patients with IPF, especially those with low daytime arterial oxygen saturation or a history of snoring during sleep, develop sleep disturbances characterized by reduced rapid eye movement sleep, lighter and more fragmented sleep, and hypoxemia during rapid eye movement sleep.[202-204] The prevalence of obstructive sleep apnea is increased in the IPF population.[202] An increased body mass index and a significant impairment in pulmonary function testing may be predictors of obstructive sleep apnea in these patients.[205] However, severe hypoxemia can be seen in the absence of obstructive sleep apnea or changes in breathing pattern. Nocturnal hypoxemia is common in patients with IPF and has an adverse effect on

quality of life.[202,206] It may also contribute to the development of PH. Identification and correction of the sleep disturbance may reduce morbidity and improve quality of life and patient survival.

Lung Cancer

Bronchogenic carcinoma (all histologic types; most commonly squamous cell carcinoma) has been identified with increased frequency in advanced IPF (eFig. 89.5).[207-213] These cancers tend to arise in peripheral lung zones involved with fibrosis.[207,212-214] It has been postulated that carcinoma arises from the metaplastic bronchiolar epithelium found in these patients, but the pathogenic mechanisms are unclear.[208] The risk of lung cancer in patients with IPF is several-fold higher compared to the general population.[211,212] One recent study identified a smoking history of 35 pack-years or more and coexisting emphysema as risk factors for the development of lung cancer in these patients.[212] Not surprisingly, the development of lung cancer increases the risk of death.[215-217] Furthermore, surgical resection and nonsurgical therapies are associated with a high prevalence of adverse events, including acute exacerbation of IPF.[215,218,219]

Other Comorbidities

Because most patients with IPF are of older age, there are other commonly encountered comorbidities, including cardiovascular diseases such as ischemic heart disease and venous thromboembolism.[216,220,221] These comorbidities need to be identified and managed appropriately because they may shorten survival and worsen quality of life.[216,217,222,223]

Rehabilitative and Palliative Care

In recent years, more attention has been focused on rehabilitative therapy and palliative care in the management of patients with IPF.[223a] Participation in a pulmonary program has been shown to improve dyspnea, fatigue, 6MWD, and quality of life.[224-230] The beneficial effects of pulmonary rehabilitation appear to be more pronounced in patients with worse baseline functional status.[229,231]

Cough can be a debilitating symptom for patients with IPF. A systematic review on the management of cough in ILDs noted a paucity of antitussive treatment options for these patients and suggested gabapentin, opiates, and speech therapy as possible options.[232] In a small crossover trial, thalidomide improved cough in patients with IPF.[233] A pilot clinical trial suggested a reduction in cough with omeprazole therapy compared to placebo in patients with IPF.[234] In an uncontrolled observational study, pirfenidone treatment was associated with improvement in measures of cough.[235] Further research is needed in assessing the efficacy of these agents for antitussive effects in IPF.

Similarly, breathlessness is a common source of suffering for patients with ILDs. Moderate doses of opioids and benzodiazepines can be used in patients with ILDs to relieve distressing symptoms, including breathlessness.[236] In a progressive disease such as IPF, early institution of integrated palliative care may help both the patients and their caregivers by improving the quality of life as well as the quality of dying.

PROGNOSIS

Although the natural history of IPF has not been fully defined, data thus far suggest the median survival after diagnosis is approximately 3 years.[33,41,93,237-241] Long-term survival in IPF is distinctly poor, with only a 20–35% survival 5 years after diagnosis.[237,240-242] Clinical deterioration in patients with IPF is expected, even in patients on antifibrotic therapy (although it may be slower in this group). Most patients experience episodes of worsening shortness of breath, decreased exercise tolerance, or other declines in functional status during the course of their illness.[237,239,242,244] Disease progression may be difficult to distinguish from disease-associated complications and adverse effects of therapy.[245-247] Frequent hospitalizations for respiratory problems are common events and are often associated with death.[239,242,248]

In a study of 42 consecutive IPF patients who died over a 9-year period, autopsies showed that IPF by itself was the immediate cause of death in half of the patients either from an acute exacerbation (see "Acute Exacerbations of Idiopathic Pulmonary Fibrosis" later) or from the gradual progression of the disease.[247] Other respiratory causes of death included pneumonia and aspiration. Cardiovascular disease including arrhythmia, myocardial infarction, and severe right heart dysfunction, was found to be the cause of death in 20% of subjects. Evidence of pulmonary hypertension was present on autopsy in 45% of patients and was the immediate cause of death in two of them. Pulmonary embolism appears to be relatively common in IPF lung transplant recipients, although its prevalence is unknown.[249] Importantly, it has been shown that patients with IPF have a higher prevalence of coronary artery disease.[250] Also, patients with clinically stable IPF exhibit not only right ventricle diastolic and systolic dysfunction but also impaired left ventricle diastolic filling, while the systolic function is preserved.[251]

Staging of IPF and Predicting Outcome

The rate of progression is variable among patients with IPF.[239,248,252] Thus prognostication for individual patients diagnosed to have IPF is difficult. Various parameters, singly or in combination, have been correlated with prognosis.

Demographic and clinical factors have been correlated with prognosis. Mortality rates are higher in men, higher with increasing age, and highest in the winter, even when infections are excluded.[239,252–254,254a] The *Medical Research Council* (MRC) Chronic Dyspnea Score estimated at the time of diagnosis is predictive of survival and may aid clinicians in assessing the prognosis of new cases of IPF.[255]

Immunologic markers, including autoantibodies, elevated sedimentation rates, circulating immune complexes, and increased serum immunoglobulins, have not been shown to correlate with the overall natural history of IPF. Serum surfactant protein (SP)-A and SP-D may have prognostic value for mortality in patients with IPF.[256] One study showed that after controlling for known clinical predictors of mortality, an increased serum SP-A level is a strong and independent predictor of early mortality among patients with IPF. A prediction model containing SP-A and SP-D was substantially superior to a model with clinical predictors alone.[257] Also, serum chemokine

ligand 18 concentrations seem to have a predictive value in IPF with higher mortality observed in patients with concentrations above 150 ng/mL.[258] At present, however, there is no biomarker signature proven to be predictive of outcome in this disease.

Chest imaging features have also been correlated with prognosis. Chest radiography is relatively insensitive in detecting progression in IPF and may demonstrate no changes despite clinically apparent physiologic deterioration. Another major problem with using chest radiography to follow the disease course or to estimate the stage of disease is that there is considerable interobserver variability in the interpretation of these studies. However, HRCT scanning in IPF depicts anatomic details better and may be useful in assessing and staging disease. The finding of a greater extent of ground-glass opacities and a lower extent of reticular opacities on the initial HRCT identifies those patients with early disease who are the most likely to survive longer[259] compared to those with a typical HRCT appearance of UIP (including honeycombing) who experience higher mortality.[260] In addition, a greater extent of fibrosis visually scored on HRCT predicts greater short-term mortality.[261,262] More recently, computer-based quantification of disease on HRCT has been investigated to aid in prognostication and has shown promise in this regard.[263-265]

Physiologic assessment with pulmonary function testing is a common component of determining disease severity at baseline and during the clinical course, allowing the assessment of response to therapy. Reductions in the vital capacity correlate with the degree of fibrosis present and show a relationship with the overall histologic derangements.[239,252,266] In general, severe pulmonary function impairment at baseline as assessed by FVC and D_{LCO} predict a higher mortality rate.[239,252,266] A marked reduction of the D_{LCO} and resting hypoxemia are associated with pulmonary hypertension and decreased survival.[187] Likewise, changes in D_{LCO}, total lung capacity, FVC, arterial P_{O_2}, oxygen saturation, and alveolar-arterial P_{O_2} difference during follow-up are predictive of survival time after adjustment for baseline values.[267,268]

BAL constituents may reflect the state of the pulmonary inflammatory response. IPF is characterized by a several-fold increase in the total number of inflammatory cells with an increase in the percentage of neutrophils and eosinophils.[25] However, studies evaluating the association of BAL fluid cellular constituents and mortality have yielded conflicting results and were limited by the size of the study cohort and duration of follow-up. In one study, it was found that SP-A in BAL is reduced in IPF, and decreases in its concentration referenced to total phospholipid (a marker of surfactant to normalize to the surface sampled by lavage and recovery) predict an adverse clinical outcome and poorer survival.[256] At present, evaluation of BAL fluid constituents has no role in determining the prognosis in IPF.

Histologic features, other than end-stage fibrosis and honeycombing, have not been shown to correlate with survival in UIP.[269] It has been proposed that an early and characteristic manifestation of active and ongoing lung injury in UIP is the presence of multiple fibroblastic foci.[37] The prognostic significance of these aggregates of fibroblasts and myofibroblasts in surgical lung biopsies from patients with IPF is unclear, and several studies quantifying them have given contradictory results.[270-274] The effect of sample size, tissue sampling bias, and the different techniques for assessing the number of foci may account for these results. Overall, detailed quantification of fibroblast foci on surgical lung biopsies may not be a useful or consistent predictor of patient survival in this disease.

Composite prediction models have been designed to help predict the clinical course and prognosis of IPF.[252,266,269,275–277] Some of these composite models require detailed radiographic analysis or exercise physiologic measurements, neither of which is readily available to many physicians and limit their utility in clinical practice.[269,275] Ley and colleagues[266] proposed a multidimensional prognostic staging system (GAP model) for IPF using only commonly measured clinical and physiologic variables (age, gender, FVC, and D_{LCO}). A simple-to-use staging system such as this may help estimate prognosis and guide management decisions such as those about the appropriate timing of lung transplantation. The CT fibrosis score may be able to replace the D_{LCO} measurement in this model.[278] In addition, including comorbidities in the GAP model may improve the discriminative performance in assessing the risk of death.[217]

Acute Exacerbations of Idiopathic Pulmonary Fibrosis

Some patients with IPF (as well as other chronic ILDs) may experience a rapid deterioration in respiratory status after a period of relative stability.[239,279,280] This acute worsening, termed *acute exacerbation,* may be related to viral or bacterial infection, aspiration, or thromboembolism. However, many of these acute clinically significant episodes do not have an identifiable trigger. The incidence of acute exacerbations in the IPF population has been reported to range from 4–15% at 1 year.[242,279,281,282]

An International Working Group Report updated the definition and diagnostic criteria for acute exacerbation of IPF.[279] This revised definition is "an acute clinically significant respiratory deterioration characterized by evidence of new widespread alveolar abnormality." The diagnostic criteria include (1) previous or concurrent diagnosis of IPF, (2) acute worsening or development of dyspnea typically less than 1 month duration, (3) CT with new bilateral ground-glass opacity and/or consolidation superimposed on a background pattern consistent with UIP pattern (eFig. 89.6A–F), and (4) deterioration not fully explained by cardiac failure or fluid overload.[279] In contrast to an earlier definition of acute exacerbation,[283] the updated definition allows for inclusion of episodes with an identifiable trigger including respiratory infection, aspiration, drug toxicity, and surgical procedures. Histologic evaluation is not required to diagnose acute exacerbation; however, when tissue is encountered by biopsy or autopsy in this setting, it typically shows diffuse alveolar damage superimposed on underlying UIP. Occasionally, other patterns of acute lung injury may be seen, such as organizing pneumonia and extensive fibroblastic foci.[284–287]

Although some acute exacerbations, as currently defined, have an identifiable trigger such as pneumonia, the etiology and pathogenesis of this phenomenon remain mostly unclear.[279] A role for occult viral infection and

microaspiration has been suggested.[279,288–290] Disordered epithelial cell integrity, acute inflammation, excessive cytokines and matrix metalloproteinases, and an antifibrinolytic alveolar milieu are all likely involved.

Once infections and other treatable causes of worsening have been excluded, management of acute exacerbation has generally consisted of enhanced immunosuppression with pulse doses of methylprednisolone (0.5 to 1 g/day), sometimes combined with another immunosuppressive agent, such as cyclophosphamide or cyclosporine, but no convincing evidence of benefit has been demonstrated.[279,291–293] There have been reports of potential benefit from the use of direct hemoperfusion with a polymyxin B–immobilized fiber column,[294] which would bind circulating endotoxin, cytokines and growth factors, and neutrophil elastase inhibitors.[293] Unfortunately, no data from controlled trials have proved the efficacy of any treatment for this condition.[279,295]

Key Points

- *Interstitial lung diseases* (ILDs) comprise a heterogeneous group of diffuse infiltrative lung diseases that disrupt the alveolar-capillary interface, leading to hypoxemia.
- ILDs are encountered in diverse clinical settings; the majority of patients will have an identifiable cause, including occupational, environmental, drug or other exogenous exposures, connective tissue diseases, and hereditary disorders, while others remain idiopathic.
- In some patients with ILDs, correlation of the clinical context (detailed history and examination along with relevant laboratory results) and radiologic features can establish the likely diagnosis; in others, histopathologic examination of lung tissue may be necessary to identify a specific diagnosis.
- *Idiopathic pulmonary fibrosis* (IPF) is one of the most common ILDs and is progressive, irreversible, and usually fatal, with a portion of these deaths attributed to the phenomenon of "acute exacerbation."
- Antifibrotic agents, pirfenidone and nintedanib, have been shown to slow progression in IPF and have been approved by the U.S. Federal Drug Administration for the treatment of IPF. In contrast, anti-inflammatory agents, such as corticosteroids, have not been of benefit.
- Comprehensive care of patients with IPF, a progressive disorder, includes management of comorbidities and counseling of patients and family members regarding prognostic aspects, management options, and goals of care that take into account their individual contexts, values, and preferences.

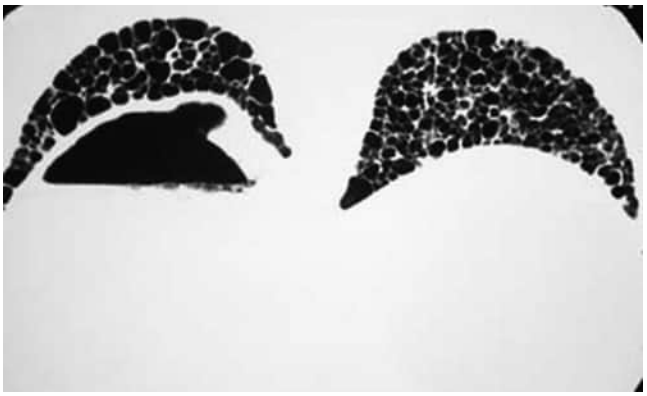
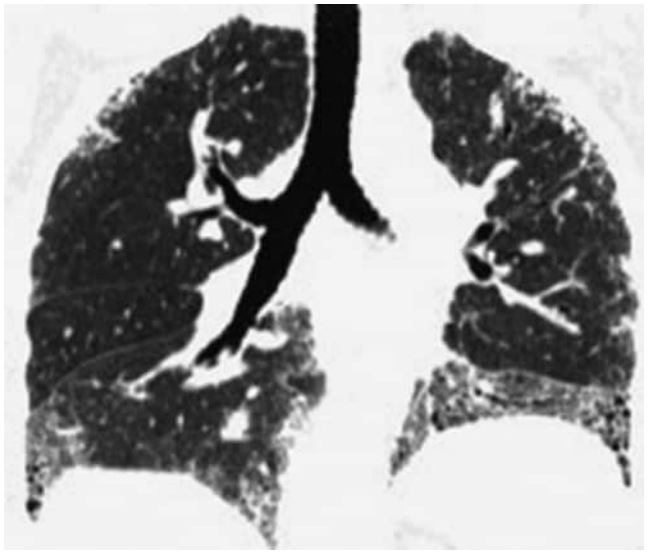
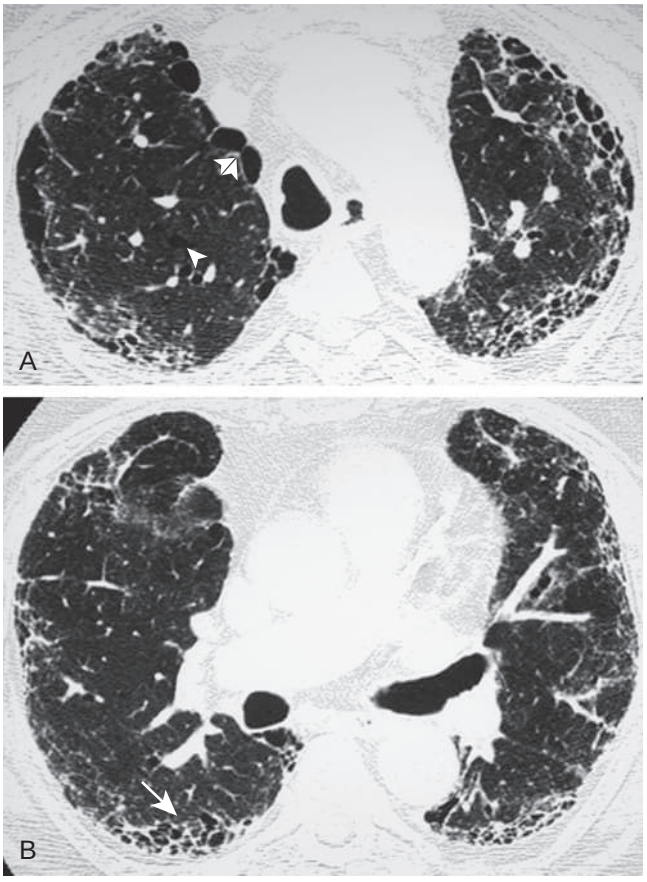
eFigure 89.1 Computed tomography of "early" usual interstitial pneumonia/idiopathic pulmonary fibrosis. Axial chest computed tomography through the lung bases shows subpleural reticulation and architectural distortion with areas of traction bronchiectasis, but no discrete honeycombing is visualized. (Courtesy Michael B. Gotway, MD.)



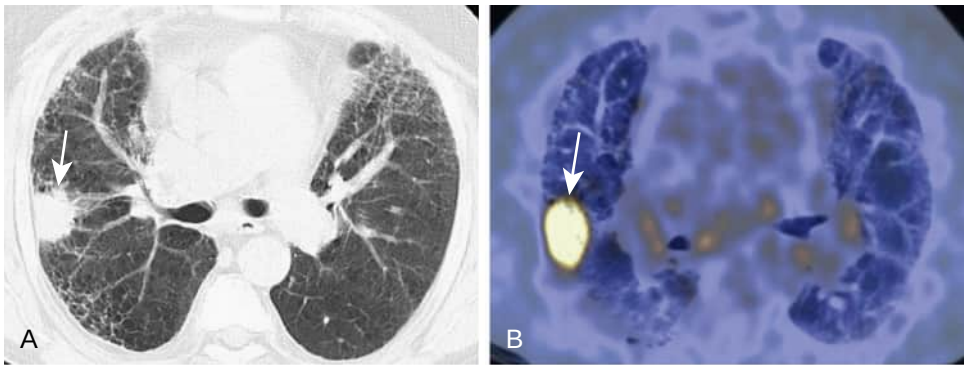
eFigure 89.3 Honeycombing on high-resolution computed tomography in usual interstitial pneumonia/idiopathic pulmonary fibrosis. Axial prone chest computed tomography through the lung bases shows extensive subpleural cystic change consistent with honeycomb lung. Note how the cyst walls are visible, are mildly thickened (measuring 1 to 2 mm), and share walls with one another. (Courtesy Michael B. Gotway, MD.)



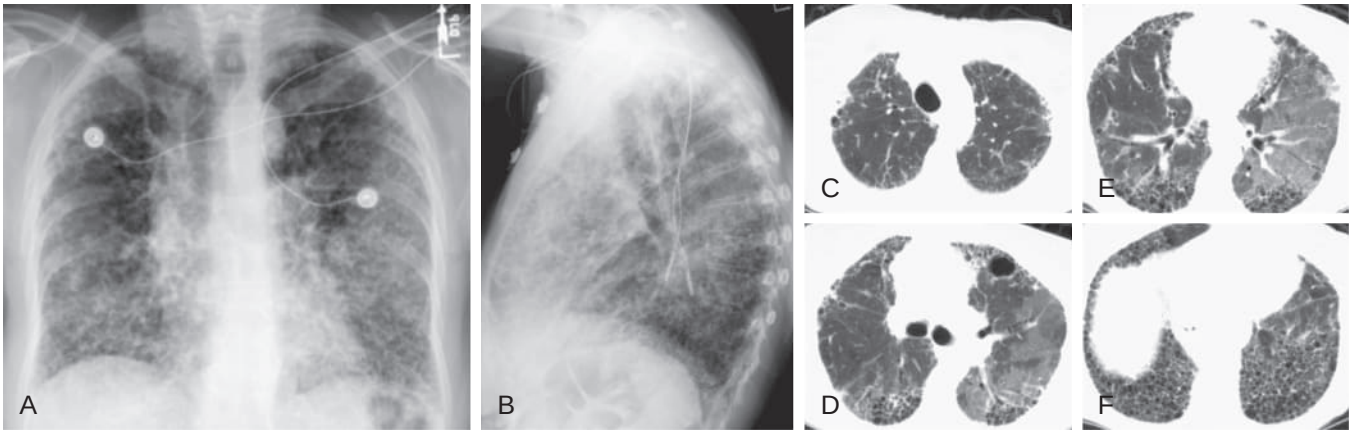
eFigure 89.2 Value of coronal computed tomography for demonstrating the basal distribution of pulmonary findings in interstitial pneumonia/idiopathic pulmonary fibrosis. Coronal chest computed tomography shows subpleural reticulation and basal predominant honeycombing. This single image captures the basal predominant nature of the high-resolution computed tomography findings in patients with idiopathic pulmonary fibrosis. (Courtesy Michael B. Gotway, MD.)



eFigure 89.4 Combined pulmonary fibrosis and emphysema. Axial chest computed tomography through the upper lungs (A) and lung bases (B) shows centrilobular *(single arrowhead)* and paraseptal *(double arrowheads)* emphysema, with basal predominant reticulation, architectural distortion, and honeycombing (*arrow*), the latter consistent with interstitial pneumonia/idiopathic pulmonary fibrosis. (See Video 89.1 for another example from a different patient.) (Courtesy Michael B. Gotway, MD.)



eFigure 89.5 Computed tomography (CT) and positron emission tomography (PET)-CT in idiopathic pulmonary fibrosis with coincident lung carcinoma. Axial chest CT (A) shows basal, subpleural reticulation and traction bronchiectasis representing idiopathic pulmonary fibrosis. A subpleural nodule (*arrow,* A) is present, representing lung carcinoma. Fused image from PET-CT (B) shows increased tracer utilization within the nodule (*arrow,* B), as well as faint tracer uptake within the areas of fibrotic lung disease. (Courtesy Michael B. Gotway, MD.)



eFigure 89.6 Chest radiography and computed tomography of acute exacerbation in idiopathic pulmonary fibrosis. Frontal (A) and lateral (B) chest radiographs show multifocal, bilateral reticular abnormalities, with cystic change most evident in the posterior and inferior lung bases on the lateral radiograph (B), consistent with fibrotic changes in a patient with idiopathic pulmonary fibrosis. In addition to these findings, more widespread areas of increased attenuation as well as a generalized nodular appearance are evident. Axial chest computed tomography images in the upper (C), mid (D), and lower (E) lungs, as well as the extreme lung bases (F), show peripheral predominant fibrotic changes consistent with idiopathic pulmonary fibrosis. However, extensive areas of ground-glass opacity are evident, particularly in the left mid (D) and lower (E) lungs, and are consistent with an acute lung injury pattern and not fibrosis. 90 NONSPECIFIC INTERSTITIAL PNEUMONITIS AND OTHER IDIOPATHIC INTERSTITIAL PNEUMONIAS

BRIDGET A. GRANEY, MD • JOYCE S. LEE, MD • TALMADGE E. KING JR, MD

INTRODUCTION
MAJOR IDIOPATHIC INTERSTITIAL PNEUMONIAS
Nonspecific Interstitial Pneumonia
Cryptogenic Organizing Pneumonia
Acute Interstitial Pneumonia
Respiratory Bronchiolitis–Associated Interstitial Lung Disease and Desquamative Interstitial Pneumonia

KEY POINTS

INTRODUCTION

The *idiopathic interstitial pneumonias* (IIPs) are a heterogeneous group of eight diffuse parenchymal lung diseases characterized by varying patterns of inflammation and fibrosis.[1,2] *Idiopathic pulmonary fibrosis* (IPF), the most common IIP, is discussed in detail in Chapter 89. This chapter describes the remaining seven IIPs with a focus on the distinct clinical, radiologic, and histopathologic patterns of each disease.

The classification, diagnosis, understanding of the pathogenic mechanisms, and management of IIPs continue to evolve.[1,3,4] The classification was most recently updated in 2013 in a joint statement by the American Thoracic Society and the European Respiratory Society.[1] In this update, the IIPs were classified into major and rare IIPs, with the major IIPs further categorized by disease behavior (Table 90.1). The IIPs have overlapping but ultimately distinct presentations (Tables 90.2 and 90.3), and they can be distinguished from other forms of *interstitial lung disease* (ILD) by clinical methods including history, physical examination, chest radiologic and laboratory studies, and histopathology. Establishing an accurate diagnosis is crucial because, despite their similarities, each of these diseases has a different treatment and prognosis.

Accurate diagnosis of any IIP can be challenging. Clinicians must be aware that the radiologic and histopathologic patterns seen in the IIPs can be encountered in patients with known, identifiable causes of their lung disease (Table 90.4). For example, *usual interstitial pneumonia* (UIP) on histopathology can be seen not only in patients with IPF but also in patients with rheumatoid arthritis as a form of rheumatoid arthritis–associated ILD.[5,6] In addition, the interstitial pneumonia patterns are associated with varying degrees of specificity with respect to etiology. For example, *respiratory bronchiolitis–associated ILD* (RB-ILD) in most patients is caused by smoking, whereas *organizing pneumonia* (OP) can be associated with a broad spectrum of causes, including infections, aspiration, drug reactions, connective tissue disorders, eosinophilic lung disease, and many others.[7-12]

This chapter presents an approach for the evaluation of patients with an emphasis on the IIPs. Despite the challenges, a specific diagnosis can be made in many patients by integrating the results of a careful history, selected laboratory results, and radiologic and histopathologic data. A dynamic, integrated approach to diagnosis through a *multidisciplinary discussion* including clinicians, radiologists, and pathologists is considered the gold standard for the diagnosis of ILDs and can be particularly helpful to diagnose IIPs.[1,13,14]

MAJOR IDIOPATHIC INTERSTITIAL PNEUMONIAS

NONSPECIFIC INTERSTITIAL PNEUMONIA

Idiopathic *nonspecific interstitial pneumonia* (NSIP) was recognized first as a provisional diagnosis in 2002 and subsequently as a distinct disease state in 2008.[13,15] Originally, NSIP referred to a histopathologic categorization reserved for surgical lung biopsies that did not demonstrate a clearly identifiable histologic pattern consistent with another IIP.[16] Although the histopathologic pattern of NSIP is found in a wide variety of diseases of known cause (e.g., hypersensitivity pneumonitis, drug-related disorders, acquired immunodeficiency syndrome, and collagen-vascular diseases),[15] idiopathic NSIP is a specific disease entity with a unique clinical presentation and overall good prognosis. Many

IPs, interstitial pneumonias.

patients diagnosed with idiopathic NSIP meet the case definition of undifferentiated connective tissue disease, a finding suggesting that idiopathic NSIP may actually be a form of autoimmune disease.[17,18] In addition, it is estimated that up to 15–20% of patients with newly diagnosed ILD either have an occult connective tissue disease or subsequently develop a clinically overt connective tissue disease. In this group of patients, the initial clinical presentation may be essentially indistinguishable from that of several IIPs, especially NSIP.[19]

Clinical Features

The presentation with respect to time course and symptoms is quite similar to that of other forms of IIPs (see Tables 90.2 and 90.3). Most patients are middle-aged adults with a subacute onset of symptoms approximately 8 months before diagnosis.[15,16,20] In contrast to IPF, up to two-thirds of the patients are female, and 70% are never smokers.[15] Cough and dyspnea are the main clinical manifestations.

Laboratory Features

Serologic abnormalities (antinuclear antibodies and rheumatoid factor) are common. *Bronchoalveolar lavage* (BAL) findings do not discriminate between UIP and NSIP and have no prognostic value.[21]

Pulmonary function testing typically shows a restrictive ventilatory defect and gas-exchange abnormalities.

Radiologic Features

Chest Radiography. In patients with early NSIP, the chest radiograph may be normal. In advanced disease, bilateral reticular or hazy opacities (eFig. 90.1) are the most prominent abnormalities. The lower lung lobes are more frequently involved, but an obvious apical-basal gradient, as seen in UIP, is often absent.[15,16]

Computed Tomography. The characteristic radiologic features of idiopathic NSIP are lower lung-zone–predominant reticular opacities, traction bronchiectasis, and lobar volume loss.[15] Ground-glass attenuation is present in nearly one half of the cases (Fig. 90.1). Other findings in advanced NSIP include subpleural cysts (eFig. 90.2). Compared with those of UIP, these cysts are smaller and limited in extent.[22] The major *computed tomography* (CT) differential diagnosis for NSIP is UIP. Favoring the diagnosis of NSIP are the following findings: homogeneous lung involvement without an obvious apical-basal gradient, extensive ground-glass opacities, a finer reticular pattern, and micronodules. NSIP, as compared with UIP, can also demonstrate subpleural sparing in 20% of cases.[15] Importantly, during follow-up, ground-glass opacities in patients with NSIP usually do not evolve to areas of honeycombing. By contrast, progression of ground-glass opacities to honeycombing is common in UIP and indicates irreversible fibrosis.[23] If honeycombing is present, an alternative diagnosis should be considered.

Histopathologic Features

The histopathologic pattern of NSIP is characterized by temporally and spatially homogeneous lung involvement. This homogeneity is a key feature in differentiating the NSIP pattern from the UIP pattern. It is characterized by varying degrees of inflammation and fibrosis, with some patients having a primarily chronic inflammatory or cellular pattern (cellular NSIP) but most cases revealing a mixed cellular-fibrotic pattern (fibrotic NSIP)[15,16] (Figs. 90.2 and 90.3). Cellular NSIP exhibits uniform alveolar septal infiltrates of lymphocytes and plasma cells. Neutrophils, eosinophils, and histiocytes are inconspicuous. Although NSIP may be associated with significant fibrosis, it is temporally uniform, with the underlying alveolar architecture most often preserved; fibroblastic foci and honeycombing, if present, are rare.[15,24] Fibrotic NSIP can be difficult to distinguish from UIP, and interobserver variability among expert pathologists is significant.[25]

Differential Diagnosis

Clinically, the most common diagnosis confused with fibrotic NSIP is IPF.[3,15,16,20] It is essential that the pathologist not use terms such as UIP or NSIP unless the defined criteria are met because some degree of fibrosis and inflammation is common in many ILDs, and sampling error can be an issue, especially in small or inadequate surgical

Figure 90.1 Nonspecific interstitial pneumonia. High-resolution chest computed tomography image shows bilateral, patchy, ground-glass opacities without evidence of subpleural honeycombing.

Table 90.2 Contrasting Clinical Features of Idiopathic Interstitial Pneumonias

Features	IPF	NSIP	COP	AIP	RB-ILD	DIP	LIP	PPFE
Mean age at onset (yr)	60s	50s	50s	50s	40s	40s	40s	50s

Table 90.4 Histologic Patterns in the Idiopathic Interstitial Pneumonias and Other Disease Associations

Histologic Patterns	Clinical Associations
Usual interstitial pneumonia	Idiopathic pulmonary fibrosis; connective tissue diseases (uncommon); asbestosis; hypersensitivity pneumonitis; chronic aspiration pneumonia; chronic radiation pneumonitis; Hermansky-Pudlak syndrome; neurofibromatosis
Nonspecific interstitial pneumonia	Idiopathic; connective tissue diseases; drugs; hypersensitivity pneumonitis; resolving diffuse alveolar damage; AIDS; infections
Diffuse alveolar damage	Acute interstitial pneumonia (Hamman-Rich syndrome); acute respiratory distress syndrome; drugs (cytotoxic agents, heroin, cocaine, paraquat, ethchlorvynol, aspirin); toxic gas inhalation; radiation therapy; oxygen toxicity; connective tissue disease; infections (*Legionella, Mycoplasma,* viral)
Organizing pneumonia	Cryptogenic organizing pneumonia; organizing stage of diffuse alveolar damage; organizing infections (e.g., influenza) as part of diffuse alveolar hemorrhage; drugs (amiodarone, cocaine); infections; connective tissue diseases; hypersensitivity pneumonitis; eosinophilic pneumonia; granulomatosis with polyangiitis
Desquamative interstitial pneumonia or respiratory bronchiolitis	Cigarette smoking; idiopathic; connective tissue diseases; primary pulmonary Langerhans cell histiocytosis; asbestosis; hard-metal pneumoconiosis (cobalt); Gaucher disease; Niemann-Pick disease; Hermansky-Pudlak syndrome; drugs (nitrofurantoin, amiodarone)
Lymphocytic interstitial pneumonia	Idiopathic; hypogammaglobulinemia; autoimmune diseases, including Hashimoto thyroiditis, systemic lupus erythematosus, primary biliary cirrhosis, Sjögren syndrome, myasthenia gravis, chronic active hepatitis; AIDS; allogeneic bone marrow transplantation

AIDS, acquired immunodeficiency syndrome.

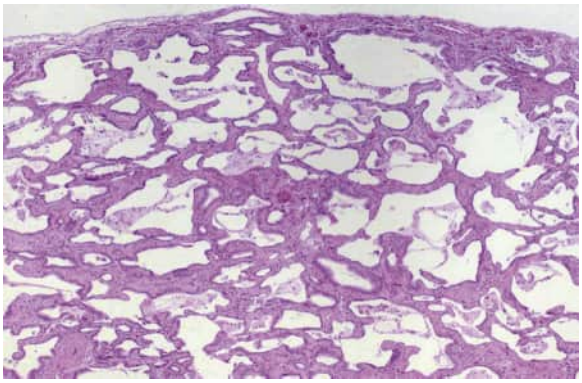

Figure 90.3 Photomicrograph of nonspecific interstitial pneumonia with a mixed cellular-fibrotic pattern. The alveolar walls are thickened by dense collagen and a few lymphocytes and plasma cells. The fibroblastic foci that are commonly found in the usual interstitial pneumonia pattern are not present in this lesion.

biopsies. Importantly, most biopsies showing an NSIP pattern are seen in patients who may have other conditions: an ill-defined or inadequately evaluated connective tissue disease, drug-induced ILD, chronic hypersensitivity pneumonitis, resolving acute lung injury (pneumonia or acute respiratory distress syndrome), or OP.[2,26-31] The NSIP pattern on surgical lung biopsy should prompt the clinician to revisit the clinical data and to look carefully for these conditions; a diagnosis of idiopathic NSIP should be given only after review by multidisciplinary discussion.

Clinical Course and Outcome

Several retrospective studies indicate the survival rate of patients with idiopathic NSIP is significantly higher than in patients with UIP.[15,16,20,25,32] This difference persists even after adjusting for age, sex, smoking history, and physiologic variables. Those patients with a purely cellular pattern on biopsy demonstrate the longest survival, a finding suggesting that this pattern may be more responsive to treatment, and overall prognosis depends primarily on the extent of fibrosis.[15,26] In those patients with an NSIP pattern in one lobe and a UIP pattern in another, the survival is similar to that in patients with UIP. In NSIP, corticosteroids combined with a steroid-sparing agent may be more effective than corticosteroids alone. The optimal dose and treatment duration remain unknown.

CRYPTOGENIC ORGANIZING PNEUMONIA

OP can be cryptogenic (i.e., COP), or it can result from various forms of lung injuries, termed *secondary OP* (e.g., postinfectious, drug-related, connective tissue disease–related, post-transplant, or related to hypersensitivity pneumonitis, radiation, or aspiration of particulate matter). COP is a specific clinicopathologic syndrome characterized by a pneumonia-like illness, with excessive proliferation of granulation tissue inside the alveolar spaces associated with chronic inflammation in the surrounding alveoli.[2,5,11] The process may also involve the small airways (bronchiolitis obliterans with organizing pneumonia).

COP and secondary OP have no major differences in clinical features.[33-35] OP may also be seen accompanying other histopathologic patterns (e.g., UIP, NSIP) but should not be a prominent finding when making the diagnosis of an alternative IIP. The diagnosis of COP is reserved for isolated OP in patients without an identifiable associated disease. Historically, the term *idiopathic bronchiolitis obliterans with organizing pneumonia* encompassed COP, but the term is no longer used for this idiopathic condition. This change in taxonomy was recommended by the American Thoracic Society and the European Respiratory Society consensus classification of IIPs in 2002 in part to avoid confusion with constrictive bronchiolitis obliterans.[2] (See Chapter 72.)

Clinical Features

The incidence of COP is similar in both men and women.[34] The mean age at presentation is about 50 to 55 years (range, 21 to 80 years). Patients with COP are frequently specific about the timing of their disease onset. This is because the disease onset is recent (usually <2 months) and is often dramatic, with the development of a flulike illness characterized by cough, mild dyspnea, fever, malaise, fatigue, and weight loss. Physical examination usually discloses focal sparse crackles but may be normal. Finger clubbing is rare.

Laboratory Features

Routine laboratory studies are nonspecific. Leukocytosis without an increase in eosinophils is seen in approximately half the patients. The initial erythrocyte sedimentation rate is frequently elevated in patients with COP.

Pulmonary function is usually impaired, with a restrictive defect being most common. An obstructive defect (ratio of *forced expiratory volume in 1 second to forced vital capacity ratio* [FEV_1/FVC] <70% of predicted) is found in almost one-fifth of subjects with COP, mostly in current or former smokers.[34,36] Gas-exchange abnormalities are extremely common, with hypoxemia at rest and with exercise. The *diffusing capacity for carbon monoxide* (D_{LCO}) is reduced (<80% of predicted) in three-fourths of patients.

The most common differential cell count on BAL shows an increase in lymphocytes (20–40%), neutrophils (10%), and eosinophils (5%), with the level of lymphocytes higher than that of eosinophils.[34] BAL lymphocytes are activated, and the CD4/CD8 ratio is usually decreased. An increase in plasma cells and/or mast cells may also be seen.

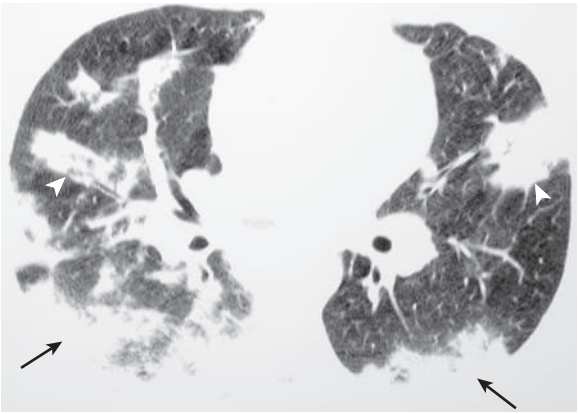

Figure 90.4 Cryptogenic organizing pneumonia. Axial computed tomography shows areas of peripheral *(arrows)* and peribronchial *(arrowheads)* consolidation. (Courtesy Michael B. Gotway, MD.)

Radiologic Features

Chest Radiography. The radiographic manifestations are distinctive, usually including unilateral or bilateral patchy consolidations that resemble pneumonic opacities in the presence of normal lung volumes (eFig. 90.3).[37,38] A peripheral distribution of the opacities, similar to that thought to be "virtually pathognomonic" for chronic eosinophilic pneumonia, is commonly seen in COP.[35,39,40] Irregular linear or nodular interstitial opacities are rarely present as the only radiographic manifestation (eFig. 90.4).[41] Honeycombing is rare and is seen only as a late manifestation in the few patients with progressive disease. Other radiographic abnormalities, such as pleural effusion, pleural thickening, hyperinflation, and cavities, are uncommon.

Computed Tomography. CT scans of the lung reveal patchy air space consolidation, small nodular opacities, and bronchial wall thickening and dilation, most frequently in the periphery of the lung and often in the lower lung zones[38,39,41,42] (Fig. 90.4, Video 90.1). Frequently, the CT findings are far more extensive than are expected by review of the chest radiograph. These opacities tend to migrate and decrease in size, even without treatment (eFig. 90.5). The CT finding of consolidation is associated with partial or complete resolution, whereas reticular opacities are associated with persistent or progressive disease (eFig. 90.6).[43] Sometimes, COP has unique findings such as the reverse halo sign (eFig. 90.7), which is defined as central ground-glass opacity surrounded by denser air space consolidation of crescentic and ring shapes. This sign is seen in approximately 20% of patients with COP.[44] The presence of enlarged lymph nodes is less common in COP than in the other IIPs.[45]

Focal OP has been described as a discrete form of COP and manifests as an isolated focal lesion on chest imaging.[46-48] Many of these patients are asymptomatic, and the lesion may be discovered incidentally by chest radiography or CT performed for other indications. It may be suspected to be a putative lung cancer because most patients with focal OP have a smoking history and are middle aged or older.[48]

Histopathologic Features

The diagnosis of COP depends on both the clinical setting and the finding of characteristic histopathologic features.

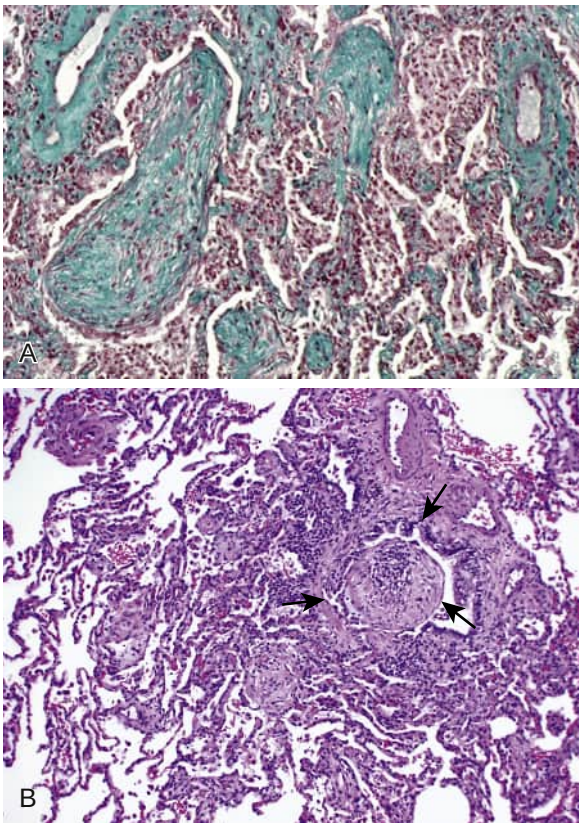

Figure 90.5 Photomicrographs of organizing pneumonia. (A) Immature connective tissue and proliferating fibroblasts (also called Masson bodies) appearing blue-green are present in alveolar ducts and alveolar spaces, as is an interstitial infiltrate consisting of mononuclear cells. (Pentachrome stain; original magnification ×40.) (B) A typical inflammatory polyp extends into the lumen of a terminal bronchiole *(arrows)*. (Original magnification ×40.)

Intraluminal fibroblastic buds, also called *Masson bodies*, seen in respiratory bronchioles, alveolar ducts, and alveoli, are the most prominent features.[2,32,49] Other histopathologic features include foamy cells in the alveolar spaces, prominent alveolar epithelial type 2 cell hyperplasia, interstitial infiltrates, and fibrinous exudates.

The characteristic Masson bodies appear in the small airways as intraluminal collections of proliferating fibroblasts and myofibroblasts in a mucopolysaccharide-rich matrix. They are most prominent in the alveolar ducts but extend distally to the alveolar lumina and proximally to the bronchioles (Fig. 90.5A). Masson bodies may also extend from one alveolus to the next through the interalveolar pores, thus creating a characteristic butterfly pattern.[34] OP can also have an interstitial lymphoplasmacytic infiltrate and hyperplasia of the alveolar epithelial type 2 cells. The organizing process, which may extend into the bronchioles, produces an intraluminal polypoid bronchiolitis obliterans (Fig. 90.5B). OP represents a common reparative response to injury seen in a variety of ILDs, infectious pneumonias, and many other processes. If the injury is unresponsive to treatment, the organizing process can progress to irreversible fibrosis and a honeycombed lung.

Clinical Course and Outcome

Corticosteroid therapy results in complete clinical, radiologic (eFig. 90.8), and physiologic recovery in two-thirds

of patients.[34] The other one-third demonstrates recurrent or persistent disease. Secondary OP is less likely to respond to corticosteroids. In general, clinical improvement is rapid, within several days or a few weeks. Occasionally, recovery is quite dramatic. When corticosteroids are withdrawn, patients can experience a relapse, usually within 1 to 3 months. Most patients with relapses improve when retreated with corticosteroids.[50] It has been suggested that COP may also respond to macrolide therapy, but studies are scant.[51] A few patients may improve spontaneously over 3 to 6 months.[34,52] A seasonal (early spring) presentation of COP with relapse every year during the same period has been reported.[53] Few patients with COP die as a result of this illness, but those with a rapidly progressive, fatal form of OP have a clinical course similar to that of patients with *acute interstitial pneumonia* (AIP).[54] In such patients, the diagnosis is usually delayed or missed. Focal OP is generally cryptogenic, does not recur after surgical resection, and does not require corticosteroid therapy.[48,55,56]

ACUTE INTERSTITIAL PNEUMONIA

AIP is a rare, fulminant form of lung injury that manifests acutely (days to weeks from onset of symptoms), usually in a previously healthy person.[57-59] AIP likely represents a subset of cases of idiopathic acute respiratory distress syndrome and is what Hamman and Rich[60] described and termed *acute diffuse interstitial fibrosis.*

Clinical Features

Most patients are older than 40 years (mean age, 50 years; range, 7 to 83 years).[57,58] Men and women are equally affected, and cigarette smoking does not seem to increase the risk. A prodromal illness, usually lasting 7 to 14 days before presentation, is common. The clinical signs and symptoms include fever, cough, and shortness of breath. Routine laboratory studies are nonspecific and generally not helpful.

Radiologic Features

Chest Radiography. Diffuse, bilateral, air space opacification is seen on the chest radiograph (eFig. 90.9).[61-63]

Computed Tomography. The typical *high-resolution CT* (HRCT) features of AIP are bilateral, multifocal, or diffuse areas of ground-glass opacity and consolidation, usually without pleural effusion (eFig. 90.10).[37,61,64,65] A predominantly subpleural distribution may be seen. These radiographic findings are similar to those seen in acute respiratory distress syndrome; however, patients with AIP are more likely to have a symmetrical, bilateral distribution with a lower lobe predominance.[66] In the early phase of AIP, ground-glass opacities and less extensive areas of consolidation make up the dominant CT pattern, reflecting the presence of alveolar septal edema and hyaline membranes.[64] During the organizing phase of the disease, HRCT findings consistent with evolving fibrosis are often present, including traction bronchiectasis, reticular opacities, and architectural distortion.[67] In this phase, consolidations resulting from intra-alveolar fibrosis may also be present, along with mild honeycombing, usually involving less than 10% of the lung.[61]

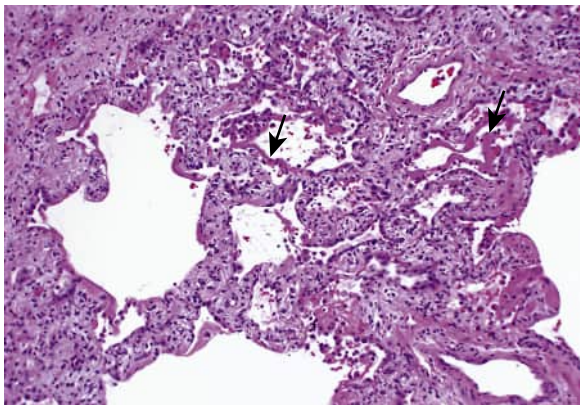

Figure 90.6 Photomicrograph of acute interstitial pneumonia shows diffuse alveolar damage. Note the hyaline membranes *(arrows)* within alveolar spaces and edema and inflammatory cell infiltration of the alveolar wall. (Original magnification ×10.)

Histopathologic Features

A surgical lung biopsy is required to confirm the diagnosis of AIP.[2,57,68] The histopathologic pattern seen in AIP is *diffuse alveolar damage* (DAD), which can be categorized into an early exudative phase, an organizing phase, and a chronic phase, depending on the timing of the biopsy in relation to the lung insult. DAD develops after an acute injury to the alveolar capillary basement membranes.[57,59] DAD is common and may be seen on biopsy in many settings, including in immunosuppressed patients who have received cytotoxic drugs or in patients who have diffuse infectious pneumonias.[69-71]

After the endothelial-epithelial injury, serum proteins and red blood cells leak into the alveolar spaces. The alveolar epithelium becomes necrotic and is sloughed, and the interstitium becomes edematous. Hyaline membranes, recognized as eosinophilic debris and consisting of necrotic epithelial cells, protein, and fibrin, form within alveolar spaces (Fig. 90.6). In the reparative or organizing stage of DAD, proliferation and hyperplasia of the alveolar epithelial type 2 cells are noted, often showing nuclear enlargement and prominent nucleoli. Extensive fibroblast proliferation is a dominant finding in the organizing phase; proliferating fibroblasts and myofibroblasts within a myxoid basophilic matrix may be seen within alveolar septa or in the alveoli, a picture resembling OP.[68] Fibrin thrombi are often present. In some cases, these changes may resolve but, in others, perhaps because of protracted or repeated parenchymal injury, they may progress to irreversible fibrosis and honeycomb lung.

Clinical Course and Outcome

Treatment is largely supportive and consists of mechanical ventilation and oxygen supplementation.[57,58,63,69] Corticosteroids seem to be effective in the early phase of disease. According to most studies, the mortality from AIP appears to be high (>50%), with the majority of patients dying within 3 months of presentation.[57-59,63] Most survivors of AIP experience recurrences and chronic, progressive ILD.[63] However, a lower hospital mortality (12.5%) with no evidence of either recurrent or progressive disease has been also described.[72]

RESPIRATORY BRONCHIOLITIS–ASSOCIATED INTERSTITIAL LUNG DISEASE AND DESQUAMATIVE INTERSTITIAL PNEUMONIA

RB-ILD and *desquamative interstitial pneumonia* (DIP) are related and, in some cases, inseparable conditions because most cases appear to represent different stages of the same process.[73-76]

These diseases represent a distinct clinical syndrome found in current heavy smokers. The term RB-ILD is more anatomically accurate because it conveys important pathogenic implications compared with the older term DIP. Both (primarily RB-ILD) account for 15–20% of patients with IIPs who have undergone biopsies.[68,77] Importantly, respiratory bronchiolitis is an accurate histologic marker of cigarette smoking, and it may be found many years after smoking ceases.[78] The level of cytoplasmic pigmentation of macrophages and the presence of peribronchial fibrosis correlate with the smoking history in pack-years.[78] Moreover, it has been reported that persons with significant lifetime secondhand smoke exposure, especially in the previous 12 months, have significant increases in ground-glass opacities on HRCT, a finding suggesting early or subclinical respiratory bronchiolitis and DIP.[79] Furthermore, RB- and DIP-like histologic changes (1) are exceedingly common in pulmonary Langerhans cell histiocytosis, (2) may be sufficiently severe to cause the appearance of ground-glass opacities on HRCT, and (3) correlate with the cumulative exposure to cigarettes smoked.[80]

Although cigarette smoking is considered the main cause of RB-ILD and DIP, genetic abnormalities of surfactant function, including mutations in the genes coding for surfactant protein B and C, account for an increasing number of ILDs, including DIP.[81,82] In addition, DIP can be observed in various occupational or drug exposures.[9,77,83]

Clinical Features

RB-ILD and DIP primarily affect cigarette smokers between the third and the sixth decades of life.[9,10,77] RB-ILD and DIP have a male preponderance, with men affected nearly twice as often as women. Patients with either RB-ILD or DIP commonly present with insidious exertional dyspnea and persistent nonproductive cough. Less frequently, patients with DIP experience fatigue and weight loss. Coarse, bibasilar end-inspiratory crackles are frequent findings on physical examination, whereas finger clubbing is uncommon.

Laboratory Features

BAL fluid in patients with RB-ILD and DIP is characterized by mild to moderate increases in total cell numbers, moderate to marked eosinophilia (a feature that, in the absence of a biopsy, could raise the consideration of chronic eosinophilic pneumonia), and moderate neutrophilia.[84,85]

Pulmonary function testing may be normal but usually shows mild to moderate restriction, normal or slightly reduced diffusing capacity, and mild hypoxemia.[9,10,85] A mixed obstructive-restrictive pattern is common, although there may be an isolated increase in residual volume.

Radiographic Features

Chest Radiography. The chest radiograph is insensitive for detection of RB-ILD and is often normal.

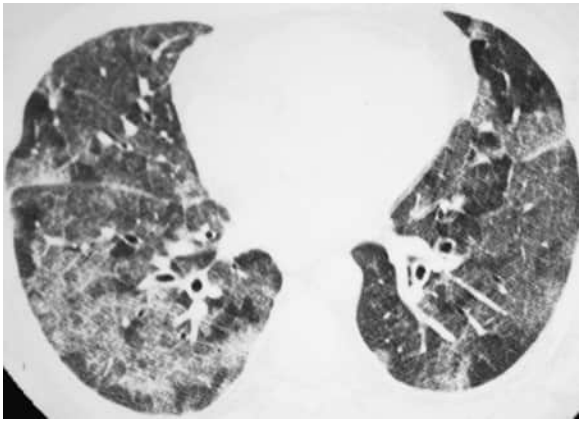

Figure 90.7 Desquamative interstitial pneumonia. Axial high-resolution computed tomography shows patchy, multifocal ground-glass opacity associated with areas of interlobular septal thickening and intralobular interstitial thickening. (Courtesy Michael B. Gotway, MD.)

Sometimes, bronchial wall thickening or reticular opacities can be seen (eFig. 90.11). Chest radiographs of DIP (eFig. 90.12) are nonspecific and usually reveal bilateral ground-glass opacities. Middle and lower lung field involvement with normal-appearing lung volumes predominates.[9,10,77] Air bronchograms can be found when the disease process surrounds the airways. The honeycomb pattern is rare.

Computed Tomography. The key HRCT features of RB-ILD include central bronchial wall thickening proximal to segmental bronchi, peripheral bronchial wall thickening distal to segmental bronchi, centrilobular nodules (eFig. 90.13), and areas of ground-glass opacity.[75,86,87] Ground-glass opacifications may be diffuse or patchy, without basal or peripheral predominance.[75,87,88] The predominant abnormality in DIP (eFig. 90.14) is the bilateral, moderately symmetrical, peripheral, and predominantly basal ground-glass attenuation Fig. 90.7, eFig. 90.14). Tiny thin-walled cysts (eFig. 90.15) are noted within the ground-glass opacities in 30–60% of cases.[84,89,90] A honeycomb pattern is rarely found.[9,84,87,90] Appearances between RB-ILD and DIP occasionally overlap, although the ground-glass attenuation of DIP is usually more extensive, and nodules are infrequent or absent.[85]

Histopathologic Features

The cardinal feature of RB-ILD is the accumulation of alveolar macrophages within the bronchioles, including the terminal and respiratory bronchioles, variably extending into alveolar ducts and alveoli.[8,68,78,91] In contrast to RB-ILD, DIP shows a much more widespread and uniform filling of all alveoli, although in any given biopsy one can find low-power fields showing only RB-ILD–type changes and others typical of DIP. This histologic observation supports the close association of RB-ILD and DIP. Macrophages are characterized by glassy eosinophilic cytoplasm, usually with brown and finely granular pigmentation (representing constituents of cigarette smoke).[2,68,85,91] A chronic inflammatory cell infiltrate in bronchiolar and surrounding alveolar walls is often noted. The changes of RB-ILD are patchy at low magnification and have a distinctly bronchiolocentric

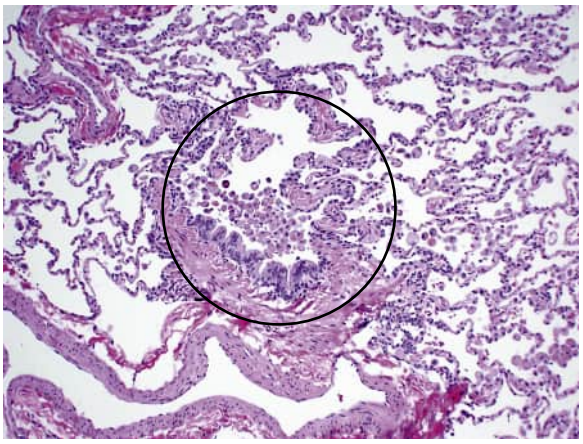

Figure 90.8 Photomicrograph of respiratory bronchiolitis. An ectatic small airway *(circle)* is visible, with thickened walls and extension of the bronchiolar metaplastic epithelium into the immediately surrounding alveoli. Intraluminal macrophages are also present within the peribronchiolar alveolar spaces.

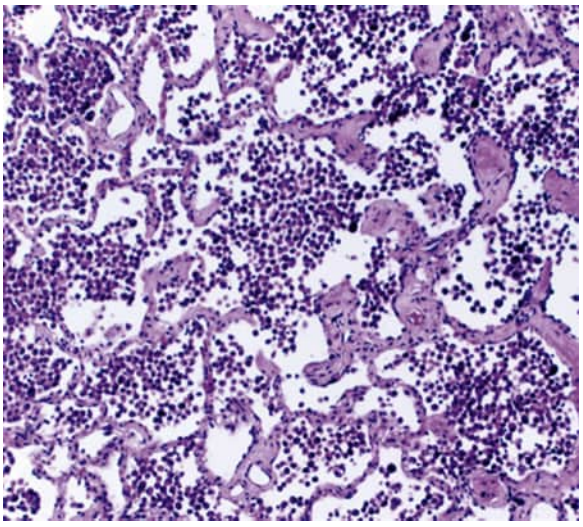

Figure 90.9 Photomicrograph of desquamative interstitial pneumonia. Characteristic dense collections of macrophages are seen filling alveolar lumina. (Original magnification ×100.)

distribution without the associated diffuse involvement and interstitial pneumonia necessary for a diagnosis of DIP (Fig. 90.8).[68]

As mentioned, the histologic hallmark of DIP is the uniform filling of the alveolar spaces by cohesive clusters of numerous pigmented alveolar macrophages, including occasional multinucleated cells, eosinophils, and lymphocytes (Fig. 90.9).[68,92] Alveolar septa are thickened by a sparse inflammatory infiltrate and lined by uniform hyperplastic alveolar epithelial type 2 cells. Peribronchiolar lymphoid hyperplasia is seen in the majority of cases.[68,92] Most DIP cases show a difference in the degree of pathologic change from one lobule to the next in a given biopsy specimen. Some degree of architectural destruction is usually observed. Akira and colleagues[90] have pointed out the presence of dilated alveolar ducts and bronchioles and/or pulmonary cysts, which corresponded to cystic spaces on HRCT.[84]

Bedrossian and coworkers[93] coined the term *DIP-like reaction* to identify prominent intra-alveolar macrophage accumulation around space-occupying pulmonary lesions. This DIP-like reaction can be seen in a number of other processes, including pulmonary Langerhans cell histiocytosis, drug reactions (e.g., amiodarone), chronic alveolar hemorrhage, eosinophilic pneumonia, pneumoconioses (e.g., talcosis, hard-metal disease, asbestosis), obstructive pneumonias, and exogenous lipoid pneumonia.[92,94] In these cases, however, the DIP-like reaction is usually focal, without the uniform involvement of lung parenchyma seen in true cases of RB-ILD and DIP.

Clinical Course and Outcome

Because there has not been a longitudinal study of a large group of participants, the clinical course and prognosis of patients with RB-ILD are unknown. Most studies suggest a favorable response to smoking cessation and the use of corticosteroids, with documented improvement in lung function and chest radiographs[91]; few deaths secondary to progressive lung disease have been reported.[10]

Patients with the DIP stage of this process also have a good prognosis, particularly with early smoking cessation. Five-year survival rates of more than 75% have been reported with mean follow-up times in these small studies ranging from 5 to 10 years.[9,83,91] Additional prospective studies with a larger number of participants will be necessary to confirm these results. In another study, symptomatic improvement (i.e., improved cough, dyspnea, or both) with prednisone treatment was noted in 24% of patients with DIP and in 55% of patients with RB-ILD.[9] Objective improvement with prednisone treatment, as evidenced by improvement in pulmonary function measurements or parenchymal opacities seen on chest radiography or CT scans, was noted in 33% of patients with DIP and in 64% of patients with RB-ILD.[9] Unfortunately, these positive responses tended to be transient in half of the patients, with recurrence of disease following tapering and discontinuation of prednisone treatment. Patients can regress to their original disease status even in the absence of smoking.[9]

Nevertheless, because smoking plays a major role in the pathogenesis, smoking cessation is always indicated in these patients. With smoking cessation, there can be significant improvement in clinical symptoms and D_{LCO}, as well as in radiologic features including ground-glass opacities and centrilobular nodules.[95] Corticosteroids may be required in refractory or recurrent cases but are not recommended if the patient continues to smoke.

RARE IDIOPATHIC INTERSTITIAL PNEUMONIAS

IDIOPATHIC LYMPHOCYTIC INTERSTITIAL PNEUMONIA

Lymphocytic IP (LIP) is an uncommon pathologic pattern characterized by the presence of widespread, monotonous sheets of lymphocytic infiltration in the interstitium of the lung.[96-98] Idiopathic LIP is rare and, in addition to being differentiated from other IIPs, it must

be distinguished from other lymphocytic infiltrations in the lung, notably lymphomas and ILDs associated with prominent lymphoid infiltrates such as collagen vascular diseases (especially Sjögren syndrome), dysproteinemia, drug reactions, hypersensitivity pneumonitis, immunodeficiency syndromes (e.g., human immunodeficiency virus infection, combined variable immunodeficiency), and hematopoietic stem cell transplantation. The LIP pattern is seen far more commonly as a secondary disease in association with systemic disorders than it is as the idiopathic disease described here. Most of the earlier reports on LIP included secondary cases (Table 90.5).[99-102]

Clinical Features

Patients most commonly present with progressive dyspnea and cough, although they may also have weight loss, pleuritic pain, arthralgias, and fever.[96-98] Bibasilar crackles can be heard on auscultation in most patients. Digital clubbing is usually absent, and cyanosis is a rare physical finding. Because LIP is more commonly a secondary process found in association with a primary underlying disease, close attention to extrapulmonary findings that may assist in diagnosing a primary condition is of utmost importance.

Laboratory Features

In idiopathic LIP, results of laboratory studies are likely to be normal. If laboratory results are abnormal, they may reflect an underlying disease state leading to secondary LIP. Dysproteinemia may be found, usually a polyclonal gammopathy. Pulmonary function testing shows a restrictive defect, reduced D_{LCO}, and hypoxemia.[96-98] If performed, the differential cell count on BAL demonstrates striking T cell lymphocytosis.[97]

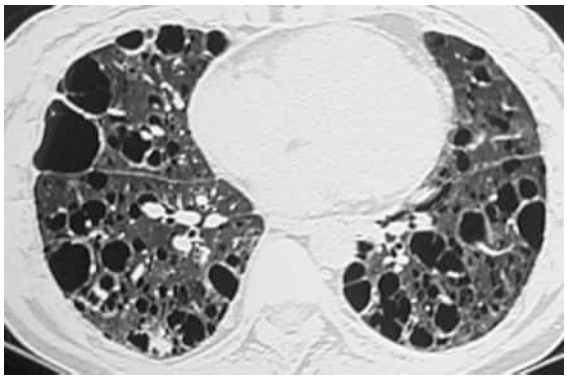

Figure 90.10 Lymphocytic interstitial pneumonia. High-resolution computed tomography image shows diffuse, randomly distributed round cysts, many of which lie near vessels.

Radiologic Features

Chest Radiography. The chest radiograph is nonspecific, with reticular opacities (eFig. 90.16) the most frequent abnormality. A mixed alveolar-interstitial pattern appears as the disease progresses because of the coalescence of the opacities. Cysts, honeycombing, and signs of pulmonary hypertension are also late manifestations.[103] Pleural effusions are infrequent and suggest a complicating lymphoma.

Computed Tomography. The main parenchymal abnormalities on CT scan consist of ground-glass opacities (eFig. 90.17), thickening of interlobular septa, centrilobular nodules (eFig. 90.18), thin-walled perivascular cysts (Fig. 90.10), and air space consolidation (see eFig. 90.17).[42,101] In contrast to the subpleural, lower lung cystic changes seen in UIP, the cysts of LIP are usually within the lung parenchyma throughout the mid-lung zones and presumably result from air trapping secondary to peribronchiolar cellular infiltration.[101-103] The cysts that may be seen in up to 80% of patients are typically scant and measure less than 3 cm in diameter. On follow-up CT, most patients show improvement in the extent of parenchymal abnormalities.[102] Cystic changes are not reversible, and some patients have enlarging cysts or develop new cysts over time (eFig. 90.19). New cysts often develop in areas with centrilobular nodules on initial CT. Although uncommon, honeycomb change in areas of previous air space consolidation has been observed on follow-up imaging.[102]

Histopathologic Features

Surgical lung biopsy is generally required for the diagnosis. The lymphocytic infiltration is usually extensive and severe, involving the alveolar septa and peribronchiolar and perivascular interstitium[2,5,96] (Fig. 90.11). Reactive lymphoid follicles are often present and distributed along the peribronchiolar regions. The lymphocytes are polytypic (both B and T cells may be found), distinguishing

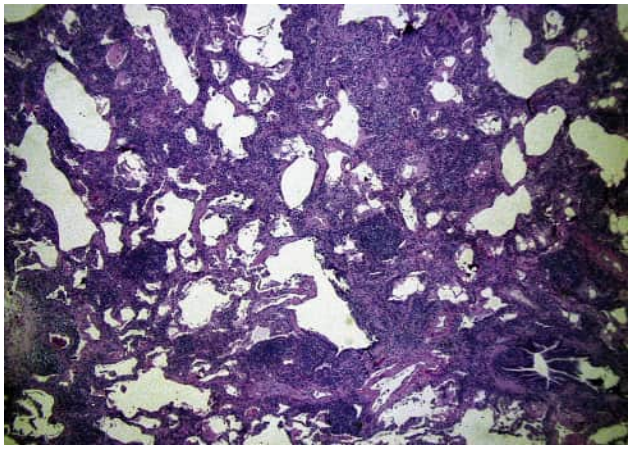

Figure 90.11 Photomicrograph of lymphocytic interstitial pneumonia. A diffuse lymphoid infiltrate extends through the pulmonary interstitium. (Original magnification ×10.)

them from the monotypic lymphocytic infiltrates characteristic of pulmonary lymphoma. Immunohistochemistry and molecular analysis may also be helpful to distinguish LIP from pulmonary lymphomas. The number of plasma cells and macrophages is also increased in these infiltrates. LIP is distinguished from DIP and NSIP by the marked density of the lymphoid infiltrate in LIP, although no precise criteria exist.[2,5,96] Other features of LIP include the interstitial accumulation of macrophages, noncaseating granulomas, perivascular amyloid deposits, and germinal lymphoid centers.

Clinical Course and Outcome

Because of the rarity of idiopathic LIP, its clinical course is unknown. When LIP is associated with another disease, the underlying disease largely determines the outcome. In many case reports, marked improvement or complete resolution has followed corticosteroid therapy.[97-99] However, the disease can progress to pulmonary fibrosis, right heart failure, and death of the patient despite therapy. Infection is a common complication, especially in patients with associated dysproteinemia.[97-100] Progression to pulmonary or systemic lymphoma appears to be rare, and it is likely that, in this group of patients, malignant lymphoma was present from the outset.[98,100,104,105]

IDIOPATHIC PLEUROPARENCHYMAL FIBROELASTOSIS

Idiopathic *pleuroparenchymal fibroelastosis* (PPFE) is another rare form of IIP and is characterized by an upper lung zone predominant fibrotic process involving the visceral pleura and adjacent subpleural parenchyma.[106-109]

A similar presentation of upper lobe subpleural fibrosis has been described in patients following bone marrow transplantation,[110] after lung transplantation, and in association with several different chemotherapeutic drugs.[111]

Radiologic PPFE-like lesions have also been found in patients with connective tissue–associated ILD, especially in patients with systemic sclerosis and primary Sjögren's syndrome.[112] Many patients diagnosed with PPFE also demonstrate radiographic or histopathologic features of a second IIP. It is important to follow these patients closely to determine the best therapeutic strategy, depending on the evolution of either IIP.

Clinical Features

The presentation of patients with PPFE is similar to that in patients with other IIPs, with progressive dyspnea on exertion the most commonly reported symptom. Cough may or may not be present. Most patients are adults in the sixth decade of life, and men and women are equally affected.[106,108] Most patients are nonsmokers and report a history of recurrent pulmonary infections in the past.[108] Patients may also present with spontaneous pneumothorax or pneumomediastinum or develop these disorders in the course of their illness.[108,113] The pulmonary examination is often normal, although a "flat chest" has been described in which the ratio of the anteroposterior to the transverse diameter is abnormally low; whether this arises congenitally or from the fibrosis of the underlying lung is not known, but it may worsen over time with disease progression.[114]

Laboratory Features

Results of pulmonary function tests are consistent with a restrictive defect and may show a decrease in FVC out of proportion to that of the D_{LCO}. Arterial blood gas analysis in the early stages of disease may show hypercapnia and a normal alveolar-arterial oxygen tension difference, possibly because, in the early stages, the major pathophysiologic defect is pleural fibrosis and an extrapulmonary restrictive defect.[115,116]

Radiologic Features

Chest Radiography. In patients with early PPFE, chest radiography may be normal. With disease progression, bilateral, irregular pleural thickening at the apices may be apparent. The hilar structures are often pulled up as a result of upper lobe volume loss and architectural distortion.[117,118]

Computed Tomography. The characteristic CT scan findings are dense, subpleural consolidations with associated traction bronchiectasis and architectural distortion in the bilateral upper lobes (Fig. 90.12).[106,108,119] The pleura is typically thickened in the areas of the subpleural fibrotic changes. A characteristic feature of PPFE is a clear delineation between areas of fibrosis and normal lung. Volume loss and architectural distortion with upward retraction of the hila and cysts and bullae may also be present. Coexistent lower lobe interstitial changes in a UIP-like or NSIP-like pattern are increasingly reported.[116]

Histopathologic Features

The histopathologic features of PPFE include subpleural, intra-alveolar fibrosis with septal elastosis and the deposition of elastic fibers with intervening collagen within the alveolar septa (Fig. 90.13).[106-108] The visceral pleura appears densely fibrotic in an upper lung zone predominance, but all lung zones may be involved histologically even if involvement is not apparent on CT

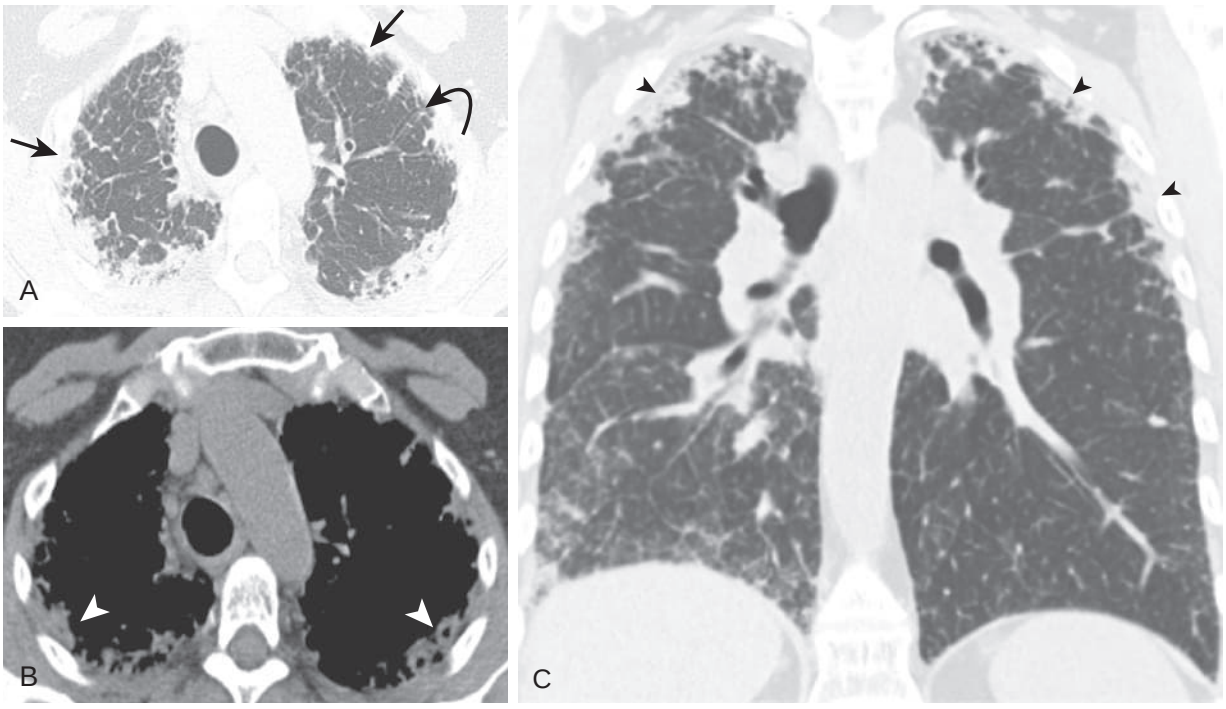

Figure 90.12 Computed tomography of idiopathic pleuroparenchymal fibroelastosis. (A) Axial image of the lung apices in lung windows demonstrates fibrosis characterized by reticulation *(straight arrows)* and traction bronchiectasis *(curved arrow)*. (B) Soft tissue windows show areas of marked pleural thickening *(arrowheads)*. (C) Coronal images in lung window demonstrate apical predominant fibrosis, resulting in volume loss and upward retraction of the hila. Marked pleural thickening is present *(arrowheads)*. imaging. The subpleural space demonstrates homogeneous fibroelastosis with a sharp delineation between the involved subpleural region and normal lung parenchyma. Rare fibroblastic foci may be found at the leading edge of the fibrotic changes adjacent to normal parenchyma.[113]

Clinical Course and Outcomes

Most patients with idiopathic PPFE experience disease progression. In a case series of 12 patients with PPFE, prednisone treatment, even with additional immunosuppressive therapy, did not appear to have a beneficial effect.[108] In a series of 52 patients with idiopathic PPFE diagnosed after multidisciplinary discussion, the 5-year mortality was reported to be 42%.[120] In patients with another coexisting IIP, particularly with lower lobe UIP, the clinical course may be more rapidly progressive.[116]

ACKNOWLEDGMENT

We acknowledge the contributions of Drs. Jay H. Ryu, Moisés Selman, and Thomas Colby to the writing of this chapter.

Key Points

- Idiopathic interstitial pneumonias are a subgroup of interstitial lung diseases of unknown etiology and are associated with variable radiologic features, response to therapy, and clinical course.
- The gold standard for diagnosis of any idiopathic interstitial pneumonia includes multidisciplinary discussion including clinicians, radiologists, and pathologists with specific expertise in interstitial lung disease.
- Nonspecific interstitial pneumonia is characterized by diffuse, temporally and geographically homogenous cellular infiltrates (cellular nonspecific interstitial pneumonia) or fibrosis (fibrotic nonspecific interstitial pneumonia). Finding a histopathologic pattern of nonspecific interstitial pneumonia on biopsy should prompt additional evaluation to identify an underlying cause because idiopathic nonspecific interstitial pneumonia is uncommon. In general, patients with nonspecific interstitial pneumonia (especially cellular nonspecific interstitial pneumonia) have a better prognosis than patients with idiopathic pulmonary fibrosis.
- Cryptogenic organizing pneumonia is characterized by patchy, migratory pulmonary opacities that are often mistaken for pneumonia. Cryptogenic organizing pneumonia is very steroid responsive but may relapse following tapering or discontinuation of steroids.
- Acute interstitial pneumonia is a rapidly progressive cause of acute respiratory failure characterized by diffuse alveolar damage and hyaline membranes on histopathology. Mortality is high.
- Respiratory bronchiolitis–associated interstitial lung disease and desquamative interstitial pneumonia are smoking related in most patients. Smoking cessation is the cornerstone of treatment for most patients with or without corticosteroids.
- Idiopathic lymphocytic interstitial pneumonia is a rare diagnosis, and clinicians should perform additional diagnostic evaluation to rule out an underlying condition.
- Idiopathic pleuroparenchymal fibroelastosis is a progressive disease with no known treatments. Standardization of diagnostic criteria and prospective research are needed in this disease.

INTRODUCTION

Hypersensitivity pneumonitis (HP) is a complex inflammatory and/or fibrotic *interstitial lung disease* (ILD) seen in susceptible individuals due to an immunologically mediated reaction to one or more inciting inhaled antigens. HP can arise after exposures in occupational, avocational, residential, or environmental settings. Due to its heterogeneous clinical course and overlap with other ILDs, diagnosis and management can be challenging. Recognizing HP requires a high index of suspicion and should be on the differential diagnosis whenever a patient presents with a syndrome suggestive of ILD.

HP is diagnosed through the integration of clinical, radiologic, and histopathologic findings consistent with the disease. As with all forms of ILD, the diagnostic gold standard is based on review of all available information in a *multidisciplinary discussion* (MDD). Recently, international consensus guidelines have been published for the diagnosis of HP.[1] These developments will help better characterize HP, ultimately improving our understanding and management of this entity. HP is currently classified into two groups, nonfibrotic (or inflammatory) and fibrotic HP. For consistency with prior terminology, acute and chronic HP may be used throughout this chapter synonymously with the nonfibrotic and fibrotic forms of disease, respectively.

CLASSIFICATION

HP is a complex lung disease arising in susceptible individuals caused by the repeated inhalation of a variety of organic or low-molecular-weight agents. For many years, a time-based classification of the clinical-radiologic-histopathologic presentation and disease behavior of HP (i.e., acute, subacute, and chronic) had been used for descriptive purposes.[1a] However, it has become evident that this classification of HP does not provide prognostic precision. A cluster analysis of a large prospective multicenter cohort study showed that most HP cases at presentation fit best into a two-cluster model.[2] This study also showed that subacute HP is particularly difficult to define because the clinical, functional, and imaging findings in this subset overlap with both the acute and chronic forms of disease. Thus, there has been a shift from a solely time-based classification to a stratification of the disease based on characteristics known to improve diagnostic certainty and prognosis, as described next.

Among patients with HP, determining the presence or absence of an inciting antigen exposure is essential for patient counseling and disease management. Furthermore, during the diagnostic workup, the identification of an inciting antigen exposure is the strongest predictor of the likelihood of HP.[3] Also, findings on chest *high-resolution computed tomography* (HRCT) can be prognostic. The initial evaluation of patients presenting with HP or any ILD requires HRCT of the chest before considering invasive testing (e.g., lung biopsy); thus, the evidence supports classifying HP according to the presence or absence of radiographic pulmonary fibrosis. Irrespective of the background pattern of involvement, the radiographic presence of fibrosis (i.e., reticulation, bronchiectasis, or honeycombing) and its extent have been consistently shown to predict a poor outcome.[4–7] The current ontologic approach to HP is conceptualized into two broad categories: inflammatory or nonfibrotic, and fibrotic HP. In general, inflammatory or nonfibrotic HP is expected to normalize with antigen remediation and/or pharmacologic treatment with immunosuppressive drugs. A nonfibrotic form of HP should result in no long-term sequelae. Conversely, patients with fibrotic HP will not have normalization of their lung function, chest imaging, or symptoms and may not achieve disease stabilization.

EPIDEMIOLOGY

HP is one of the most common diagnoses encountered at ILD referral centers worldwide. Population-level databases have helped improve our understanding of disease burden attributable to HP. However, in contrast to work-related HP, nonoccupational HP cases are not reportable and therefore likely underrepresented.[8]

Several factors influence estimates of HP frequency. First, several lines of evidence suggest aging-related mechanisms in HP pathogenesis since its prevalence increases with increasing age. In an analysis of a large U.S. health care database with 150 million unique enrollees, the prevalence of HP increased with age from 0.95 per 100,000 in children aged 0 to 9 years to 11.2 per 100,000 in adults older than 65 years.[9] Second, it is known that environment-specific variations in HP frequency can indicate differences in occupational exposures. The most convincing evidence of the impact of the occupation and the risk of HP comes from epidemiologic studies focusing on *farmer's lung disease* (FLD) and HP among pigeon breeders.[10] Also, there are numerous reports of occupational outbreaks in specific settings such as after exposure to various low-molecular-weight chemicals and contaminated metalworking fluids, ventilation, and water humidification systems.[11] Third, the duration or frequency of exposure to the antigen and weather conditions may contribute to the prevalence and environmental distribution of HP in populations at risk. For example, FLD is prevalent during late winter and the early spring cattle feeding period and after the harvest season, when farmers may be reexposed to a heavy spore concentration from stored moldy hay.[12,13] Similarly, in Japan, the incidence rate of summer-type HP has been reported to increase in years with increased rainfall and decreased daylight hours.[14]

The epidemiologic impact of fibrotic HP (representing a subgroup at high risk for disease progression) was highlighted in an administrative claims-based analysis carried out from 2004 through 2013 that found the 1-year prevalence rate of HP ranged from 1.7 to 2.7 per 100,000 persons. From 56–68% of HP cases in each year were classified as chronic (prevalence, 0.9–1.7 per 100,000 persons). Moreover, up to 25% of cases met the criteria set for fibrotic HP (prevalence ranged 0.4–0.8 per 100,000 persons), which was associated with a higher mortality rate.[15]

Only two countrywide studies have evaluated trends in HP mortality, both from the United States. The overall age-adjusted HP-related mortality rate increased from 0.1 per 1,000,000 in 1988 to 0.7 per 1,000,000 persons in 2016, equating to an average annual percentage increase in mortality rate of 5.6%. Mortality rates increased with increasing age and rates were highest in men and in those from the farming states of the Midwestern United States.[16] Using the same database, an earlier study identified a similar mortality trend over time, observing a significant increase in overall age-adjusted mortality rate between 1980 and 2002 from 0.1 to 0.3 per million.[17] It is unknown whether these trends were caused by an increase in true incidence or disease-related mortality, or by an increase in disease recognition.

ETIOLOGY

More than 200 sources of exposure have been implicated in HP, and new exposures continue to be reported. These causes are frequently named according to the setting in which the patient was exposed (e.g., hot tub lung, cheese washer's lung), but there is significant overlap with the specific antigenic agents implicated in disease. HP antigens can be grouped according to three main categories: microbes, animal proteins, and chemical sensitizers. These exposures can take place in residential, occupational, avocational, or environmental settings, highlighting the importance of a thorough and comprehensive exposure assessment. Importantly, in up to 50% of chronic HP patients at tertiary referral centers, no causative antigen can be identified despite a comprehensive assessment and exhaustive search.[5,18] The prevalence of HP without an identified antigen suggests that either there are unrecognized causes of HP and/or current exposure assessment and identification tools have limited ability to identify the inciting antigen source. Table 91.1 provides a list of commonly reported causes of HP. More comprehensive summaries of the causes of HP are available elsewhere.[19,20]

MICROBES

Microbial organisms such as bacteria and fungi flourish in both indoor and outdoor environments. Many microbes are ubiquitous, and their inhalation may initiate sensitizing diseases of the lung, including HP. Several species of bacteria are known to cause HP. Thermophilic actinomycetes are causally associated with FLD. These bacteria thrive in hot temperatures and damp conditions, secreting enzymes that digest agricultural products, and can cause FLD when inhaled in large quantities, such as by pitching moldy hay. Thermophilic actinomycetes are also found in moldy sugar cane and mushroom compost. Water sources such as humidifiers, showerheads, and swamp coolers have been associated with multiple forms of bacteria causing HP, including *Thermoactinomyces vulgaris* and *Mycobacterium avium complex*. In metalworking fluid used in several industrial work environments, contamination by nontuberculous mycobacteria led to isolated cases and outbreaks.[21–23] Mycobacterial exposures have also been reported to cause HP from exposures to contaminated water sources such as swimming pools (lifeguard's lung) and hot tubs (hot tub lung).[24–26]

Fungal antigen exposure can cause some forms of HP via the inhalation of airborne spores, mycelial fragments, metabolites, and toxins of different fungi.[27] Multiple fungi have been cultured from these environments, highlighting the general point that sensitizing and inciting exposures may not be single, but may be multiple with additive or even synergistic effects. Indoor environments ripe for fungal growth include garbage containers, food storage areas, wallpaper, curtains, carpeting, and areas of moisture such as shower curtains, damp basements, air conditioners, and emissions from cool mist vaporizers.[28,29] Several different fungal species are implicated in causing HP. *Aspergillus* species have been associated with HP in esparto lung, caused by exposure to esparto grass fibers and often seen in plasterers.[30] *Penicillium* species can cause HP in cheese washers, cork workers, sausage makers, and tree cutters. Summer-type HP is the most common form of HP reported in Japan, caused by residential mold contamination with

Table 91.1 Common Causes of Hypersensitivity Pneumonitis (HP)

Disease	Antigen	Scenario/Source
MICROBES		
Farmer's lung	Thermophilic actinomycetes, *Faeni rectovirgula*	Moldy hay, silage, grain
Humidifier lung	*Thermoactinomyces vulgaris*, *T. sacchari*, *T. candidus*	Contaminated forced air systems, water reservoirs
Hot tub lung	*Mycobacterium* avian complex spp	Contaminated hot tubs
Wind instrument lung	*Fusarium* sp, *Penicillium* sp, *M. chelonae*, *Candida* sp, *Cryptococcus* sp	Contaminated trombone, bagpipe, saxophone
Metalworking fluid lung	*M. immunogenum, Pseudomonas* sp	Aerosolized metalworking fluid
Summer-type HP	*Trichosporum cutaneum*	Contaminated old houses
Mushroom worker's lung	*T. sacchari*	Mushroom compost
Suberosis	*T. viridis, Aspergillus fumigatus, Pseudomonas* spp	Cork molds
Esparto lung	*Aspergillus fumigatus*	Moldy *Stipa tenacissima* grass
Woodworker's lung	*Alternaria* sp wood dusts	Moldy oak, cedar, mahogany
ANIMAL PROTEINS		
Pigeon breeder's lung	Pigeon droppings, feathers, serum	Pigeons, domestic and environmental
Bird fancier's lung	Avian droppings, feathers, serum	Parakeets, budgerigars, love birds, cockatiels, chickens
Duvet lung	Avian feathers	Pillows, duvets, sleeping bags stuffed with feathers
Animal handler's lung	Rats, gerbils	Urine, pelts, serum, proteins
Bat lung	Bat proteins	Bat droppings
CHEMICAL SENSITIZERS		
Chemical worker's lung	Isocyanates	Spray paints, polyurethane foams, glues
Epoxy resin lung	Phthalic anhydride	Heated epoxy resin
Pauli's reagent alveolitis	Sodium diazobenzene sulfate	Laboratory reagent

Trichosporon sp, typically in wood flooring.[31–33] The most common cause of HP in Australia is domestic fungal exposure from decaying wood and damp walls in urban dwellings.[34] Contaminated wind instruments (e.g., trombones, saxophones) can harbor multiple different microbes, including *Penicillium* sp, *Fusarium* sp, and mixed fungi.[35–37]

ANIMAL PROTEINS

Inhaled particulates from a wide variety of animals have been associated with HP. Bird exposure is the most frequently reported animal cause of HP. Avian antigens are high- and low-molecular-weight proteins found in the serum, droppings, and feathers and are highly immunogenic. Bird "bloom" is a fine respirable dust that coats bird feathers. It is composed of keratin and immunoglobulins and is highly immunogenic. Flying birds such as pigeons and parakeets can produce a considerable amount of bloom and are the birds most often associated with HP. Bird antigen exposure is at its highest level with activities such as cleaning out cages and coops. Duvet lung is an established form of HP, reported in patients using feather down duvets and bedding.[38–40] Down products also are used as filler for pillows, coats, and high-end furniture, including sofas or decorative cushions. There appears to be cross reactivity across sources of bird antigens, with HP exacerbations after exposure to down bedding in hotels or guest rooms.[41] Patients with *bird-exposure HP* (BHP) should avoid all potential sources, including feathers and down products.

Avoidance or complete removal of bird antigens can be very difficult, particularly in a home environment. Despite thorough cleaning, bird antigen can persist in residential dust samples for years and may explain why some patients continue to have progressive disease despite apparent remediation.[42] Moreover, some patients with bird exposure may be reluctant to remove the family bird from the home and are at risk of persistent exposure.

Animal handlers, laboratory workers, and veterinary workers can develop HP after sensitization and subsequent inhalational exposure to animal proteins in pelts, serum, and feces of rodents, including rats and gerbils. Those involved in the production of silks can develop HP from larval and cocoon particulates, while production workers exposed to mollusk shells can develop HP from the shell dust during cutting and polishing shells to make buttons.[43]

CHEMICAL SENSITIZERS

HP is caused less commonly from low-molecular-weight chemical sensitizers than by microbes and animal proteins, but these exposures are widespread across many industries and present risk for occupational HP. Isocyanates are used in large-scale production of polyurethane polymers for foams, adhesives, paints, and surface coatings and are recognized as a cause of HP.[44,45] Acid anhydrides used in plastics, paints, and epoxy resins have been reported to cause HP.[46] There are rare reports of HP from exposure to the pesticide pyrethrum, Pauli's reagent in chromatography, copper sulfate in fungicides used in vineyards, and the enzyme

phytase used as an additive in cattle feed.[47] Other chemicals reported to cause HP include styrene, formaldehyde, and dimethyl phthalate.[48,49]

IMMUNOPATHOGENESIS

The pathobiology of HP is complex and incompletely characterized for both the inflammatory and fibrotic forms of the disease. Overall, the development of HP appears to involve (1) inhalational antigen exposure, (2) host sensitization to the antigen, and (3) immune-mediated lung damage. The lung damage may regress or progress depending on host factors and/or ongoing antigen exposure. Antigenic exposure assessment is challenging for several reasons, including the unknown latency period between exposure and clinical disease and the lack of a clearly defined dose-response relationship. This makes it difficult to identify the timing of sensitization or exposure, particularly in cases of fibrotic HP.

Both humoral and cellular mechanisms are likely important in the development of HP, and their relative activity may influence the phenotype of disease (e.g., nonfibrotic vs. fibrotic). Early reports suggested a role of immune complexes in the development of HP, but the lack of immune complexes in *bronchoalveolar lavage* (BAL) fluid and the fact that HP develops in the presence of hypogammaglobulinemia indicate this to be an unlikely mechanism.[50,51] T cell–mediated delayed-type hypersensitivity appears to play a key role in the pathogenesis of HP. This is supported by the increased number of T cells in BAL fluid, lymphokine production by antigen-stimulated T cells of the lung, and the transferability of disease via sensitized T cells in animal models.[52–54]

In acute HP, BAL fluid cellular profiles show an alveolitis in which neutrophilic influx peaks 48 hours after exposure followed by a subsequent lymphocytic alveolitis. $CD4^+$ lymphocytes predominate early, between 48 and 72 hours, due to redistribution from peripheral blood and due to local lymphocyte proliferation. An influx of $CD8^+$ lymphocytes typically lags that of the $CD4^+$ cells, although the CD4:CD8 ratio can be unpredictable. Activated alveolar macrophages contribute to the production of reactive oxygen species, leading to damage of alveoli. The lymphocytes and antigen-presenting cells release inflammatory chemokines and cytokines, further perpetuating the inflammatory response.

In persistent forms of HP, the adaptive immune response is characterized by a profound BAL lymphocytosis comprised of $CD4^+$ and $CD8^+$ cells. A cell-mediated type IV hypersensitivity reaction is essential to its pathogenesis. Lymphocytes accumulate in the interstitium and peribronchial tissue, leading to the formation of poorly formed granulomas. Granuloma formation is supported by *type 1 T helper* (Th1) lymphocyte and macrophage secretion of cytokines including interferon-γ, tumor necrosis factor-α, and interleukin 18 (see also Chapter 16).

The pathobiology of fibrotic HP is not clear. After induction by the antigen and promoting factors that drive inflammation, progression factors promote fibrosis and chronicity.[55] Chronic lower-level antigen exposure may contribute to a smoldering low-grade subclinical inflammation that leads to fibrosis. Conversely, this form may be driven by profibrotic aberrant wound healing and not arise from unsuppressed inflammation, as seen in the acute form of HP. Again, the BAL cellular profiles provide insight into the pathophysiology of the disease. In fibrotic HP, there is a shift toward a profibrotic pathway with a loss of effector T cell function, and increases in the Th2 lymphocyte profile and CD4:CD8 ratio.[56] Polarization of $CD4^+$ lymphocytes to a Th2 phenotype may be important for the fibrotic response. Mice genetically programmed for enhanced Th2 response were more likely to develop lung fibrosis.[57] It remains unclear how host factors, antigen exposure, and immunologic reactivity interact to drive the chronic and progressive form of the disease.

HOST FACTORS AND GENETICS

The development of HP depends not only on the type, intensity, and duration of exposure to an inciting antigen but also on individual susceptibility. Only a small proportion of any population of exposed individuals develops HP, suggesting a prerequisite for an underlying susceptible genetic predisposition. Studies have reported familial clustering of patients with chronic HP in different environments and the development of summer-type HP in monozygotic twins.[58] Also, early studies showed an increased relative risk for the development of HP in subjects with specific polymorphisms of major histocompatability class I (A2, A11),[59] class III (tumor necrosis factor-α),[60] class II (DP, DQ, DR) antigens,[60–62] and transporters associated with antigen processing and antigen loading on major histocompatability class I.[63] Variations in immune responses may also be important determinants of the clinical phenotype of HP. Human and animal studies suggest that patients with chronic HP may lose effector T cell function, exhibit skewing toward Th2 and/or Th17 activity, and exhibit a decrease in gamma-delta T cells (implicated in the regulation of the immune response generated against microbial pathogens and allergens), which may be involved in the fibrotic response that characterizes this clinical form.[56,64]

Genomic factors have been examined to help stratify risk and provide insights into the pathogenesis of HP. In familial pulmonary fibrosis associated with abnormal telomere-related genes, 12% of affected individuals have chronic HP even if the index case or affected family member has a different diagnosis of fibrotic ILD such as *idiopathic pulmonary fibrosis* (IPF).[65,66] Thus, a family history should be obtained to identify potentially familial forms of ILD because this may help identify underlying genetic drivers of disease.

A *MUC5B* promoter variant and mutations in the telomere reverse transcriptase gene and telomere attrition have been associated with an increased risk for the development of fibrotic HP.[67] The prevailing hypothesis is that the *MUC5B* promoter variant may impair mucociliary clearance, mucosal host defense, and alveolar repair and contribute to lung injury and inflammation. In turn, persistent inflammation in chronic HP may promote accelerated alveolar epithelial cell turnover, contributing to telomere shortening in these cells and increasing the risk for lung remodeling and fibrosis. In a multicenter study of patients with chronic HP, short telomere length (<10th percentile for age) in peripheral blood

leukocytes and the *MUC5B* promoter variant were associated with radiographic fibrosis. Short telomere length was also strongly associated with histopathologic features typical of *usual interstitial pneumonia* (UIP) and reduced survival.[67] Furthermore, in chronic HP, the presence of protein-altering variants in telomere-related genes, which are associated with short peripheral blood telomere length, are found in approximately 10% of chronic HP patients and correlate with reduced transplant-free survival.[68]

In addition to inherent biologic susceptibility, external risk factors may modify the development and expression of HP.

Tobacco Use

Interestingly, smokers are less likely than nonsmokers to develop HP, attributed to a reduced immune response to inhaled antigenic exposure. In an animal model of HP, nicotine exposure reduced cellular responses, lymphocyte and total cell counts in BAL, and overall lung inflammation. Pigeon fanciers who smoked had lower levels of *immunoglobulin* (Ig) A and IgG antibodies to pigeon proteins compared to former and nonsmokers, suggesting that smoking reduces T cell–dependent and –independent responses to inhaled antigens.

However, despite the apparent preventive effect of smoking, smoking has a harmful effect on those who already have HP. Patients with chronic HP who are cigarette smokers at diagnosis have a worse prognosis even after adjusting for the presence of fibrosis.[18] In a case-control study, patients with chronic FLD who were current or former smokers had a lower survival rate compared with nonsmokers.[69] As in IPF, a subset of patients with significant smoking history might present with simultaneous fibrotic HP and emphysema. Such patients can present with significant hypoxemia and a marked reduction in the *diffusing capacity of the lungs for carbon monoxide* (D_{LCO}) out of proportion to relatively preserved lung volumes on pulmonary function tests.

Viral Infections

Viruses are known to enhance the pathology of experimental HP induced in mice by repeated exposures to causative HP antigens.[70] Similarly, common respiratory viruses have been isolated from the lower airways of patients with acute HP.[71]

Pathogen Virulence

In a mouse HP model of exposure to different mycobacterial genotypes belonging to three different species, the extent of the inflammatory cell response on BAL and extent of disease is highly dependent on the type of bacteria. This suggests that, in addition to host susceptibility, differential immunogenicity of mycobacteria strains may also impact the development of disease.[72]

HISTOPATHOLOGY

The hallmarks of histopathology in HP have been referred to as "the triad of four." This includes (1a) a diffuse lymphoplasmacytic interstitial infiltrate, (1b) with bronchiolocentric accentuation, (2) poorly formed granulomas, and (3) foci of organizing pneumonia (Fig. 91.1).[73] The

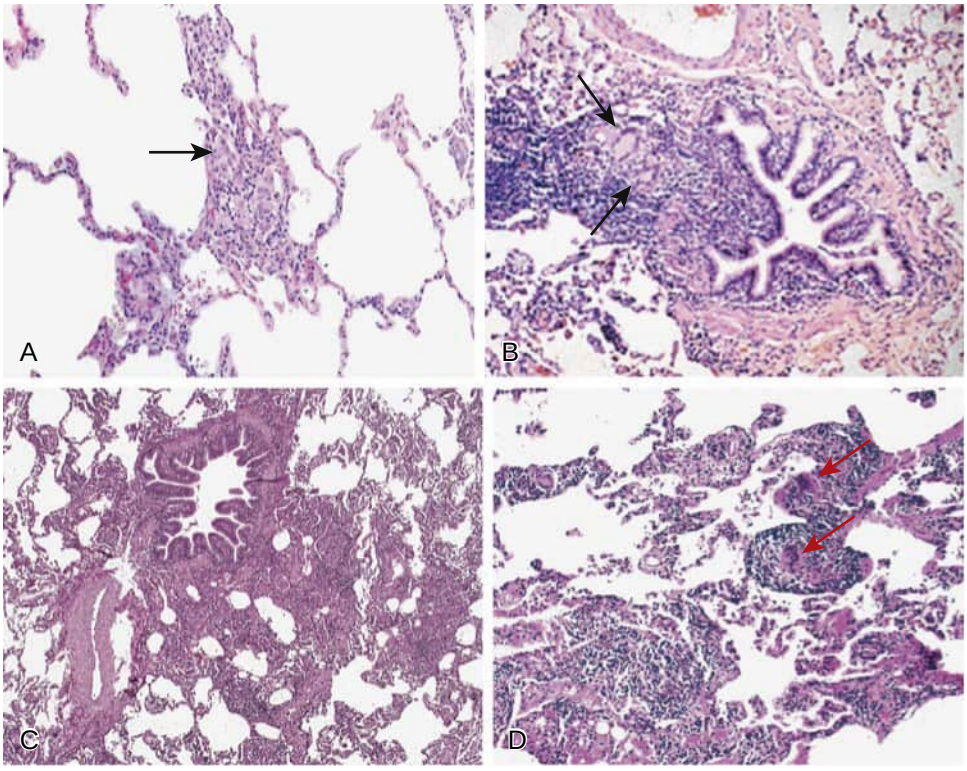

Figure 91.1 Granulomatous involvement seen in hypersensitivity pneumonitis. (A) Several poorly formed non-necrotizing granulomas are present (*arrow*). (B) Airway-centered interstitial fibrosis is seen together with giant cells (*arrows*). (C) A bronchiolocentric distribution may be evident, as indicated either by the presence of a terminal bronchiole or by some degree of nodularity to the infiltrates at low magnification. (D) Multinucleate giant cells (*arrows*) may also be seen in the interstitium and constitute a helpful feature at low magnification in drawing the eye to features meriting closer examination.

poorly formed granulomas of HP consist of loose aggregates of epithelioid histiocytes with or without multinucleate giant cells. Not all features of the triad may be identified on lung biopsy, especially depending on the stage of disease and type of biopsy performed (surgical vs. transbronchial). Cholesterol clefts in the interstitium are a common but nonspecific finding in HP. Giant cells with cholesterol clefts can be found in the airways in obstructive lung disease but, when present in the interstitium, are suggestive of HP.

Specific histologic findings of acute or nonfibrotic HP are poorly understood, given the infrequent rate of surgical lung biopsy in this clinical context. Biopsies generally show lymphocytic interstitial infiltrates and a neutrophilic and lymphocytic alveolitis, similar to the BAL findings in the acute phase. Focal areas of eosinophilic infiltration may also be found. As the disease progresses in nonfibrotic HP, the lymphocytic infiltrate may become most prominent in peribronchiolar areas and may resemble the *nonspecific interstitial pneumonitis* (NSIP) pattern with a uniform distribution. The presence of poorly formed granulomas may be a helpful distinguishing feature. The exception to this is in hot tub lung, where granulomas may be more well formed, although smaller and more loosely organized than those found in sarcoidosis.[74] Granulomas in HP rarely hyalinize; thus they can resolve after disease remission and antigen remediation. Focal areas of organizing pneumonia and constrictive bronchiolitis may be observed.

With increasing fibrosis in chronic HP, features of the triad may be identified, but other patterns can exist. Bridging fibrosis may be seen between perilobular and peribronchiolar areas, and granulomatous inflammation may or may not be present. Organizing pneumonia, cellular or fibrotic NSIP, and UIP with honeycombing and fibroblastic foci have all been described in chronic HP.[75] In the UIP-like pattern, a bronchiolocentric distribution of disease raises the likelihood of HP over IPF. More recent data suggest, however, that fibrotic bronchiolocentricity may also be identified in patients with IPF and is not as specific for HP as previously thought.[76] That no single feature is pathognomonic for HP reinforces the importance of incorporating pathologic data into the overall clinical and radiologic context, which should then be reviewed in an experienced MDD.

DIAGNOSIS

No single test can confidently establish or exclude a diagnosis of HP. Multiple domains, including clinical, radiologic, and histopathologic information, must be incorporated into the diagnostic pathway (Fig. 91.2). Because there are no universally agreed-upon diagnostic criteria for HP, clinical prediction models have been developed to discriminate HP from other forms of non-HP ILD.[77–80]

EXPOSURE ASSESSMENT

Identifying a potential causative exposure in HP relies upon the application and interpretation of a host of clinical tools. Most HP diagnostic algorithms start with antigen identification, because it is essential in establishing a confident diagnosis. Nevertheless, a positive exposure history or serologic testing does not necessarily imply disease causality, and judgment must be applied when interpreting findings. Furthermore, an unidentified antigen does not rule out the diagnosis of HP because antigen indeterminate status may signify exposure to an unrecognized or to a novel, as of yet unidentified, antigen. HP can present in patients with autoimmune features[81,82]; therefore, the presence of autoimmune features or positive serology does not necessarily exclude a diagnosis of HP.

History

The first step towards identifying a potentially relevant exposure is taking a comprehensive history aimed at identifying the antigen. This can be achieved through direct questioning or by the completion of HP-specific questionnaires, the latter of which may be helpful because they are less dependent on the clinician's memory. To date, no such questionnaire has been validated for clinical use, and many exposures vary geographically, seasonally, and/or culturally. Therefore, a focused history should be contextualized to relevant exposures in the current environment. The history should focus on current and previous occupations, with detailed descriptions of work settings and exposures. Questions should cover the home environment, with a focus on contaminated water sources or mold, including musty odors and previous water damage. It is also essential to ask about current and past bird and down exposures, with detailed histories of pet birds and bird-related activities, as well as use of down-stuffed bedding or furniture, as well as about hobbies such as woodworking, spray painting, musical instruments, and those that include use of glues or resins. Consultation with an occupational medicine expert should be considered, particularly when the exposure is thought to arise in a workplace setting or when a home or avocational setting requires a more thorough evaluation than can be addressed by clinical history alone.

Antibody Testing

Serum-specific antibody tests are neither sensitive nor specific for the diagnosis of HP but may identify immunologic reactivity by measuring the patient's IgG reaction to specific antigens.[83] There are two main methods of serum IgG testing: qualitative IgG measurement using double diffusion (i.e., serum precipitins) and quantitative IgG measurement (e.g., enzyme-linked immunosorbent assay). In some circumstances, when the inciting antigen is known, positive antibodies may support the diagnosis. In a study of French farmers, serum antibody tests had good sensitivity and specificity for distinguishing those with HP from those without.[27] Antibody testing should not be used as a screening tool given the high false-positive rate in those exposed to the antigen but without evidence of disease. In a large study of bird fanciers, 92% of those with BHP had positive antibodies, but so did 87% of control bird fanciers without HP.[84]

There are important limitations to the use of antibody tests, and their results must be interpreted with care. Serum antibodies can wane over time with decreased exposure or may be undetectable with chronic low-level exposure. Antigens included in standard HP panels may not be applicable to the individual patient's environment,

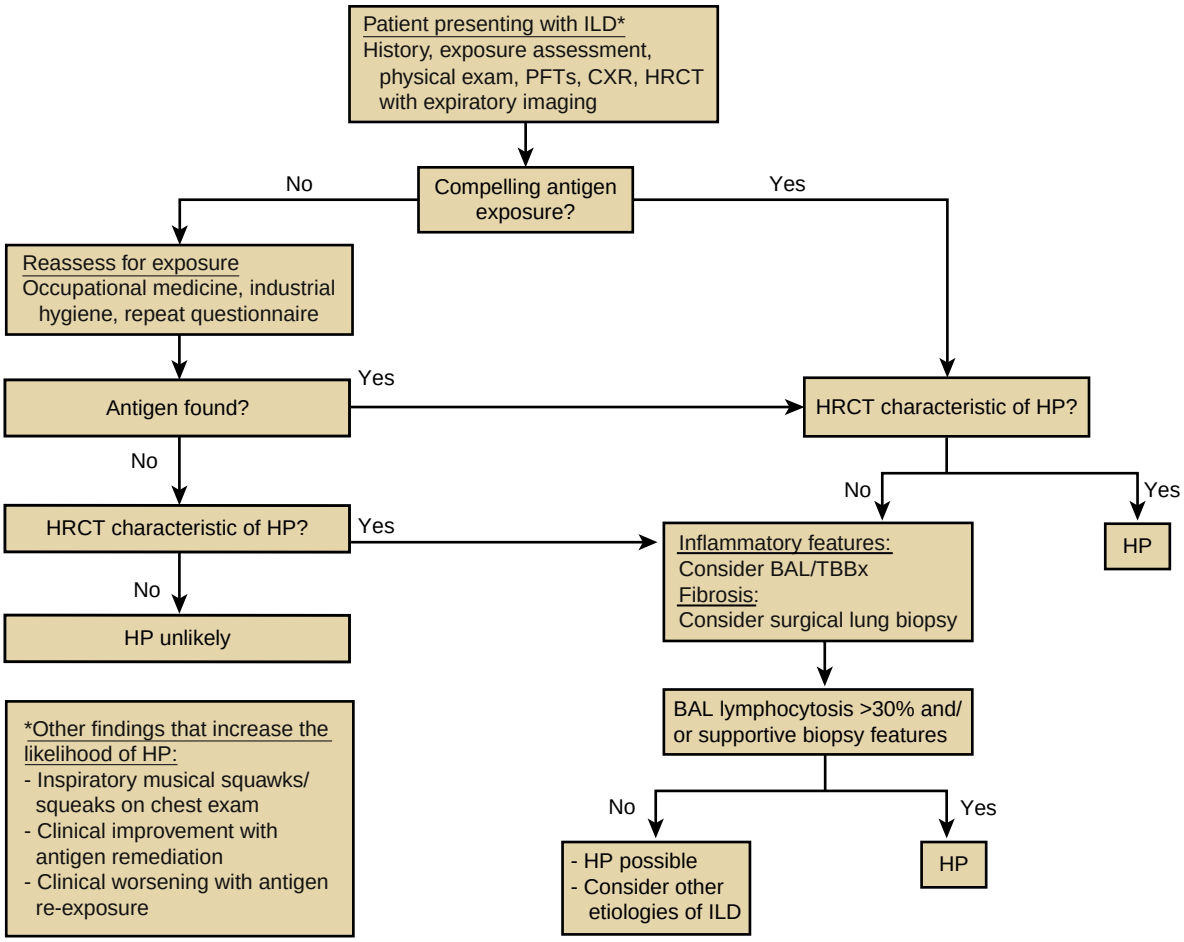

Figure 91.2 Approach to the diagnosis of *hypersensitivity pneumonitis* (HP). The diagnostic HP approach requires thorough exposure evaluation, exclusion of alternative etiologies, and multidisciplinary evaluation. The first and most crucial step in determining the likelihood of diagnosis is characterizing the occupational and environmental exposure by a comprehensive history and/or exposure questionnaire. Because the identification of the inciting antigen source and mitigation are critical, referral to an occupational medicine specialist or industrial hygienist may be helpful, especially when a more detailed investigation is needed. The combination of the clinical context, exposure history, and chest *high-resolution computed tomography* (HRCT) pattern inform the degree of diagnostic certainty: confident vs. working diagnosis vs. unlikely. For patients with a working diagnosis, on a case-by-case basis and in the setting of multidisciplinary discussion, further testing including *bronchoalveolar lavage* (BAL)/*transbronchial biopsy* (TBBx) and/or surgical lung biopsy may be considered. After the HP diagnosis is made, if not previously done in a patient with suspected HP, removal of the inciting antigen and careful reevaluation for possible ongoing reexposure are vital. CXR, chest radiograph; ILD, interstitial lung disease; PFTs, pulmonary function tests.

presenting a risk of false-negative results.[85] On the other hand, a positive result confirms that the patient has been exposed to that antigen, but it does not necessarily equate to causation of disease. Results may be most informative if antigens are prepared from a direct sample of the patient's environment, although this requires highly specific expertise and the cost and effort required make it largely prohibitive at present.[85,86]

Inhalational Challenge

Skin tests for immediate and delayed hypersensitivity reactions are not recommended in the diagnostic testing for HP.[87] *Specific inhalational challenge* (SIC) exposes the patient to the suspected inciting antigen via an inhalational circuit, and the physiologic reaction is measured. A positive SIC can support the diagnosis of HP and implicate the causative agent,[80,88–90] but SIC testing requires skilled personnel and specialized equipment and is performed at only a few centers worldwide. It remains unclear what SIC adds beyond a positive exposure history because the causative antigen must be suspected in the first place to select the exposure reagent. In vitro lymphocyte proliferation testing has been described in avian HP but is not widely available, and its diagnostic performance characteristics remain unclear and is therefore not recommended.[91,92]

CLINICAL FEATURES

Signs and Symptoms

The clinical presentation of a patient with HP varies substantially depending on the type, duration, and intensity of exposure and whether the patient has an acute or chronic illness (Table 91.2). Symptoms of acute HP typically arise 4 to 8 hours after the exposure and consist of a flulike syndrome with malaise, fever, and chills.[93] Respiratory symptoms include nonproductive cough and dyspnea. Symptoms usually resolve within 24 to 48 hours but may recur upon reexposure to the antigen. The presentation of chronic HP

Table 91.2 Typical Features and Differential Diagnosis of Hypersensitivity Pneumonitis

	Nonfibrotic	Fibrotic
Time course of presentation and inciting antigen exposure	▪ Acute symptom onset ▪ Exposure to antigen ▪ Temporal relation of symptoms to exposure usually recognized ▪ Chronic presentations are less common	▪ Chronic, insidious symptom onset ▪ Inciting antigen may not be recognized ▪ Unclear relation between exposure and symptoms
Symptoms	▪ Cough, dyspnea at rest and/or with exertion ▪ Systemic symptoms including fever, chills, myalgias	▪ Dyspnea on exertion ▪ Cough, typically nonproductive
Physical examination	▪ Fever, tachypnea, hypoxemia ▪ Crackles on chest exam ▪ Inspiratory musical squeaks/squawks ▪ May have normal exam	▪ Inspiratory Velcro crackles ▪ Inspiratory musical squeaks/squawks ▪ Hypoxemia on exertion ▪ May have normal exam
HRCT chest imaging	▪ Diffuse ground-glass opacities ▪ Centrilobular nodules ▪ Bronchovascular distribution ▪ Mosaic attenuation ± air trapping on expiratory imaging ▪ Mixed interstitial (ground-glass opacities or high-attenuation areas) and obstructive (mosaic changes or low-attenuation areas), i.e., "headcheese" sign	▪ May have similar findings as acute HP, but also: ▪ Fibrosis—reticulation, traction bronchiectasis or bronchiolectasis, honeycombing
Bronchoalveolar lavage fluid analysis	▪ Lymphocytosis (lack of this finding does not exclude HP)	▪ Lymphocytosis less common (lack of this finding does not exclude HP)

Histopathologic findings	▪ Neutrophilic and lymphocytic infiltrates involving bronchioles and alveolar interstitium
	▪ Poorly formed granulomas
	▪ Lymphocytic bronchiolitis
	▪ Foci of organizing pneumonia
		▪ Features seen in acute HP, plus:
		  ▪ Peribronchiolar fibrosis
		  ▪ Interstitial fibrosis ± bridging features
		  ▪ UIP-like pattern with honeycombing and fibroblastic foci

Differential diagnosis	▪ Viral, atypical pneumonia
	▪ CTD-ILD
	▪ Drug reaction
	▪ Inhalational fever (e.g., organic dust toxic syndrome)
	▪ Toxic fume inhalation
	▪ Asthma
	▪ Sarcoidosis
	▪ Mycobacterial infection
	▪ Aspiration pneumonitis
	▪ Bronchiolitis obliterans
	▪ Organizing pneumonia
	▪ Acute fibrinous and organizing pneumonia
	▪ Granulomatous-lymphocytic interstitial lung disease
		▪ Other ILD:
		  ▪ CTD-ILD
		  ▪ NSIP
		  ▪ IPF
		▪ Sarcoidosis
		▪ Familial ILD
		▪ Pleuroparenchymal fibroelastosis

CTD, connective tissue disease; HP, hypersensitivity pneumonitis; ILD, interstitial lung disease; HRCT, high-resolution computed tomography; IPF, idiopathic pulmonary fibrosis; NSIP, nonspecific interstitial pneumonitis.

has a more insidious onset with nonproductive cough and exertional dyspnea being the most common symptoms. The presentation frequently overlaps with other fibrotic ILDs such as IPF. Symptoms may be episodic or situational in relation to exposure or persistent due to low-level chronic exposure.

Patients with acute HP may have a normal physical examination or demonstrate inspiratory crackles or expiratory wheeze. They may have low-grade fever, tachycardia, and tachypnea. Oxygen saturation may be low at rest or solely with exertion. Patients with fibrotic HP typically have inspiratory Velcro-like crackles but may have clubbing and other findings associated with fibrotic ILD such as right heart dysfunction. Notably, patients with HP may demonstrate high-pitched inspiratory musical squeaks or squawks in the chest corresponding to bronchiolitis and small airways involvement.[94] In a study of 14 patients with ILD and inspiratory squawks, nine had HP.[95] HP-related squawks were of shorter duration and higher frequency and were heard later in inspiration. They are localized most commonly in the upper lobes but may be heard anywhere in the chest.[96] The sensitivity and specificity of these auscultatory findings have not been studied within clinical prediction models but may serve to identify HP and are an important physical exam finding.

Lung Function

Pulmonary function tests (PFTs) should be obtained on every patient presenting with suspected HP. PFTs can demonstrate an obstructive, restrictive, or mixed defect, often with a reduced D_{LCO}. Spirometry and lung volumes may be preserved, with an isolated low D_{LCO}, or in some cases PFTs may be within normal limits. Exercise testing may reveal normal oxygen saturation at rest with isolated exertional desaturation. Nonspecific bronchial hyperreactivity has been described in HP and identified on methacholine challenge testing. In patients diagnosed with HP, longitudinal serial PFTs should be conducted to monitor for disease stability or progression. As in other forms of ILD, exercise oxygenation studies should also be conducted periodically, because new-onset exertional desaturation may herald disease recurrence or progression.

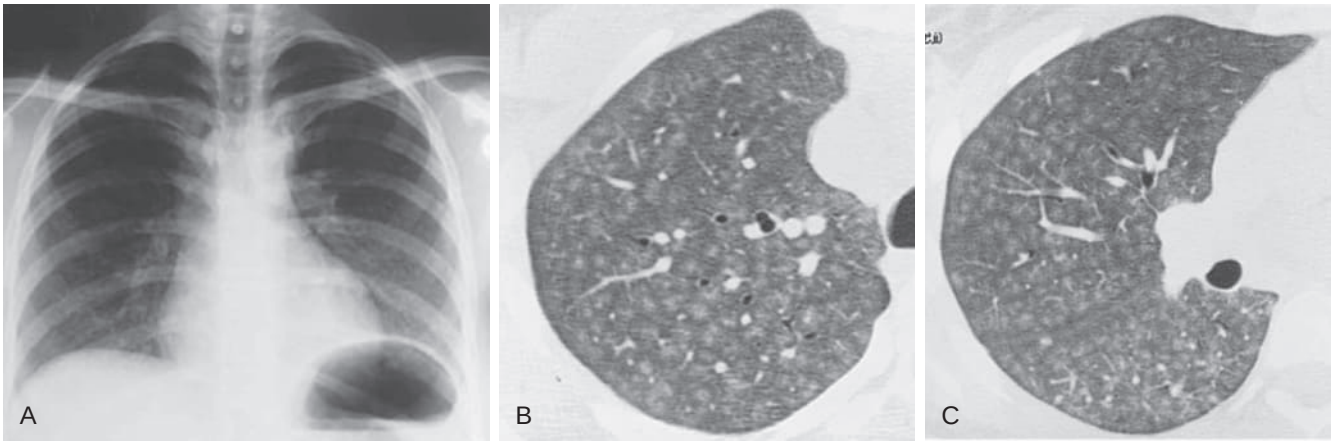

Figure 91.3 Nonfibrotic hypersensitivity pneumonitis. (A) Chest radiograph of a patient with hypersensitivity pnemonitis shows diffuse poorly defined nodular opacities. (B) *High-resolution computed tomography* (HRCT; 1.5-mm thin section) image through the lung of the same patient shows profuse centrilobular ground-glass opacity nodules. (C) HRCT scan of a different patient with bird breeder's lung shows diffuse ground-glass attenuation with reticular opacities and centrilobular ground-glass opacity nodules.

Bronchoalveolar Lavage

BAL fluid cellular analysis may be performed as part of the diagnostic workup of patients with suspected HP. It is a relatively safe, minimally invasive procedure that can identify alveolitis and help support a diagnosis. However, BAL findings are neither sensitive nor specific for HP. Antigen-exposed but healthy individuals can have a BAL alveolitis, and HP patients can demonstrate persistent alveolitis despite a lack of ongoing exposure to the inciting antigen or even when in disease remission.[97] Classically, a marked lymphocytosis with greater than 50% lymphocytes is highly suggestive of HP, although this degree of lymphocytosis can also be seen in other entities such as cryptogenic organizing pneumonia and NSIP.[98]

Patients with fibrotic HP may not demonstrate active alveolitis. In a large epidemiologic study of chronic HP from Japan, the median BAL lymphocyte rate was 24.5%, with substantial variability across individuals and etiologies.[99] Of 86 patients with bird fancier's lung, 15 (17%) had the fibrotic form of disease.[84] BAL was performed in a subset of patients (7/15), finding a BAL lymphocytosis greater than 20% in 6 of 7 (85%), but these findings may not be generalizable to an unselected population. In a study of 139 HP patients where 41 of 139 (29.5%) had chronic disease, the mean lymphocyte percentage was elevated in all forms of disease but was significantly lower in chronic HP than in acute HP.[100] In a study of 72 HP patients, 44 of whom had histopathologic fibrosis, the average BAL lymphocyte count was significantly lower in fibrotic HP compared to nonfibrotic HP (15 ± 31 vs. $46 \pm 31 \times 10^6$ cells/mL).[101] A systematic review and meta-analysis found that BAL lymphocyte percentage was higher in patients with chronic HP (42.8%) compared to patients with IPF (23.1%), non-IPF IIP (23.4%), and CTD-ILD (23.4%) but not sarcoidosis (31.2%).[101a] Using individual patient data, the optimal performance of BAL lymphocyte percentage was at a threshold greater than 20%, differentiating chronic HP from other forms of ILD with a sensitivity of 68.1% and a specificity of 64.8%. The presence of radiographic fibrosis is generally associated with the absence of BAL lymphocytosis in ILD[102] and, in advanced fibrotic HP with a histologic pattern resembling UIP, BAL lymphocytosis is unlikely.[91] Older age and a positive smoking history are also associated with lower BAL lymphocyte percentage in chronic HP.[101a] Overall, BAL fluid lymphocytosis is less likely to be present with increasing fibrosis and/or with remote or uncharacterized antigen exposure. The CD4:CD8 ratio is often elevated in HP, particularly in comparison to sarcoidosis, but the diagnostic performance characteristics of this test are unclear, particularly in chronic HP, and it is not recommended. BAL measurement of interleukins, matrix metalloproteinases, and other chemokines and cytokines is currently considered a research tool.[20,103]

Chest Imaging

HRCT is an essential tool for the evaluation and diagnosis of HP. It is more accurate than chest radiography in capturing the variety of different patterns and distribution of abnormalities observed in HP, such as areas of inspiratory mosaicism, ground-glass attenuation, and poorly defined centrilobular nodules (Fig. 91.3 and eFig. 91.1). Early in the course of HP, these abnormal imaging features are frequently seen next to areas of normal attenuation and generally observed in the mid to upper and peripheral lung zones with a diffuse and/or peribronchiolar distribution. Regardless of smoking history, these features may sometimes coexist with zones of predominantly upper lung and centrilobular emphysema.[104] As part of the standard evaluation of a subject with suspected ILD, the HRCT protocol needs to include end-expiratory images for evaluation of air trapping, which may be indicative of small airway disease, a finding suggestive of the diagnosis of HP. Air trapping appears as areas of decreased attenuation resulting from the presence of trapped gas (eFig. 91.2).

In subjects presenting with acute clinical manifestations living in areas where HP is highly prevalent, an HRCT demonstrating diffuse and symmetrical homogenous ground-glass opacities or nodules with a centrilobular distribution and absence of fibrotic findings has an estimated sensitivity of 66–74%, specificity of 90–96%, and likelihood ratio of 7.7 to 16 for the diagnosis of HP.[105] Therefore, in the correct clinical context and, after excluding other known causes of ILD, the combination of characteristic HRCT findings and a temporal pattern of environmental exposure to

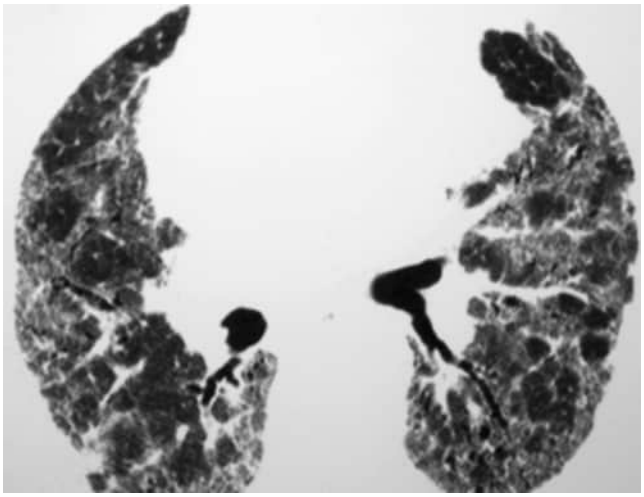

Figure 91.4 Fibrotic hypersensitivity pneumonitis. Areas of ground-glass opacity admixed with a few small areas of fairly normal appearing lung are associated with extensive reticulation, traction bronchiectasis, and architectural distortion.

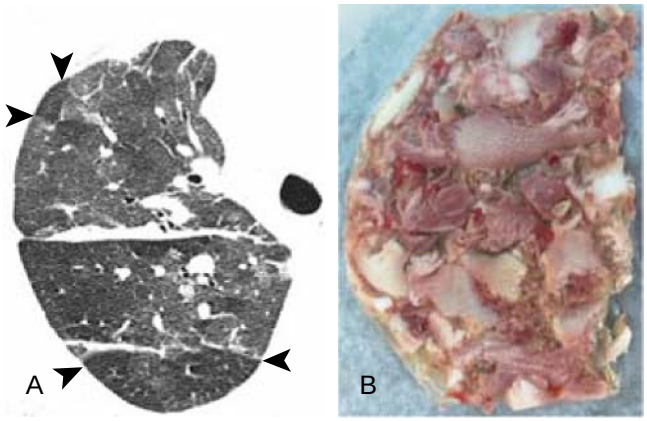

Figure 91.5 The "headcheese" sign at *computed tomography* (CT) in hypersensitivity pneumonitis. (A) Axial high-resolution chest CT image shows multifocal ground-glass opacity with areas of mosaic perfusion manifesting as lobular low attenuation (*arrowheads*) on the same inspiratory scan image. This scan pattern reflects the simultaneous presence of an infiltrative (ground-glass opacity) and obstructive (mosaic perfusion) abnormality and suggests the diagnosis of hypersensitivity pneumonitis. The mixed restrictive and obstructive process creates a variegated appearance at CT that has been likened to headcheese (B), a terrine or meat jelly typically made with flesh from the head of a pig or calf, less commonly from a cow or sheep, frequently encased in a savory jelly made from meat stock set in a mold, referred to as aspic. (A, Courtesy Michael B. Gotway, MD. B, From Shroff GS, Marom EM, Godoy MCB, et al. CT signs in the lungs. *Semin Ultrasound CT MRI.* 2019;40[3]:265–274.)

a relevant antigen or antigens can often lead to a confident diagnosis without the need for lung biopsy.

For chronic HP, classic radiologic appearances can help in the diagnosis. A subgroup of subjects with disease progression develop chest imaging features of pulmonary fibrosis, which include peripheral reticulation, traction bronchiectasis and/or bronchiolectasis, honeycombing, architectural distortion, and volume loss, findings that often coexist with nonfibrotic findings (Fig. 91.4). A peribronchiolar disease distribution of fibrotic features, the presence of the aforementioned nonfibrotic findings, and the absence of lower-zone predominance help distinguish fibrotic HP from fibrotic NSIP and IPF.[106] Among subjects with chronic HP, the presence of nonfibrotic CT features and the distribution of disease outperform fibrotic findings in discriminating HP from other fibrotic lung diseases.[106,107] For example, in HP, mixed interstitial (ground-glass opacities or high-attenuation areas) and obstructive (mosaic changes or low-attenuation areas) findings next to areas of normal attenuation (normal lung) on thin-section CT can give rise to the "headcheese" sign (Fig. 91.5). The headcheese sign was found to be moderately sensitive (49%) and highly specific (93%) for a high confidence diagnosis of fibrotic HP.[107] In a study that included a derivation cohort comprised of 124 subjects (35% of which had HP) and a validation cohort comprised of 66 subjects (33% of which had HP), a diagnostic predictive model that included patient age, a history of down feather and/or bird exposure, the presence of diffuse craniocaudal ground-glass opacity, and mosaic perfusion on HRCT had a sensitivity of 48% and a specificity of 91% for the diagnosis of chronic HP.[108] Similarly, another study that analyzed a derivation cohort comprised of 356 subjects (34% of which had HP) and a validation cohort comprised of 424 subjects (16% of which had HP) showed that, when radiologic mosaic attenuation or air trapping (Videos 91.1A and 91.1B) is more extensive than reticulation, and the disease has a diffuse axial distribution, the specificity for an HP diagnosis is high at 90% (with a sensitivity of 65%).[79] It should be noted that these predictive models were derived in patients diagnosed after review in an MDD, and patients did not necessarily undergo lung biopsy.

Lung Biopsy

The decision to pursue lung biopsy should be made in the context of all other available data and based on the need to establish a confident diagnosis and/or guide management. A diagnosis of HP can be established in the absence of histopathology; thus, biopsy is not necessary in every case. Lung biopsy can be performed using transbronchial biopsy, *transbronchial lung cryobiopsy* (TBLC), or *surgical lung biopsy* (SLB) using video-assisted thoracic surgery or an open approach. The decision to pursue lung biopsy should be reached only after consideration of the anticipated risks of the procedure, experience of the proceduralist/surgeon, and patient preference.

Transbronchial biopsy may be informative in nonfibrotic HP, although the diagnostic yield is not well characterized.[109] Histologic findings supportive of HP can preclude the need for more invasive testing such as SLB. The absence of typical histologic findings does not exclude HP, and finding normal lung tissue or nonspecific abnormalities may be due to sampling error. Small blind forceps biopsies may miss the pathologic pattern in a patchy or heterogeneously distributed disease such as HP. SLB should be considered if a confident diagnosis cannot be established based on all other available data, if the findings of biopsy will influence treatment decisions, or if it is necessary to exclude other forms of fibrotic ILD such as IPF. Ideally, patients will be reviewed in a formal MDD before referral for SLB to confirm that biopsy is indicated.[110] The biopsy findings should then be reviewed in the MDD, taking all other clinical and radiologic data into consideration. TBLC has been used in the evaluation of patients with chronic HP, with most studies reporting

on diagnostic yield in cohorts of patients presenting with unspecified ILD.[108] No studies have evaluated the ability of TBLC to diagnose chronic HP accurately. The largest study to date assessed diagnostic accuracy in 65 patients with ILD deemed to have an indication for SLB.[111] Of the 65 patients who underwent concurrent TBLC and SLB, 15 were diagnosed with chronic HP after MDD that incorporated results of the TBLC, while 18 were diagnosed incorporating findings of SLB, suggesting higher sensitivity of SLB. Overall agreement between SLB and TBLC for the specific histopathologic pattern as well as MDD-based final diagnosis was good, suggesting a role for TBLC in experienced centers in an appropriately selected group of patients with ILD. However, international societies have not taken a formal stance on the role of TBLC in the evaluation of chronic HP.

MULTIDISCIPLINARY DISCUSSION

There is no test specific for the diagnosis of HP and histologic diagnosis is no longer regarded as the gold standard for the diagnosis. Several diagnostic criteria for HP have been proposed, most characterizing acute HP but not the complex nature of chronic HP. The MDD has been shown to increase the level of confidence in ILD diagnosis and to help determine whether additional, invasive procedures are necessary to support or confirm a diagnosis.[112] Given the complex clinical presentation and disease course, integrating the radiographic and histopathologic findings in the context of the exposure history by a multidisciplinary team to arrive at a diagnosis of HP is recommended.[113] Formal MDD may not be available at each center, but we would encourage all clinicians to collaborate with exposure assessment, radiology, and pathology experts where available when considering a diagnosis of HP. Inter-MDD agreement on a diagnosis of HP is fair when comparing one MDD to the next.[114] The lack of standardized diagnostic criteria has surely contributed to this low level of agreement, and it is hoped that upcoming consensus criteria for HP will improve the agreement between groups, ultimately improving the accuracy of diagnosis.

PROGNOSIS AND DISEASE BEHAVIOR

The natural history of patients with HP is variable. While patients may encounter periods of clinical, radiologic, and functional stability after removal of the inciting antigen, a subgroup of patients with HP without a known exposure develops chronic disease and often progressive pulmonary fibrosis. The significant morbidity and mortality in the latter group has prompted a search for baseline markers of disease progression. Several clinical, physiologic, and radiologic prognostic factors of disease severity and mortality in HP have been identified (eTable 91.1).

Age has an impact on outcome in these patients because the prevalence and mortality of HP increase with age regardless of the severity of disease.[9] In addition, men have a prognosis worse than women.[16] Baseline auscultatory crackles on lung examination are an independent predictor of time to death or lung transplantation.[5] A history of cigarette smoking is associated with worse survival.[18,115]

Identifying an antigen and avoiding it are associated with better prognosis. In patients with chronic HP, while the disease can progress even after eliminating relevant antigenic exposure, avoidance of inciting antigen exposure is associated with a better prognosis. In a cohort of 142 consecutive adult patients with clinical-radiologic-pathologic chronic HP (47% with an unidentified exposure), after adjusting for the presence of fibrosis, patient age, pulmonary function, and smoking history, survival was longer for patients with an identified inciting antigen exposure than for those without an identified inciting antigen exposure (median survival of 8.8 years vs. 4.9 years).[18] In a study of 202 patients with HP, 41 (20%) had an unidentified inciting antigen; a trend towards worse survival was reported for patients with no identified inciting antigen exposure after multivariate correction for age, gender, and baseline percentage of *forced vital capacity* (FVC) (hazard ratio, 2.1).[116] In a cohort of 112 patients with fibrotic HP, 25 experienced clinical improvement after antigen avoidance (characterized as a decrease in dyspnea and cough in two consecutive visits); clinical improvement after antigen avoidance was associated with a decreased mortality (hazard ratio, 0.14).[117] Such findings emphasize the importance of finding an antigen if possible.

On chest imaging, HRCT features of fibrosis (e.g., bronchiectasis, reticulation, honeycombing) and the extent of fibrosis evaluated by semiquantitative scoring have been associated with shortened survival.[5–7] Other CT measures with negative prognostic significance include the presence of inspiratory mosaic attenuation and expiratory air trapping, and an increased pulmonary artery/aorta ratio.[4,118,119] Baseline pulmonary physiologic measures of disease severity, particularly FVC and D_{LCO}, have been shown to be predictors of early mortality. The ILD-GAP index is a metric for evaluation of prognosis that integrates gender (G), age (A), and physiology (P), (e.g., FVC and D_{LCO}) that has been shown to predict mortality across different forms of chronic ILD, including HP.[120] Also, a more rapid longitudinal decline in FVC has been associated with shorter survival. Patients with 10% or greater decline in predicted FVC after 6 to 12 months had a significantly increased risk of all-cause mortality (median survival, 53 months vs. 139 months).[117] Such prognostic indicators may help guide timing of therapy, referral to a lung transplantation program, and patient expectations. They may also be useful for cohort enrichment in clinical trials of therapeutics.

MANAGEMENT

ANTIGEN AVOIDANCE

Management of HP is primarily aimed at antigen identification and avoidance (Fig. 91.6). Antigen avoidance is the only nonpharmacologic measure known to improve the clinical course and survival of patients with HP. Organic antigen sources (e.g., bacteria, fungi, mycobacteria, animal proteins) are a frequent cause of nonoccupational HP. BHP can be particularly difficult to manage given the persistent nature of exposure in the home despite apparent remediation. In a study of patients with BHP that measured the amount of avian antigen and collected questionnaires on the

eTable 91.1 Baseline Prognostic Indicators of Disease Severity and Mortality in Hypersensitivity Pneumonitis

Demographics	■ Male sex ■ Older age
Physical exam	■ Auscultatory crackles
Pulmonary physiology	■ Low FVC % ■ Low DL_{CO} %
High-resolution computed tomography	■ Increased fibrosis ■ Honeycombing ■ Traction bronchiectasis ■ Inspiratory mosaic attenuation and expiratory air trapping ■ Increased pulmonary artery/aorta ratio
Pathology	■ Increased fibrosis ■ Fibroblast foci
Genomic factors	■ Mucin 5B rs35705950 single nucleotide polymorphism ■ Shorter telomere length (<tenth percentile for age)
Composite measures	■ Abnormal ILD-GAP index
Other	■ No known inciting antigen exposure ■ Smoking ■ Acute exacerbation ■ Pulmonary hypertension

DL_{CO}, diffusing capacity for carbon monoxide; FVC, forced vital capacity; GAP, gender, age, physiology; ILD, interstitial lung disease.

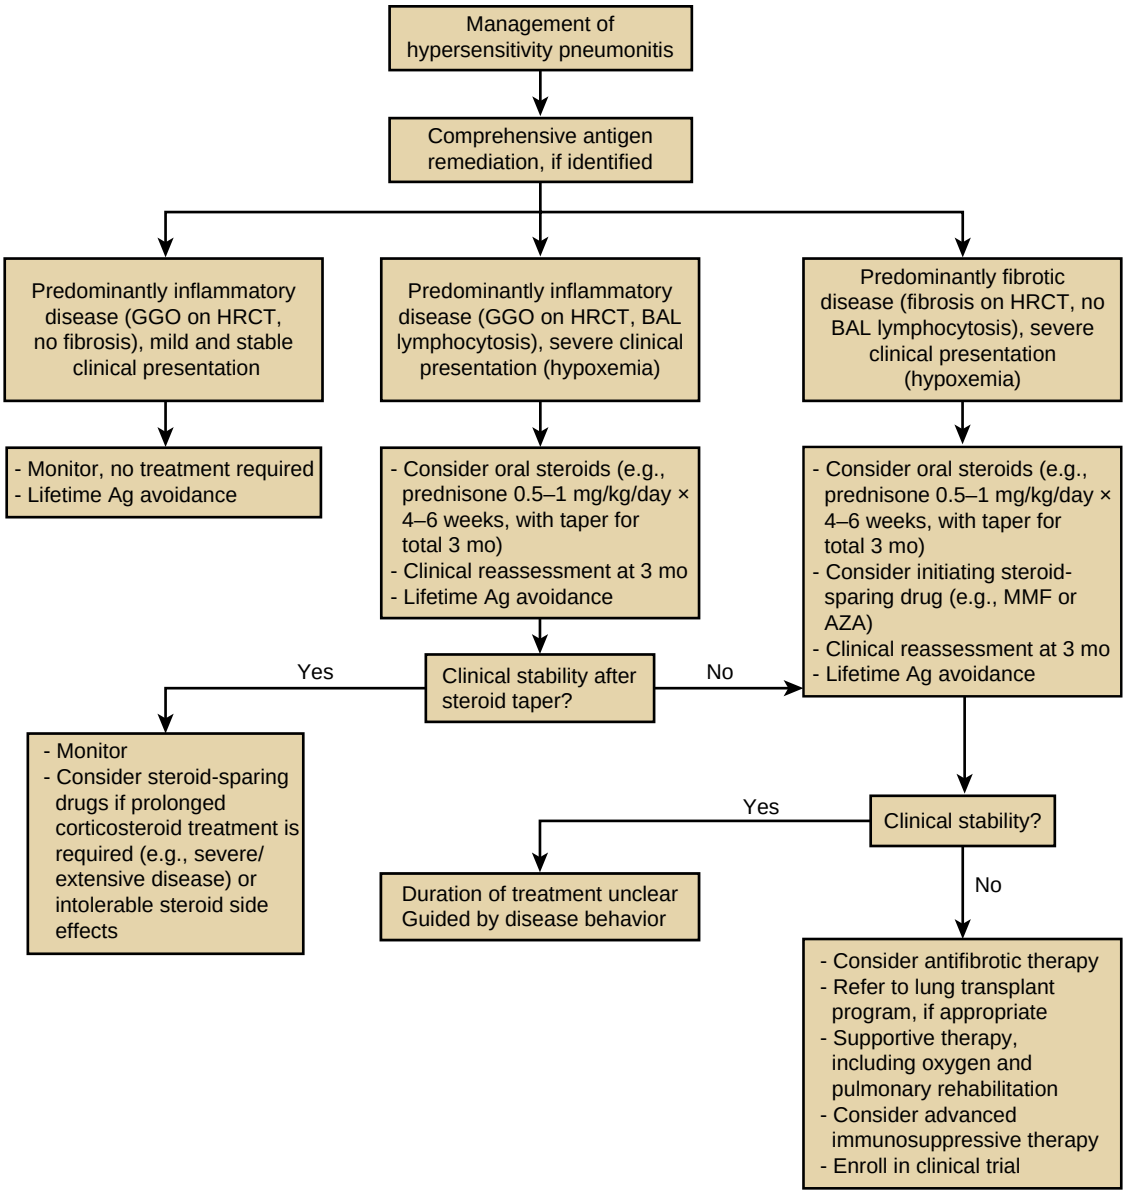

Figure 91.6 Approach to the management of *hypersensitivity pneumonitis* (HP). Pharmacologic therapy is often initiated when clinically significant disease progression is recognized despite comprehensive inciting antigen remediation or avoidance. Initial treatment is often with systemic corticosteroids in the form of prednisone with a tapering schedule. Patients require monitoring and management of corticosteroid adverse reactions as well as assessment for clinical, physiologic, and/or radiographic response before considering coadministering and/or transition to corticosteroid-sparing agents. The multidisciplinary approach to HP includes symptom management, supplemental oxygen for hypoxemic patients, pulmonary rehabilitation, smoking cessation, appropriate vaccinations, referral for lung transplant evaluation if indicated, treatment of comorbid conditions, and palliative/end-of-life care. Ag, antigen; AZA, azathioprine; BAL, bronchoalveolar lavage; GGO, ground-glass opacity; HRCT, high-resolution computed tomography; MMF, mycophenolate mofetil.

environmental conditions of their homes, patients exposed to a higher amount of avian antigen in household dust samples had a worse trajectory of disease over 1 year of follow-up than patients with a lower amount.[121] Furthermore, subtle exposures to avian antigens such as sleeping with feather duvets and pillows may cause HP.[122,123] The risk of disease is more likely with prolonged exposure. The potential for a fibrotic response of the lungs emphasizes the importance of screening and questioning for occult exposure to avian antigens in the patient's environment.

When action to reduce and prevent a known antigen exposure is not feasible or if the source of exposure is unknown, removing the patient from the likely antigen-containing environment should be considered, especially when HP is severe and progressive over time. However, this may not be feasible in all cases and can be particularly challenging with occupational HP. Therefore, close clinical surveillance and/or workplace monitoring by an occupational hygienist is essential to ensure that prevention strategies are effective.

PHARMACOLOGIC THERAPY

There are few data guiding the use of therapeutics in patients with HP. Immunosuppression with systemic corticosteroids is a frequently employed adjunctive management strategy for HP. A few early reports in FLD demonstrated short-term improvements in symptom resolution and D_{LCO}, but no sustained differences in long-term outcomes were detected in prednisolone-treated versus nontreated groups.[124,125] No prospective studies have evaluated the efficacy of corticosteroids in treating fibrotic HP. Frequently, corticosteroids are given when there is evidence of active inflammation or severe physiologic impairment. Corticosteroids carry important potential risk and side effects. Therefore, their empiric use in treating HP is not recommended and should be reserved for cases where the anticipated benefits outweigh the potential risks.

Steroid-sparing agents such as *azathioprine* (AZA) and *mycophenolate mofetil* (MMF) have been used to treat chronic HP in an effort to reduce steroid dose while preserving lung function. Two retrospective observational studies have evaluated the role of AZA or MMF in treating chronic HP. In a multicenter study of 70 chronic HP patients treated with AZA or MMF, there was no improvement in FVC but an increase in D_{LCO} at 1 year, and a reduction in prednisone dose.[126] In a study of 131 patients with chronic HP in which 93 received immunosuppression, treated patients had worse lung function and survival than those not treated, suggesting that sicker patients are more likely to be treated with immunosuppressing drugs.[127] There were no survival or longitudinal lung function differences among those treated with AZA, MMF, or prednisone. The AZA and MMF groups had fewer treatment-related adverse events compared to the prednisone group. In both studies, more patients switched from AZA to MMF than vice versa, citing either a failure of therapy or drug intolerance.

Rituximab is another steroid-sparing agent utilized in patients with progressive disease despite apparent antigen remediation and treatment with prednisone, AZA, or MMF. In a retrospective report of six patients whose chronic HP progressed despite immunosuppression who were then treated with rituximab infusion, three patients stabilized at 1 year while three had disease progression and died.[128] Antifibrotic therapies have been investigated as treatments for non-IPF forms of progressive fibrosing ILD, including fibrotic HP. In the INBUILD trial, nintedanib was effective at slowing the rate of disease progression as measured by a change in FVC percentage over 52 weeks, with a between-group difference of 107 mL/year (95% CI, 70.8 to 185.6; $P < 0.001$).[128a] Subgroup analysis demonstrated that this difference was consistent across diagnostic categories, including for patients with HP.[128b]

LUNG TRANSPLANTATION

Lung transplantation should be considered for patients with progressive disease despite comprehensive management. The indications for a lung transplant in patients with chronic HP are similar to those for other forms of fibrotic ILD.[129] Chronic HP patients undergoing lung transplantation have excellent outcomes posttransplantation, with better survival than patients with IPF.[130] The risk of HP recurrence in the allograft lung appears low. However, patients with chronic HP may have worse health-related quality of life than patients with IPF, even after accounting for disease severity, and these issues are important to address and support.[131] The relationships among the impacts of chronic lung disease and age, sex, and socioeconomic factors deserve further study. Other supportive management approaches include infection prevention, pulmonary rehabilitation, oxygen supplementation, education, symptom management, and palliative care where appropriate.

PREVENTION AND OUTBREAK IDENTIFICATION

Recognition of an index case of HP is often a sentinel health event indicating an inciting antigen exposure and a population at risk, particularly in occupational settings. When one or more individuals develop HP in a shared environment, measures must be taken to protect the individuals from further exposure, identify the potential antigen sources, and modify the environment to prevent additional exposure. For example, interventions taken to minimize the risk of metalworking fluid HP have included the enclosure of machining operations, improved ventilation and engineering controls that decrease aerosolization of metalworking fluids, and worker education.[132]

Indoor microbe contamination is often associated with poor moisture control. Thus, source control should be implemented where appropriate to reduce indoor contamination. Source control involves preventing water intrusion, removing standing water sources (e.g., humidifiers, hot tubs), and keeping indoor relative humidity below 60%. Humidifiers and other water sources should follow factory-recommended maintenance schedules, with water frequently changed to prevent microbial growth. Work practices recommended to prevent FLD include drying of hay and grains before storage, use of mechanized feeding systems, improving ventilation in farm buildings, and education of workers on safe work practices.

Personal protective equipment may be helpful in reducing exposure to inciting antigens. In bird breeders with HP, serum antibody levels declined by 65% over 14 months in those using respirators, with no decline in those without respirators.[133] However, no data compared changes in symptoms or physiology between the two groups; therefore the clinical relevance is unknown. In another study of bird breeders, high-efficiency respirator masks nearly normalized lung function and serologic responses upon antigen rechallenge.[134] The long-term safety or feasibility of these masks is unknown, and compliance with masks is often poor due to discomfort and their cumbersome nature. Dust respirators and simple face masks can reduce the volume of particulate exposure but, given the minimal exposure needed to trigger a response in a sensitized individual, they may not provide adequate protection to at-risk individuals. A high index of suspicion and early recognition can reduce the subsequent risk to the index case and prevent future cases of the disease in at-risk individuals.

Key Points

- *Hypersensitivity pneumonitis* (HP) is a complex pulmonary syndrome caused by an immunologic reaction to an inhaled inciting antigen. The diagnosis of HP requires a high index of suspicion given its heterogeneous presentation. HP should be considered whenever a patient presents with an undifferentiated interstitial lung disease.
- HP is classified into nonfibrotic or fibrotic disease, depending on the presence of radiographic or histopathologic fibrosis, with an identifiable, indeterminate, or unidentifiable inhaled antigen exposure. The terms acute, subacute, and chronic HP have fallen out of favor because this arbitrary time classification does not stratify the disease based on characteristics known to improve diagnostic certainty and prognosis.
- Combinations of variables must be integrated to establish a confident diagnosis of HP. Exposure to an inciting antigen plus a high-resolution computed tomography pattern consistent with HP can establish the diagnosis in the appropriate clinical context. In some cases, bronchoscopy with bronchoalveolar lavage or lung biopsy may be necessary for diagnosis.
- Nonfibrotic HP lacks radiographic or histologic fibrosis, and the patient is anticipated to improve with antigen removal and, if indicated, systemic corticosteroid therapy.
- Fibrotic HP commonly does not normalize, and the patient may develop progressive pulmonary fibrosis despite apparent antigen remediation. Systemic immunomodulatory and/or antifibrotic therapy may be required, but a subset of patients will progress nonetheless.

INTRODUCTION

The lung may be involved in all *connective tissue diseases* (CTDs). The involvement is often subclinical, but its true extent may be masked by exercise limitation due to musculoskeletal features of the CTD. Patterns of lung involvement vary considerably within each CTD.[1] The differential diagnosis is made even wider by inclusion of drug-induced pulmonary reactions and opportunistic infections secondary to therapy for lung disease, which may present with features indistinguishable from diffuse lung disease.

It is not surprising that the lung is involved frequently in CTDs because these are systemic syndromes, but it is disappointing that so little is known about the true incidence and prevalence of lung disease because of a dearth of well-controlled, prospective, unselected series. Imprecision of nomenclature has also confused the issue. With this background, the aims of this chapter are to highlight the ways in which the lung may be involved in the most common CTDs and to indicate, when appropriate, the most usual pattern of lung disease for each CTD, with an emphasis on approaches to diagnosis and efficient management.

Interstitial lung disease (ILD) has been evaluated in much more detail in *systemic sclerosis* (SSc) than in other CTDs, probably because patients with SSc tend to be managed at referral centers. The broad approach to clinical presentation, prognostic evaluation, and management of ILD in the setting of CTD is outlined before discussing the specific data available for disease subgroups.

APPROACH TO DIAGNOSING AND TREATING CONNECTIVE TISSUE DISEASE–INTERSTITIAL LUNG DISEASE

CLINICAL FEATURES

Patients with CTD-ILD are more likely to be younger, female, and nonsmokers compared to those *with idiopathic interstitial pneumonia* (IIP).[2] A thorough clinical examination to identify extrathoracic manifestations, including Raynaud phenomenon, inflammatory arthritis, pleuropericardial involvement, sicca symptoms, and esophageal dysmotility, is recommended for any patient with suspected CTD-ILD.

RADIOLOGIC FEATURES

All radiologic patterns of IIP can be present in a patient with CTD-ILD (Table 92.1).[3] Overall, the most frequent radiologic pattern is *nonspecific interstitial pneumonia* (NSIP), characterized by homogenous ground-glass opacity, reticulation, and traction bronchiectasis, often with a peribronchovascular distribution.[4] A patient with radiographic NSIP should always be comprehensively investigated for an underlying CTD, which may present later in the disease course.[5] *Usual interstitial pneumonia* (UIP) is the second most common radiologic pattern seen in CTD-ILD and the most common pattern identified in *rheumatoid arthritis* (RA).[3] The

Table 92.1 Prevalence and Radiologic/Histologic Pattern for ILD in Major Connective Tissue Diseases

CTD Type	Prevalence of ILD	Radiologic/Histopathologic Pattern
SSc	40–75% with clinically significant disease (at least moderate impairment on pulmonary function) Up to 70% with detectable interstitial changes on HRCT	Most common: NSIP Other: UIP
RA	Detectable on HRCT: 30–60% Clinically evident 10–30%	Most common: UIP Other: NSIP, OP, LIP
SLE	3–11% chronic diffuse interstitial disease Up to 30% with detectable interstitial changes on HRCT Need to distinguish from acute pneumonitis (1–10%) and alveolar hemorrhage (rare)	Most common: NSIP Other: LIP, OP, UIP
SS	10–30% Need to exclude pulmonary lymphoma	Most common: NSIP Other: LIP, OP, UIP
PM/DM	30–50%	Most common: NSIP Other: UIP, OP, DAD
MCTD	20–85%	Common: NSIP Other: UIP

CTD, connective tissue disease; DAD, diffuse alveolar damage; HRCT, high-resolution computed tomography; ILD, interstitial lung disease; LIP, lymphocytic interstitial pneumonia; MCTD, mixed connective tissue disease; NSIP, nonspecific interstitial pneumonia; OP, organizing pneumonia; PM/DM, polymyositis/dermatomyositis; RA, rheumatoid arthritis; SSc, systemic sclerosis; SLE, systemic lupus erythematosus; SS, Sjögren syndrome; UIP, usual interstitial pneumonia.
From Jee A, Adelstein S, Bleasel J, et al. Role of Autoantibodies in the diagnosis of connective-tissue disease ILD (CTD-ILD) and interstitial pneumonia with autoimmune features (IPAF). *J Clin Med*. 2017;6:51.

UIP pattern seen in CTD-ILD is often indistinguishable from that of *idiopathic pulmonary fibrosis* (IPF) and is characterized by honeycombing, reticulation, and traction bronchiectasis in a subpleural basal distribution.[3,6] Other radiologic patterns seen in CTD-ILD include *organizing pneumonia* (OP), most commonly associated with *polymyositis/dermatomyositis* (PM/DM), mixed NSIP with OP overlap pattern and, less commonly, *lymphocytic interstitial pneumonia* (LIP), a pattern most closely associated with Sjögren syndrome.[4,6]

Radiologic features that may be more suggestive of an underlying CTD include multicompartment involvement, such as esophageal dilation and pleural and/or pericardial involvement; subpleural sparing and extensive honeycombing are rare.[4,7,8]

HISTOPATHOLOGIC FEATURES

Surgical lung biopsy is usually not required in the setting of CTD-ILD because the underlying histopathologic pattern has little impact on management and prognosis.[9,10] In cases where surgical lung biopsy has been performed, NSIP is the most common histopathologic pattern, except in RA, where UIP predominates (see Table 92.1).[11] Other patterns include OP, LIP, diffuse alveolar damage, and overlap patterns.[12] Specific features suggestive of an underlying CTD include involvement of airways, vasculature, or pleura; evidence of inflammation with follicular bronchiolitis; or lymphoplasmacytic inflammation.[12,13]

ROLE OF AUTOANTIBODIES IN THE DIAGNOSIS OF CTD-ILD

Distinguishing CTD-ILD from idiopathic ILD is essential and has major implications for prognosis and management. The role of autoantibodies in the diagnosis and management of patients with ILD is highlighted in the 2018 *American Thoracic Society* (*ATS*), *European Respiratory Society* (*ERS*), Japanese Respiratory Society, and Latin American Thoracic Society guidelines for the diagnosis of IIP, which recommend testing for *antinuclear antibody* (ANA), anti–cyclic citrullinated peptide, and *rheumatoid factor* (RF) in all patients, even in those without overt features of CTD.[14] More specific tests, including extractable nuclear antigen antibodies (e.g., anti–Sc-l70, SSA/Ro, SSB/La, *ribonucleoprotein* [RNP], and Sm antibodies) and selected myositis antibodies (e.g., anti-Jo1, PL7, and PL12), are recommended only in selected cases (eTable 92.1).[14–16]

Repeat serologic testing is also recommended. A study of 1044 Chinese CTD-ILD patients demonstrated seroconversion in 51.2% of patients at follow-up, 32% of which were initially given an alternative ILD diagnosis, most likely due to the absence of autoantibodies and overt rheumatologic features at first assessment.[17]

APPROACH TO TREATMENT OF CTD-ILD

The goal of treatment in CTD-ILD is to maximize lung function and minimize symptom burden. Often, stability of disease reflects successful treatment, and improvement is possible only in a smaller subset. Not all patients will require therapeutic intervention. The decision to treat is often difficult, requiring consideration of the severity of the ILD, rate of progression, age, comorbidities, underlying CTD-ILD subtype, and time since onset of CTD. A summary of the therapeutic agents considered in the management of CTD-ILD is given in eTable 92.2.

eTable 92.1 Autoantibodies in Connective Tissue Disease With the Percentages Positive in Different Disease Settings

CTD	Autoantibody	Target	Comments
SSc	Anticentromere	Centromere proteins (CENP A–F)	20–40% positive in total SSc, wide racial variation 70–80% positive in limited cutaneous variant with pulmonary hypertension
	Scl-70	DNA topoisomerase 1	28–70% total SSc, wide racial variation; >30% diffuse cutaneous disease with ILD
	PM-Scl	—	Scleroderma-myositis overlap syndromes
	Antinucleolar	RNA polymerase-1	8–20% SSc suggests poorest 10-yr survival, renal crisis
	Ku	DNA binding proteins	Scleroderma-myositis overlap syndromes
Rheumatoid arthritis	Rheumatoid factor	IgG	Seropositive disease more frequent with pulmonary nodules
	Antinuclear antibody	—	—
	Histone	Histone proteins	5% rheumatoid vasculitis
SLE	dsDNA	dsDNA	50–75%, strong association with nephritis
	ANA	—	90–95%
	Ro/La	RNA transcription factors	60%/20%
	Histone	Histone proteins	>90% drug-induced lupus, 20–30% primary SLE
	Sm	—	10% whites and 30% Blacks and Chinese
	Lupus anticoagulant	Phospholipid	20–30%
Antiphospholipid syndrome	Anticardiolipin Lupus anticoagulant	Membrane phospholipids	Disease diagnosis depends on presence of clinical features
Sjögren syndrome	Ro (SS-A) La (SS-B)	RNA transcription factors	40–50% primary Sjögren syndrome (25–30% SLE) 50% Sjögren (10% SLE)
PM/DM	Jo-1	Histidyl tRNA synthetase	20–30% inflammatory myopathy but 50–100% when associated with diffuse fibrosing lung disease
	PL-7	Threonyl tRNA synthetase	<3% antisynthetase syndrome
	PL-12	Alanyl tRNA synthetase	<3% antisynthetase syndrome
	EJ	Glycyl tRNA synthetase	<2% antisynthetase syndrome
	OJ	Isoleucyl tRNA synthetase	<2% antisynthetase syndrome
	Mi-2	Nuclear proteins	<8% DM, associated with acute onset of classic DM
	Ku	Nuclear proteins	Associated with myositis-CTD overlap syndromes
	Anti-CADM140 (MDA5)	Cytoplasmic proteins	Clinically amyopathic PM/DM ILD; poor prognosis
MCTD	U1-RNP	Small nuclear proteins	Myositis overlap syndromes (10% SSc)
	U2-RNP	—	Myositis, SLE, SSc
Relapsing polychondritis	Anticartilage Anticollagen	Cartilage Collagen	Unknown sensitivity

Percent (%) range indicates the percentage of patients with the listed disease who are positive for the antibody listed.
ANA, antinuclear antibody; CTD, connective tissue disease; dsDNA, double-stranded DNA; IgG, immunoglobulin G; ILD, interstitial lung disease; MCTD, mixed connective tissue disease; PM/DM, polymyositis/dermatomyositis; RNP, ribonuclear protein; Scl, scleroderma; SLE, systemic lupus erythematosus; Sm, Smith; SSc, systemic sclerosis; tRNA, transfer RNA.

eTable 92.2 Common Drugs Used in the Treatment of the Major Pulmonary Complications of Connective Tissue Diseases

Drug	Dose	Duration	Comments	Monitoring
IMMUNOSUPPRESSIVE AGENTS				
Azathioprine	2.5 mg/kg/day, max 200 mg/day	Continuous	Maximal effect may not be evident for 6–9 mo but has better adverse effect profile than cyclophosphamide May be used long term Starting dose, 50 mg daily with monitoring full blood count in case of thiopurine methyltransferase deficiency; maintenance dose from 1 mo	Full blood count Liver function tests
Cyclophosphamide, oral	2 mg/kg/day	Variable	May be used continuously or substituted at 3 mo for azathioprine because of more favorable adverse effect profile in DLD	Full blood count Liver function tests Urinalysis for blood
Cyclophosphamide, IV	15 mg/kg monthly for 1–6 mo	Variable	IV therapy for rapid induction of remission at 2–4 mg/kg/day for 3–4 days, especially for vasculitis Pulsed IV cyclophosphamide may be given at 1- to 3-mo intervals with better adverse effect profile and lower long-term cumulative dose, particularly in nonvasculitic disease	Full blood count Liver function tests Urinalysis for blood
Cyclosporin A	5 mg/kg/day	Continuous	Bioavailability variable, thus blood monitoring necessary May be used in combination with prednisolone	Blood pressure Urea and creatinine Cyclosporin A level
Mycophenolate mofetil	1–3 g/day	Continuous	Increasingly favored as best second-line therapy, usually in combination with low-dose prednisolone Usually well tolerated with gastrointestinal symptoms as the major side effects	Full blood count Liver function tests
Methotrexate	7.5–25 mg/wk	Continuous	Little information to support use except as second-line therapy Pulmonary toxicity may be limiting	Full blood count Liver function tests
Prednisolone	1 mg/kg/day or 20 mg alternate days	Continuous	Prednisolone used alone in high dose for cellular DLD and then titrated to control Low-dose regimen is used in conjunction with immunosuppressants	Blood pressure Blood glucose Weight Bone densitometry
Methylprednisolone	500–1000 mg	3–5 days	Used for aggressive induction of remission, particularly for vasculitis or acute pneumonitis, then followed by maintenance therapy of prednisolone or prednisolone plus immunosuppressive agent	
BIOLOGIC AGENTS				
Rituximab	1g IV	Induction and maintenance regimen	Usually reserved for rapidly progressive and resistant CTD-ILD, although clinical trial of up-front therapy with rituximab is ongoing	Full blood count Electrolytes Liver function tests Immunoglobulins
Tocilizumab	162 mg/wk SC	Maintenance	Used for RA joint disease; recent study suggesting a reduction in decline in FVC in SSc-ILD needs confirmation	Full blood count Electrolytes Liver function tests
ANTIFIBROTIC AGENTS				
Nintedanib	150 mg bid	Maintenance	42% reduction in the rate of decline of FVC in SSc-ILD patients; ongoing study including other CTD-ILD	Full blood count Electrolytes Liver function tests
Pirfenidone	801 mg tid	Maintenance	Ongoing studies for SSc-ILD and RA-ILD and unclassifiable ILD (including IPAF) at present	LOTUSS Trial: IPAF; ongoing

bid, twice daily; CTD, connective tissue disease; DLD, diffuse lung disease; FVC, forced vital capacity; ILD, interstitial lung disease; IPAF, idiopathic pneumonia with autoimmune features; IV, intravenous; RA, rheumatoid arthritis; SC, subcutaneous; SSc, systemic sclerosis; tid, three times daily.

SYSTEMIC SCLEROSIS (SCLERODERMA)

The preliminary criteria for classification of SSc require that one major or two or more of three minor criteria be present (Table 92.2).[18] The skin changes may affect the entire extremity or the face, neck, and trunk (thorax and abdomen). Scleroderma is traditionally classified on the basis of the extent of skin disease. Limited disease can involve the face, but the trunk and limbs proximal to the elbows and knees are spared. Diffuse disease can involve any part of the body. Nail fold capillaroscopy, a noninvasive technique in which a magnifying lens is used to assess the nail bed microcirculation,[19] is now included in current *European League Against Rheumatism* (EULAR) classification criteria for SSc diagnosis. Characteristic findings include decreased capillary density, neovascularization, and microhemorrhages.[20,21]

Table 92.2 Systemic Sclerosis (Scleroderma)

CRITERIA FOR DIAGNOSIS*
Major
Thickening of the skin of the hands
Minor
Sclerodactyly (i.e., the changes of the major criterion but limited to the fingers)
Digital pitting scars or loss of substance from the finger pad: depressed areas at tips of fingers or loss of digital pad tissue as a result of ischemia
Bibasilar pulmonary fibrosis
LUNG MANIFESTATIONS
Interstitial pulmonary fibrosis
Organizing pneumonia
Isolated pulmonary vascular disease
Aspiration pneumonia (secondary to esophageal dysmotility)
Chest wall restriction

*The major or ≥2 minor criteria required for diagnosis.
From Jee AS, Corte TJ. Current and emerging drug therapies for connective tissue disease–interstitial lung disease (CTD-ILD). *Drugs*. 2019;79(14):1511–1528.

EPIDEMIOLOGY AND RISK FACTORS

The incidence of SSc is approximately 2 to 20 per 100,000 per year, with a peak incidence in the fourth to sixth decades. The prevalence is 30 to 120 per 100,000, with a 3:1 to 8:1 female preponderance. Mortality rates have been remarkably consistent over the years, varying from 0.9 to 1.5 per million for men and 2.1 to 3.8 per million for women in the United States. The disease is present worldwide.

Although scleroderma clusters in families with other autoimmune disease, there are few reports of first-degree relatives having SSc. The importance of genetics to SSc is illustrated by a study of Choctaw Indians residing in southeastern Oklahoma. The prevalence of SSc in full-blooded Choctaws is roughly 1:200, which is significantly higher than is found in non–full-blooded Choctaws (1:3000) and strikingly higher than the prevalence of SSc in other Native Americans in Oklahoma (1:10,000).[22]

Genetic involvement in the disease has been determined by the identification of chromosomal abnormalities and by studies of the major histocompatibility complex genes. Although many of the early studies were serologic, more recently, polymerase chain reaction technology has been used. With this latter approach, an association between diffuse lung disease and *human leukocyte antigens* (HLAs)—HLA-DR3, HLA-DR52a, HLA-DRB1*11, and HLA-DPB1*1301—has been recognized.[23,24]

CHEMICALLY INDUCED SCLERODERMA-LIKE DISORDERS

A variety of agents are known to induce SSc-like disease, often with lung involvement, including D-penicillamine, tryptophan, bleomycin, pentazocine and, particularly in men, the industrial agents vinyl chloride, benzene, toluene, and trichloroethylene. Silica exposure increases the relative risk of developing SSc, and silicosis increases the risk even further.[25] The toxic oil syndrome, first recognized in Madrid in 1981, results from ingestion of an adulterated cooking oil containing rapeseed oil denatured with aniline.[26] This provokes a scleroderma-like syndrome with pulmonary involvement. An association with silicone breast implants is unproved.

PULMONARY MANIFESTATIONS

More is known about the pulmonary complications associated with SSc than with any other CTD. Pulmonary involvement has emerged as the major cause of excess morbidity and mortality in SSc.[27] The patterns of lung disease with which SSc may present are variable and are shown in Table 92.1.

Interstitial Lung Disease

Pathogenesis

Predisposition. Individuals may be predisposed genetically to develop SSc, and there are emerging markers that define risks for diffuse lung disease. Class II major histocompatibility complex associations increase the risk of ILD in SSc. The relative risk is increased if the anti-DNA topoisomerase (Scl-70) antibody is present. There may also be an association between Scl-70 and an allele of the major histocompatibility complex *DPB1* gene.

The genetic susceptibility for SSc probably results in injury and an immune response. It has been shown that there are highly restricted T-cell responses to epitopes of DNA topoisomerase 1, both in healthy individuals and in those with SSc. Thus, in individuals with Scl-70–responsive T-cell clones, the autoantibody may be responsible for driving the immune response. In the lung, there is an accumulation of "memory-type" CD45 Ro lymphocytes and secondary lymphoid follicles with true germinal centers within lung biopsy samples.[28] Furthermore, the T cells present within the lung express cytokines of both the *T helper 1* (Th1) and *T helper 2* (Th2) subsets.[29] Genetic susceptibility is also relevant to noninflammatory mediators on the basis of genome-wide association studies.[30,31]

Inflammation Amplification. A wide variety of cytokines identified in *bronchoalveolar lavage* (BAL) fluid clearly contribute to the cascade of inflammation in the lungs.[32] The most striking of these are *interleukin* (IL)-8 (neutrophil chemoattractant and activator), *tumor necrosis factor*-α (TNF-α; an early cytokine involved in many pathologic processes), macrophage inflammatory protein-1α (important in neutrophil chemotaxis), and RANTES (*regulated on activation normal*

T-cell expressed and secreted; important in T-cell and eosinophil recruitment and activation). It is clear that the downstream events of the initiation result in the release of a number of proinflammatory cytokines responsible for further recruitment and activation of inflammatory cells at disease sites.

Fibrogenetic Factors. The hallmark of SSc in both lung and skin is the accumulation of connective tissue matrix cells and proteins.[33,34] Many factors have been studied in this regard, and a wide variety of growth factors have been identified. Perhaps the most striking of these is connective tissue growth factor, which appears to depend on *transforming growth factor-β* (TGF-β) for up-regulation and has a potent effect on collagen production, as evidenced by collagen gel retraction studies. TGF-β is found in high amounts in the lungs of patients with SSc[35] and, when TGF-β signaling is perturbed, minor epithelial injury leads to extensive fibrosis.[36] *Endothelin* (ET)-1 and coagulation cascade proteins are also present in high amounts in BAL fluid.[37] Fibroblasts from patients with lung disease exhibit dysregulated type I collagen biosynthesis and impaired messenger RNA downregulation. The balance of ET receptors (A and B) is modified in the lungs of patients with SSc, with a consistent decrease in ETA and an increase in ETB receptors.[38] ET-1 may contribute to epithelial-mesenchymal transition of airway epithelial cells, resulting in fibrosis.[39]

Epithelial Damage. Although a key pathogenic event in idiopathic ILD, epithelial damage has been relatively underemphasized in disease models of pulmonary fibrosis in CTD. The intratracheal instillation of normal saline in a mouse strain with SSc features, including skin fibrosis and other universal characteristics, leads to lung injury and fibrosis, with evidence of epithelial injury on electron micrographic studies, attenuated alveolar epithelial type 2 cell proliferation, and persistence of the myofibroblast population after injury.[40,41] Chronic microaspiration, believed to happen in many patients with SSc,[42] is a plausible trigger of recurrent epithelial injury.

A number of parallel events result in the development of lung injury and subsequent fibrosis, and there seems little doubt that the key cytokines in the cascade include TNF-α, because it appears early in disease and has been shown in animal models to be a pivotal factor in lung fibrosis,[43] and TGF-β receptor, which up-regulates collagen gene expression and is important in connective tissue growth factor release. Other important cytokines may include hepatocyte growth factor and insulin-like growth factor-II.[44,45] The balance of Th1 to Th2 cytokines is also key because, when the shift is in favor of Th2 cytokines, such as in IPF, the prognosis is worse and there is a much higher eosinophil influx into the lung compared with patients with SSc, in whom the Th1/Th2 ratio is balanced and there is less eosinophil influx per unit of lung involvement.[29]

Clinical Features

Dyspnea is present in 21–80%.[46] Cough, a less frequently reported symptom, tends to be dry and nonproductive. Hemoptysis is rare but may complicate carcinoma or bronchial telangiectasia.[47] Fine crackles are heard at the lung bases and are of a "Velcro" character. Digital clubbing is extremely rare. Secondary pulmonary hypertension with appropriate clinical features of right ventricular strain, raised jugular venous pressure, and ankle edema may be seen during the terminal stages of the disease.

The lung is involved more commonly in patients with diffuse rather than limited cutaneous SSc, but the extent of skin involvement does not correlate with lung function changes. Patients can often be asymptomatic, even with moderate pulmonary function impairment, whereas, in other cases, patients can have exertional dyspnea when ILD is trivial or absent due to pulmonary vascular limitation, cardiac involvement, musculoskeletal problems, general debility, loss of fitness, or a variable combination of these factors. Rarely, scleroderma of the chest wall may cause extrathoracic restriction.

Lung disease may be the first manifestation of SSc and thus may not be recognized as a CTD-ILD. In this setting, a history of Raynaud phenomenon is often helpful. In addition, careful examination of the capillaries in the nail beds reveals the typical feature associated with scleroderma: abnormal loops associated with capillary "dropout" (Fig. 92.1A). The presence of autoantibodies, particularly ANAs, is helpful in suggesting a CTD etiology (see eTable 92.1).

Imaging

Chest radiographic abnormalities are present in 25–67% of patients, and lung function is impaired in up to 90%, although a large subset of patients has only a minor reduction in gas transfer or *diffusing capacity for carbon monoxide* (DL_{CO}). Chest radiography typically shows a reticular pattern in the lung bases and periphery in early disease (see

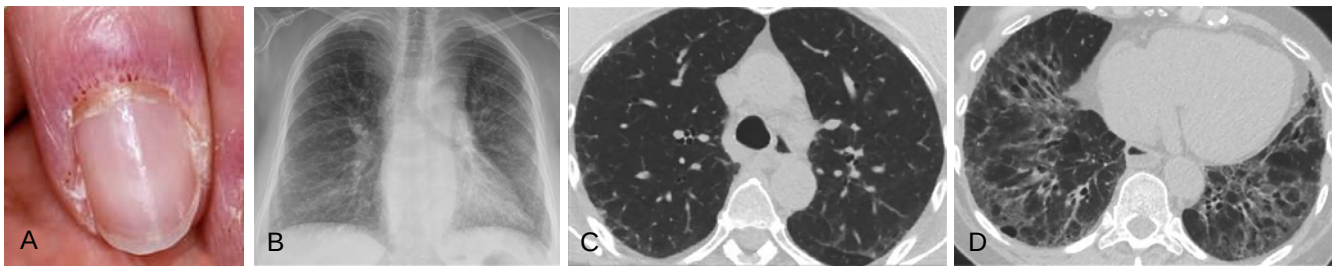

Figure 92.1 Imaging of systemic sclerosis. (A) Nail bed showing abnormal capillary loops in the cuticle. (B) Frontal chest radiograph shows bilateral, symmetric, fine linear and reticular opacities with a basal predominance. (C–D) Axial chest computed tomography through the middle (C) and lower (D) lungs shows nonsegmental, peripheral, and fine reticulation reflecting intralobular interstitial thickening, with a clear basal predominance. The reticulation is associated with ground-glass opacity in the bases and traction bronchiectasis is present in this region as well. Mild gas and fluid distension of the esophagus is visible and commonly visible with computed tomography in patients with systemic sclerosis. The dilated esophagus indicates that this disease is likely to be part of systemic sclerosis. (A, Modified from Iaccarino L, Ghirardello A, Bettio S, et al. The clinical features, diagnosis and classification of dermatomyositis. *J Autoimmun.* 2014;48–49:122–127. B–D, Courtesy Michael B. Gotway, MD.)

Fig. 92.1B). There is obvious loss of volume with more extensive reticular shadowing in more advanced disease. In this situation honeycombing may be present.

High-resolution computed tomography (HRCT) has revolutionized the interpretation of the pattern and extent of disease. Disease is localized to the lung periphery, appearing earliest at the bases and posteriorly (see Fig. 92.1C–D, eFigs. 92.1 to 92.3). As disease becomes more advanced, it progresses superiorly, centrally, and anteriorly. Esophageal dilation is common (see Fig. 92.1C–D).[48] The pattern may be ground-glass (reflecting either fine intralobular fibrosis or a more cellular histopathology) or an overtly fibrotic reticular pattern consisting of intersecting linear abnormalities, often associated with traction bronchiectasis.[49] Honeycomb change is present in up to one-third of cases but is usually limited in extent.[50] HRCT extent correlates moderately well with lung function variables, particularly measures of D_{LCO}.[51] In the absence of overt pulmonary hypertension, individuals with SSc are less hypoxemic than those with IPF, once the extent of disease on HRCT has been taken into account, which has been ascribed to a relative absence of new and abnormal vessel formation in SSc lung.[52]

Gallium scans and technetium-99m–labeled diethylenetriaminepentaacetic acid clearance provide little additional prognostic benefit.

Pulmonary Function Tests

The interstitial pulmonary fibrosis of SSc is characterized by a restrictive ventilatory defect, which results in reduced pulmonary compliance, vital capacity, and total lung capacity. Residual volume is decreased. D_{LCO} is reduced and may be the only abnormality in early disease. Arterial blood gas analysis usually reveals a normal or reduced arterial oxygen partial pressure, reflecting regional vasoconstriction in diseased lung, with a normal or low arterial carbon dioxide partial pressure. In the absence of pulmonary hypertension, hypoxemia is seldom marked until late in the disease process.

There have been a number of studies of the rate of decline of lung function in SSc.[53,54] In one study of 38 patients with SSc, the mean loss of vital capacity was 100 mL/yr; 20 to 30 mL/yr is the normal rate of decline.[55] A second study showed that vital capacity loss was greater in patients who had evidence of an active alveolitis on BAL.[44] Lower *forced vital capacity* (FVC) within 3 years of disease onset predicts decline in pulmonary function,[55] which in turn is associated with increased mortality.[56] Rates of decline are often higher within the first few years of onset of SSc, emphasizing the importance of identifying lung disease early and initiating therapy.

On cardiopulmonary exercise testing (see Chapter 33), ventilation-perfusion mismatching and diffusion abnormalities increase, resulting in hypoxemia and widening of the alveolar-arterial oxygen tension difference. Minute ventilation increases generally as a consequence of increased respiratory rate rather than tidal volume. Dead space ventilation may increase with exercise, with a rise in the dead space/tidal volume ratio. For a given degree of lung involvement defined by CT, abnormalities on exercise gas exchange are less severe in patients with interstitial pulmonary fibrosis of SSc than in those with IPF.[52]

Bronchoalveolar Lavage

BAL may identify alveolitis in SSc before the onset of pulmonary symptoms.[57] A neutrophil alveolitis has been described by some authors to predict more progressive disease.[53,58,59] However, it has been shown that an increase in neutrophils reflects an increase in the extent of disease on CT, particularly of the reticular pattern; thus this increase is likely to be a marker of more extensive disease rather than an independent index of progressive disease.[38,46,47] BAL should not be used alone to determine whether treatment should be started. Many patients with apparently normal BAL findings may exhibit progressive disease. BAL is therefore not recommended routinely for the diagnosis or monitoring of SSc-related interstitial disease.

Biopsy

Surgical lung biopsy is virtually never required in the diagnosis of SSc-related interstitial disease unless clinical and CT findings are atypical for ILD in SSc and an alternative diagnosis is suspected. Furthermore, transbronchial biopsy or transbronchial cryobiopsy provide no useful information. Pathologically, the most prevalent pattern is NSIP[59] (eFig. 92.4). Less commonly, a UIP pattern is seen, or indeed a combination of patterns.[60] Crucially, outcome does not differ materially among these patterns. In idiopathic disease, the UIP pattern of injury is associated with a worse outcome compared with the NSIP pattern.[61] However, in SSc, outcome was not related to the histologic pattern in the largest series,[59] although there is evidence in a smaller series that some patients with a UIP pattern have a more progressive course.[62] Overall, biopsy does not provide sufficient prognostic information to justify the procedure in SSc.

Electron microscopy shows early endothelial and epithelial cell injury, even without abnormalities on light microscopy. Autopsy studies show diffuse lung disease in up to 80% of cases and pulmonary vascular disease in up to 30% (see eFig. 92.4C). In some patients with a more accelerated course of disease, histopathologic examination has shown a diffuse alveolar damage pattern.[63]

Serologic Investigations

Although SSc is traditionally defined on the basis of the extent of the skin disease, as outlined previously, the pattern of autoantibodies appears to be a much stronger determinant of the associated internal organ involvement.[64,65] ANAs are found in 90–100% of patients with SSc, although even normal individuals often have positive ANAs (roughly 30% of normal individuals have an ANA titer of 1:40). Three major autoantibodies include anticentromere, seen in 57% of patients with limited cutaneous disease; Scl-70, seen in 40% of patients with diffuse disease; and PM-Scl, seen in a small fraction of cases in association with the PM overlap syndrome. It is rare to have both Scl-70 and anticentromere antibodies. Diffuse lung disease is rare in the presence of anticentromere antibodies, and a protective role for this autoantibody has been argued but not substantiated. IPF is strongly associated with the Scl-70 antibody and with diffuse scleroderma. Limited cutaneous disease associates with vascular disease and the anticentromere antibody. Both forms of lung disease may progress to pulmonary

hypertension. Other autoantibody studies have shown associations with organ involvement, including a nucleolar pattern associated with diffuse lung disease and pulmonary hypertension[66]; the antibody against B23, a nucleolar phosphoprotein associated with pulmonary hypertension and the presence of the antifibrillarin antibody; and anti-Th/To antibodies associated with pulmonary hypertension and diffuse lung disease.

Prognosis

Crude mortality rates are 3.9% per year for men and 2.6% per year for women, and lung disease remains the most common cause of death in patients with SSc.[67] In one series, lung disease accounted for 21% of all deaths.[68] There is also an increased risk of lung cancer in SSc. With the widespread use of HRCT, mild ILD (see eFigs. 92.1 and 92.3) is detected in many SSc patients, leaving the clinician with difficult decisions as to whether to introduce therapy or to observe carefully without immediate intervention. In overtly severe ILD, the decision to treat is straightforward. However, the majority of SSc patients have milder lung involvement, and a reliable means of discriminating between stable and progressive ILD would be useful in management. On the basis of clinical series and accumulated experience, prognostic evaluation should focus on three main considerations: the extent of disease at presentation, the duration of systemic disease, and recent progression of disease.[69]

Extent of disease at the time of presentation is the strongest consideration in the decision to treat patients with SSc. The extent of disease is best judged by lung function tests, particularly FVC and D_{LCO}, and the extent of disease on CT. A simple staging system using CT extent (above and below 20%) and FVC at presentation (above and below 70%), the *United Kingdom Raynaud's and Scleroderma Association* (UKRSA) staging system, is highly discriminatory for both progression and death (eFig. 92.5).[70] The prognostic value of the UKRSA staging system has been confirmed,[71] and the severity thresholds were virtually identical to those found to identify the likelihood of a treatment effect in the first controlled study of oral cyclophosphamide in SSc.[72]

Duration of systemic disease is also an important consideration in the decision to treat. The greatest risk of ILD progression is during the first 4 years of SSc. Early declines in FVC are strongly predictive of subsequent severe ILD,[73] which most often develops in the first 4 years.[74] Put simply, in SSc and other CTDs, the early development of mild to moderate ILD is a marker of likely rapid disease progression, which should reduce the threshold for initiating therapy.

Finally, recent disease progression is an important justification for treatment. It should be acknowledged that the long-term prognostic value of observed disease progression has not been quantified in SSc or, indeed, in other CTDs. However, declines in lung function variables, especially FVC, have consistently been predictive of long-term mortality in other forms of pulmonary fibrosis, and these observations can reasonably be extrapolated to CTDs.

Although no overall treatment algorithm of ILD has been devised to integrate extent of disease, duration of systemic disease, and evidence of recent progression, consideration of all three factors provides a basis for rational treatment decisions. More recently, attention has focused on refining the selection of appropriate SSc patients with pulmonary fibrosis to participate in controlled treatment trials. For treatment effects to be demonstrated, it is necessary to enroll patients with progressive disease: The UKRSA staging system has been endorsed for this purpose by an expert group.[75] Biomarker data might, in principle, be used both for clinical prognostication and for selecting patients for trial involvement but, at present, despite promising preliminary data, no single biomarker is currently fit for routine use.

Treatment

The treatment paradigm for SSc-ILD is rapidly changing. The Scleroderma Lung Study demonstrated a small but significant benefit of oral cyclophosphamide compared with placebo for FVC, skin scores, and quality of life and dyspnea scores at 12 months.[72] The oral cyclophosphamide treatment regimen used most commonly is 2 mg/kg/day orally, up to a maximum of 150 mg with moderately low dosages of prednisolone at 10 mg/day or 20 mg every other day. Close scrutiny with full blood counts, liver function tests, and urine testing for evidence of hemorrhagic cystitis is necessary.

Intravenous (IV) cyclophosphamide may have a better safety profile.[76] Studies of IV cyclophosphamide (750–1000 mg/m^2) given at 2- to 4-week intervals for 6 to 12 months tended toward significance, as judged by CT and pulmonary function data.[77,78] The similarity in the amplitude of treatment effects in the Scleroderma Lung Study[72] and a smaller placebo-controlled trial of IV cyclophosphamide[78] prompted the EULAR to state that "in view of the results from two high-quality RCTs and despite its known toxicity, cyclophosphamide should be considered for treatment of SSc-ILD."[79] However, careful selection of patients with severe or progressive lung disease is required given the toxicity associated with intense immunosuppressive therapy.

In controlled trials[72,78] treatment effects largely consisted of stopping or slowing progression of lung disease, as judged by serial lung function trends, with the greatest benefit seen in patients with extensive fibrotic disease.[72] This endorses the important principle of intervention in apparently irreversible fibrotic lung disease, with the primary aim of achieving stabilization, as opposed to regression of disease. However, in the Scleroderma Lung Study, after the cessation of active treatment, therapeutic benefits were transient.[79] Longer-term treatment approaches have not been evaluated in controlled studies.

Other less toxic immunosuppressive agents have been widely used, including azathioprine, methotrexate, and *mycophenolate mofetil* (MMF), on the basis of accumulated clinical experience and small retrospective case series.[80–82] In one retrospective series of 100 CTD-ILD patients, treatment with MMF was well tolerated and was associated, on average, with stabilization of pulmonary fibrosis over a number of years.[83] The Scleroderma Lung Study 2 demonstrated similar treatment effects between MMF over 1 to 2 years to cyclophosphamide for 1 year, followed by placebo. Patients were able to tolerate MMF significantly better, and it is considered by many as a first-line therapy for SSc-ILD.[84]

The SENSCIS study evaluated an antifibrotic agent, nintedanib, in patients with mild to moderate SSc-ILD. Nintedanib, a tyrosine kinase inhibitor, was found to reduce the rate of decline of FVC at 52 weeks by 41 mL/yr, which is a relative reduction of 44%.[85] This effect appears to be additive to background MMF, which also had a benefit in slowing FVC decline.

Tocilizumab is an anti–IL-6 receptor monoclonal antibody used for the treatment of RA, and also studied in SSc, including in a subset of patients with SSc-ILD. A phase II study (FaSScinate)[86] demonstrated that, over 48 weeks, more patients on placebo demonstrated a decline in FVC greater than 10% compared to those receiving tocilizumab. Similar results were shown in a phase III study (focuSSced); there was no change in the primary end point (modified Rodnan skin scores), but patients with SSc-ILD had a significant reduction in FVC decline.[87]

The question of *Pneumocystis* prophylaxis has not been resolved. Some medical centers use cotrimoxazole three times a week if immunosuppressive agents are being given.

Steroid therapy is associated with scleroderma renal crisis, a life-threatening complication due to rapidly progressive renal failure. This complication has been seen both with moderate- to high-dose therapy (≥15 mg/day prednisone or equivalent)[88] and, more recently, with prednisolone doses of less than 10 mg daily.[89] However, confounding by severity cannot be excluded because patients with more aggressive systemic disease are more likely to receive corticosteroids, nonetheless, occasional cases of renal crisis are undoubtedly linked to high-dose corticosteroid therapy.[90]

Hematopoietic stem cell transplantation (HSCT) can now be considered for the treatment of selected patients with rapidly progressive SSc at risk of organ failure (EULAR SSc treatment recommendations, 2017).[91] In principle, HSCT may work to "reset" the immune system. The Autologous Stem Cell Transplantation International Scleroderma Trial compared nonmyeloablative HSCT with monthly IV cyclophosphamide in patients with early diffuse SSc. Despite higher early treatment-related mortality, there was superior long-term event-free and overall survival.[92] The Scleroderma: Cyclophosphamide or Transplantation Trial compared monthly IV cyclophosphamide with HSCT using a lower dose of pretransplant cyclophosphamide and fully myeloablative total-body irradiation conditioning.[93] HSCT demonstrated superiority in the primary outcome of global rank composite score at 54 months. Autologous HSCT has demonstrated long-term survival and lung function benefit in carefully selected SSc patients with rapidly progressive disease at risk of organ failure.

Single-lung transplantation has been offered to those with end-stage lung disease, provided there is no evidence of disease activity in other organs and no major esophageal dysfunction. With careful selection of patients, outcome with transplantation may differ little from that in individuals with idiopathic diffuse lung disease, although it should be understood that perceived contraindications to lung transplantation due to systemic disease activity vary widely between transplant units.

In terminal disease, consideration must be given to oxygen therapy, treatment of supervening heart failure, and infection and advanced care planning, with palliative care specialists often having an invaluable input.

PULMONARY VASCULAR DISEASE

Pulmonary arterial hypertension (PAH; World Health Organization Group 1) may develop in patients with SSc. Unlike the other CTDs, vascular involvement in SSc is caused by concentric fibrosis of small arterioles replacing the normal intima and media, but the plexiform lesions and fibrinoid necrosis of idiopathic PAH are not seen. Isolated vascular disease arises mainly in the limited form of SSc. Associated features are those of the CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias) with prominent telangiectasia, esophageal disease, abnormal nail fold capillaries (dilated capillaries and dropout of capillary loops), and a positive anticentromere antibody. Lung function studies show an isolated or disproportionate fall in D_{LCO}, quantified by a decline in D_{LCO} adjusted for the alveolar volume (D_{LCO}/alveolar volume or carbon monoxide transfer coefficient) or a rise in the FVC/D_{LCO} ratio. Although routine annual echocardiography has been advocated in all SSc patients, the stated gas transfer variables can reasonably be used to select patients for echocardiography.[94] When damage to the pulmonary vascular bed is extensive (D_{LCO} < 50% of predicted), the risk of pulmonary hypertension increases.[95] Mortality rates increase with increasing pulmonary hypertension[96,97] (see also Chapter 84).

Doppler echocardiography has been shown to correlate with measurements of pulmonary artery pressures made at right heart catheterization. Qualitative features found on echocardiography may also suggest pulmonary hypertension even when the absence of a tricuspid regurgitant jet precludes measurement of the gradient across the tricuspid valve and thus an estimate of pulmonary artery pressure. These qualitative features include right ventricular dilation and right ventricular hypertrophy. Overall, echocardiography is moderately sensitive for the diagnosis of PAH (47–88%).[98,99] However, echocardiography is less accurate at borderline and mild levels of pulmonary hypertension. Stress (exercise) echocardiography may be able to identify preclinical PAH.[100,101] N-Terminal pro–brain natriuretic peptide, released from cardiac ventricles in response to stretch, is elevated in SSc and inversely related to D_{LCO}. Elevated N-terminal pro–brain natriuretic peptide levels may predict the development of pulmonary hypertension in SSc.[102,103] Worse functional class and impaired D_{LCO} predict worse outcomes in scleroderma-associated PAH.[104]

Although there are a number of emerging therapeutic options, optimal treatment of pulmonary vascular disease (see Chapter 84) in SSc has not yet been defined.[1,105]

OTHER PULMONARY COMPLICATIONS

Classical aspiration pneumonia is uncommon, particularly considering the prevalence of esophageal dysfunction in SSc. It is not yet clear whether microaspiration from reflux may in some cases serve as an important cofactor leading to progression of lung disease and therefore whether active treatment of symptomatic reflux is advisable. Pleural disease is uncommon. Rarely, the extent of skin tightness over the chest wall produces an

extrinsic restriction of ventilation. On occasion the first manifestation of pulmonary parenchymal disease is OP. This responds well to corticosteroid therapy, as does OP in other contexts.

RHEUMATOID ARTHRITIS

The American Rheumatism Association revised criteria for the classification of RA require that at least four of the criteria listed in Table 92.3 be satisfied for a minimum of 6 weeks.[106]

EPIDEMIOLOGY AND RISK FACTORS

The reported incidence of RA ranges from 0.2 to 3 per 1000 person-years (<0.5/1000 person-years in most surveys), with a rising incidence with increasing age into the seventh decade. In white adults, the prevalence of RA ranges from 0.5–2%, with a male-to-female ratio between 1:2 and 1:4. Depending on disease severity, as judged by disability scales and the need for long-term corticosteroid therapy, the age-matched mortality rate of RA is up to twofold higher than in the general population, with this increased mortality being attributed to cardiorespiratory complications.[107,108] The prevalence of RA is similar throughout the world. Evidence in support of a genetic predisposition includes familial and twin clustering and associations between RA and HLA-DRB1 alleles.[109] Hormonal factors may play a role, judging from the female preponderance of RA and a reduced incidence during pregnancy. Infectious agents and socioeconomic factors have not been shown to be etiologically important.

PULMONARY MANIFESTATIONS

Pleuropulmonary manifestations are multiple and are listed in Table 92.3 and shown in Fig. 92.2.

Interstitial Lung Disease

The interstitial pulmonary fibrosis of RA has a male predominance (male/female ratio of 3:1).[110] High titers of RF[111] and the presence of rheumatoid nodules[112,113] are associated with an increased prevalence of pulmonary fibrosis in RA. Smoking is a risk factor for the development of overt pulmonary fibrosis in RA, predisposes to the phenotype of combined pulmonary fibrosis and emphysema,[114,115] and has also been associated with subclinical disease.[116,117] In the presence of HLA-DR susceptibility genes, smoking is strongly associated with development of anti–citrulline-positive RA.[114,117–119] It has been suggested that the seropositive RA actually starts in the lungs.[120] The *MUC5B* promoter variant gene was found to be associated with the presence of RA-associated ILD in a population of RA patients, suggesting an underlying genetic susceptibility to developing ILD, and specifically UIP, in these patients.[121]

In early disease, a lymphocytic interstitial infiltrate is often the predominant abnormality,[122] and prominent peribronchiolar follicles, containing aggregates of lymphocytes with germinal centers, are often seen.[123] In long-standing disease, fibrosis predominates, often resulting in cystic changes or honeycombing. Both NSIP and UIP are present in significant proportions of patients with interstitial fibrosis[124,125] (eFig. 92.6A). UIP is associated with a better outcome in CTD than in an idiopathic setting.[60,126,127] In RA, UIP is associated with a worse outcome than NSIP.[128,129] Furthermore, UIP has a worse outcome in RA than in other CTDs.[130]

In RA patients with UIP, with HRCT appearances similar to classical IPF (consisting of predominantly basal subpleural honeycomb change and little or no ground-glass attenuation; see Fig. 92.2A), average short to intermediate outcomes are similar to those with IPF.[131] However, approximately 25% of these RA patients with a CT pattern of UIP have a good long-term outcome.[132]

Minor pulmonary fibrosis is common in RA; in one open-lung biopsy series performed in the previous century in volunteers with RA (some without clinical evidence of ILD), pulmonary fibrosis was seen in 60% of patients.[133] Reductions in D_{LCO} are found in 40% of unselected RA patients.[134] However, radiologically overt pulmonary fibrosis is found in only 1–5% of RA patients, based on three large chest radiographic series.[112,115,135] In the largest prospective series reported to date, 150 consecutive patients were screened for pulmonary disease.[136] Of these, 19% had CT evidence of interstitial fibrosis, which was often subtle; 43% of those with interstitial abnormalities also had emphysematous bullae. Chest radiography identified abnormalities in only 14% of the whole cohort, but physiologic abnormalities were seen in 82% (D_{LCO}) and 14% (restrictive pattern of ventilatory defect).[136] Disease severity as judged by CT generally reflects functional impairment.[137–139]

The most frequent symptom is exertional dyspnea, although this may be masked by a general loss of mobility due to systemic disease. The clinical picture is usually

Table 92.3 Rheumatoid Arthritis

CRITERIA FOR DIAGNOSIS*
Morning stiffness (lasting at least 1 hour)
Arthritis (soft tissue swelling or fluid) of three or more joints (PIP, MCP, wrist, elbow, knee, ankle, MTP joints)
Arthritis of hand joints (swelling of at least one wrist, MCP, or PIP joint)
Symmetrical arthritis (i.e., simultaneous arthritis of the same joints on both sides of the body)
Rheumatoid nodules
Serum rheumatoid factor positivity (at a level such that <5% of normal controls are positive)
Radiographic hand or wrist changes typical of rheumatoid arthritis
LUNG MANIFESTATIONS
Interstitial pulmonary fibrosis
Organizing pneumonia
Obliterative bronchiolitis
Follicular bronchiolitis
Bronchiectasis
Vasculitis
Nodules
Pleural disease
Lymphocytic interstitial pneumonia
Drug induced

*At least four criteria for a minimum of 6 weeks.
MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal.

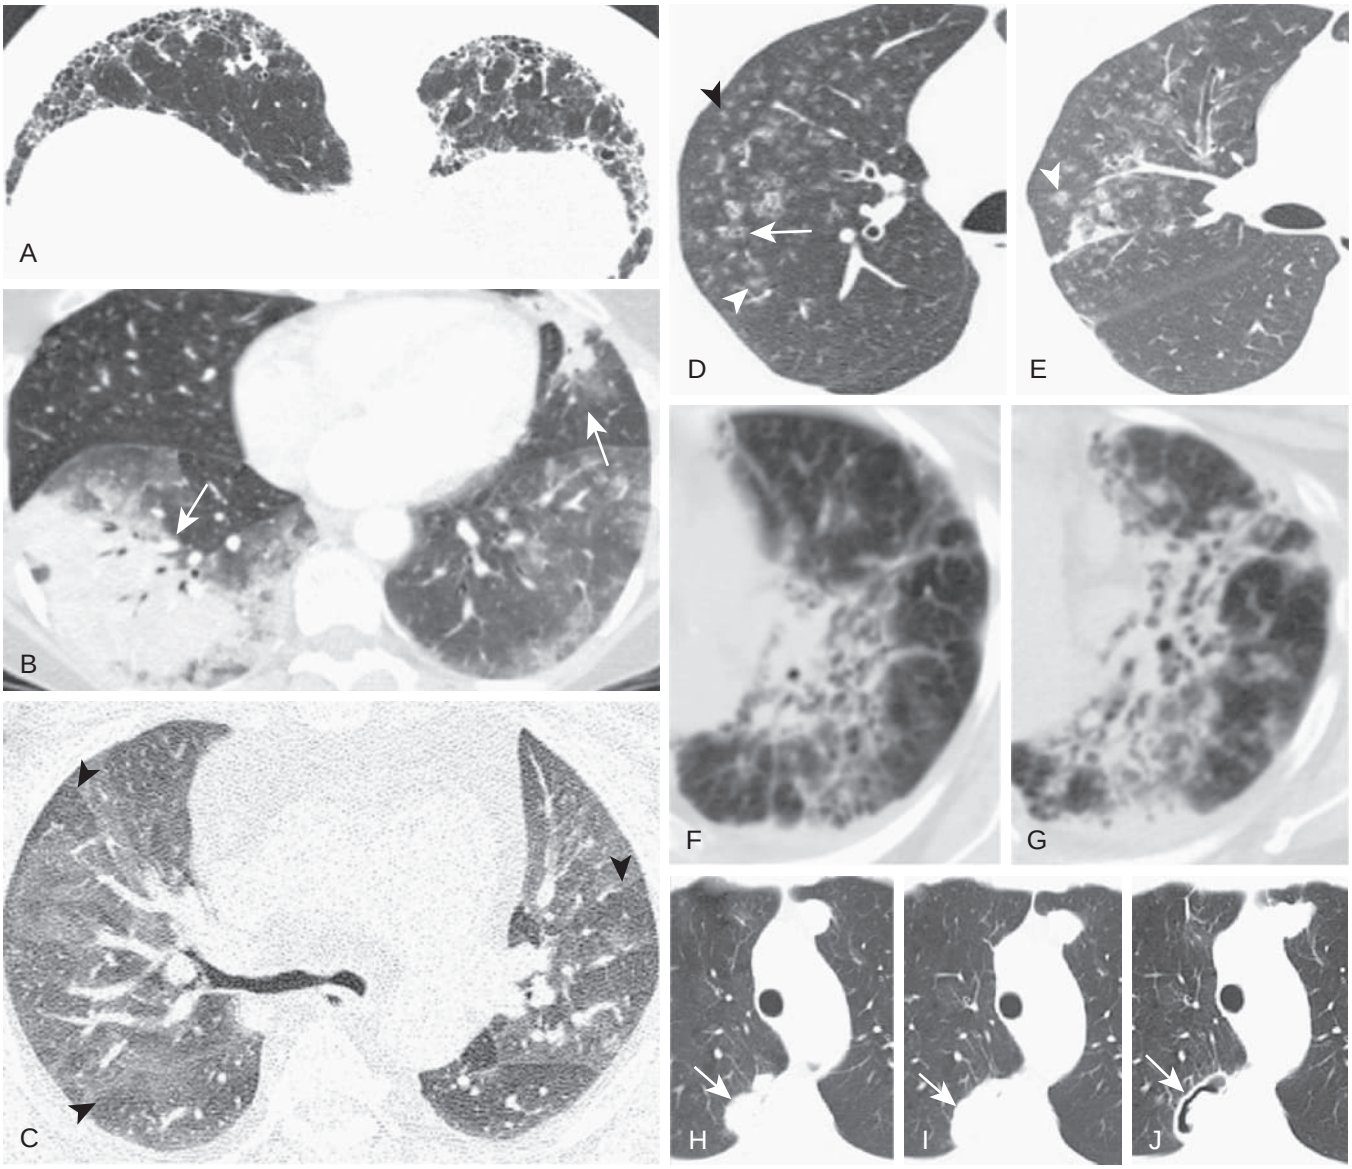

Figure 92.2 Rheumatoid arthritis–associated pulmonary abnormalities shown on axial chest computed tomography. (A) Usual interstitial pneumonia pattern. Axial prone *high-resolution computed tomography* (HRCT) image shows basal and subpleural coarse reticulation, architectural distortion, and honeycombing identical to the interstitial pneumonia pattern in patients with idiopathic pulmonary fibrosis. (B) Organizing pneumonia. Axial HRCT image shows bilateral peripheral consolidation (*arrows*). (C) Bronchiolitis obliterans. Axial supine HRCT image shows extensive, multifocal, bilateral areas of low attenuation (*arrowheads*) reflecting air trapping due to small airway obstruction. (D–E) Axial supine HRCT images show centrilobular ground-glass opacity nodules (*arrowheads*) in the right upper lobe, some of which show early cavitation (*arrow*), shown on biopsy to represent follicular bronchiolitis. (F–G) Axial supine HRCT images show bronchiectasis in the left upper lobe, progressing over the 4-year interval between the two studies. (H–J), Axial supine HRCT images show progressive enlargement of a rheumatoid nodule (*arrows*) over 1 year (H–I), with cavitation developing 3 years later (J). (Courtesy Michael B. Gotway, MD.)

identical to that of IPF, with bilateral, predominantly basal crackles and tachypnea; cyanosis; and right heart failure in advanced disease. Finger clubbing, which is occasionally striking, is more prevalent than in other CTDs. Severe progressive disease requiring hospitalization may be associated with right heart dysfunction and respiratory failure and has a poor prognosis, with a 5-year survival rate of less than 50%.[66] A subgroup of patients has more indolent disease that progresses little during prolonged follow-up. A strong predictor of clinical decline is a $D_{L_{CO}}$ less than 55% of predicted at presentation.[140]

Organizing Pneumonia

OP is characterized by plugs of granulation tissue in the air spaces distal to and including the terminal bronchioles, associated with lymphocytic infiltration within well-preserved bronchiolar walls and the surrounding lung interstitium. OP has a very different profile from the entity of *bronchiolitis obliterans* (BO; also found in RA); in OP, there is a clinical presentation of pneumonia (as opposed to airflow obstruction), multifocal consolidation on chest radiograph and CT (see Fig. 92.2B), a restrictive functional defect, and a much higher chance of responsiveness to corticosteroids than BO, with a good outcome in 15 of the first 17 reported cases.[141]

OP is more common in RA than in other CTDs, with the exception of inflammatory myopathy and *mixed connective tissue disease* (MCTD).

Bronchiolitis Obliterans

BO, synonymous with obliterative bronchiolitis and constrictive bronchiolitis, is characterized histologically by destruction of the bronchiolar wall by granulation tissue and eventual replacement of the bronchiole by fibrous tissue. In some cases BO may be preceded by an inflammatory exudate; prominent bronchiolar inflammation may be found in patients with the shortest symptomatic course.[142] The expression of HLA antigens B40 and DR1 is increased in BO associated with RA but not in isolated BO.[143]

There is great heterogeneity in the speed of progression, with some patients having indolent disease and others a rapidly progressive and fatal course[144]; the use of CT in RA patients with suspected pulmonary complications has now identified a subgroup with occult bronchiolitis (see Fig. 92.2C), often admixed with ILD. The prevalence of unsuspected BO in unselected RA patients remains uncertain, with unexplained airflow obstruction identified in a significant minority, including many nonsmokers in one study,[145] but no increase in the prevalence of pulmonary function abnormalities suggestive of isolated small airway disease in two subsequent controlled series.[146,147]

Two major associations with the development of BO in RA have been reported. It is likely that secondary Sjögren syndrome is an important predisposing factor.[144] Because the presence or absence of Sjögren syndrome is not documented in many case reports of BO in RA, the etiologic importance of Sjögren syndrome in this context remains uncertain. More contentious is the reported association between BO and the use of penicillamine, first reported in the late 1970s.[148] After a number of case reports and small series, a significantly higher prevalence of BO was identified in RA patients who took penicillamine (3 of 133) than in other RA patients (0 of 469) in a large cohort.[142] It is possible that the development of BO and the use of penicillamine are both markers of more aggressive RA and are linked for this reason; however, BO developed less than 1 year after penicillamine was begun in 19 of the first 20 cases,[142] and thus the association is unlikely to be entirely spurious. Because BO has been reported in many RA patients not taking penicillamine, it is likely that an underlying predisposition to BO in RA is unmasked by penicillamine, which disrupts collagen linkage and thus interferes with tissue repair. A relationship between BO and gold therapy has been suggested but is not endorsed by clinical experience.

Follicular Bronchiolitis

Follicular bronchiolitis (FB) is characterized by external compression of bronchioles by hyperplastic lymphoid follicles, with variable lymphocytic infiltration of the bronchiolar wall (see eFig. 92.6B). FB is associated more commonly with RA than with other CTDs[149] and is often found incidentally at lung biopsy in RA patients with interstitial pulmonary fibrosis. No causative mechanism has been identified, and it is unclear whether FB predisposes to the subsequent development of BO. When found in isolation, FB simulates ILD, with reticular or nodular opacities on chest radiography and a pattern of functional impairment that may be restrictive or obstructive. Clinically significant isolated FB is rare in RA, but its recognition is important because a response to corticosteroid therapy, although not the rule, is much more likely than in BO; in six of the first nine reported cases, disease stabilized or regressed with treatment.[141] In a CT study of patients with histopathologically proven FB, the most prominent features were centrilobular (see Fig. 92.2D–E) and peribronchial nodules, together with patchy ground-glass increases in attenuation in a bronchocentric distribution.[150]

Bronchiectasis

The prevalence of bronchiectasis is higher in RA than in other CTDs. One literature review identified 289 patients with bronchiectasis associated with RA reported since 1928; however, because respiratory symptoms preceded the systemic manifestations of RA in 90%, it is likely that chance association accounts for a high proportion of early reported cases.[151] Although associated with long-standing RA in one study,[152] on prospective evaluation of 50 RA patients, bronchiectasis was present on 30% of CT scans (see Fig. 92.2F–G).[153] Bronchiectasis in RA is not associated with more aggressive systemic disease and is often clinically silent, with little or no sputum production and a less progressive and disabling course than in patients with idiopathic bronchiectasis.

Pulmonary Vasculitis

There is a relatively high prevalence of systemic vasculitis in patients with RA. Pulmonary hypertension resulting from pulmonary vascular disease, as opposed to extensive pulmonary fibrosis, is uncommon, although occasional cases of pulmonary vasculitis have been found at autopsy.[149] Similarly, diffuse alveolar hemorrhage is a rare complication of RA.

Pulmonary Rheumatoid Nodules

Pulmonary rheumatoid nodules may be single or multiple, are found on chest radiography in less than 1% of RA patients,[113] and are usually associated with rheumatoid nodules elsewhere in the body.[154] On occasion, pulmonary rheumatoid nodules precede the development of systemic disease. Nodules are circumscribed, with central necrotic material contained by palisading epithelioid cells and surrounded by fibrosis and lymphocytic infiltration (see eFig. 92.6C). Nodule cavitation occasionally causes hemoptysis, and pneumothorax may result from the rupture of subpleural nodules. Diffuse infiltration by small nodules, leading to respiratory failure, has been reported.[155] However, nodules generally present as asymptomatic abnormalities on imaging (see Fig. 92.2H–J) and may vary in size according to underlying rheumatoid activity; thus, when solitary, their growth as judged by chest radiography may simulate malignancy. Caplan syndrome consists of the association of single or multiple nodules with coal workers' pneumoconiosis, which is often trivial, in keeping with the suggestion that nodule formation results from a hypersensitivity reaction to inhaled coal dust, perhaps amplified by immunologic overactivity.

Pleural Disease

Pleural disease is seen at autopsy in approximately 50% of patients,[113] and 20% give a history of pleuritic chest pain[156] (see eFig. 92.6D). However, pleural effusions are found in less than 5%,[111,112] usually in men,[154] and are frequently asymptomatic, often being identified on routine chest radiography. In a minority, pleuritic pain and fever are prominent, and the exclusion of empyema, which may be more prevalent in RA, is required. On occasion, effusions may develop acutely in association with pericarditis or exacerbations of arthritis; more typically, radiographic abnormalities are chronic, often remaining unchanged for years. The fluid is an exudate, with a low glucose level, correlating poorly with serum glucose,[157] a low pH, and usually a predominant lymphocytosis, although a neutrophilia is occasionally found. Pleural fluid RF levels tend to mirror serum levels, and the clinical utility of measuring RF in pleural fluid is not clear.

Other Pulmonary Complications

Other pulmonary complications of RA are rare. *Lymphocytic interstitial pneumonia* (LIP) is an occasional finding at lung biopsy and responds variably to corticosteroid therapy. Apical fibrosis mimicking the lung disease ankylosing spondylitis has been reported.[158] Extensive apical cavitation in the absence of nodules or other causes of fibrocavitary disease, including tuberculosis, has been described in a handful of cases and may follow a fulminant course.[159] Pulmonary amyloidosis has been reported occasionally. The incidence of secondary pulmonary hypertension increases with time from diagnosis.[160] Lower respiratory tract infection is increased in frequency in RA; bronchopneumonia is a common terminal event, accounting for 15–20% of deaths in RA patients.[161,162] An increase in lung cancer has been reported in RA.[163]

Drug-Induced Pulmonary Disease

Drug-induced pulmonary disease is a particular problem in RA because of the widespread use of methotrexate in routine clinical practice, and lung disease has been reported in 3–18% of RA patients treated with methotrexate.[164,165] Methotrexate pneumonitis is potentially life-threatening. It presents with cough, dyspnea, fever, widespread crackles, and pulmonary opacities on chest radiography and CT (see eFig. 99.4), which may be focal or diffuse.[166] Although the presentation is sometimes explosive, more often the onset is subacute, with symptoms evolving for up to 2 months before diagnosis[166]; 50% of cases are diagnosed within 4 months of initiation of methotrexate therapy. Because the clinical and radiographic features are nonspecific, methotrexate-induced lung disease should always be suspected in the treated patient presenting with progressive lung disease. Unfortunately, histologic findings are nonspecific, although finding a prominent lymphocytic infiltration increases the likelihood of methotrexate pneumonitis.[167] There is conflicting evidence on whether preexisting lung disease predisposes to lung injury caused by methotrexate, but the published evidence does not suggest that functional impairment is an absolute contraindication to its use, although particular caution is warranted when pulmonary reserve is grossly compromised. Patients with previous methotrexate toxicity should not be retreated.[166,168] Pulmonary methotrexate toxicity is associated with a mortality rate of 15–20%.[166] Because the lymphocytic component of disease is wholly or partially reversible, immediate withdrawal of methotrexate and the early institution of steroid therapy are warranted.

Pulmonary toxicity in RA has also been documented with sulfasalazine, gold therapy, and penicillamine (discussed earlier; see also Chapter 99). Pulmonary opacities (due to OP) associated with sulfasalazine most commonly present in the upper lobes; this side effect is rare in RA, with only a handful of cases reported (most cases were reported in ulcerative colitis).[169] Pulmonary disease induced by gold takes the form of alveolar opacities adjacent to bronchovascular bundles, best demonstrated by HRCT, and often associated with fever or skin rash, relatively low RF titers, and a BAL lymphocytosis.[170] In most patients with sulfasalazine or gold toxicity, lung disease largely regresses with withdrawal of the agent and corticosteroid therapy.

There have been a number of reports of rapidly progressive ILD associated with anti–TNF-α and other biologic therapies, including etanercept, infliximab, and rituximab (an anti-CD20 B-cell–depleting monoclonal antibody), although there are divergent views on whether these reports are truly indicative of drug toxicity or reflect the selective use of these therapies in more aggressive RA. The scope of reported toxicity ranges from infection (with particular focus on reactivation of tuberculosis), undoubtedly a true association, to interstitial disease and vasculitis.[171,172] Leflunomide has also been associated with pulmonary rheumatoid nodules and interstitial disease.[173,174]

Acute Exacerbations of Interstitial Lung Disease

Acute exacerbations of ILD, representing the development of diffuse alveolar damage, are less prevalent in CTD than in IPF. In both settings, presenting features include worsening dyspnea over 2 to 4 weeks, new ground-glass opacities on HRCT (eFig. 92.7), and the absence of infection or other overt causes of decline.[175] Acute exacerbations are more common in RA than in other CTDs, with a high early mortality.[176–178] Triggers of acute exacerbations have not been identified in RA and there is currently no proven therapy, although high-dose corticosteroid therapy is usually given.

PULMONARY FUNCTION TESTS

Patterns of functional impairment in RA have been variable in unselected populations. Predominant airflow obstruction was a frequent finding in one cohort,[145] and reductions in D_{LCO} were ascribed to occult interstitial fibrosis in at least 40%.[134] Inconsistencies in published data can be ascribed to the confounding effects of smoking and variations in the type and severity of associated pulmonary disease. Airflow obstruction may result from bronchiectasis or BO. Interstitial pulmonary fibrosis, OP, and LIP give rise to restrictive defects.

RADIOLOGIC FEATURES

In chest radiographic series of unselected patients with RA, appearances indicative of ILD are found in 1–5% of cases.[111,112,135,138] In interstitial pulmonary fibrosis, appearances are indistinguishable from IPF in a minority of cases, with symmetrical basal interstitial opacification in limited disease and diffuse coarse reticular abnormalities in extensive disease. In the majority of cases, CT appearances are intermediate between those of IPF (see Fig. 92.2A) and NSIP or are suggestive of the latter pattern.[179] Ground-glass opacity, consisting of a patchy or diffuse increase in lung density, is likely to denote inflammatory histologic appearances or fine intralobular fibrosis, as in other fibrosing lung diseases. Rheumatoid nodules (see Fig. 92.2H–J) are usually radiologically discrete and small but are often multiple and may reach up to 7 cm in diameter; in Caplan syndrome, nodules appear in crops, often grow rapidly, and may cavitate. Other chest radiographic findings in RA include focal consolidation (in OP [see Fig. 92.2B], infectious pneumonia, and lung disease induced by methotrexate); focal areas of hyperinflation (in BO; see Fig. 92.2C); and pleural thickening or effusion.

The cardinal CT feature of OP is patchy bilateral air space consolidation, often with associated ground-glass attenuation, which is often predominantly subpleural[180] but may have a bronchovascular distribution (see Fig. 92.2B).[181] Small nodules (≤1 cm in diameter) are common in OP; small pleural effusions and limited fibrosis, probably resulting from prolonged untreated inflammation, are occasional findings.

In bronchiolitis, bronchiolar structures are occasionally visualized directly on CT as centrilobular (see Fig. 92.2D–E) micronodular opacities and peripheral branching structures, denoting marked thickening of the bronchiolar wall; this appearance may be most frequent in FB.[182] In BO, areas of reduced lung density in a patchy distribution ("mosaic perfusion"; see Fig. 92.2C) are associated with a reduction in the caliber of pulmonary vessels in areas of decreased attenuation, indicative of regional hypoxic vasoconstriction in areas of severe bronchiolitis. Bronchiectasis and bronchial wall thickening on CT are common in constrictive bronchiolitis.

TREATMENT OF PULMONARY COMPLICATIONS

The treatment of ILD has usually consisted of corticosteroid therapy, with or without immunosuppressive agents, extrapolated from the SSc-ILD literature. However, when CT appearances are similar to those of IPF, immunomodulation, and especially high-dose corticosteroid therapy, should be used with caution due to the major toxicity with this approach in IPF.[183] It can reasonably be argued that, in this context, high-dose steroid therapy should be largely confined to those with suspected supervening drug-induced lung toxicity or diffuse alveolar damage. Owing to small numbers, regimens have remained anecdotal. Evaluation of the role of antifibrotic agents in RA-ILD is being evaluated in ongoing clinical trials (pirfenidone in TRAIL and nintedanib in IN-BUILD), although the use of antifibrotic agents is currently not approved for the management of RA-ILD.[184,185] Tocilizumab appears to slow progression of decline in lung function.[186] Rituximab has an uncertain role, although it may slow progression of physiologic decline.[187,188] Abatacept was associated with stabilization of lung function in some patients.[189]

Lung function may improve in response to treatment in interstitial pulmonary fibrosis, but a more realistic goal in most cases is to prevent further progression of disease, especially when lung disease is extensive. OP and methotrexate pneumonitis often respond well to treatment. Regression of disease is highly variable in FB and LIP and is virtually never seen in BO.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an inflammatory multisystem disorder of unknown etiology with protean clinical and laboratory manifestations and a variable course and prognosis. The 1982 revised American College of Rheumatology criteria for the diagnosis of SLE require that a minimum of four of the criteria listed in Table 92.4 be satisfied, although SLE is sometimes diagnosed with fewer than four criteria.[190]

EPIDEMIOLOGY AND RISK FACTORS

SLE appears throughout the world; the reported prevalence ranges from 12 to 50 per 100,000 population, and the incidence ranges from 1.8 to 7.6 per 100,000 population per year.[191] There is a 6- to 10-fold female excess, and the disease is three times more common in Blacks than in whites. The 5-year survival rate exceeds 90%, but the mortality rate is three times higher than in the general population. Support for a genetic contribution to disease includes a high prevalence in monozygotic twins, familial clustering, and associations among SLE and HLA-DR2, HLA-DR3, and the C4A null allele.[192] No infectious or other environmental factor has been shown to play a major etiologic role.

PULMONARY MANIFESTATIONS

Pleuropulmonary manifestations are common in SLE, with 50–70% of SLE patients experiencing pleuropulmonary complications at some point in their disease course. Pleuropulmonary manifestations of SLE are listed in Table 92.4.

Diffuse Lung Disease

Diffuse lung disease on lung biopsy or at autopsy has been reported in 4%, 33%, and 70% of SLE patients.[193–195] These striking inconsistencies undoubtedly reflect major variations in the histologic diagnostic criteria. In the series with the highest prevalence, trivial interstitial thickening was categorized as "pulmonary fibrosis" but likely represented the minor residuum of infection or inflammatory complications of SLE. Only 3% of SLE patients have clinical evidence of diffuse lung disease at the onset of systemic disease, and a disease resembling interstitial pulmonary fibrosis (eFig. 92.8) develops during follow-up in less than 5%.[196] Risk factors for pulmonary fibrosis in SLE include increasing

Table 92.4 Systemic Lupus Erythematosus

CRITERIA FOR DIAGNOSIS*
Malar rash
Discoid rash
Photosensitivity skin rash
Oral or nasopharyngeal ulceration
Nonerosive arthritis involving ≥2 peripheral joints
Serositis (pleuritis or pericarditis)
Renal disorder (persistent proteinuria or cellular casts)
Neurologic disorder (unexplained seizures or psychosis)
Hematologic disorder (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia)
Immunologic disorder (positive LE cell, anti-DNA antibody, anti-Sm antibody, false-positive syphilis serology)
Elevated antinuclear antibodies
LUNG MANIFESTATIONS
Acute lupus pneumonitis
Interstitial pulmonary fibrosis
Pulmonary vasculitis
Diffuse alveolar hemorrhage
Pulmonary hypertension
Shrinking lung syndrome
Antiphospholipid antibody syndrome
Organizing pneumonia
Pleural disease

*Minimum of four criteria required.
LE, lupus erythematosus; Sm, Smith.

age, a history of pneumonitis, and the presence of anti-RNP antibodies.[197]

Interstitial Lung Disease. ILD is uncommon in SLE, affecting only 1–15% of patients. It is usually mild, with slow progression or stability over time. ILD is most commonly seen in patients with long-standing SLE, in patients older than 50 years, and in patients with scleroderma-like features. The clinical presentation (dyspnea, cough, predominantly basal crackles, a restrictive lung function defect or isolated reduction in D_{LCO}, basal opacities on chest radiography) is similar to idiopathic ILD. Features suggestive of SLE include pleuritic pain, functionally severe lung fibrosis, and the frequent presence of enlarged peribronchiolar lymphoid follicles at lung biopsy. OP, NSIP, and LIP are the ILD patterns usually seen in ILD associated with SLE, although a UIP pattern can be seen less commonly. Partial regression of disease with corticosteroids in 9 of 14 cases in one series[198] suggests that an empirical trial of therapy is usually warranted.

Acute Lupus Pneumonitis. Although seen in approximately 1–4% of SLE patients, acute lupus pneumonitis is often life-threatening, with a mortality rate of more than 50% (once respiratory failure has supervened) despite treatment.[199] It can be clinically difficult to distinguish from severe infection and acute respiratory distress syndrome, particularly when it is the first presentation of SLE. The predominant histologic feature of diffuse alveolar damage is nonspecific, and it has been argued that acute lupus pneumonitis is merely a manifestation of aspiration, bacterial infection, or cardiac dysfunction.[193] However, striking responses to corticosteroids and immunosuppressive agents after antibiotic failure suggest strongly that the disorder is a true, albeit rare, entity.

Acute lupus pneumonitis is not to be confused with OP, discussed elsewhere in this chapter and reported in only a handful of adult patients with SLE, or with LIP, described in a small number of patients with SLE.

Shrinking Lung Syndrome

Extrapulmonary restriction, resulting in exertional dyspnea, a restrictive functional defect, and marked decrease of D_{LCO}, is a well-recognized complication of SLE but seen in less than 1% of SLE patients. The shrinking lung syndrome was first described in patients with severe restriction and a marked reduction in lung volume on chest radiography and is associated with progressive breathlessness on exertion and pleuritic chest pain. Lung function tests show reduced lung volumes in a restricted pattern with a normal D_{LCO} when corrected for carbon monoxide transfer coefficient. Chest radiography usually shows reduced lung volumes with raised hemidiaphragm and may also show pleural effusions or atelectasis.

The pathophysiology of shrinking lung syndrome is not clear, and it is generally ascribed to respiratory muscle weakness (Fig. 92.3).[200] However, the use of sniff pressures to evaluate diaphragmatic strength may be confounded by concurrent lung restriction or airflow obstruction; in one study, with the use of alternative methods to evaluate diaphragmatic function, the characteristic restrictive defect was attributed to an "unspecified restriction in chest wall expansion."[201] Pleural inflammation and/or adhesions and pain are also potential contributors to the pathophysiology of shrinking lung syndrome. No treatment of proven efficacy currently exists, although a handful of patients have improved in association with corticosteroid or immunosuppressive therapy.[202] The disorder is almost always self-limited, although sometimes it is severe.

Diffuse Alveolar Hemorrhage (see Chapter 94)

Although seen more frequently in SLE than in other CTDs, *diffuse alveolar hemorrhage* (DAH) is a rare but serious complication of SLE. DAH develops in 1.5–4% of SLE patients, usually early in the disease course. It is more common in patients with active SLE, particularly in those patients with active lupus nephritis.

The typical presentation of DAH with acute dyspnea over hours to days, fever, and extensive pulmonary opacities on imaging (eFig. 92.9) may mimic acute lupus pneumonitis, especially in the absence of hemoptysis, which is only present in 30% of patients.[203] A fall in hemoglobin is common, as is elevation of the D_{LCO}.

DAH is often life-threatening, with a mortality rate of approximately 50%, similar to that of acute lupus pneumonitis. Poor prognostic markers include renal involvement, thrombocytopenia, and the need for assisted ventilation.

Treatment for DAH is not clear but usually includes high-dose corticosteroids, cytotoxic therapy, and plasmapheresis in resistant cases. Treatment responses in both acute lupus pneumonitis and DAH have been observed with IV immunoglobulins, plasmapheresis, and rituximab.[204–207] Patients with SLE have underlying defects in most arms of the immune system and are at added risk of fulminant infection with the use of corticosteroids or immunosuppressive agents.[204] In this context, a misdiagnosis of acute lupus

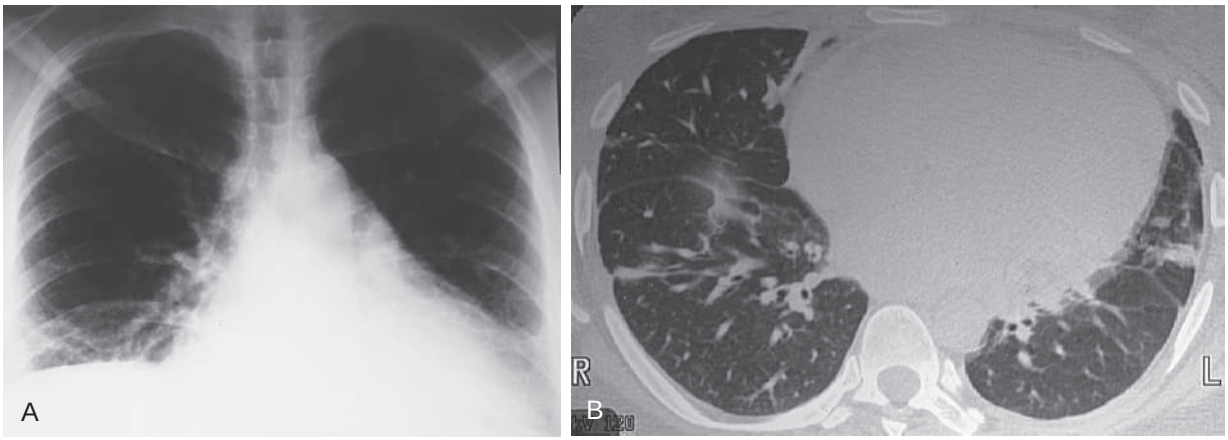

Figure 92.3 Systemic lupus erythematosis. (A) Chest radiograph from a patient with systemic lupus erythematosus shows elevation of both hemidiaphragms, in keeping with shrinking lung syndrome. (B) On a computed tomography scan from the same patient as in part A, linear abnormalities are seen that denote subsegmental atelectasis resulting from regional hypoventilation due to diaphragmatic weakness. The heart is enlarged.

pneumonitis or DAH may lead to a potentially disastrous increase in immunosuppression. Thus the performance of BAL to exclude opportunistic infection may be crucial in SLE patients with unexplained extensive pulmonary opacities.

Pulmonary Arterial Hypertension

PAH was once considered rare in SLE, but it is now reported with a frequency of 0.5–17.5%[208] and has a 2-year survival rate of less than 50% in severe disease. PAH usually affects younger women who have been diagnosed with SLE for more than 5 years. PAH is more common in those with a history of Raynaud phenomenon and serositis and with the presence of anticardiolipin and RNP antibodies. PAH presents with exercise-induced breathlessness and decreased exercise tolerance. Echocardiography can estimate the pulmonary arterial pressure, but the definitive diagnostic test is a right heart catheterization.[209]

The pathophysiology of PAH in SLE is largely related to pulmonary vasoconstriction. Important alternative mechanisms for pulmonary hypertension include vasculitis and thromboembolism.[210] Thromboembolism has a high prevalence in SLE, especially in patients with antiphospholipid antibodies, which cross-react with coagulation factors.[211,212] In a 1993 study of 842 SLE patients, immunoglobulin G anticardiolipin antibodies were present more frequently than immunoglobulin M antibodies (24% vs. 13%), but both were associated with a 30% prevalence of thrombosis as opposed to 10% in SLE patients without these antibodies.[213] Patients with antiphospholipid antibody syndrome also have a higher incidence of impaired lung function than normal control patients.[214]

In view of the multiplicity of mechanisms potentially responsible for pulmonary hypertension, vasodilators and anticoagulation have all been advocated empirically for patients with the pulmonary vascular disease of SLE. Corticosteroid or immunosuppressive agents may be effective therapy for SLE-associated pulmonary hypertension.[210] With the availability of PAH-specific therapies, including prostanoids, endothelin receptor antagonists, and phosphodiesterase-5 inhibitors, outcomes have improved.

Pleural Disease

Pleural disease is the most common pulmonary manifestation of SLE. Clinical or radiographic evidence of pleural involvement is seen in 20% of patients at the onset of systemic disease and in at least 50% at some time,[215] with pleural abnormalities at autopsy in 50–100%. Pleural disease is often asymptomatic, but pleuritic pain may be recurrent or intractable. Acute pleurisy may present with chest pain, dyspnea, fever, and cough. Pleural effusions are often small and bilateral in 50% of patients. Pleural fluid is usually serosanguineous (but occasionally hemorrhagic) and exudative, with a neutrophilia in patients with pleurisy but a predominant lymphocytosis in chronic effusions.[215] The nonspecific histologic appearance of fibrinous pleuritis is not diagnostically useful. The identification of lupus erythematosus cells has largely fallen out of favor because technical difficulties greatly reduce the sensitivity of the test in confirming that a pleural effusion is due to SLE.[216] The measurement of pleural fluid ANA titers may be more diagnostically useful when the etiology of pleural disease is in doubt[217] (see also Chapter 108). Drug-induced lupus also often has pleural involvement, including acute pleurisy and pleural effusions requiring cessation of the offending drug.

SJÖGREN SYNDROME

Sjögren syndrome is an autoimmune disorder characterized by mononuclear cell (primarily lymphocyte) infiltration of the lacrimal, salivary, conjunctival, and pharyngeal mucosal glands, with variable involvement of extraglandular tissue. The cardinal clinical features of keratoconjunctivitis sicca (dry eyes) and xerostomia (dry mouth) may exist in isolation (primary Sjögren syndrome, typically seen in women older than 40 years) but are more often associated with CTDs, such as RA, SSc, or SLE (secondary Sjögren syndrome). Sicca symptoms (e.g., dry eyes and mouth) are common in lung disease, however, and such patients need to be carefully evaluated for the presence of subclinical Sjögren syndrome.[218] Variable diagnostic criteria are used internationally; in one proposed diagnostic algorithm, sicca

symptoms are mandatory, with supportive evidence including ocular signs (positive Schirmer test for testing reduced tear formation, rose bengal score greater than 3 for staining of damaged conjunctiva and cornea), typical histologic appearances on salivary gland biopsy, antibodies to Ro (SS-A) or La (SS-B), or reduced salivary flow.[219]

EPIDEMIOLOGY AND RISK FACTORS

Primary Sjögren syndrome has a reported annual incidence of 6.9 per 100,000 with a prevalence of 60.8 per 100,000. Reported prevalence rates vary, largely due to differences in diagnostic criteria used, but range from 4.2 per 100,000 in a cohort in Minnesota to 93 per 100,000 in a Greek study.[220,221] Some evidence suggests a genetic predisposition, including familial clustering and an association with HLA-Dw2 and HLA-Dw3, but no environmental triggers have been identified. Primary Sjögren syndrome is more common in women and presents at two age peaks: at 20 to 30 years and older than 50 years.

PULMONARY MANIFESTATIONS

Pulmonary involvement is common in Sjögren syndrome. In early series, primary and secondary Sjögren syndromes were combined; it is likely that many of the pulmonary abnormalities seen in secondary Sjögren syndrome were ascribed to the underlying CTD. Careful evaluation of patients with primary Sjögren syndrome has shown that cough and dyspnea are common,[222] with objective evidence of pulmonary abnormalities in approximately one-fourth of cases.[223] Lung involvement usually consists of lymphocytic infiltration similar to that seen in salivary glands and resulting in tracheobronchial disease or ILD, depending on whether involvement is limited to secretory glandular tissue or is more widespread. However, population studies of respiratory involvement in Sjögren syndrome have been hampered by variations in diagnostic criteria, failure to discriminate between primary and secondary Sjögren syndrome, and failure to control for confounding features, such as drug treatment and smoking. Lung manifestations include diffuse lung disease and tracheobronchial disease.

In a CT study of 35 patients, the most prevalent findings were large and/or small airway disease ($n = 19$) and diffuse lung disease ($n = 12$, including 7 in whom the features were suggestive of LIP). The patterns of physiologic abnormalities were consistent with the predominant CT pattern.[224]

Interstitial Lung Disease

Although often asymptomatic, clinically significant ILD in Sjögren syndrome may develop in 8–27% of patients and, when present, ILD is associated with a poorer quality of life and increased mortality. ILD is more common in older, male patients with a history of smoking and positive antinuclear antibody testing.[225] ILD tends to develop early in the disease course, with a cumulative incidence of 10% at 1 year after the diagnosis of systemic disease.[223]

ILD usually presents with cough, increasing dyspnea on exertion, crackles on auscultation, reticular or nodular opacities on chest radiography, and a restrictive pattern of functional impairment. ILD frequently takes the form of fibrotic NSIP with lung biopsies showing an NSIP pattern in 45.5% of patients (eFig. 92.10A–B) and, less commonly, UIP or LIP (eFig. 92.10C and E), OP or pulmonary amyloidosis, or lymphoma.[226] Although ILD associated with Sjögren syndrome is usually regarded as clinically insignificant, Gardiner and coworkers[227] found that patients with primary Sjögren syndrome reporting dyspnea (≈10%) have a high prevalence of histologic abnormalities (fibrosis or lymphocytic infiltration) on transbronchial biopsy.[227] In one study, the 5-year survival rate of patients with ILD associated with Sjögren syndrome was 84%.[217]

Lymphocytic interstitial infiltration may take the form of LIP, pseudolymphoma (extensive pulmonary lymphocytic infiltration with the formation of lymphoid follicles; see eFig. 92.10E), or pulmonary lymphoma (see eFig. 92.10F–G). LIP is characterized by a diffuse lymphocytic infiltrate, with or without histiocytes and multinucleated giant cells, most prominent around bronchioles. Regression of disease with corticosteroids, in isolation or in combination with immunosuppressants, is highly variable. There are anecdotal reports of responses to rituximab. Pseudolymphoma, characterized by pulmonary infiltration, may regress spontaneously and often responds well to corticosteroid therapy; however, some patients progress to pulmonary lymphoma. The prevalence of lymphoma is increased 40- to 50-fold in Sjögren syndrome[228]; pulmonary lymphoma has a highly variable clinical and radiographic presentation, with the spectrum of disease ranging from diffuse interstitial involvement to discrete (often perihilar) masses (see eFig. 92.10F–G).

OP has been reported in Sjögren syndrome (see eFig. 92.10D) but is less common than in RA or PM. A response to corticosteroid therapy is usual but not invariable.

Tracheobronchial Disease

Tracheobronchial disease may take the form of loss of mucous secretion in the trachea (xerotrachea), chronic bronchitis, or small airway disease. Xerotrachea develops in up to 25% of patients with primary Sjögren syndrome and consists of atrophy of tracheobronchial mucous glands in association with a lymphoplasmacytic infiltrate, manifesting clinically as a relentless dry cough and endobronchial inflammation at bronchoscopy.[229] It is likely that similar histologic abnormalities in bronchi and bronchioles account for an increased prevalence of bronchial hyperresponsiveness, reported in 40–60% of patients with primary and secondary Sjögren syndrome.[230]

Subclinical bronchiolitis may be common in Sjögren syndrome. In the ILD of Sjögren syndrome, lymphocytic infiltration is more prominent around small bronchioles, resulting in a BAL lymphocytosis[231]; thus it is likely that the occasional cases of isolated lymphocytic bronchiolitis, presenting with a clinical picture of COPD, represent a more limited form of Sjögren syndrome involving only the airways. The evaluation of airflow at low lung volumes in unselected patients with primary and secondary Sjögren syndrome has demonstrated a high prevalence of small airway dysfunction[222]; aerosol penetration from central airways to the lung periphery is reduced, indicating small airway obstruction.[232] These abnormalities lead to cough, bronchial hyperreactivity in up to 60% of patients, bronchitis, and bronchiectasis. There may be evidence of either BO or mucous plugging, which

may contribute to an increased prevalence of bronchopneumonia but not evolve into severe BO, which is not generally a feature of Sjögren syndrome, except in occasional cases with associated RA. FB has been reported in a handful of patients with primary Sjögren syndrome but may be more frequently seen in secondary Sjögren syndrome; in a number of reported cases of FB associated with RA, the presence of Sjögren syndrome is not explicitly excluded. FB and diffuse bronchiolar lymphocytic infiltration may be part of the same spectrum of disease, but the relationship between the two disorders is uncertain.

Due to the association between Sjögren syndrome and bronchial reactivity, some have postulated that asthma and COPD may be more common in patients with Sjögren syndrome. Indeed, studies have demonstrated that the incidence of asthma and COPD was 1.6-fold and 1.4-fold higher, respectively, compared to matched control patients.[233,234] Of interest, inhaled anti-inflammatories, including inhaled budesonide and inhaled cromoglycate, appear to have no effect on patients with Sjögren syndrome and bronchial hyperreactivity.

POLYMYOSITIS AND DERMATOMYOSITIS

The defining criteria for PM and DM are listed in Table 92.5. For PM, a definite diagnosis is made if the first four features are present, a probable diagnosis is made if any three of the first four features are present, and a possible diagnosis is made if any two of the first four features are present. For DM, the typical rash must be present, plus any three of the first four for a definite diagnosis, two of the first four for a probable diagnosis, and one of the first four for a possible diagnosis (the Bohan and Peter criteria).[235]

Skin problems of DM include the presence of scaly cutaneous eruptions affecting extensor surfaces of the finger joints (Gottron tubercles or papules) (see Fig. 92.4A) and the characteristic edema and violaceous or purplish, heliotrope rash that involves and surrounds the eyelids (see Fig. 92.4B). Proximal muscle weakness tends to be insidious, progressive, and painless, affecting head, neck, and limb girdles and eventually involving the muscles of the tongue and pharynx and the respiratory muscles. Pulmonary complications arise in approximately 45% of patients and are the most frequent cause of death.

EPIDEMIOLOGY AND RISK FACTORS

The inflammatory myopathies are relatively rare, affecting 2 to 10 per 100,000 population, with a female-to-male predominance of 2.5:1 and with a bimodal age distribution peaking in childhood and in the fourth to fifth decades. PM associates with HLA-B8/DR3 and in Blacks with HLA-B7 and HLA-DRw6,[236] whereas DM appears to have a higher expression of HLA-B8/DR3, HLA-B14, and HLA-B40. There are multiple manifestations of lung disease, as listed in Table 92.5. The presence of diffuse lung disease has been associated with two specific HLA haplotypes.[237] In combined series, the prevalence of diffuse lung disease can be up to 64%. The disease may also present with pulmonary symptoms; in one series, this was the case in 21 of 70 patients.[238] The prevalence of lung disease varies from series to series, and the respiratory symptoms often are masked by muscle fatigue. Nonetheless, pulmonary complications of the disease can be a frequent cause of death.

Table 92.5 Polymyositis and Dermatomyositis

CRITERIA FOR DIAGNOSIS*
Symmetrical proximal muscle weakness
Muscle biopsy specimen showing myositis
Elevation of serum skeletal muscle enzymes
Characteristic electromyographic pattern of myositis
Typical rash of dermatomyositis
LUNG MANIFESTATIONS
Interstitial pulmonary fibrosis
Acute pneumonitis (with diffuse alveolar damage)
Organizing pneumonia
Aspiration pneumonia
Pulmonary vasculitis and alveolar hemorrhage
Respiratory muscle weakness

*For defining criteria, see text.

Figure 92.4 Skin changes seen in dermatomyositis. (A) Gottron papules. A discrete scaly rash is seen over the extensor surfaces of the joints. (B) Heliotrope rash. Named after a lilac-like flower with purple petals, this purplish rash and associated edema particularly involve the eyelids. (Modified from Iaccarino L, Ghirardello A, Bettio S, et al. The clinical features, diagnosis and classification of dermatomyositis. *J Autoimmun.* 2014;48–49:122–127.)

PULMONARY MANIFESTATIONS

Interstitial Lung Disease

ILD is the most common problem encountered in the context of PM and DM and may develop in up to 32% of patients.[239] This has been described as antisynthetase syndrome when

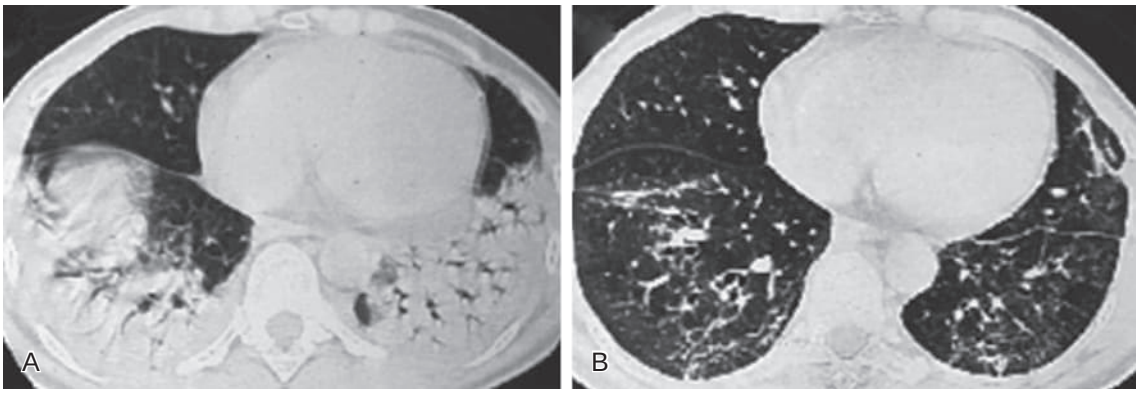

Figure 92.5 Organizing pneumonia in polymyositis. (A) Computed tomography scan shows dense consolidation that denotes organizing pneumonia in a patient with polymyositis. As shown in this example, the disease tends to be most prominent posteriorly in the lower lobes. (B) After treatment, the dense consolidation has regressed, but there is extensive residual linear opacification, representing residual fibrosis and resulting in traction bronchiectasis on the right and a restrictive functional defect. (Courtesy Michael B. Gotway, MD.)

associated with an anti–*transfer RNA* (tRNA) antibody. The prevalence of diffuse lung disease may be less common in patients with amyotrophic DM, a small subgroup of patients with the rash of DM but not the muscle involvement, and is three to five times more common in women than men, most commonly presenting in the fifth decade. The pattern of diffuse lung disease is most often that of NSIP. In many cases, a major component of OP, admixed with fibrotic abnormalities, is a prominent early feature, both histologically and on HRCT[240–242] (Fig. 92.5). However, in a distinct minority of cases with supervening diffuse alveolar damage (eFig. 92.11), the onset is subacute, rapidly progressive, and often resistant to treatment.[243] The histopathologic features associated with these forms of presentation include NSIP, UIP, and OP, and diffuse alveolar damage in the acute setting.[244–246] In a large series of 70 patients, Douglas and colleagues[238] reported that 82% of patients who were biopsied had an NSIP pattern. One report described an acute presentation of pulmonary capillaritis with alveolar hemorrhage in association with PM.[247]

Clinical Features. The clinical features of diffuse lung disease in PM and DM depend on the nature of the lung process. Dyspnea and nonproductive cough are the most common presenting symptoms. Breathlessness on exertion without wheeze is common and, if the myopathy is severe, orthopnea may be striking. Hemoptysis may develop if there is capillaritis. Pleural disease is uncommon. Pulmonary involvement can develop before the systemic disease or at any time in the disease course. There is no correlation between the severity of pulmonary parenchymal involvement and the systemic musculoskeletal manifestations. Rarely, patients present acutely with, or progress rapidly to, acute respiratory failure.

Imaging. Chronic diffuse lung disease is associated with peripheral reticular opacities, particularly in the lung bases. Acute pneumonitis can result in ground-glass opacification on chest radiography and alveolar hemorrhage with areas of consolidation.

HRCT is more sensitive and specific than chest radiography at highlighting the distributions of the different processes. CT findings include thickened interlobular septa, linear opacities, ground-glass opacification (see eFig. 92.11), and patchy consolidation. A combination of consolidation with a peripheral reticular pattern is highly characteristic.[248] Traction bronchiectasis and honeycombing are less common. The consolidation may evolve into a reticular pattern.[249] PM and DM are well-recognized paraneoplastic phenomena, so it is sometimes difficult to determine which condition presented first.[250] Screening for occult carcinoma is recommended with mammography, abdominal CT, pelvic ultrasonography, tumor markers and, in some settings, positron emission tomograpy.

Pulmonary Function. Lung function tests show a restrictive ventilatory defect with reduced D_{LCO}. With recent hemorrhage or marked myopathy, there may be a disproportionate preservation of the D_{LCO}. However, it must be remembered that acute hemorrhage can present in the context of previous chronic disease, so the D_{LCO} may be normal or subnormal but elevated from a level that was previously lower. Severe reduction in D_{LCO} is associated with increased mortality.

Bronchoalveolar Lavage. BAL lymphocytosis and neutrophilia have been described in diffuse lung disease associated with PM/DM. The significance of BAL is debated, but it appears that neutrophilia on BAL is associated with clinical deterioration.[251]

Laboratory Tests. Several studies have reported no association between creatine kinase levels and respiratory disease. In fact, the presence of a low creatine kinase has been associated with more rapidly progressive diffuse lung disease.[252,253] Studies of autoantibodies have highlighted the association between the presence of antibodies to aminoacyl-tRNA synthetases, inflammatory myopathies, and diffuse lung disease.[252] These antibodies help to define the clinical antisynthetase syndrome: the coexistence of myositis, diffuse lung disease, and arthritis (Table 92.6). The most common autoantibody is Jo-1 (a cytoplasmic antihistidyl tRNA synthetase), found in 20–30% of patients with inflammatory myopathy and correlating strongly with the presence of diffuse lung disease. Jo-1 antibodies are present in 50–100% of cases of inflammatory myopathy and diffuse lung disease, in contrast to less

Table 92.6 Antisynthetase Syndrome

Patient must have:
Positive anti-tRNA antibody
Plus one or more of the following:
Myositis by Bohan and Peter criteria
ILD by ATS criteria
Arthritis by clinical examination, radiographic findings or patient self-report
Unexplained, persistent fever
Raynaud phenomenon
Distal digital fissuring ("mechanic's hands")

ATS, American Thoracic Society; ILD, interstitial lung disease; tRNA, transfer RNA.

Modified from Connors GR, Christopher-Stine L, Oddis CV, Danoff SK. Interstitial lung disease associated with the idiopathic inflammatory myopathies: what progress has been made in the past 35 years? *Chest*. 2010;138(6):1464–1474.

than 5% of patients without diffuse lung disease. A variety of novel autoantibodies have been described with affinity for other tRNA synthetase molecules: PL-12, PL-7, EJ, OJ, Ku, and melanoma differentiation–associated gene 5 (see eTable 92.1).[254] Melanoma differentiation–associated gene 5 antibodies are associated with rapidly progressive forms of ILD.[255]

OTHER PULMONARY MANIFESTATIONS

Muscular weakness may lead to aspiration pneumonia in up to 20% of patients and is usually associated with dysphagia. Respiratory muscle weakness and hypercapnic respiratory failure develop in up to 25% of patients, although severe respiratory failure requiring ventilatory support is less common. Bilateral diaphragmatic paralysis has been reported.

TREATMENT OF PULMONARY COMPLICATIONS

Diffuse lung disease is a serious complication of PM/DM and is associated with increased mortality.[256] The clinical course and prognosis of PM/DM-associated diffuse lung disease is heterogeneous and depends on the histologic pattern of disease. The decision to treat and the choice of therapy therefore needs to be individualized. Corticosteroids are the preferred initial therapy. Oral prednisolone (0.75–1 mg/kg/day) is usual, but IV corticosteroids are required in more severe or rapidly progressive disease. Immunosuppressive therapy may be used in patients who are steroid resistant or experiencing adverse effects from corticosteroids. There are some reports of efficacy of cyclophosphamide,[257,258] cyclosporin A,[259] azathioprine, mycophenolate, and tacrolimus, a calcineurin inhibitor.[260,261] In refractory cases, IV immunoglobulin should be considered. Rituximab is a promising treatment for the antisynthetase syndrome,[262] including for patients with life-threatening disease refractory to other immunomodulatory therapies.[263] Retrospective studies demonstrate stabilization of CTD-ILD with rituximab. Patients with myositis-associated ILD may represent the subgroup of CTD-ILD with the greatest response to rituximab.[264]

MIXED CONNECTIVE TISSUE DISEASE

MCTD is defined by the presence of features of SLE, SSc, and PM (Sjögren syndrome may also be seen) in association with high titers of autoantibody (>1:1600) directed against the ribonucleoprotein U1-RNP.[265,266] Criteria that have been suggested for the diagnosis of MCTD include the presence of antibody to U1-RNP, together with the clinical features of hand edema, synovitis, Raynaud phenomenon, acrosclerosis, and myositis. At least three of these clinical features are needed in addition to the autoantibody finding. A fourth clinical feature is required if the initial three are Raynaud phenomenon, edema, and acrosclerosis. The difference between MCTD and an overlap syndrome may be semantic, but the former often presents more acutely and with greater specificity for U1-RNP. MCTD may differentiate into specific rheumatologic diseases. This differentiation may be genetically determined.[267]

Overlap syndromes are reported in which clinical features of more than one CTD are present in the same patient. Although MCTD tissue disease remains the most clearly definable, other overlap syndromes are seen both with and without typical autoantibody association. Of the former, overlapping clinical features found in association with U2-RNP and U3-RNP and the tRNA synthetase–associated diseases (see earlier) can be considered to be part of an overlap syndrome. Antibodies to PM-Scl, KU, and U2-RNP are associated with overlaps of SSc and PM.[266]

The prevalence of MCTD is unclear, but it is estimated at 1 in 10,000, with a 9:1 female preponderance, most frequently presenting in the fourth decade. Pleuropulmonary complications are seen in 20–85% of patients, but diffuse lung disease, most commonly with an NSIP CT pattern, is the most common lung complication.[268] In a CT study of 41 patients, the major abnormalities were ground-glass opacities in all, subpleural micronodules in 40 of 41, and nonseptal linear opacities in 32 of 41.[269] Pleural effusions develop in patients with other clinical features of SLE and are usually small, exudative, and often resolve spontaneously. Pulmonary hypertension may also develop.[270] Respiratory muscle weakness, DAH, and small airway disease are less common complications.

Survival is difficult to quantify owing to the heterogeneity of disease. The individual disease course tends to be similar to that of the CTD most closely resembled in that patient. Survival is better for those with CTD-ILD if the diffuse lung disease is associated with U1-RNP positivity than with no U1-RNP. Treatment depends on the nature of the lung disease and is identical to the approaches used for the other CTDs. Pleural effusions are often responsive to corticosteroids. A combination of low-dose prednisolone and an immunosuppressant, such as cyclophosphamide or azathioprine, is generally used to treat interstitial fibrosis, with an approach similar to that for SSc.

IDIOPATHIC PNEUMONIA WITH AUTOIMMUNE FEATURES

Although most patients with CTD-ILD will develop an ILD in the context of a previously diagnosed CTD, in some cases,

ILD can be the first and/or only manifestation of CTD.[271] CTD is eventually diagnosed in approximately 15% of patients presenting with idiopathic interstitial pneumonia[272,273] and in 30% of patients with idiopathic NSIP.[274] It is now recognized that there is a cohort of patients with ILD meeting some, but not all, diagnostic criteria for CTD. This group has now been defined by an ATS/ERS taskforce, and termed *idiopathic pneumonia with autoimmune features* (IPAF).[275] To fulfill criteria for IPAF, patients must have (1) presence of an interstitial pneumonia (by HRCT or surgical lung biopsy), (2) exclusion of alternative etiologies, (3) incomplete features of a defined CTD, and (4) at least one variable from at least two of three domains (clinical, serologic, and morphologic; Table 92.7).[275] IPAF is currently a provisional entity, pending validation by ongoing clinical studies.

Table 92.7 Classification Criteria for Interstitial Pneumonia With Autoimmune Features

Clinical domain	▪ Distal digital fissuring (i.e., "mechanic's hands") ▪ Distal digital tip ulceration ▪ Inflammatory arthritis or polyarticular morning joint stiffness ≥60 min ▪ Palmar telangiectasia ▪ Raynaud phenomenon ▪ Unexplained digital edema ▪ Unexplained fixed rash on the digital extensor surfaces (Gottron sign)
Serologic domain	▪ ANA ≥ 1:320 titer, diffuse, speckled, homogeneous patterns *or* ANA nucleolar pattern (any titer) *or* ANA centromere pattern (any titer) ▪ RF ≥ 2 × ULN ▪ Anti-CCP ▪ Anti-dsDNA ▪ Anti-Ro (SS-A) ▪ Anti-La (SS-B) ▪ Anti-ribonucleoprotein ▪ Anti-Smith ▪ Antitopoisomerase (Scl-70) ▪ Anti-tRNA synthetase (e.g., Jo-1, PL-7, PL-12, others are: EJ, OJ, KS, Zo, tRS) ▪ Anti–PM-Scl ▪ Anti-CADM (MDA-5)
Morphologic domain	Suggestive radiology patterns by HRCT: ▪ NSIP ▪ OP ▪ NSIP with OP overlap ▪ LIP Histopathology patterns or features by surgical lung biopsy: ▪ NSIP ▪ OP ▪ NSIP with OP overlap ▪ LIP ▪ Interstitial lymphoid aggregates with germinal centers ▪ Diffuse lymphoplasmacytic infiltration (with or without lymphoid follicles) Multicompartment involvement (in addition to IPAF): ▪ Pleural effusion or thickening (not otherwise explained) ▪ Pericardial effusion or thickening (not otherwise explained) ▪ Small airways disease (by PFTs, imaging or pathology) ▪ Pulmonary vasculopathy

ANA, antinuclear antibody; anti-CCP, anti–cyclic citrullinated peptide; anti-dsDNA, anti–double-stranded DNA; CADM, clinically amyopathic dermatomyositis; HRCT, high-resolution computed tomography; IPAF, interstitial pneumonia with autoimmune factors; LIP, lymphocytic interstitial pneumonitis; MDA-5, melanoma differentiation–associated gene 5; NSIP, nonspecific interstitial pneumonia; OP, organizing pneumonia; PFTs, pulmonary function tests; RF, rheumatoid factor; Scl, scleroderma; ULN, upper limit of normal.

From Fischer A, Antoniou KM, Brown KK, et al. An official European Society/American Thoracic Society research statement: interstitial pneumonia with autoimmune features. *Eur Resp J*. 2015;46:976–987.

RELAPSING POLYCHONDRITIS

Relapsing polychondritis is a rare disease characterized by recurrent progressive cartilaginous inflammation. The episodic and painful inflammation results eventually in the widespread degeneration of cartilaginous structures. The diagnosis of relapsing polychondritis requires the presence of three or more of the following clinical features[276]: bilateral auricular chondritis, nonerosive seronegative inflammatory polyarthritis, nasal chondritis, ocular inflammation, respiratory tract involvement (either upper or lower respiratory tract); cochlear involvement with or without vestibular abnormality; and a positive biopsy specimen. The presence of anticartilage antibodies may be helpful in the diagnosis. (See Chapter 71.)

The condition affects men and women equally and has a peak incidence between ages 40 and 60 years. It is considered an autoimmune process, and autoantibodies have been found directed against cartilage and type II collagen. A weak association with HLA-DR4 has been reported.[277] Diagnosis is chiefly clinical but can be confirmed by biopsy of affected cartilage, including tracheal rings.

Relapsing polychondritis is usually multifocal, affecting cartilage of the ear (85–94%), nose (54–57%) (see Fig. 92.6A–B), upper respiratory tract (31–48%), and ribs. In addition, patients frequently have ocular inflammation, nonerosive arthropathy (52%), and vestibulocochlear dysfunction.[276,278] Relapsing polychondritis may be associated with a wide range of other conditions, especially CTD and vasculitis. Approximately 30% of patients have a preexisting CTD.

Respiratory involvement probably accounts for around 10% of deaths in this condition. Up to 25% of cases present with focal or generalized respiratory tract involvement. The larynx and upper trachea are the most common focal areas involved, but large or small airways may also be affected. Laryngotracheal involvement is a poor prognostic determinant. Destruction and obstruction of the glottis, trachea, and bronchi may lead to airway stricture, lobar collapse/consolidation, and distal infection.[279] Pulmonary parenchymal disease is rare, with the exception of pulmonary vasculitis.

The site of cartilaginous involvement determines the clinical presentation. Upper airway involvement typically presents with wheezing and hoarseness. Lung function testing shows diminution in maximal inspiratory (large, extrathoracic airways) and expiratory (smaller, intrathoracic airways) flow rates, suggesting airway collapse. Static recoil pressures are preserved. Chest radiography may show ectopic airway cartilage calcification or large airway narrowing (see Fig. 92.6C) but is often insensitive. However, HRCT scanning shows tracheal ring thickening,

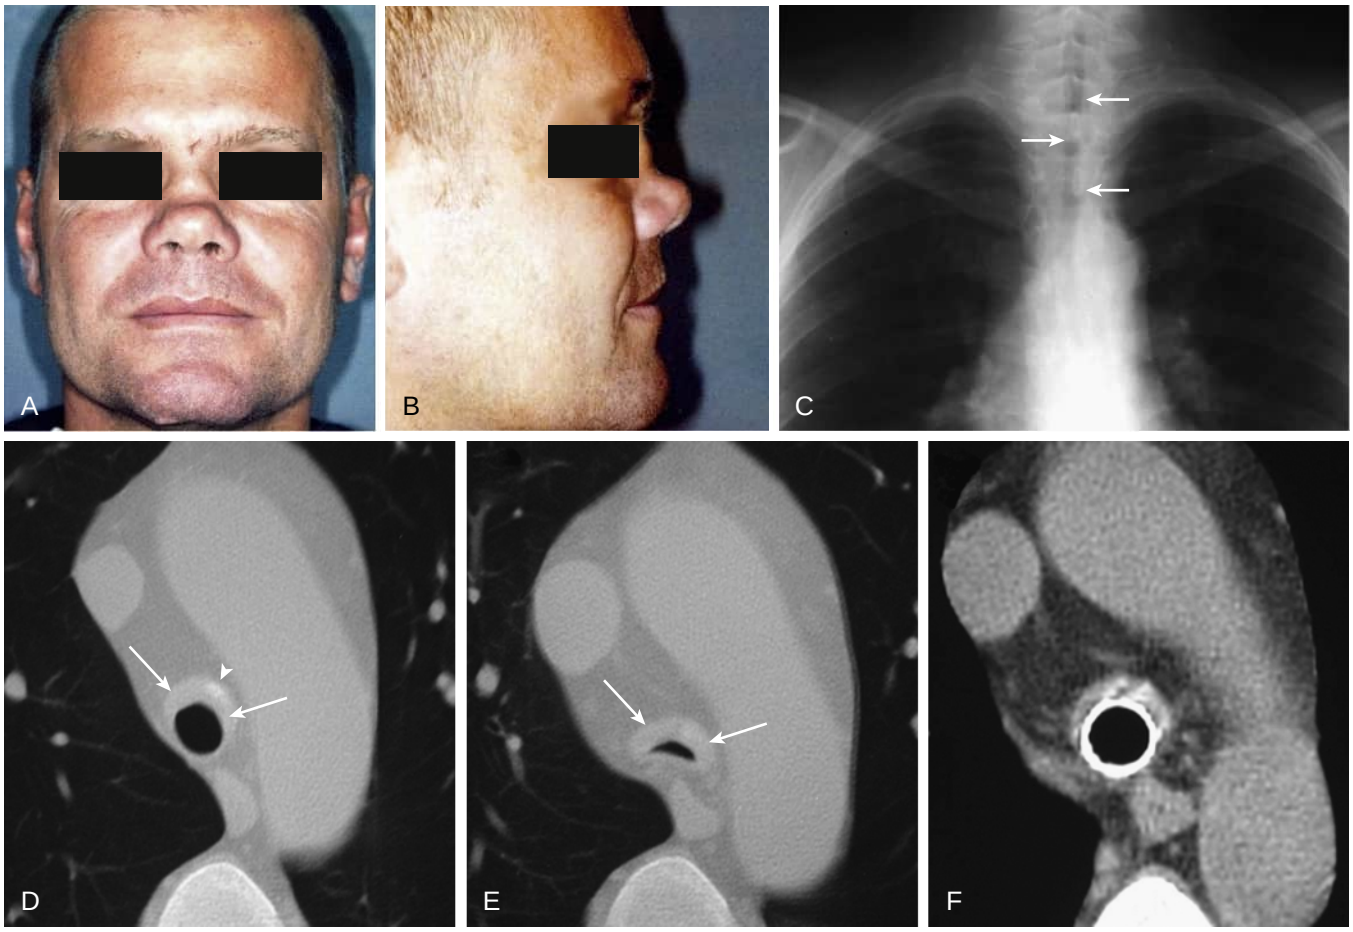

Figure 92.6 Relapsing polychondritis. (A–B) Saddle nose deformity indicating loss of cartilage of the nose due to inflammatory deterioration of cartilage structure. In this 42-year-old man, destruction of the nasal septum led to restriction of ventilation, with collapse of the internal nasal valves during a rapid inspiration. (C) Focused frontal chest radiograph shows smooth sagittal narrowing of the trachea (*arrows*). (D) Axial unenhanced chest computed tomography shows thickening of the anterior two-thirds of the trachea (*arrows*), with sparing of the posterior tracheal membrane; this pattern is typical of relapsing polychondritis. A small focus of calcification is present in the anterior tracheal wall at the 1 o'clock position (*arrowhead*). (E) Axial postexpiratory high-resolution computed tomography image shows extensive tracheal collapse (*arrows*) consistent with tracheomalacia and typical of relapsing polychondritis. (F) Treatment of relapsing polychondritis with a self-expandable endoluminal metallic stent shows patency of the tracheal lumen. (A–B, From Haug MD, Witt P, Kalbermatten FD, et al: Severe respiratory dysfunction in a patient with relapsing polychondritis: should we treat the saddle nose deformity? *J Plast Reconstr Aesthet Surg.* 2009;62:e7–e10. C–F, Courtesy Michael B. Gotway, MD.)

airway wall attenuation, and calcification (see Figs. 92.6D and Fig. 20.30). Postexpiratory CT scanning, using either scanning at the completion of an FVC maneuver (see Fig. 92.6E) or cine scanning during such a maneuver, shows extensive tracheobronchial collapsibility and can help to localize the large airway disease.[280] Bronchoscopy may show endobronchial inflammation or stenosis and is useful in the exclusion of mechanical obstruction. Endobronchial biopsy may be diagnostic but is insensitive. Laryngoscopy and bronchoscopy are associated with risk of acute airway compromise, however.[279]

Treatment depends on disease severity. Mild cases may be controlled with nonsteroidal anti-inflammatory drugs, but troublesome relapses may require short-term high-dose corticosteroid therapy. In acute airway involvement, high-dose IV corticosteroid is used. In one large review of 159 reported cases, three-fourths of the patients required chronic corticosteroid therapy, which, in that series, decreased the frequency, duration, and severity of flare-ups but did not prevent disease progression.[281] Steroid-resistant lesions have been treated with immunosuppressive agents such as cyclophosphamide. Despite short-term improvement with steroid and immunosuppressive therapy, relapse and disease progression are common. There have also been a number of reported responses to biologic agents, including TNF-α antagonists, anti–IL-6 therapy, and rituximab, with efficacy or partial efficacy in more than half of cases.[282,283] Currently, biologics cannot be recommended as first-line therapy but may have an important role in cases refractory to corticosteroids and as steroid-sparing agents. Tracheostomy and stenting are occasionally indicated, but other surgical treatment is difficult owing to the diffuse nature of involvement and risk of relapse.[284] In one study, the use of multiple, self-expandable stents (see Fig. 92.6F) via fiberoptic bronchoscopy in five patients requiring mechanical ventilation resulted in improvement in four patients who were all able to live without mechanical ventilation for up to 20 months.[285] Newer self-expanding silicone stents have been used with variable effect in palliative cases.[286] Intraluminal stents may be complicated by hemorrhage, tracheal erosion, ulceration, or airway obstruction, however. Survival has been reported at 94% at 8 years.[287]

Table 92.8 Behçet Syndrome

CRITERIA FOR DIAGNOSIS
Major (Required)
Recurrent aphthous ulceration at least three times in a 12-mo period
Minor (Two of Four)
Recurrent genital ulceration
Ocular disease
Skin lesions (erythema nodosum, skin ulcers)
Positive pathergy test (a 2-mm erythematous papule or pustule at the prick site 48 hr after the application of a sterile hypodermic 20- to 22-gauge needle that obliquely penetrated avascular antecubital skin to a depth of 5 mm)

Data from Cambrey AD, Harrison NK, Dawes KE, et al. Increased levels of endothelin-1 in bronchoalveolar lavage fluid from patients with systemic sclerosis contribute to fibroblast mitogenic activity in vitro. *Am J Respir Cell Mol Biol* 1994;11:439–445; and Shi-Wen X, Denton CP, McWhirter A, et al. Scleroderma lung fibroblasts exhibit elevated and dysregulated type I collagen biosynthesis. *Arthritis Rheum*. 1997;40:1237–1244.

BEHÇET SYNDROME

Behçet syndrome is found predominantly in the countries bordering the Mediterranean Sea. Prevalence estimates approach 80 to 370 per 100,000 population in Turkey. Men and women are affected equally, and age of onset is usually in the second or third decade. There is an association between the HLA-B51 allele and Behçet syndrome; the relative risk of HLA-B51 carriers for Behçet syndrome is roughly 13:1. Herpes simplex type 1 and streptococci have been suggested as causative agents.[288] Diagnosis requires the development of recurrent oral ulceration at least three times in a 12-month period and the presence of two of the four minor features listed in Table 92.8.[289] Mucocutaneous ulceration is the clinical hallmark, with aphthous oral and genital ulceration seen in almost all patients. Other cutaneous features include erythema nodosum, an acneiform rash, and papular lesions of cutaneous vasculitis. Uveitis is the major cause of morbidity, but systemic vasculitis may affect all systems.

Pulmonary involvement is seen in 1–7% and tends to affect HLA-B51–positive younger men (<25 years) more severely. The major pulmonary manifestations are pulmonary vasculitis,[290] pulmonary artery aneurysms, arterial and venous thromboses, pulmonary infarction, OP, and pleurisy.[291] Symptoms include dyspnea, chest pain, and recurrent hemoptysis that can be massive and fatal.[292]

The cardinal histologic feature is vasculitis affecting arterial and venous vessels of all sizes. Pulmonary arterial aneurysms are surrounded by inflammatory infiltrates and have thickened intima and degeneration of the elastic lamina with thrombosis. Behçet syndrome may be accompanied by arterial and venous thromboses, pulmonary infarcts and, on occasion, pleural effusion.[293] The radiographic abnormalities are nonspecific but may include the features of small airway disease, pulmonary hemorrhage, vascular occlusion, or mass lesions representing arterial aneurysm(s) (see eFig. 94.2).[294,295] Prognosis is variable. The disease course is relapsing remitting. Pulmonary artery aneurysm carries the worst prognosis, with a 2-year survival of 70%.

Treatment is complex and depends on presentation. Steroids and immunosuppressive agents are used to control vasculitis, particularly in cases of pulmonary artery aneurysm, in which eventual regression is sometimes observed. Cyclosporin A and tacrolimus have been successful in some patients.[291] Anticoagulants may be required for control of thrombosis but should be used only if immunosuppression is insufficient because there is a significant risk of hemorrhage. However, controlled data are lacking, and accumulated experience mostly relates to the treatment of systemic disease, including orogenital ulceration, and must be applied to pulmonary disease with caution. Acknowledging this caveat, the major change in treatment has been the increasing use of anti-TNF therapy, found to be efficacious for oral ulceration and skin lesions in a randomized controlled trial[296] and endorsed for eye disease, neurologic disease, and gastrointestinal disease by a position paper, based on a definitive review of uncontrolled treatment data.[297] For pulmonary artery aneurysms, pulmonary embolization and surgical resection have been reported to be successful, but surgical treatment of aneurysms can result in aneurysms at the anastomosis site.[298]

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is a seronegative spondyloarthritis developing in 0.05–1.5% of the general population and is associated with the major histocompatibility antigen HLA-B27.[299] The prevalence of AS is higher in white men, with a male-to-female ratio of 10:1. The cardinal site of disease is the vertebral column. As the disease progresses, inflammation leads to fibrosis and ossification, with ankylosis of the vertebral joints. Peripheral joint arthritis is seen in approximately one-third of patients, and extra-articular features include aortic regurgitation, uveitis, pulmonary disease, and extrapulmonary restriction.

Lung disease, mainly upper zone fibrosis, can be present in up to 30% of case series, but fibrobullous disease is less common (see eFigs. 131.4 and 131.6). In a series of 2080 patients with AS, this pattern was seen in only 1–2% of patients.[300] Limited ILD, small airway disease, bronchiectasis, and paraseptal emphysema are frequently present even when chest radiographic appearances are normal.[301–303] In another study, abnormalities were seen in 15 of 21 patients, comprising thickened interlobular septa (33%), bronchial wall thickening (29%), pleuropulmonary abnormalities (29%), and linear septal thickening (29%).[304] Pulmonary involvement, often subclinical, is an early manifestation of AS.[305]

A subclinical lymphocytic alveolitis may be evident with BAL.[306] Histologically, lung abnormalities consist of a variable mixture of lymphocytic infiltration, fibrosis, and bullous change. On chest radiography, diffuse reticular opacities in the upper zones are usually symmetrical and are seldom extensive except in patients with severe spinal disease[307] or a long history of AS.[300] However, apical fibrosis occasionally may precede the development of extrapulmonary disease. No proven treatment exists to prevent the development of apical fibrosis; resistance to corticosteroid therapy is the rule.

Cavities may develop within distorted fibrotic apical tissue and are sometimes colonized by mycobacteria or fungi, especially *Aspergillus fumigatus* (see eFig. 131.6), which are

isolated in up to 60% of AS patients with apical cavitation.[308] Life-threatening hemoptysis is an occasional complication of mycetoma formation within cavities and may be controllable by bronchial artery embolization; the resection of a mycetoma is a treatment of last resort owing to the high prevalence of postoperative bronchopleural fistula or empyema. Advanced apical fibrosis is often associated with apical pleural thickening, but pleural disease is seldom seen adjacent to normal lung parenchyma elsewhere in the thorax. There is an increased (≤10%) prevalence of pneumothorax in AS patients with apical fibrosis,[300] probably due to subpleural bullous degeneration in advancing disease.

Extrapulmonary restriction due to immobilization of the chest wall with costovertebral ankylosis is an occasional complication of AS. Extrapulmonary restriction is often asymptomatic and associated with surprisingly little impairment in pulmonary function, perhaps because the diaphragm is able to make a major contribution in the presence of a high resting volume. Lung volumes may be mildly reduced, but the D_{LCO} is almost always preserved in the absence of parenchymal disease.[309]

MARFAN SYNDROME

Marfan syndrome (MS) is an autosomal dominant condition of variable penetrance affecting approximately 5 per 100,000 population. MS is characterized by abnormalities of fibrous connective tissue with abnormal type I collagen, in some cases due to mutations on chromosome 15, especially in the skeleton (long limbs, arachnodactyly, pectus excavatum, kyphoscoliosis), eyes (subluxation of the lens), and cardiovascular system (aortic or mitral regurgitation, aortic aneurysm). The reduced life expectancy of MS is largely attributable to cardiac complications; there is no effective treatment to reverse disease or slow progression.

Respiratory complications can be subdivided into pulmonary and extrapulmonary abnormalities. From 10–15% of patients with MS have pulmonary involvement. The most common pulmonary complication is pneumothorax, often recurrent and bilateral. The high prevalence of pneumothorax in MS of 5–10%[310] (>100-fold higher than in the general population) can be ascribed to the rupture of subpleural bullae. Localized bulla formation with a predilection for the lung apex[311] is an occasional striking finding in young patients. Emphysema is present on chest radiography in the majority of MS patients with pneumothoraces.[310,312] Lung histologic appearance in MS is poorly characterized but, in a small series of patients with absent or minimal smoking histories, a pattern of distal acinar emphysema was evident in all cases.[313] Generalized emphysema in nonsmoking patients with MS may become evident at any age and is sometimes fatal in childhood.[314] Underlying apical fibrosis has been reported in a handful of cases. Other less frequent parenchymal manifestations include congenital malformations of the middle lobes, which may be absent or rudimentary, and an increased prevalence of bronchopneumonia.[310]

Thoracic cage involvement is present in greater than 50% of MS patients. Isolated pectus excavatum in MS is seldom associated with significant impairment in lung function. However, on occasion, kyphoscoliosis is associated with fatal right heart failure.[315] It is likely that nocturnal desaturation amplifies hypoxemia from the kyphoscoliosis. Increased upper airway collapsibility during sleep is common in MS, accounting for an association between MS and obstructive sleep apnea.[316]

Key Points

- In *connective tissue diseases* (CTD), the lung can be involved by a wide variety of patterns of pathology, from the trachea to the parenchyma to the pleura.
- Sometimes, pulmonary manifestations may precede the systemic features of CTD.
- The true extent of lung involvement is often masked by exercise limitation due to musculoskeletal features of the CTD.
- Often, combinations of patterns exist that raise the likelihood that CTD is the underlying problem. Some patterns of lung disease are more common in one CTD than the others. Specific pathologic entities seen in these diseases do not generally follow the same course as their idiopathic counterparts.
- Distinguishing CTD–interstitial lung disease from idiopathic interstitial lung disease is essential and has major implications for prognosis and management. Therefore serologic testing and repeat testing, if needed, are recommended to distinguish these two entities.
- Common drugs used in the treatment of CTD may result in major pulmonary complications.
- Increasing recognition of the pulmonary manifestations of these protean disorders is resulting in better outcomes.

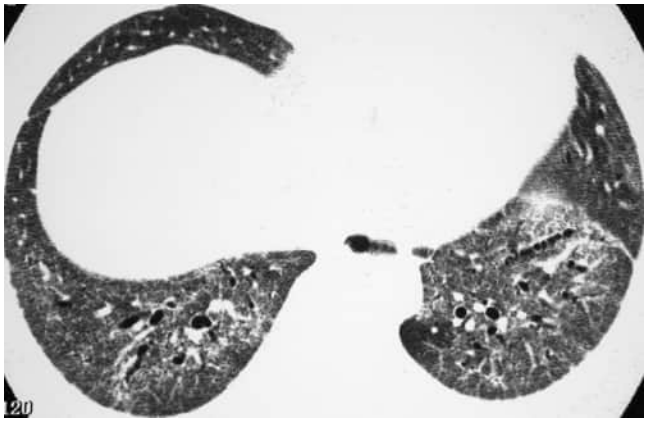
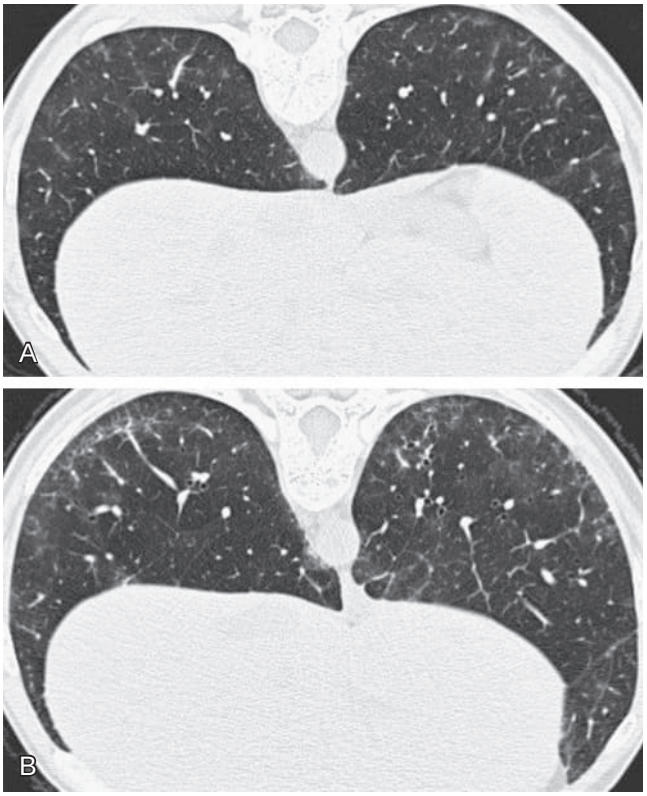
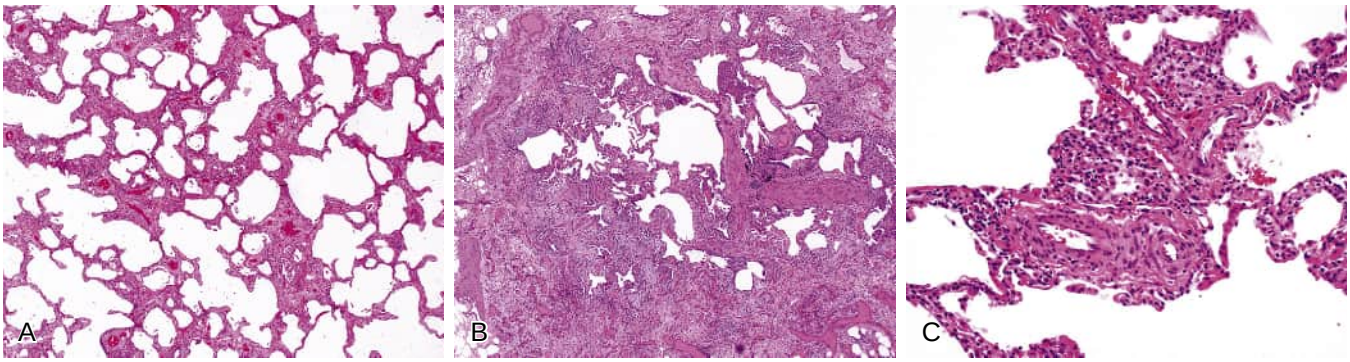
eFigure 92.1 High-resolution computed tomography of mild systemic sclerosis lung disease. (A–B) Axial prone imaging in a patient with scleroderma shows mild, faint reticulation. (C–D) Axial prone imaging in a patient with scleroderma shows some faint reticulation, with more prominent subpleural ground-glass opacity. (Courtesy Michael B. Gotway, MD.)



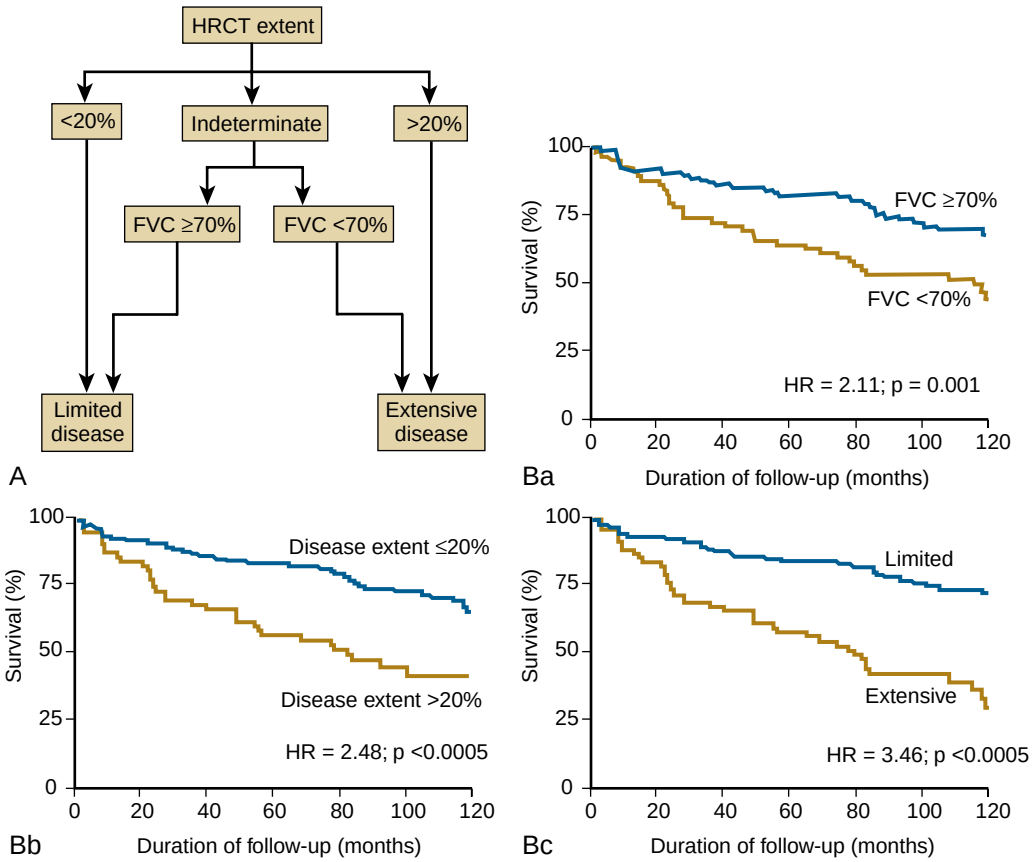
eFigure 92.2 High-resolution computed tomography of moderate systemic sclerosis lung disease. Axial supine imaging shows moderate basal, subpleural ground-glass opacity associated with reticulation. The pattern is identical to idiopathic nonspecific interstitial pneumonia. (Courtesy Michael B. Gotway, MD.)



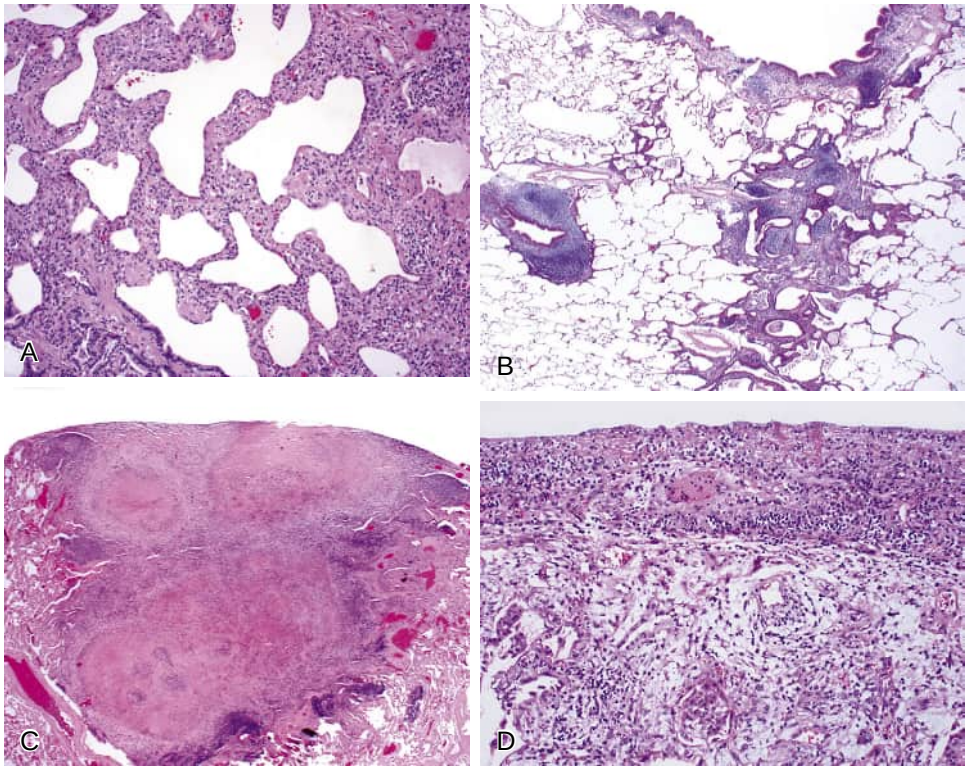
eFigure 92.3 High-resolution computed tomography of progressive systemic sclerosis lung disease. (A) Axial prone imaging shows faint, subpleural basal ground-glass opacity. (B) Axial prone imaging 1 year after part A shows worsening of basal subpleural ground-glass opacity and reticulation. (Courtesy Michael B. Gotway, MD.)



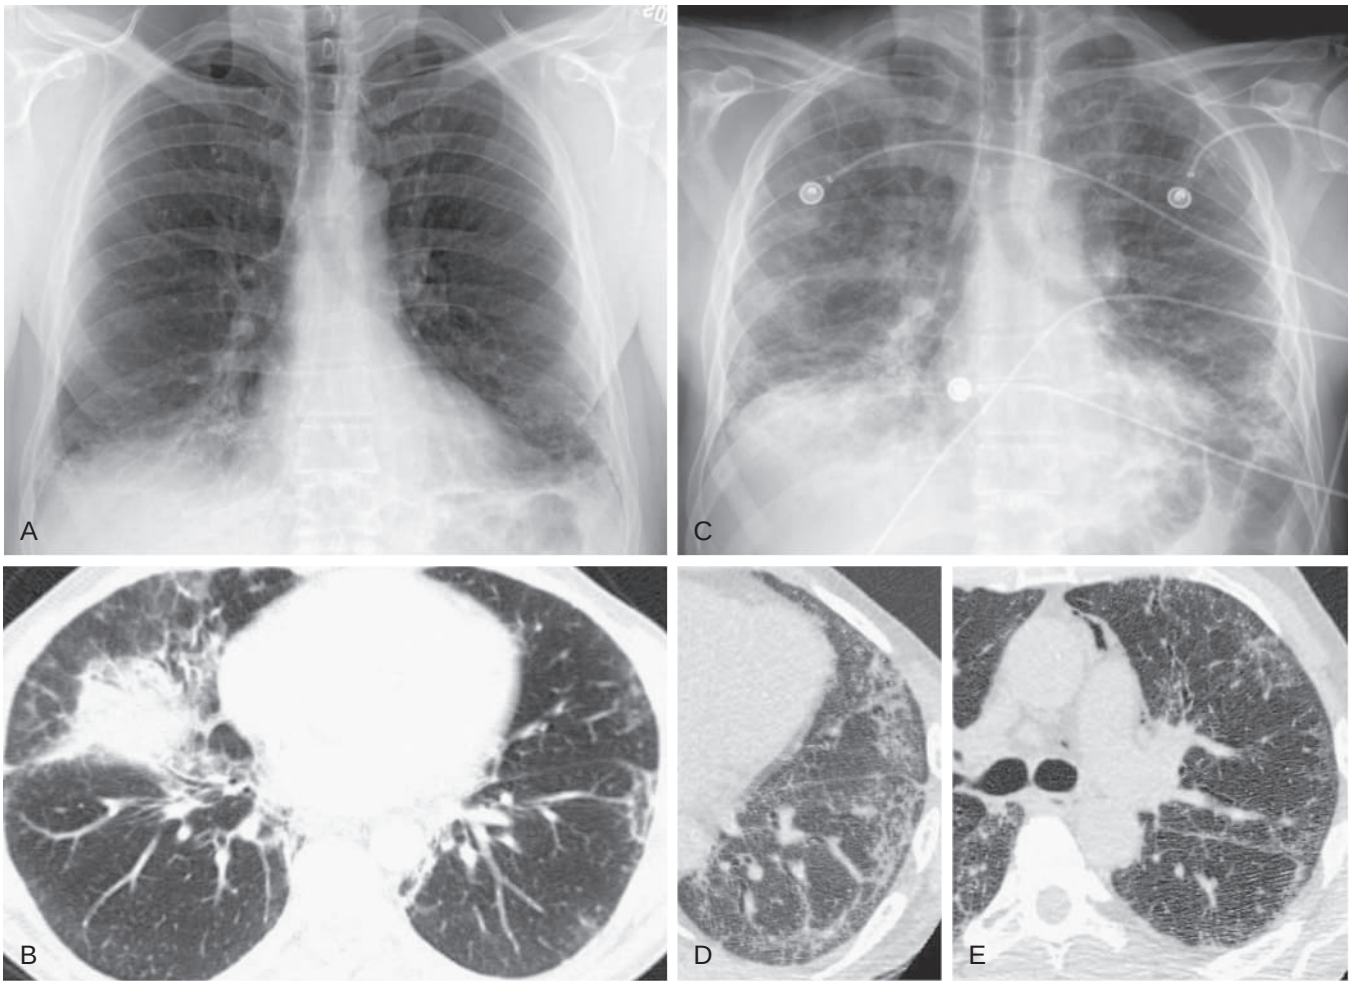
eFigure 92.4 Progressive systemic sclerosis. (A) The interstitial fibrosis of progressive systemic sclerosis is typically paucicellular and diffuse, with preservation of underlying lung architecture. (B) When fibrosis is more advanced, distinction from usual interstitial pneumonia (of idiopathic pulmonary fibrosis) may be difficult on morphologic grounds. (C) Pulmonary hypertensive changes may be present and deserve careful attention because this is a major cause of mortality in scleroderma patients with lung disease. (From Leslie KO, Wick MR. *Practical Pulmonary Pathology: A Diagnostic Approach*, ed 2. Philadelphia: Elsevier; 2011.)



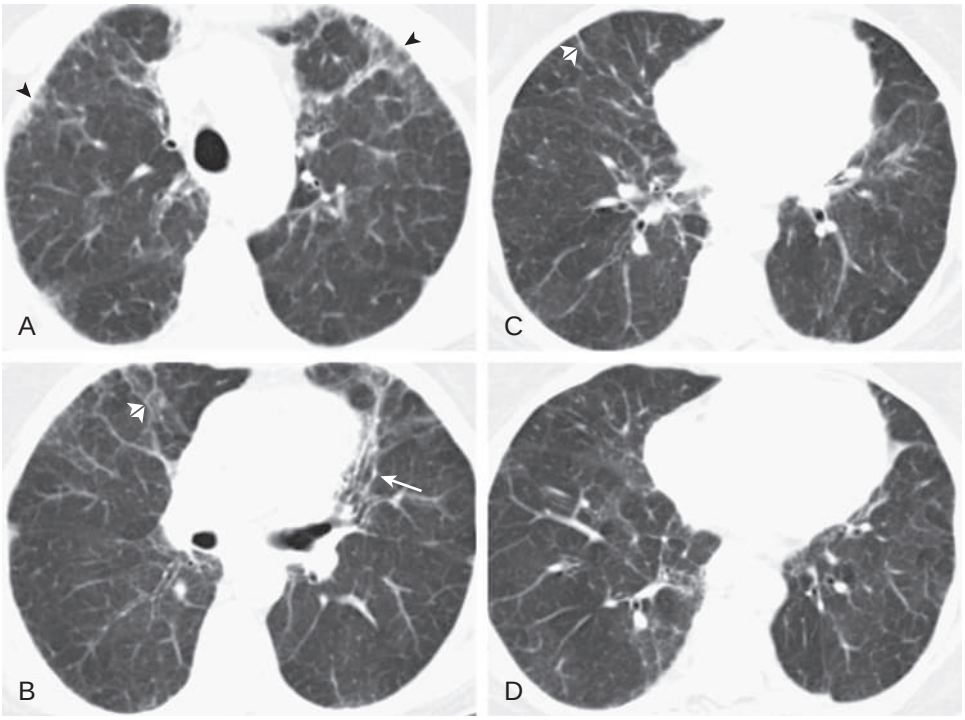
eFigure 92.5 Staging algorithm for interstitial lung disease due to systemic sclerosis. (A) Flow diagram of limited/extensive staging system with use of high-resolution computed tomography (HRCT) scores and pulmonary function test data. Identification of overtly minimal/limited disease is based on a disease extent threshold of 20% on HRCT vs. severe/extensive disease that is identified by HRCT disease extent greater than 20%. In cases with an indeterminate extent of disease on HRCT, a forced vital capacity (FVC) threshold of 70% is used to separate the cases into limited or extensive disease. The HRCT scans are scored at five levels for total disease extent, extent of reticulation, proportion of ground-glass, and coarseness of reticulation. (B) Survival compared between patient subgroups with (Ba) FVC levels above and below a threshold value of 70%; (Bb) HRCT disease extent above and below a threshold value of 20%; and (Bc) limited disease (HRCT extent ≤ 10%, or when HRCT extent was 10–30%, FVC ≥ 70%) vs. extensive disease (HRCT > 30%, or when HRCT extent was 10–30%, FVC < 70%). **HR, hazard ratio.** (Data from Goh NS, Desai SR, Veeraraghavan S, et al. Interstitial lung disease in systemic sclerosis: a simple staging system. *Am J Respir Crit Care Med.* 2008;177:1248–1254.)



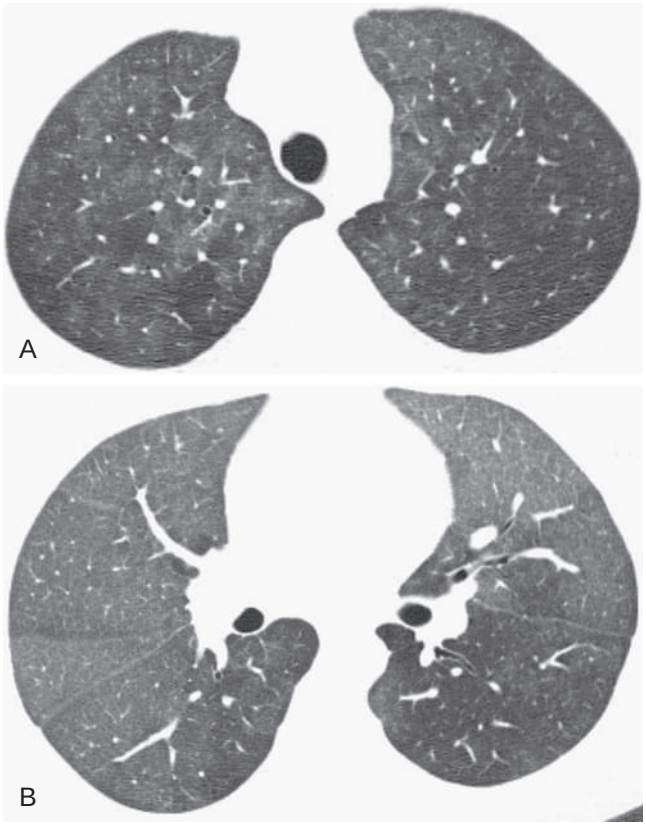
eFigure 92.6 *Rheumatoid arthritis* (RA) lung disease. (A) Variable interstitial fibrosis is typical and often resembles the fibrotic form of nonspecific interstitial pneumonia. (B) Most of the lymphoid aggregations in RA are present around the terminal airways ("follicular bronchiolitis" when lymphoid germinal centers are prominent), but lymphoid follicles may also be present in the pleura. (C) Typical rheumatoid nodules may appear in the RA lung and must be distinguished from lesions seen with infection and in granulomatosis with polyangiitis. (D) The presence of chronic pleuritis should always raise the possibility of RA in the differential diagnosis. (From Leslie KO, Wick MR: *Practical Pulmonary Pathology: A Diagnostic Approach,* ed 2. Philadelphia: Elsevier; 2011.)



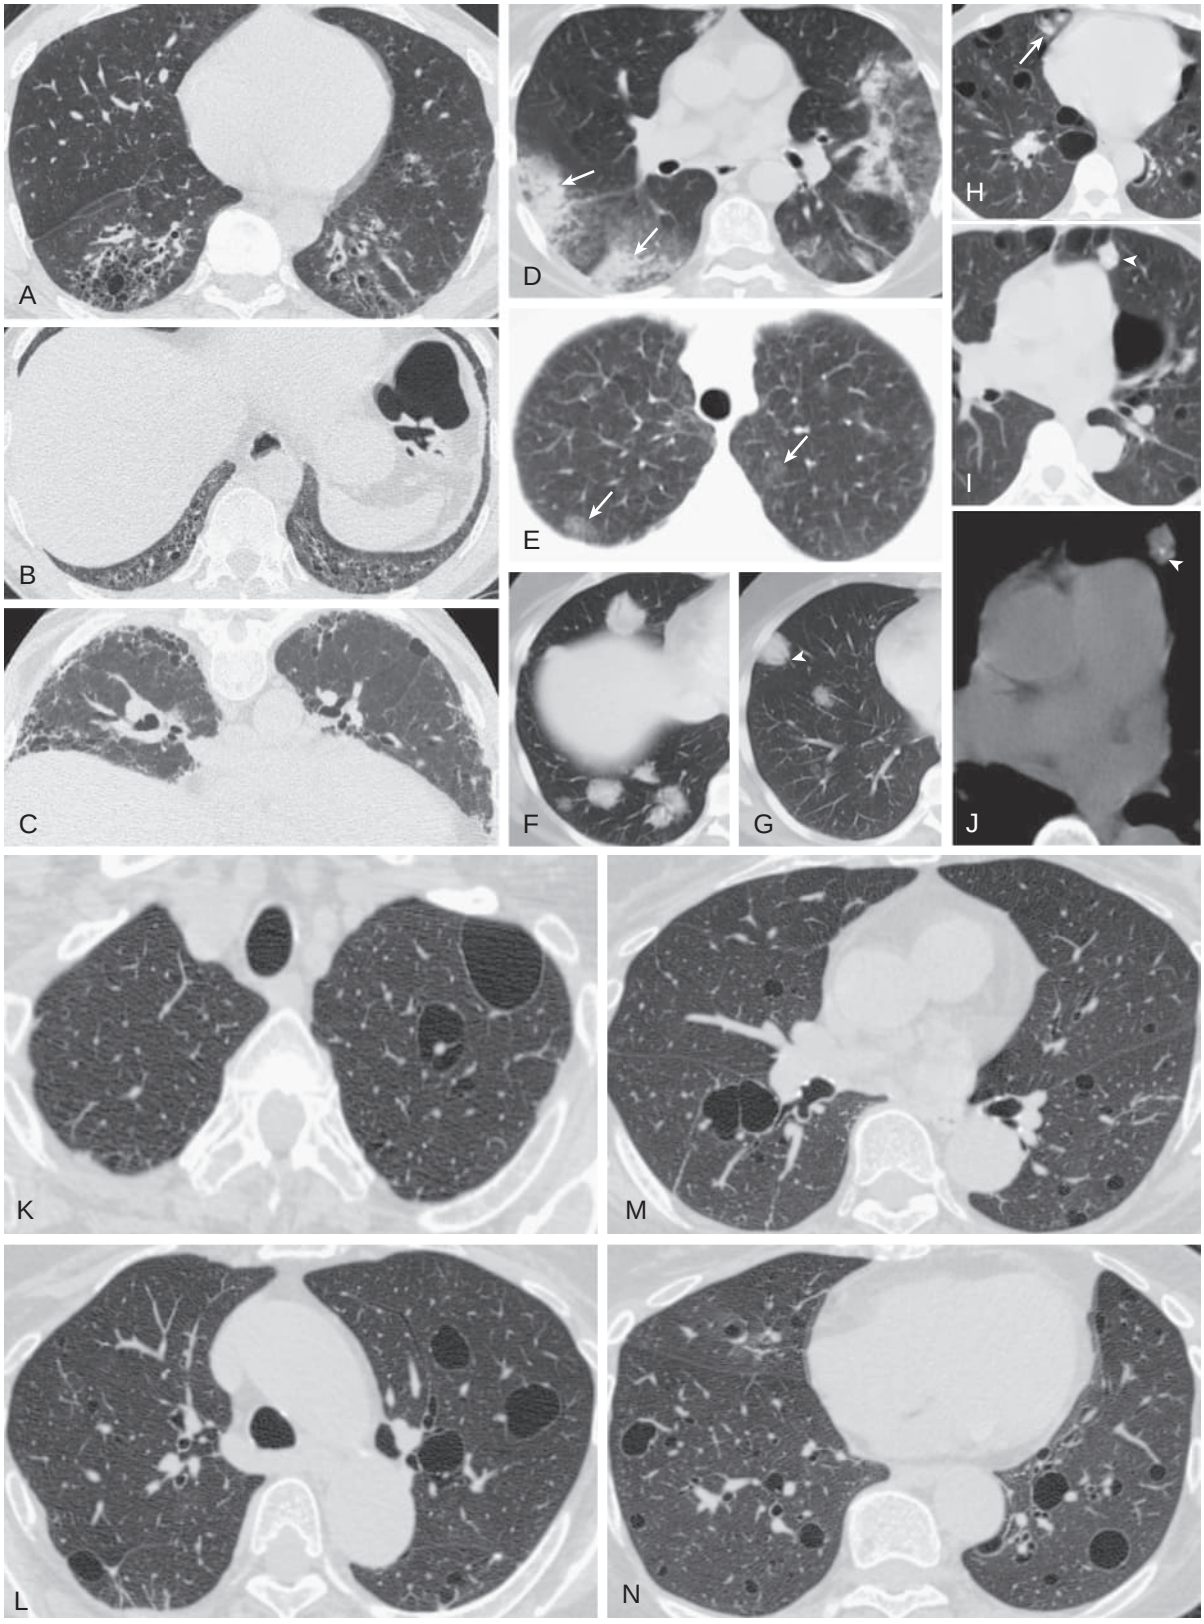
eFigure 92.7 High-resolution computed tomography of accelerated interstitial pneumonia in a patient with rheumatoid arthritis. (A) Frontal chest radiography shows basal reticulation and linear opacities consistent with interstitial lung disease in the setting of rheumatoid arthritis. (B) Axial supine image shows basal reticulation, patchy subpleural ground-glass opacity, and traction bronchiectasis. (C) Frontal chest radiography performed several years after parts A and B, when the patient developed severe shortness of breath, shows diminished lung volumes with development of extensive bilateral opacities. (D) Axial supine image focused on the left base shows progression of the basal lung abnormalities seen previously; similar findings were now also present in the mid and upper lungs (E). Surgical lung biopsy showed diffuse alveolar damage. The pneumomediastinum was postoperative in nature. (Courtesy Michael B. Gotway, MD.)



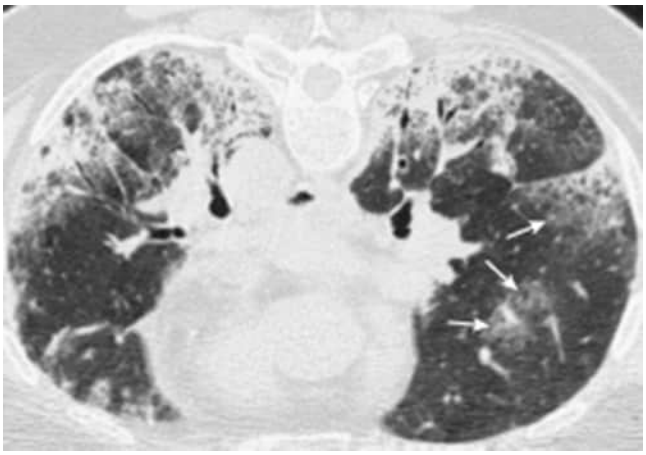
eFigure 92.8 High-resolution computed tomography of diffuse interstitial fibrosis in systemic lupus erythematosus. (A–D) Axial supine images show multifocal, bilateral, patchy areas of reticular and linear opacities, including interlobular septal thickening (white arrowheads), associated with ground-glass opacity (black arrowheads) and mild architectural distortion. Mild traction bronchiectasis (arrow) is evident. The findings are nonspecific, but surgical lung biopsy showed features suggestive of a connective tissue disorder (enlarged peribronchiolar lymphoid follicles). (Courtesy Michael B. Gotway, MD.)



eFigure 92.9 High-resolution computed tomography of diffuse alveolar hemorrhage in systemic lupus erythematosus. (A–B) Axial supine images show multifocal bilateral ground-glass opacity, with a somewhat centrilobular nodular appearance in the upper lobes (A). (Courtesy Michael B. Gotway, MD.)



eFigure 92.10 High-resolution computed tomography showing spectrum of Sjögren-related pulmonary abnormalities. (A–B) Axial supine images show basal reticulation, mild ground-glass opacity, and traction bronchiectasis in the subpleural lower lobes, consistent with a nonspecific interstitial pneumonia pattern. (C) Axial prone image shows coarse basal reticulation, subpleural cystic change, and traction bronchiectasis, consistent with a usual interstitial pneumonia pattern. (D) Axial supine image shows peripheral consolidation (*arrows*) consistent with an organizing pneumonia pattern. (E) Axial supine image shows several poorly defined ground-glass opacity nodules (*arrows*), representing lymphocytic interstitial pneumonia. This appearance is nonspecific and can be seen with other lymphoproliferative disorders that may be encountered in Sjögren patients, including follicular bronchiolitis, nodular lymphoid hyperplasia, and even *mucosa-associated lymphoid tissue* (MALT) lymphoma. (F–G) Axial supine image shows multiple, bilateral poorly defined pulmonary nodules found to represent MALT lymphoma. Note the air bronchograms associated with one of the nodules (*arrowhead*), indicating the bronchiolocentric nature of the process. (H–I) Axial supine images show multiple thin-walled cysts and small nodules (*arrow*), one of which shows a small focus of calcification (*arrowhead*) on the images displayed in soft tissue windows (J). (K–N) Axial supine images in a patient with Sjögren syndrome show multiple, bilateral, thin-walled cysts with normal intervening lung parenchyma. (Courtesy Michael B. Gotway, MD.)



eFigure 92.11 Diffuse alveolar damage superimposed on pulmonary interstitial abnormalities in a patient with polymyositis-dermatomyositis. Axial prone high-resolution computed tomography image shows patchy, subpleural reticulation and areas of consolidation, consistent with a mixture of nonspecific interstitial pneumonia and organizing pneumonia injury patterns. Patchy areas of ground-glass opacity *(arrows)*, spatially separated from the subpleural process, represent areas of diffuse alveolar damage. (Courtesy Michael B. Gotway, MD.)

KEY POINTS

INTRODUCTION

Sarcoidosis has been defined as a multisystem granulomatous disorder of unknown cause.[1] Histologic evidence of granulomatous inflammation is inadequate for the diagnosis of sarcoidosis because alternative causes of granulomatous inflammation need to be excluded. Additionally, with some exceptions (see later), clinical findings without histologic confirmation of granulomatous inflammation are inadequate to confirm a diagnosis of sarcoidosis. Sarcoidosis affects the lung in more than 90% of cases, but it can affect any part of the body. For many patients, the disease is self-limited and resolves within 2 to 5 years.[2] However, a chronic form of the disease can lead to significant morbidity and some mortality.[3,4] Glucocorticoids are usually effective for treating the disease. However, because long-term treatment may be required, steroid-sparing agents are often used.[5]

EPIDEMIOLOGY

Sarcoidosis is a worldwide disease. However, it is more common in some parts of the world and within certain ethnic groups. Figure 93.1 summarizes the reported rates of sarcoidosis around the world.[6,7] Sarcoidosis is rare before adulthood.[8] When it does manifest in childhood, there is a different clinical phenotype with more eye, skin, and joint involvement than seen in adult sarcoidosis.[9,10]

Although sarcoidosis was previously thought to be a disease mostly of young adults, it has been increasingly diagnosed in older patients. In more recent studies, more than half the patients are diagnosed when they are more than 40 years of age.[7,11,12] Sarcoidosis is believed to be more common in women than in men, at a ratio of almost 2:1.[8,13] In the United States, it is more common in African Americans than in whites and less common in Hispanics and Asians.[7,14] The disease seems to be more common in the eastern third of the United States,[7] but that finding may reflect the distribution of African Americans.

ETIOLOGY, IMMUNOLOGY, AND GENETICS

ETIOLOGY

Although sarcoidosis was first described as a distinct clinical entity more than 140 years ago, its cause still remains unknown. By extension from other granulomatous diseases, sarcoidosis is thought to be caused initially by an antigen processed by an *antigen-presenting cell* (APC). The APC then presents the antigen through a *human leukocyte antigen* (HLA) class II molecule to a restrictive set of T cell receptors on a T lymphocyte, usually of the $CD4^+$ class.[15,16] This interaction results in a polarization of the T lymphocytes to a T helper phenotype and is followed by monocyte recruitment, T cell proliferation, and differentiation leading to the development of the sarcoidosis granuloma. In this process, a myriad of cytokines and chemokines are released to maintain granuloma integrity (see Chapter 16).

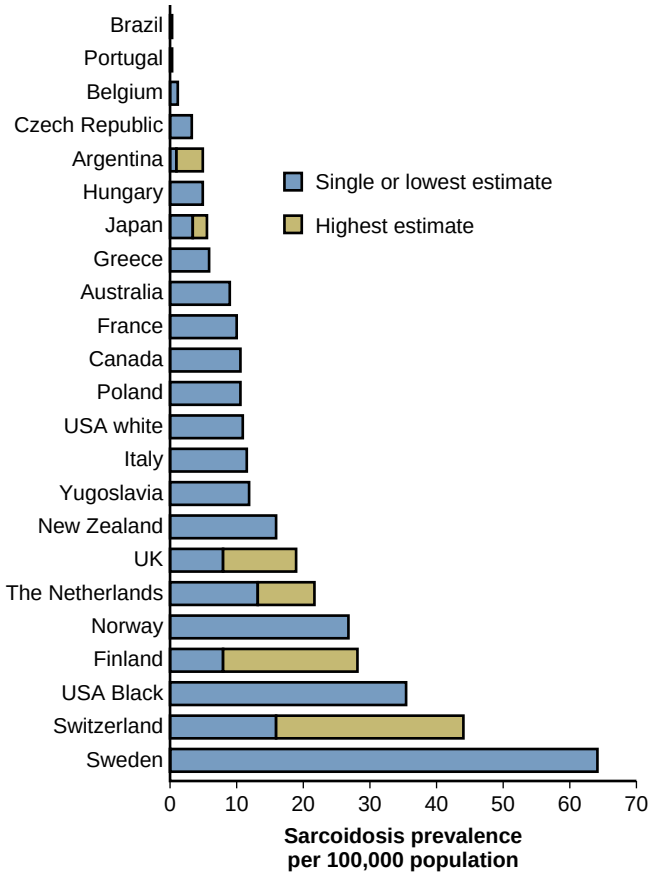

Figure 93.1 Prevalence of sarcoidosis around the world. (Modified from Denning DW, Pleuvry A, Cole DC. Global burden of chronic pulmonary aspergillosis complicating sarcoidosis. *Eur Respir J.* 2013;41:621-626.)

Infectious pathogens have been implicated as the source of antigen leading to sarcoidosis because many infections induce a granulomatous response. For example, remnants of bacterial components of propionibacteria and mycobacteria have been detected in sarcoidal tissues.[17-20] Subsequent studies have demonstrated a T-lymphocyte response to a mycobacterial protein, mKatG, both in the peripheral blood and in *bronchoalveolar lavage* (BAL) samples of sarcoidosis patients.[18,21,22] One problem with viewing sarcoidosis as an invasive infectious disease is that sarcoidal inflammation usually improves with immunosuppressive therapy. Moreover, sarcoid granulomas are typically nonnecrotizing. Although there is no consensus on whether sarcoidosis represents an autoimmune disease,[23] evidence is accumulating that autoimmunity may play a role in some forms of sarcoidosis. The immunologic phenomenon referred to as molecular mimicry is a mechanism that could explain an association between sarcoidosis and infectious microorganisms. Molecular mimicry is initiated by stimuli, often infectious or chemical, that trigger inflammation leading to exposure of self-peptides.[24] Immunologic similarities between the "foreign" trigger and the "self" peptide promote autoreactive T or B cells in a susceptible individual. In such a scenario, the inflammation can be self-limiting or prolonged, depending on the balance of mediators that favor resolution versus persistence of the inflammation. Although there are reports of autoimmune phenomenon and mycobacterial infections,[25] the best evidence for autoimmunity is the self-limiting form of Löfgren syndrome associated with individuals who carry the *HLA-DRB1*03* allele.[26,27] Most of these patients develop a clonal expansion of $CD4^+$ T cells expressing the T cell receptor α chain variable segment Vα2.3 in the lungs.[28,29] Independent groups have identified vimentin as a possible autoantigen in these patients by using proteomic techniques on lung macrophages and homogenized spleen tissue.[30-34] Follow-up studies on blood and lung samples from these patients have demonstrated antivimentin antibodies and functional T cell responses to vimentin.[31,35] Although these data are compelling, it may be that these observations are the effect of ongoing inflammation and not part of the trigger causing the disease.[36] The role of autoimmunity in sarcoidosis may be an area of research deserving of more attention.

Other triggers associated with the etiology of sarcoidosis include certain environmental and occupational exposures.[37,38] Sarcoidosis has been reported in individuals with heavy exposure to combustible wood products[39,40] and with the particulates and chemicals from the World Trade Center disaster.[41,42] There are reports of sarcoidosis in the metal industry with exposure to titanium,[43] metal working, metal machining,[43] and photocopier toner (which contains silicates, iron, and copper).[44] Analysis of lung biopsy specimens from sarcoidosis patients has revealed metals, including silicates, aluminum, and titanium.[45] Sarcoidosis has also been associated with occupations and exposures, including hairdressers,[46] health care workers,[47] agricultural employment,[38] insecticide use at work,[38] work environments with mold or mildew,[38] industrial organic dust exposure, educators, and workers of suppliers of building materials, hardware, and gardening materials.[37] Many of these exposures may, in and of themselves, cause granulomas. Sarcoidosis associated with environmental exposure to respirable material is often isolated to the lung.[48] It is not clear whether these are cases of sarcoidosis or sarcoid-like conditions.

IMMUNOLOGY AND GENETICS

Clues to mechanisms causing sarcoidosis may eventually be revealed as we understand the molecular interactions that initiate granulomatous reactions. Although rare, granulomatous reactions in patients treated with programmed cell death protein 1 and/or cytotoxic T lymphocyte–associated protein 4 blockade may offer mechanistic insights.[49-51] Molecular targets can also be discovered using large genome-wide association studies. [52-61] Putting genetics together with environmental triggers, the current paradigm is that sarcoidosis develops in an immunogenetically susceptible host after exposure to a particular antigen.[62] One reason that no common antigen has been found in sarcoidosis is that granulomatous inflammation is likely a final pathway for many different types of antigen exposures. Thus, in some sense, sarcoidosis may represent a collection of diseases with diverse genetic susceptibility loci and diverse environmental antigen triggers.[63,64]

Immunologically, the sarcoid granuloma is a complex structure, and its integrity depends on the interaction of innate and adaptive immunity (see Chapters 15 and 16). Studies of targeted cell types involved in granuloma formation have opened up new areas of research that may provide opportunities for new therapies. Novel research tools

have facilitated studies of mouse and human dendritic cell populations.[65] A Scandinavian study of patients with newly diagnosed sarcoidosis found that, unlike in healthy individuals, myeloid dendritic cells from the lung and blood of the sarcoid patients were activated.[66] Blood dendritic cells from the patients induced *tumor necrosis factor-α* (TNF-α) production in co-culture experiments with allogenic naive $CD4^+$ T cells, whereas dendritic cells from unaffected control samples did not. This finding suggests that dendritic cells are functionally capable of contributing to sarcoidal inflammation and, if so, the availability of current reagents that affect dendritic cell function may lead to future therapies. Another notable discovery has provided a new perspective about mechanisms contributing to granuloma formation; in a mouse model of constitutively active mammalian target of rapamycin complex 1 restricted to myeloid cells (macrophages), granulomas formed spontaneously in the lung and liver.[67] A genetic link with the target of rapamycin signaling pathway was then identified in a study of five French families with autosomal transmission of non-Löfgren sarcoidosis.[68] There has also been progress in the development of in vitro human granuloma models. A model using peripheral blood mononuclear cells from sarcoid patients revealed up-regulation of genes related to *interleukin* (IL)-13 signaling pathways when the cells were incubated with polystyrene beads coated with purified protein derivative.[69,70] The results were corroborated using immunohistochemical methods that identified intense staining for a marker, CD163, in macrophages and giant cells from granulomatous tissue sections from patients with sarcoidosis compared with tuberculosis.[71] These findings and others related to $CD4^+$ type 2 T helper cell (Th) inflammation[72] raise many new questions about granuloma biology in sarcoidosis.

There have also been complementary studies performed on lymphocytes providing additional insight into how they contribute to granuloma biology. Using a combination of transcription factors and/or chemokine receptors to identify blood and lung $CD4^+$ cells, studies from independent sarcoidosis cohorts suggest that cells that produce higher amounts of IL-17 relative to interferon-γ are associated with better clinical outcomes in patients with Löfgren syndrome compared with chronic sarcoidosis.[73-75] These studies have provided evidence for Th17 cell plasticity[76] in sarcoidosis through identification of a subset of $CD4^+$ T cells, called Th17.1, in lung lavage expressing the transcription factors T-bet and RORγt and chemokine receptors CXCR3 and CCR6. Cell-based in vitro co-culture experiments have revealed hypoxia-inducible factor-1α as a possible regulator of IL-17 production by activated $CD4^+$ T cells.[77] Although few studies related to other types of lymphocytes have been conducted, the available data suggest that there may be activation or dysfunction of B cells,[78-80] CD8 T cells,[81] and T-regulatory cells,[82,83] which deserves further attention. Collectively, these findings highlight the complexity of roles that lymphocytes play in sarcoidal inflammation.

DIAGNOSTIC APPROACH

GENERAL CONSIDERATIONS

Figure 93.2 outlines the approach to the diagnosis of sarcoidosis. In general, this process involves a review of clinical information and histologic examination of tissue for the presence of granulomatous inflammation. At every step, it is important to consider and exclude other known causes of granulomatous inflammation.[84] This diagnostic approach is discussed here.

One can never be certain of the diagnosis of sarcoidosis. Similar to other diseases, sarcoidosis may be considered a probable diagnosis if clinical data exceed a certain threshold, thus making the diagnosis plausible. Table 93.1 outlines clinical findings that are often used to gauge the likelihood of the diagnosis of sarcoidosis. For most patients, the clinical information suggests the diagnosis, but a tissue biopsy is usually indicated to enhance the probability of sarcoidosis.

Patients with sarcoidosis may present with no symptoms, a feature more common in white than Black patients.[85] Therefore, sarcoidosis should be considered not only in symptomatic patients but also in asymptomatic patients with hilar adenopathy, mediastinal adenopathy, and/or diffuse parenchymal opacities on lung imaging.[85-87] An inquiry should be made about a family history of sarcoidosis because the prevalence rate of sarcoidosis is much higher in first-degree relatives of sarcoidosis patients than in the general population.[53] Sarcoidosis is more common in nonsmokers in most, but not all, studies.[38,88,89]

Alternative causes of granulomatous inflammation should be reasonably excluded before a diagnosis of sarcoidosis is rendered. A history of active tuberculosis, latent tuberculosis, and tuberculosis exposure should be obtained. *Chronic beryllium disease* (CBD) can mimic sarcoidosis radiographically[90] and histologically.[91,92] CBD has been misdiagnosed as sarcoidosis in up to 40% of cases.[93] Because most patients are unaware of potential exposures to beryllium, it is important to ask about work where exposure to beryllium is plausible, including work in aerospace, nuclear weapons, electronics, jewelry, sporting goods, ceramics, and dental industries.[94] Furthermore, minimal beryllium exposure may lead to significant disease.[95,96] Hypersensitivity pneumonitis is a granulomatous pulmonary disease that may mimic sarcoidosis. Although it may result from exposure to numerous agents, hypersensitivity pneumonitis is most commonly caused by antigens from birds and hot tubs (see also Chapters 91 and 101).

EXTRAPULMONARY INVOLVEMENT

At presentation, 90% of sarcoidosis patients will have clinical evidence of pulmonary involvement, and more than 40% have evidence of involvement in the skin, liver, peripheral lymph node, or eye.[11,97] Therefore, evaluation for involvement of these organs should be performed in any patient being assessed for possible sarcoidosis. Specific criteria for individual organ involvement have been proposed.[98] A diagnostic scoring system (Sarcoidosis Diagnostic Score) has been developed, which emphasizes that the higher the number of organs involved, the more confident one can be of the diagnosis.[99]

RADIOGRAPHIC FINDINGS

Bilateral hilar adenopathy on chest radiograph suggests the diagnosis of sarcoidosis, especially if the patient has no

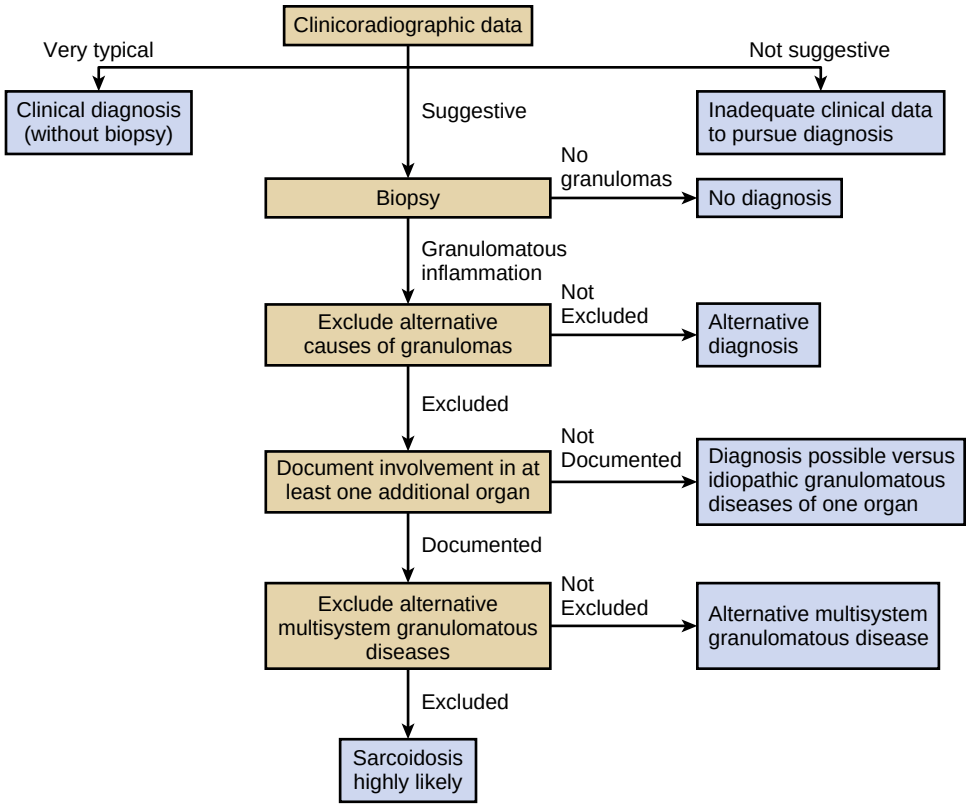

Figure 93.2 Diagnostic algorithm for sarcoidosis. The diagnostic approach for sarcoidosis with consideration of clinical information and tissue biopsy demonstration of granulomatous inflammation as well as exclusion of known causes of granulomatous inflammation (see text for details). (Modified from Judson MA. The diagnosis of sarcoidosis. *Clin Chest Med.* 2008;29:415-427.)

Table 93.1 Clinicoradiographic Data Supporting or Weakening the Likelihood of Sarcoidosis

	Supports	Weakens
Demographics	▪ U.S. African American ▪ Northern European	▪ Age <18 years
Medical history	▪ Nonsmoking ▪ No symptoms (in patients with CXR findings) ▪ Positive family history of sarcoidosis ▪ Symptoms involving ≥2 organs commonly involved with sarcoidosis (e.g., lung and eyes)	▪ Exposure to tuberculosis ▪ Exposure to organic bioaerosol ▪ Exposure to beryllium ▪ Intravenous drug abuse
Laboratory data	▪ Elevated SACE, especially if >2× ULN ▪ Elevated serum calcium ▪ Elevated serum alkaline phosphatase ▪ Leukopenia	
Radiographic findings	▪ CXR: bilateral hilar adenopathy (especially if without symptoms) ▪ HRCT: disease along the bronchovascular bundles	

CXR, chest radiograph; HRCT, high-resolution computed tomography; SACE, serum angiotensin-converting enzyme; 2× ULN, twice the upper limit of normal. Modified from Judson MA. The diagnosis of sarcoidosis. *Clin Chest Med.* 2008;29:415-427.

fever, night sweats, or weight loss.[86,87] The chest radiograph often demonstrates bilateral enlargement of the hilar lymph nodes, as well as concomitant enlargement of the right paratracheal lymph nodes[100] (Fig. 93.3). Scadding defined four patterns of chest radiographic findings: stage 1, with adenopathy alone (see Fig. 93.3); stage 2, with adenopathy and parenchymal opacities (Fig. 93.4); stage 3, with opacities alone (Fig. 93.5); and stage 4, with fibrosis (see Fig. 93.11).[101]

Findings on *high-resolution chest computed tomography* (HRCT) are likely more specific for the diagnosis of sarcoidosis than findings on chest radiography. Typical HRCT findings that suggest sarcoidosis include the presence of parenchymal nodules and opacities that represent conglomerations of these nodules and their location in a perilymphatic distribution along the bronchovascular bundles, as well as in subpleural locations[102-104] (see Fig. 93.4).

SERUM MARKERS

Angiotensin-converting enzyme (ACE) is produced in the epithelioid cell of the sarcoid granuloma,[105] and *serum ACE* (SACE) levels may reflect the total sarcoid granuloma

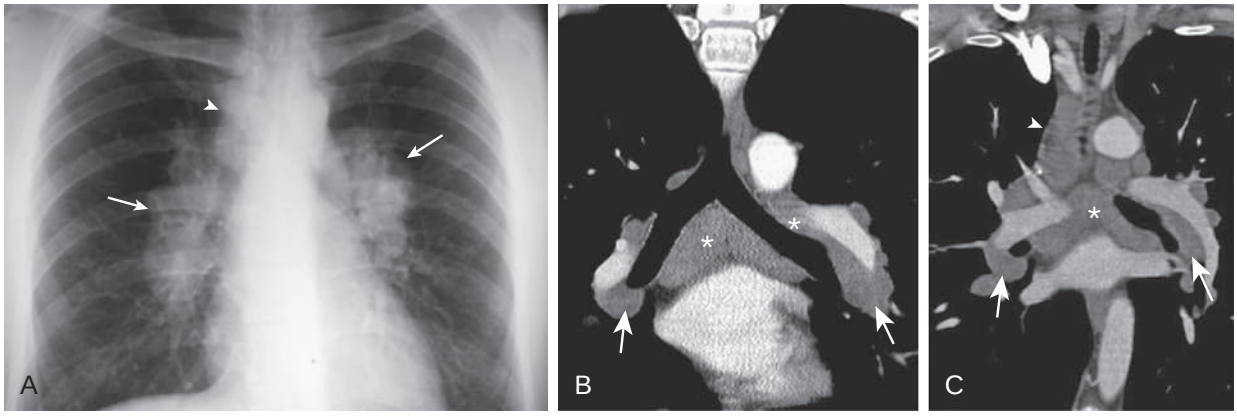

Figure 93.3 Sarcoidosis: Scadding stage 1. (A) Frontal chest radiograph shows symmetrical, bilateral peribronchial *(arrows)* and right paratracheal lymphadenopathy *(arrowhead),* typical of sarcoidosis. (B–C) Contrast-enhanced chest computed tomography confirms the presence of symmetrical, bilateral peribronchial *(arrows)* and right paratracheal *(arrowhead)* lymphadenopathy, as well as enlargement of other mediastinal lymph nodes *(asterisks).* (Courtesy Michael B. Gotway, MD.)

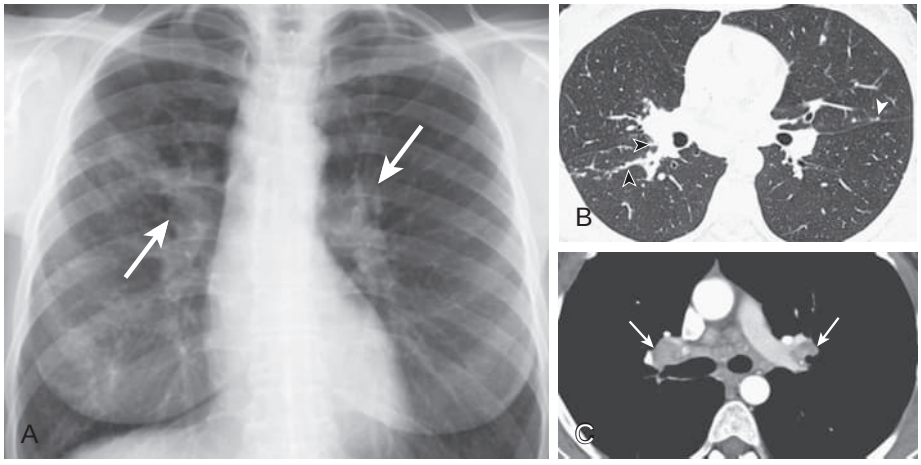

Figure 93.4 Sarcoidosis: Scadding stage 2. (A) Frontal chest radiograph shows symmetrical, bilateral peribronchial lymph node enlargement *(arrows)* as well as small, well-defined nodules best visualized in the right suprahilar region. The oblong opacity in this area represents a conglomeration of granulomatous inflammation. (B–C) Axial enhanced chest computed tomography (CT) in lung (B) and soft tissue (C) shows small, circumscribed nodules distributed along the fissural surfaces *(white arrowhead),* as well as along the more central peribronchovascular interstitium *(black arrowheads),* the latter resulting in a "beaded" appearance of the pulmonary vessels. Chest CT also confirms the presence of peribronchial lymph node enlargement (*arrows*, C). (Courtesy Michael B. Gotway, MD.)

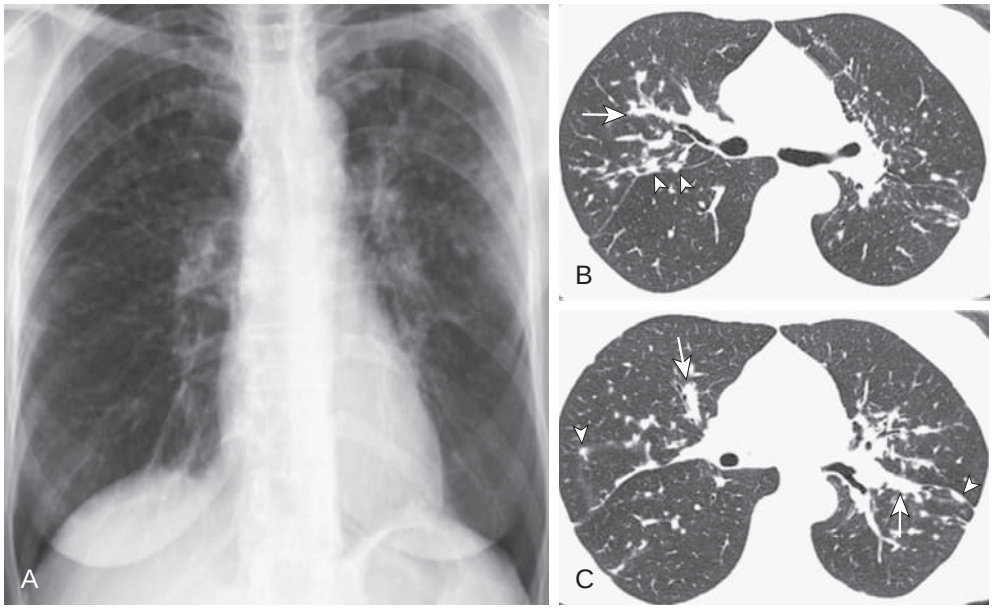

Figure 93.5 Sarcoidosis: Scadding stage 3. (A) Frontal chest radiograph shows upper lobe–predominant nodular opacities with little evidence of architectural distortion to suggest associated parenchymal fibrosis. No clear evidence of peribronchial or mediastinal lymph node enlargement is present. Mild prominence of the left hilum is the result of parenchymal opacity projected over this region, as shown on chest *computed tomography* (CT). (B–C) Axial chest CT displayed in lung windows shows small, circumscribed nodules distributed along the fissural surfaces *(arrowheads),* as well as along the more central peribronchovascular interstitium *(arrows),* the latter resulting in a "beaded" appearance of the pulmonary vessels. Additional chest CT images also confirmed the lack of significant peribronchial and mediastinal lymph node enlargement. (Courtesy Michael B. Gotway, MD.)

burden.[105] Although SACE has been suggested as a diagnostic test for sarcoidosis,[106] elevated SACE levels in isolation are inadequately sensitive or specific either to diagnose or to exclude the disease. In a review of 14 studies encompassing 4195 patients concerning the diagnostic accuracy of SACE for sarcoidosis, the sensitivity was 77% (range, 41–100%), and the specificity was 93% (range, 83–99%).[107] The likelihood of sarcoidosis increases with higher SACE levels,[107,108] and SACE levels greater than twice the upper limits of normal are rarely seen in other diseases and are not seen in cancer or lymphoma.[106,109] Polymorphisms of the ACE gene also influence the SACE.[110] However, none of these polymorphisms has been shown to be associated with increased incidence or worsening of the disease.[111]

Other serum markers have been studied in sarcoidosis. Chitotriosidase, an enzyme produced by activated macrophages, has been described in sarcoidosis, and higher levels within the serum may be associated with a worse prognosis of the disease.[112,113] The soluble IL-2 receptor, a marker of T cell activation, has been found to be elevated in sarcoidosis patients.[113,114] In small studies, the level of this receptor was an effective measure of disease activity.[102,114] The value of these biomarkers regarding diagnosis and prognosis needs to be verified by larger, multinational trials.

HISTOLOGIC EXAMINATION

With the exception of the rare instances where the clinical findings are highly specific for sarcoidosis, the diagnosis requires a tissue biopsy demonstrating granulomas (Fig. 93.6). Our approach to the selection of a biopsy site is summarized in Figure 93.7. It is in the patient's best interest for the biopsy to be minimally invasive and associated with the least morbidity. For these reasons, biopsy of superficial sites is preferred to biopsy of visceral organs.[115] Even in patients suspected to have sarcoidosis on the basis of obvious thoracic or abdominal disease, a thorough skin, conjunctival, lacrimal gland, and peripheral lymph node examination should be performed. The patient should be questioned about the presence of scars or tattoos because skin nodules of sarcoidosis have a predilection to form in these areas (see Fig. 93.10).

When there is no clinical evidence that a superficial site is involved with sarcoidosis, a biopsy is usually attempted in an organ where sarcoidosis involvement is suspected. This is very often the lung because the lung is involved in more than 90% of sarcoidosis patients early in the course of the disease.[11,116] Bronchoscopy is the most commonly used procedure to obtain tissue from the lung. More invasive techniques such as mediastinoscopy are reserved for cases in which bronchoscopy was not diagnostic. Video-assisted thoracoscopic biopsy is rarely needed to confirm the diagnosis of sarcoidosis.

Fiberoptic bronchoscopy allows for several different samples, including the *transbronchial lung biopsy* (TBLB), endobronchial biopsy, and *transbronchial needle aspirate* (TBNA) of a mediastinal lymph node. The yield of TBLB for the diagnosis of pulmonary sarcoidosis ranges from 60–97%, depending on the number of biopsies taken and the presence of parenchymal disease on chest

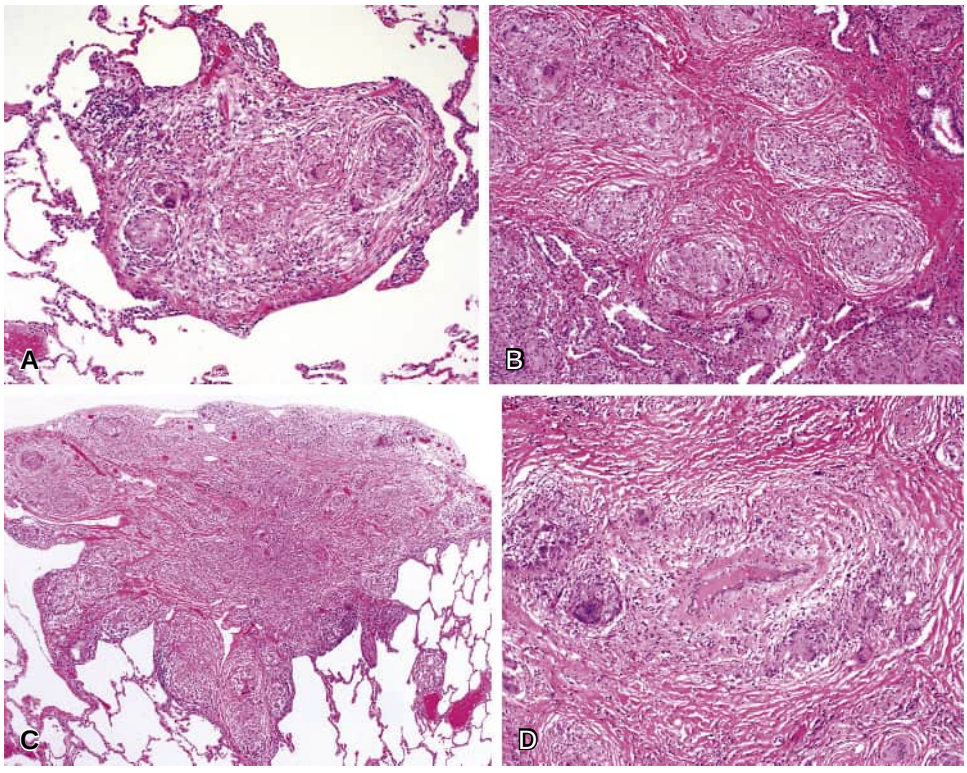

Figure 93.6 Sarcoidosis. (A) The characteristic pathologic lesion of pulmonary sarcoidosis is the non-necrotizing (immune) granuloma. (B) Granuloma within sclerotic fibrosis. (C) Granulomas distributed along lymphatic routes in the pleura, within the intralobular septa, and along the bronchovascular bundles. This image is diagnostic of sarcoidosis, but berylliosis should always be included as a diagnostic possibility. (D) Perivascular granulomas embedded in sclerosis are commonly seen. Despite this potential for vasocentric growth, pulmonary hypertension is an uncommon complication of sarcoidosis. (Modified from Leslie KO, Wick MR. *Practical Pulmonary Pathology: A Diagnostic Approach.* 2nd ed. Philadelphia: Elsevier; 2011.)

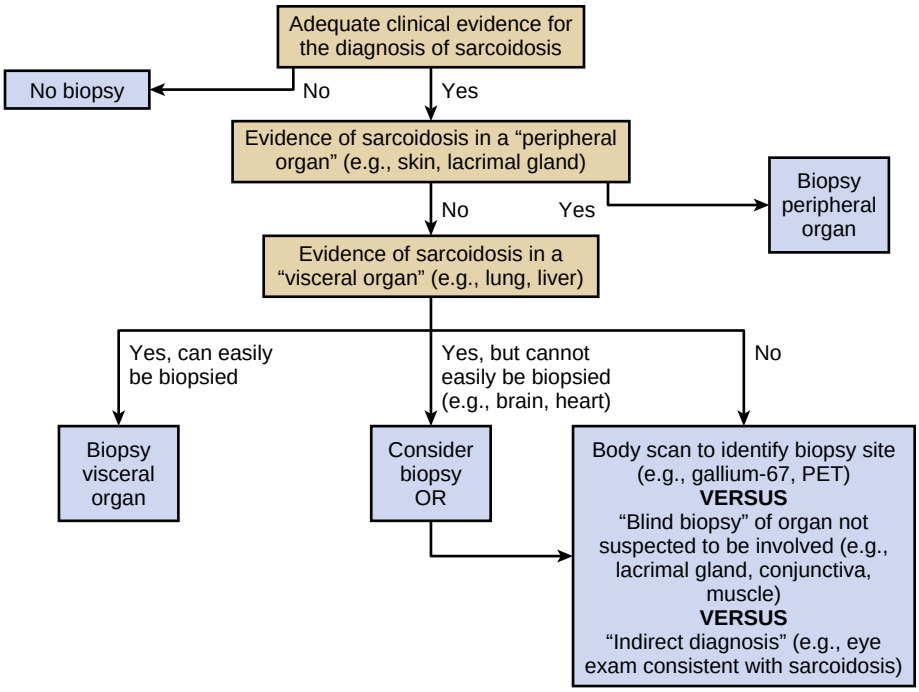

Figure 93.7 Diagnostic approach to selecting a biopsy site for pathologic confirmation of granulomatous inflammation consistent with sarcoidosis. This approach emphasizes selection of a relatively noninvasive biopsy site when possible, biopsy of a site suspected to be clinically involved unless the biopsy would be highly invasive, and various approaches when no obvious organ involvement is demonstrated or only organs requiring very invasive biopsies demonstrate potential involvement. PET, positron emission tomography.

radiograph.[117-119] Endobronchial biopsy results may be positive in up to 60% of patients with pulmonary sarcoidosis.[120,121] Biopsy results are more frequently positive in individuals with abnormal-appearing airways.[120] Furthermore, endobronchial biopsy can be performed at the time of TBLB and increases the yield for sarcoidosis above biopsy using TBLB alone.

Endobronchial ultrasound (EBUS) was shown to be superior to blind TBNA for obtaining diagnostic material in two randomized trials.[122,123] The yield for EBUS or TBNA is much higher for patients with adenopathy on chest radiograph (stage 1 or 2), whereas the yield for TBLB is higher for patients with a stage 3 chest radiograph.[123,124] The use of on-site cytopathology allows for rapid review of the EBUS-TBNA specimen, and the bronchoscopist may not require TBLB.[125] In a meta-analysis, it was found that EBUS had a significantly higher diagnostic yield than TBLB alone. However, the combination of EBUS, TBLB, and endobronchial biopsy had a significantly higher yield than EBUS alone.[126] The addition of cryobiopsy may further enhance the diagnostic yield.[127]

BAL is sometimes used to examine inflammatory cells as a complementary test for the diagnosis of pulmonary sarcoidosis.[128] The diagnostic accuracy of the percentage of lymphocytes and of the CD4/CD8 lymphocyte subpopulation ratio in BAL has been assessed. In general, BAL lymphocytosis (>15% lymphocytes) has a 90% sensitivity for the diagnosis of sarcoidosis,[128-130] although the specificity is lower. Other conditions that lead to BAL lymphocytosis must be excluded, including infections such as tuberculosis and fungal infections, lymphoma, and hypersensitivity pneumonitis.[130,131] BAL lymphocytosis of more than 60% and the presence of mast cells are more common with hypersensitivity pneumonitis than sarcoidosis.[129] The BAL CD4/CD8 ratio is greater than 3.5 in 50–60% of pulmonary sarcoidosis patients. However, the specificity of the BAL CD4/CD8 ratio criterion has approached 95% in some,[130-132] but not all,[133] studies. Some investigators have advocated that the BAL CD4/CD8 criterion is diagnostic of sarcoidosis when there are concomitant chest imaging findings compatible with sarcoidosis[128]; however, these criteria not been formally tested. BAL samples can be tested along with bronchial washings for evidence of fungal or mycobacterial infection.[134]

Tissue biopsy can be used to detect granulomas in any organ involved with sarcoidosis.[115] However, biopsy of neural tissue and biopsy of the heart raise serious concerns because of the potential morbidity associated with these procedures. Because patients with neurosarcoidosis have extraneural sarcoidosis nearly 90% of the time,[135] an extraneural biopsy site can usually be found. In addition, although endomyocardial biopsy is a fairly specific test for cardiac sarcoidosis in the proper clinical setting, its sensitivity is very low.[136] For this reason, endomyocardial biopsy is rarely performed for the diagnosis of sarcoidosis. Often, imaging studies are used as surrogate tests for the diagnosis of neurosarcoidosis (e.g., *magnetic resonance imaging* [MRI] with gadolinium enhancement) and cardiac sarcoidosis (e.g., ^{18}F-fluorodeoxyglucose *positron emission tomography* [PET] or MRI with gadolinium enhancement). Cardiac MRI and PET are often performed to evaluate nonischemic cardiomyopathy. Although these tests may suggest cardiac sarcoidosis, such studies should be interpreted cautiously because their specificity depends on associated clinical evidence for sarcoidosis, which should almost always include previous biopsy confirmation of granulomatous inflammation of unknown cause in another organ (see earlier).

When a confirmatory biopsy is performed for sarcoidosis, a meticulous histologic examination with appropriate

Table 93.2 Clinical Presentations That May Be Assumed to Be Sarcoidosis Without Tissue Confirmation as Long as Additional Data Do Not Suggest an Alternative Diagnosis

- Lupus pernio
- Löfgren syndrome[26]
  - Bilateral hilar adenopathy on chest radiograph
  - Erythema nodosum skin lesions
  - Periarticular inflammation or arthritis of the ankles with or without erythema nodosum
- Heerfordt syndrome[138]
  - Uveitis
  - Parotitis
  - Fever (often)
- Bilateral hilar adenopathy on chest radiograph without symptoms
- Positive panda sign (parotid and lacrimal gland uptake) and lambda sign (bilateral hilar and right paratracheal lymph node uptake) on gallium-67 scan[141]

Modified from Judson MA. The diagnosis of sarcoidosis. *Clin Chest Med.* 2008;29:415-427.

staining should also be performed to search for known causes of granulomatous inflammation, such as mycobacteria, fungi, parasites, and foreign material (e.g., talc). Although no specific histologic features are diagnostic of sarcoid granulomas, certain features suggest this diagnosis. The sarcoid granuloma usually consists of a compact (organized) collection of mononuclear phagocytes (macrophages and epithelioid cells).[137] Typically, there is no necrosis within the sarcoid granuloma; however, on occasion, a small to moderate amount of necrosis is present. Usually, giant cells fuse within the sarcoid granuloma to form multinucleated giant cells (see Fig. 93.6). These granulomas are typically surrounded by lymphocytes in the periphery. A variety of inclusions may be present within the sarcoid granuloma, including asteroid bodies (star-shaped inclusions), Schaumann bodies (lamellated calcified inclusions), birefringent crystals, and Hamazaki-Wesenberg bodies (pigmented oval inclusions); however, these inclusions are neither specific nor diagnostic of sarcoidosis[137] (eFig. 93.1). In particular, birefringent crystals within the sarcoid granuloma may lead to a misdiagnosis of talc granulomatosis.[92] Care must be taken to ensure that the crystal morphology and size are compatible with intravenously injected talc before making the diagnosis of talc granulomatosis.

DIAGNOSIS OF SARCOIDOSIS WITHOUT CONFIRMATORY BIOPSY

In some cases, the clinical presentation of sarcoidosis is so specific that the diagnosis can be made without performing a confirmatory tissue biopsy. These presentations are listed in Table 93.2.[84] In patients with these presentations, performing bronchoscopy can be considered to exclude other possible causes, including infection. In patients whose bronchoscopy findings are not diagnostic, the presence of factors shown in Table 93.2 may help bolster the confidence of the diagnosis

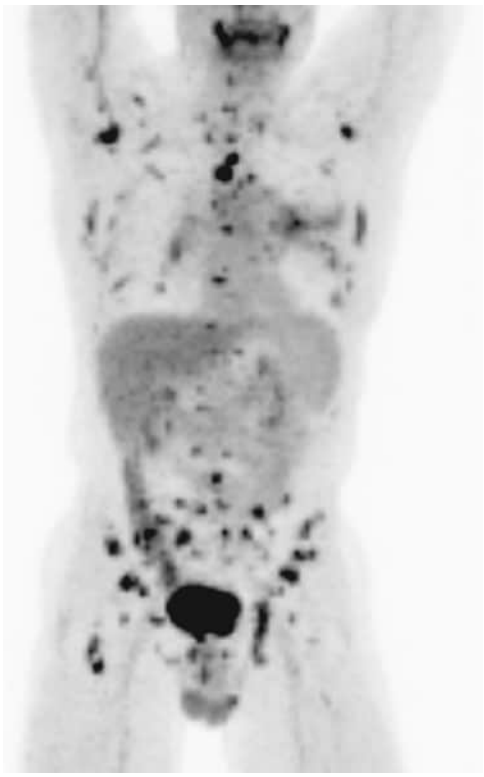

Figure 93.8 Positron emission tomography scan demonstrating both lung parenchymal and mediastinal nodal uptake. Also demonstrated are several extrapulmonary lymph nodes and other areas with increased activity.

of sarcoidosis. Löfgren syndrome initially included only patients with erythema nodosum of lower legs or forearms (eFig. 93.2). However, periarticular inflammation or arthritis of the ankles with or without erythema nodosum has been added to the expanded definition of Löfgren syndrome.[26] Uveoparotid fever, also known as Heerfordt syndrome, is an uncommon, specific manifestation of sarcoidosis that establishes the diagnosis without the need for a confirmatory biopsy.[138]

On some occasions, the diagnosis of sarcoidosis is suspected on clinical grounds although no specific organ is identified to biopsy. This would include patients presenting with disease of the eye, brain, or heart that is consistent with sarcoidosis but who have no organ that can be safely sampled by biopsy. There is no established approach for this situation. Total body imaging using ^{18}F-FDG-PET[139,140] or gallium-67 scanning[141] has been proposed in such cases to identify an organ for biopsy (Fig. 93.8), although no rigorous analysis of this approach has been undertaken. Another suggested approach in this situation is to perform a biopsy in organs that are commonly affected, even in the absence of symptoms or of other clinical findings suggestive of sarcoidosis. Conjunctival biopsies have been performed in this situation, and the yield has ranged from 27–55% in patients without ocular symptoms.[142-145] In vivo confocal microscopy of the conjunctiva can detect multinucleated giant cells without the need for a biopsy, and this has also been advocated as a noninvasive way to confirm granulomatous inflammation in sarcoidosis

patients.[146] Liver biopsy demonstrates granulomas in 24–78% of sarcoidosis patients, even when they have no symptoms attributable to the liver and have normal serum liver function test results.[147,148] However, hepatic granulomas are not specific for sarcoidosis, so clinical evidence of extrahepatic sarcoidosis must be present for the diagnosis to be secure.[149] A gastrocnemius muscle biopsy was shown to reveal granulomas in patients without muscle symptoms who had bilateral hilar adenopathy on chest radiograph.[150] However, most of these patients had strong clinical evidence of sarcoidosis; furthermore, this procedure is fairly invasive.

As a mostly historical test, the Kveim test involved the intradermal inoculation of a suspension of splenic tissue from spleen that was involved with sarcoidosis.[151] If a skin nodule developed at the inoculation site in 4 to 6 weeks, it was sampled by biopsy. A biopsy demonstrating nonnecrotizing granulomatous inflammation was considered highly specific for the diagnosis of sarcoidosis.[152] The Kveim test had a false-negative rate of approximately 20–40%. At present, the Kveim test is rarely performed because of lack of properly prepared Kveim reagent and concern for transmission of an infectious agent.

CONTROVERSIES CONCERNING THE NUMBER OF ORGANS TO SAMPLE BY BIOPSY

Sarcoidosis has been defined as multisystem granulomatous disorder of unknown cause.[1] For this reason, it has been stated that the diagnosis of sarcoidosis requires demonstration of granulomatous inflammation in at least two organs.[1] This diagnostic criterion is controversial.[153] Sarcoidosis is clearly a systemic disease by virtue of its association with specific inflammatory syndromes such as anergy,[154] erythema nodosum,[26] and the recurrence of sarcoidosis in organ transplant recipients with sarcoidosis.[155] The presence of sarcoidosis in a second organ increases the specificity of the diagnosis by excluding conditions involving a single organ such as idiopathic granulomatous hepatitis[156,157] and localized granulomatous skin reactions. However, some clinical presentations are adequately specific for sarcoidosis that the diagnosis can be established on the basis of granulomatous inflammation in one organ. This belief is consistent with the National Institutes of Health *A Case Control Etiology of Sarcoidosis Study* (ACCESS), in which 50% of the sarcoidosis cohort enrolled by sarcoidosis experts had evidence of sarcoidosis in only one organ.[11]

Other multiorgan granulomatous syndromes should be considered in the differential diagnosis of sarcoidosis. These include infections such as tuberculosis. There are also some idiopathic multiorgan granulomatous diseases. Blau syndrome consists of granulomatous iritis, arthritis, and skin rash.[158,159] Blau syndrome may be distinguished from sarcoidosis because it is a genetic disorder[160] with an autosomal dominant pattern of inheritance with variable penetrance[158,159]; it has a lack of visceral (e.g., pulmonary) involvement, and it usually manifests before 12 years of age.

Necrotizing sarcoid granulomatosis is a type of systemic granulomatous vasculitis.[161,162] Because of vascular involvement, necrosis is a prominent feature, unlike in most cases of sarcoidosis. Although the lung is commonly involved, extrapulmonary involvement is also common.[163] It is debated whether necrotizing sarcoid granulomatosis is a distinct clinical entity or a form of systemic sarcoidosis.[163-165]

In summary, the diagnosis of sarcoidosis is never secure. Clinical criteria, including the presence of multiple organ involvement as reflected by a high Sarcoidosis Diagnostic Score, may provide sufficient confidence in the diagnosis.[99] The presence of granulomas in one or more organs further enhances the diagnostic certainty.

EVALUATION OF PULMONARY DISEASE

IMPORTANCE OF SYMPTOMS AND QUALITY OF LIFE

The evaluation of pulmonary disease in sarcoidosis patients relies on three major determinants: pulmonary function, chest imaging, and symptoms. The clinician often focuses on pulmonary function testing and chest imaging as methods to assess lung involvement. However, the patient's major concerns are how they feel and how their lung disease affects their quality of life, and clinicians need to understand that maximizing quality of life is of greater importance to the patient than maximizing an objective assessment of lung involvement or function. Dyspnea and cough are the major reasons for treatment of pulmonary sarcoidosis.

PULMONARY FUNCTION TESTING

Sarcoidosis is classically a restrictive lung disease with reduction of lung volumes, including *forced vital capacity* (FVC). However, many sarcoidosis patients have obstructive lung disease.[166,167] In fact, a significant proportion of sarcoidosis patients will have a normal FVC at the time of diagnosis.[11,116] Over time, some of these patients will develop more restrictive disease.[3,168] The *diffusing capacity for carbon monoxide* (D_{LCO}) is a more sensitive measure of early interstitial lung disease. Abnormalities in D_{LCO} are found in less than half of sarcoidosis patients.[169] These reduced values of D_{LCO} often predict a reduction in exercise capacity.[169,170] A disproportionately reduced D_{LCO} may also be an indicator of sarcoidosis-associated pulmonary hypertension.[171,172]

Clinical pulmonary exercise testing may be useful in assessing dyspnea and functional limitation in sarcoidosis patients.[169] Patients with normal lung function testing may still have abnormalities in exercise testing.[173] However, exercise testing is not well standardized and is relatively cumbersome to perform.

The *6-minute walk distance* (6MWD) test has been widely used to assess exercise capacity.[174] In sarcoidosis, reduction in 6MWD has been found to correlate with reduced FVC, fatigue, and quality-of-life measures.[175] Reduced 6MWD and oxygen desaturation have been found in patients with sarcoidosis-associated pulmonary hypertension.[175,176]

However, several factors besides cardiopulmonary function influence the 6MWD, including muscle strength, joint disease, neurologic symptoms, and the degree of motivation.[174,177]

LUNG IMAGING

The routine chest radiograph has been characterized by stages, originally proposed by Scadding, as described earlier.[101] The Scadding stage correlates with prognosis of the chest radiograph, but not with sarcoidosis itself. Patients with stage 1 (see Fig. 93.3) have a more than 80% chance of resolution of hilar adenopathy 2 to 5 years after presentation, whereas those with stage 3 (see Fig. 93.5) have a less than a 30% chance of resolving to a normal chest radiograph. Fibrotic changes (stage 4) do not resolve. The difficulty with chest radiographic staging is that it does not characterize extrapulmonary manifestations of sarcoidosis. In addition, there is significant variability in the classification of radiographic stage even among experienced radiologists.[178]

Comparing chest radiographs over time is an alternative to assessing the chest radiograph by Scadding staging. This comparison reading is commonly done in clinical practice. The change in the chest radiograph has been shown to have good reproducibility and correlates with changes in pulmonary function.[179,180] In one study, the interobserver agreement for comparison reading was superior to that using the Scadding scoring system.[178]

Another method used for assessing the chest radiograph is similar to a scoring system for pneumoconiosis.[181] This system scores the radiograph in four categories: reticulonodular opacities, mass opacities, confluence, and fibrosis. It was shown that the "reticulation" portion of this score detected changes after corticosteroid therapy[182] and after treatment with infliximab[183] versus placebo. The scoring system was reproducible with a good interobserver agreement.[178] However, the scoring is tedious and does not appear practical for routine clinical practice.

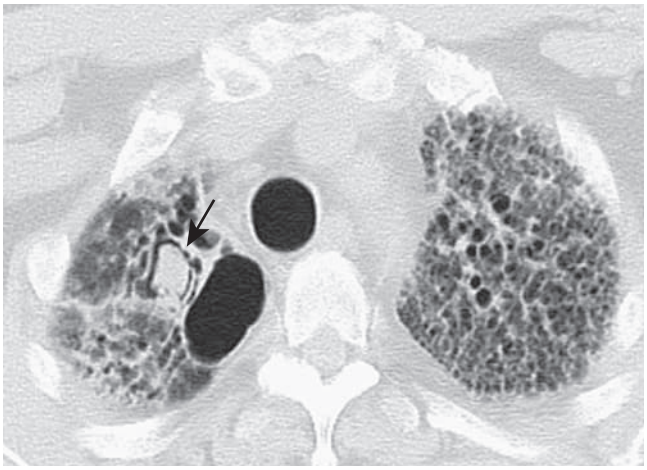

Figure 93.9 Aspergilloma in a patient with sarcoidosis. High-resolution computed tomography demonstrating upper lobe fibrosis with presence of an aspergilloma in the right upper lobe (*arrow*).

As noted earlier, chest CT imaging, including HRCT, has proved useful in the diagnosis of sarcoidosis (see Fig. 93.4).[184] A scoring system for CT scans in sarcoidosis has been described,[102] and it has been suggested to assess severity of disease.[185] However, it is unclear what features of the CT scan are important for management of the disease. Some HRCT scan features correlate with physiologic impairment in sarcoidosis, such as honeycombing, which is associated with reduced D_{LCO} and increased alveolar-arterial oxygen tension difference,[186,187] and peribronchial thickening, which may lead to airway obstruction and air trapping.[188,189] HRCT is useful in defining the extent of bronchiectasis and the presence of complications, such as aspergilloma (Fig. 93.9).[190] The extent of pulmonary fibrosis can be estimated from HRCT findings. Patients with more than 20% pulmonary fibrosis have increased mortality rates.[191,192]

Radionuclide scanning has been used as an aid in the diagnosis of sarcoidosis and the assessment of organ involvement.[140] Early studies focused on the gallium scan as a method of identifying inflammation.[193,194] The presence of extrapulmonary disease was often useful in identifying potential biopsy sites. In addition, uptake in the parotid and lacrimal glands ("panda sign") and/or right paratracheal and bilateral hilar areas ("lambda sign") was highly supportive of the diagnosis of sarcoidosis.[141] Octreotide scanning,[195] as well as somatostatin receptor scintigraphy,[140,195] has also been used as a marker of lung inflammation in sarcoidosis.

PET scan activity can be quite enhanced in sarcoidosis and can demonstrate diffuse activity in the lungs, mediastinal lymph nodes, and other parts of the body (see Fig. 93.8).[139,140] The PET scan proved useful in identifying potential biopsy sites in suspected sarcoidosis.[139] It has also been found to demonstrate ongoing activity in patients who are receiving immunosuppressive therapy and may suggest that the patient will have a relapse when therapy is withdrawn.[196,197] In a study comparing PET with gallium scan, the PET scan was found to be more sensitive and reproducible.[198]

PET may also provide clinically useful information. Patients with positive PET uptake demonstrated evidence of active disease by virtue of a significant improvement in their FVC and D_{LCO} with an increased immunosuppressive regimen and a significant fall in the D_{LCO} when therapy was not changed.[199] Additionally, a negative PET scan result was associated with a stable FVC and D_{LCO} without therapy.[199] The intensity of PET activity can be expressed as the *maximal standardized uptake value* (SUV_{max}) in a region of interest. In patients treated for pulmonary sarcoidosis, a linear relationship was shown between the reduction of SUV_{max} and improvement in FVC.[200] A fall in SUV_{max} has also been demonstrated with successful treatment of pulmonary sarcoidosis with a variety of immunosuppressive agents.[201-203]

Imaging of the heart with either PET or MRI scanning can detect cardiac involvement in sarcoidosis.[204] Cardiac MRI appears to be more sensitive and specific.[205] However, cardiac MRI requires special expertise to interpret properly and is contraindicated if an implanted defibrillator or pacemaker is not MRI compatible.

HEALTH-RELATED QUALITY OF LIFE

Sarcoidosis has been associated with impaired health-related quality of life.[206-208] In a survey of more than 1800 European patients with sarcoidosis, quality of life and functional status were more important to the patients than blood tests or pulmonary function test results.[209] These data have influenced sarcoidosis clinicians to focus more on patient priorities and less on objective test measurements of granulomatous inflammation or physiologic changes.[210] Health-related quality of life has been measured in sarcoidosis patients by using instruments that are not disease specific, such as the Short Form 36 (SF-36)[208,211,212] and the Saint George Respiratory Questionnaire.[213,214] Three sarcoidosis-specific quality-of-life instruments have been developed: the Sarcoidosis Health Questionnaire,[215] the King's Sarcoidosis Questionnaire,[206] and the Sarcoidosis Assessment Tool.[216]

Fatigue is a common complaint in sarcoidosis patients.[217,218] It has been reported by more than half of sarcoidosis patients in both Europe and the United States.[219] Although fatigue is a complaint in patients with pulmonary sarcoidosis, it is more common in those with extrapulmonary involvement.[220] Fatigue may persist long after other evidence of disease has regressed.[218] Several fatigue scales that have been used for sarcoidosis are not disease specific.[217,220,221] The Fatigue Assessment Scale and Sarcoidosis Assessment Tool fatigue module are sarcoidosis-specific fatigue questionnaires.[216,222]

SARCOIDOSIS-ASSOCIATED PULMONARY HYPERTENSION

Sarcoidosis-associated pulmonary hypertension (SAPH) can be caused by a variety of mechanisms, including left ventricular diastolic dysfunction, pulmonary arterial vasculitis, pulmonary veno-occlusive disease, pulmonary fibrosis, and hypoxia.[223] The overall incidence of pulmonary hypertension in sarcoidosis appears to be 5–15%.[171,176,224,225] However, in patients with moderate to severe pulmonary symptoms, the rate of pulmonary hypertension has been reported to be 50% or greater.[172,226-228] Precapillary pulmonary hypertension is the most common cause of SAPH, but left ventricular diastolic dysfunction is a cause in a significant proportion of cases.[225,228] More than one-third of SAPH patients have moderate to severe pulmonary hypertension, with a mean pulmonary artery pressure greater than 35 mm Hg.[229,230] The survival of patients with precapillary SAPH is significantly worse than in patients with SAPH and diastolic dysfunction.[228]

EVALUATION FOR EXTRAPULMONARY DISEASE

GENERAL CONSIDERATIONS

Sarcoidosis is a multiorgan disease. Pulmonary involvement has been reported in more than 90% of cases in most large series.[11,116,231] However, several other organs are commonly affected with the disease. Table 93.3 lists organ involvement as detected by two large clinics in the United States including a total of more than 2700 patients.[231] Both groups used the same standardized criteria for organ involvement and listed only those organs with definite or probable disease.[232]

EYE

The eye is involved in about one-third of patients in the United States and Europe. Eye disease is more common in African Americans and women.[11,231] In Japan, up to 80% of patients with sarcoidosis have eye disease.[233] Table 93.4 lists some of the more common ocular manifestations of sarcoidosis.[234] Uveitis is the most common manifestation of ocular sarcoidosis and at times can be clinically silent.[235] It is recommended that all sarcoidosis patients undergo an ocular examination by a specialist at the time of initial evaluation.[1] Patients with ocular sarcoidosis may develop complications from eye involvement such as sicca syndrome, glaucoma, and cataracts. Cataracts and glaucoma can also be complications of local or systemic corticosteroid treatment.

Table 93.4 Areas of Eye Involvement in Sarcoidosis

Figure 93.10 Multiple skin lesions associated with chronic cutaneous sarcoidosis. (A) Lupus pernio. Violaceous nodular plaques on the nose, cheek, and lip. (B) Lupus pernio. Violaceous swelling of the distal digits. (C) Papular sarcoidosis. Multiple papules in a periorbital distribution. (D) Cutaneous sarcoidosis manifesting as pink, indurated areas within and around a tattoo.

SKIN

The skin is involved in about one-third of sarcoidosis patients.[236] Skin manifestations include maculopapular lesions, papules, hyperpigmentation, and hypopigmentation (Fig. 93.10).[237] Lupus pernio is a disfiguring facial lesion specific for sarcoidosis.[238] It is more common in African Americans . It is usually chronic,[239] and it can be resistant to usual therapy.[240] Erythema nodosum, as noted earlier, is often, but not always, associated with a good prognosis.[26] In particular, African Americans with erythema nodosum often have chronic disease.[241] In addition, a study of Scandinavian patients with Löfgren syndrome found that those who had the HLA DRB1*03 polymorphism uniformly had an excellent prognosis, whereas those lacking this antigen had unresolving disease almost half the time.[26]

NERVOUS SYSTEM

Neurologic disease can develop centrally, affecting the spinal cord, causing meningitis, or involving the cranial nerves.[242-244] The most sensitive method of detecting neurologic disease is with an MRI scan with gadolinium contrast because neurologic lesions often enhance.[244,245] Spinal fluid analysis may demonstrate lymphocytosis and elevated protein levels.[245] An elevated level of ACE in spinal fluid has been reported to be specific for neurosarcoidosis, but the sensitivity is as low as 50%.[246] In patients suspected of having neurosarcoidosis, especially those who present with isolated disease,[247] multiple sclerosis should be considered as an alternate diagnosis.[248] As in multiple sclerosis, patients with sarcoidosis can develop optic neuritis with or without uveitis.[249] It is important to distinguish patients with neurosarcoidosis from those with multiple sclerosis because neurosarcoidosis patients often improve with treatment, including anti-TNF treatments such as infliximab.[249,250]

HEART

The heart can be affected by sarcoidosis with two major manifestations: arrhythmias and reduced ejection fraction. The detection of cardiac sarcoidosis can be quite difficult.[251] The presence of cardiac symptoms, including palpitations and syncope, is as good as or better than any single screening test for cardiac sarcoidosis.[204,252] Rhythm monitoring and echocardiography are useful supplemental tests for screening.[204] Currently, imaging with MRI and/or PET scanning is believed to be the most specific for diagnosing cardiac sarcoidosis.[251] Arrhythmias, especially ventricular arrhythmias, remain a potential cause of death in cardiac sarcoidosis.[253] However, the use of implantable defibrillators has markedly reduced the mortality from this manifestation.[254,255] The role of prophylactic defibrillators is controversial but, at a minimum, patients with potential cardiac sarcoidosis should be screened for ventricular arrhythmias.

LIVER

Liver involvement is common in sarcoidosis.[256] The usual pattern of serum chemistry markers includes elevated alkaline phosphatase, but elevated transaminases have been seen.[147,257] Imaging of the liver with contrast CT scan can support the diagnosis. Liver biopsy usually detects granulomatous disease, even in patients with no symptoms or blood chemistry abnormalities.[147,257,258] Liver sarcoidosis can lead to end-stage hepatic fibrosis, but this is uncommon.

VITAMIN D DYSREGULATION

Hypercalcemia or hypercalcuria has been reported in up to 30% of sarcoidosis patients.[259,260] The most common mechanism is from excessive levels of $1,25\text{-}(OH)_2$ vitamin D_3 secondary to autonomous 1-α-hydroxylase activity.[261,262]

*The grading scheme classifies recommendations as strong (grade 1) or weak (grade 2), according to the balance among benefits, risks, burdens, and possibly cost, and the degree of confidence in estimates of benefits, risks, and burdens. The system classifies quality of evidence as high (grade A), moderate (grade B), or low (grade C) according to factors that include the study design, the consistency of the results, and the directness of the evidence.

From James WE, Baughman R. Treatment of sarcoidosis: grading the evidence. *Expert Rev Clin Pharmacol*. 2018;11:677-687.

Levels of 1,25-$(OH)_2$ vitamin D_3 may be elevated despite low levels of 25-(OH) vitamin D_3.[259] There are other causes of hypercalcemia in sarcoidosis, including hyperparathyroidism.[259] Hypercalcemia in sarcoidosis patients can be associated with renal failure, which may reverse with treatment of the hypercalcemia.[263]

PARASARCOIDOSIS SYNDROMES

Besides specific sarcoidosis organ involvement, sarcoidosis may also cause symptoms or abnormalities not directly related to granulomatous tissue invasion or fibrosis. These entities are collectively known as *parasarcoidosis syndromes.*[264] Parasarcoidosis syndromes include sarcoidosis-associated fatigue, small fiber neuropathy, pain syndromes, depression, cognitive impairment, Löfgren syndrome, and vitamin D dysregulation. Because many of these syndromes are not directly related to granuloma formation, the treatment of many of them requires nonstandard therapies.

TREATMENT

GENERAL CONSIDERATIONS

The treatment of sarcoidosis requires consideration of sarcoidosis-related inflammation, the consequences of the disease, and the consequences of therapy. Table 93.5 lists these aspects of the disease and potential treatments that have been reported, with a level of evidence to support their use in sarcoidosis.[265-267]

ANTI-INFLAMMATORY AGENTS

General Comments

Because sarcoidosis patients are frequently asymptomatic and many have spontaneous resolution of their sarcoidosis within 6 months of diagnosis,[182] not all patients require initial therapy.[182,268,269] Usually, the decision to treat patients is based on symptoms and, when sarcoidosis involves the lungs, on a decline in pulmonary function.[268]

Corticosteroids

Corticosteroids remain the most widely used, well-documented, and most effective treatments for sarcoidosis; however, many patients require treatment for a prolonged time (>1 year), and steroid-sparing medications should be considered early in treatment.[5,270,271]

The reported initial dose of corticosteroids varies widely. In one retrospective study of patients with exacerbations of pulmonary sarcoidosis, a short course of prednisone (20 mg/day) led to a significant improvement in FVC and pulmonary symptoms in less than 1 month.[272] Whatever dose of steroid is selected, once the patient has shown improvement, the dose of drug is usually tapered to minimize toxicity but maintain benefit from the initial induction of response. In some cases, the patient may have a relapse as treatment is being reduced, thus leading to a return to a higher

dosage.[273] Slow withdrawal over the course of months is usually recommended.[274] Even those patients treated with glucocorticoids for 2 or more years have at least a 50% chance of relapse when drug is withdrawn.[275,276]

Patients who do not respond to the equivalent of prednisone 40 mg daily are considered refractory to standard treatment and should be considered for alternative therapy. However, such patients are relatively rare.

Rationale for Corticosteroid-Sparing Agents

For patients who are started on therapy, a significant percentage will require long-term treatment beyond 2 years.[182,268,269,274,277] Corticosteroid-sparing agents and alternative agents are often considered in sarcoidosis patients who require corticosteroids for more than 1 year because significant cumulative toxicities from corticosteroids are common. Evidence-based recommendations have been published regarding monitoring patients while being treated for pulmonary disease for many of the nonsteroidal immunosuppressive agents.[278]

Antimalarial Agents

The antimalarial agents chloroquine and hydroxychloroquine are effective in treating certain aspects of extrapulmonary disease,[279,280] especially cutaneous and sinonasal disease.[279,281] They have also proved useful in treating hypercalcemia,[282] and they may be more effective in treating sarcoidosis-associated fatigue than other anti-inflammatory agents.[219] The major toxicity encountered with antimalarial agents has been ocular. Hydroxychloroquine appears to have a lower rate of ocular toxicity. However, routine screening is still recommended.[283-285] For most patients, a hydroxychloroquine dose of less than 5 mg/kg of real body weight appears to be safe.[286]

Antimetabolites

Methotrexate is a commonly used steroid-sparing cytotoxic agent for sarcoidosis.[270,287] Methotrexate has been shown to be effective in remitting and persistent disease, as well as in ocular,[234,288] cutaneous,[289-291] sinus,[292,293] and neurologic disease.[294,295] A major potential toxicity of methotrexate and other cytotoxic drugs is bone marrow suppression. The effect is dose dependent. Evidence-based and expert opinion recommendations for monitoring patients while receiving methotrexate therapy have been published.[278,296]

Azathioprine is another cytotoxic agent commonly used in chronic sarcoidosis. Limited data suggest that it is as effective as methotrexate, but it results in greater toxicity.[297] It has been shown to be effective in pulmonary[298] and extrapulmonary disease.[292,299,300] Compared with other cytotoxic agents, azathioprine is associated with a greater risk for malignancy and myelodysplastic syndrome.[301]

Leflunomide is an antimetabolite similar in action to methotrexate originally developed for treating rheumatoid arthritis.[302] It has been reported to be effective in treating sarcoidosis either alone or in combination with methotrexate.[303,304] Compared with methotrexate, the drug has less gastrointestinal toxicity but a similar rate of liver function test abnormalities.[302] Although pulmonary toxicity with leflunomide is less common than with methotrexate, leflunomide can still cause pulmonary toxicity.[305,306] Leflunomide can also cause peripheral neuropathy that usually resolves with discontinuation of the drug.[307,308]

Mycophenolate analogues have been increasingly used to treat inflammatory lung diseases.[309,310] They have been reported to be effective as steroid-sparing agents for patients with persistent disease, especially neurosarcoidosis.[311,312] In a retrospective report of neurosarcoidosis patients, mycophenolate was associated with a higher rate of relapse than methotrexate.[313] Although mycophenolate treatment is associated with less bone marrow and hepatotoxicity, it is associated with significant gastrointestinal and infectious complications.[314]

Tumor Necrosis Factor Antagonists

Infliximab is a chimeric monoclonal antibody directed against TNF. It was first shown to be effective in treating refractory sarcoidosis in 2001.[315,316] The drug has been widely used for various forms of refractory disease, including pulmonary, skin, eye, and neurologic disease.[317-321] Two double-blind placebo-control trials demonstrated a benefit of infliximab as additional therapy to maintenance therapy.[183,212] The drug has also proved to be effective for some patients with extrapulmonary disease.[322,323] In a large retrospective study of patients with lupus pernio, infliximab was superior to all other treatment options[240] and was superior to placebo in a randomized trial.[324] It has also proved to be useful in treating refractory neurosarcoidosis.[325,326] Adverse effects of the drug may be considerable, and a high rate of relapse has been reported within a year after the drug is withdrawn.[327]

The toxicity of infliximab includes an allergic reaction to the chimeric antibody that can manifest as an acute reaction, including anaphylaxis, vasculitis, or a subacute, lupus-like reaction.[328] Infliximab has also been associated with a high risk for reactivation of tuberculosis.[329] This risk for reactivation can be significantly reduced by adhering to guidelines for screening and treating latent tuberculosis.[330] Testing for latent tuberculosis with skin testing may not be adequate in sarcoidosis because anergy is common and can interfere with the skin test. [331] A quantitative interferon-γ test seems to be more reliable for screening for latent tuberculosis in anergic or immunosuppressed patients.[332] The anti-TNF treatments are believed to be relatively contraindicated in advanced congestive heart failure because one large study demonstrated increased mortality in patients with advanced heart failure who were treated with infliximab.[333] However, infliximab has been used successfully in treatment of cardiomyopathy secondary to sarcoidosis.[334-336] The potential increased risk for malignancy with the use of anti-TNF agents is still unclear. In rheumatoid arthritis, a meta-analysis found an increased incidence only of nonmelanoma skin cancers.[337] However, another study suggested a potential increased risk for lymphoma, although the relative risk was not significantly increased compared with control subjects.[338] The risk for developing cancer in sarcoidosis patients treated with anti-TNF therapy is unknown, and one should remain cautious regarding this risk when using this class of drugs.

Adalimumab, a totally humanized anti-TNF antibody, has been reported to be effective in treating some sarcoidosis cases.[321,339-341] In a randomized trial, it was superior to placebo for chronic cutaneous disease.[342] Compared

with infliximab, adalimumab appears to have a lower response rate and takes longer to demonstrate effectiveness.[320] This finding may reflect the relatively lower doses of drug initially used. For example, adalimumab was shown to be more effective in treating Crohn disease when a higher induction and maintenance dose was used.[343] This higher dose of the anti-TNF antibody may be necessary to achieve clinical response in sarcoidosis, but it remains unclear how often these increased doses are required.[344] Golimumab, another humanized monoclonal anti-TNF antibody, failed to demonstrate efficacy for the treatment of lung and skin sarcoidosis, possibly as the result of an inadequate dosing regimen.[345] Etanercept is a TNF-receptor antagonist and has been reported to be effective in some cases of refractory sarcoidosis.[346] However, the drug was not found to be effective in an open-label trial of pulmonary sarcoidosis[347] or in a placebo-controlled, double-blind randomized controlled trial of ocular sarcoidosis.[348]

Interestingly, patients treated with anti-TNF therapy can develop a granulomatous disease indistinguishable from sarcoidosis.[349,350] The mechanism of this reaction is unknown, but one possible mechanism is through T regulatory cells.[351] As noted earlier, abnormalities of T regulatory cells have been described in sarcoidosis.[83,352] There are several new anti-inflammatory therapies being evaluated in sarcoidosis.[5]

Given the high cost of anti-TNF therapy, there is a recent interest in the use of biosimilars of these agents for the treatment of sarcoidosis. A recent retrospective report found a biosimilar to infliximab to be effective in advanced sarcoidosis.[202] We suspect that biosimilars will be more frequently used for the treatment of sarcoidosis in the future.

APPROACH TO EXTRAPULMONARY DISEASE

In general, the treatment of extrapulmonary disease is similar to the treatment of pulmonary disease. However, there are a few special considerations. For ocular sarcoidosis, local therapy with topical steroids, periocular steroid injections, and steroid implants may be sufficient to control disease.[234] However, use of corticosteroids may cause cataracts or glaucoma. Therefore, the use of cytotoxic agents such as methotrexate should be considered early in the management of chronic ocular sarcoidosis.[288,321] For cutaneous sarcoidosis, patients may often respond to hydroxychloroquine or local corticosteroid therapy.[281,353] However, lupus pernio requires long-term therapy, with infliximab proving to be superior to corticosteroid or cytotoxic therapy.[354] Neurologic disease often requires more intense treatment with either higher doses of corticosteroids or cytotoxic treatments.[294] Anti-TNF treatment may be particularly helpful in the treatment of refractory neurosarcoidosis.[312,355]

FIBROTIC SARCOIDOSIS

Patients with significant pulmonary fibrosis from sarcoidosis have increased mortality.[187,191,192] The fibrosis usually appears in the upper lobes and can lead to airway distortion and cystic changes (Fig. 93.11 and eFig. 93.3). Radiographic and histologic data suggest that the fibrosis in sarcoidosis is derived from the granulomatous inflammation.[356,357] To date, there is limited understanding of the pathophysiologic mechanisms that underlie fibrosis, and no specific therapy is known to be effective for the fibrotic component of sarcoidosis.[358] Supportive care is the mainstay of therapy for these patients. This includes

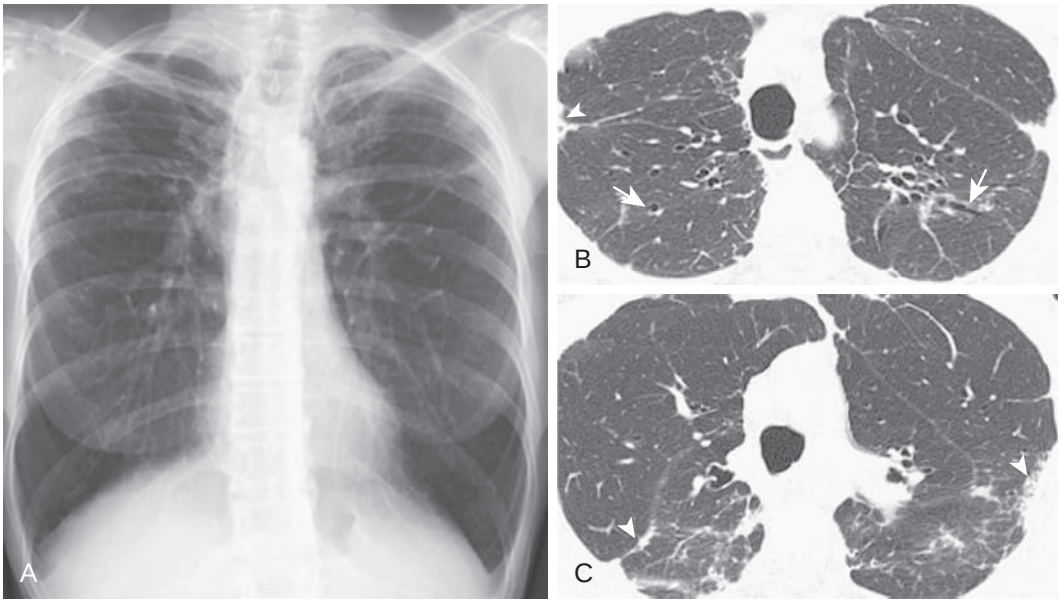

Figure 93.11 Sarcoidosis: Scadding stage 4. (A) Frontal chest radiograph shows upper lobe linear and reticular opacities associated with architectural distortion consistent with a fibrosing process; note bilateral superior hilar retraction. Little pleural abnormality is noted; this image is typical of granulomatous inflammation secondary to sarcoidosis, as opposed to granulomatous infections. (B–C) Axial chest computed tomography in lung windows shows patchy, upper lobe linear opacities associated with architectural distortion and traction bronchiectasis *(arrows)*. Subpleural and perifissural nodular opacities *(arrowheads)* are present. (Courtesy Michael B. Gotway, MD.)

Table 93.6 Treatment of Sarcoidosis-Associated Pulmonary Hypertension

Class	Therapy	Significant Improvement	Improvement Seen in Some Cases
Prostanoids	Epoprostenol[363,364]		Improved hemodynamics
	Iloprostenol[365]		Improved hemodynamics and HRQoL
Endothelin-receptor antagonists	Bosentan[369]	Improved hemodynamics	
	Ambrisentan[366]		Improved HRQoL
Phosphodiesterase-5 inhibitors	Sildenafil[370]		Improved hemodynamics
Combination therapy	PAH-specific therapy[390]	Improved hemodynamics	Improved 6MWD

HRQoL, health-related quality of life; 6MWD, 6-minute walk distance.

facilitation of mucociliary clearance and treatment of infections associated with bronchiectasis, supplemental oxygen, and pulmonary rehabilitation when appropriate.[359] Focus should be on the treatment of superimposed infections because they are common complications of the bronchiectasis seen in fibrotic sarcoidosis. These infections may be among the events leading to acute decompensation.[360]

LUNG TRANSPLANTATION

Lung transplantation has been successfully performed in sarcoidosis patients.[361] Patients may develop granulomas in the transplanted lung.[155] The clinical outcome of transplant recipients is seldom altered by recurrence, however, because posttransplant immunosuppression is often adequate treatment for the sarcoidosis. [360,362]

PULMONARY HYPERTENSION

For precapillary *sarcoidosis-associated pulmonary hypertension* (SAPH), several pulmonary hypertension agents have been studied. Table 93.6 lists some of the studies that were specifically designed to determine the efficacy of treatment, including the prostanoids, including intravenous prostacyclin (epoprostenol)[363,364] and inhaled iloprost.[365] Long-term use of intravenous epoprostenol was associated with prolonged clinical improvement in some cases.[363] The endothelin-receptor antagonists have also been reported to be safe in treating SAPH.[366-368] A double-blind, placebo-controlled study demonstrated significant improvement of pulmonary hemodynamics for SAPH patients treated with bosentan but not for those treated with placebo.[369] Sildenafil has also been shown to improve hemodynamics in patients with SAPH.[370]

For several of the studies cited in Table 93.6, the response to treatment for SAPH was in pulmonary hemodynamics and/or quality of life.[365,366,370] In part, that was because the studies examined patients only after a relatively short period, usually 4 months. In one study that evaluated SAPH patients after more prolonged therapy, there was not only improvement in hemodynamics, but also improvement in 6MWD.[367] However, that improvement in 6MWD was seen only in patients with mild to moderate restrictive disease and was unusual in patients with an FVC of less than 50% of predicted value. In one large series, SAPH treatment usually improved hemodynamics, but it did not improve 6MWD.[230]

FATIGUE

As noted earlier, fatigue is a common manifestation of sarcoidosis.[217] Fatigue can be associated with several factors, including diabetes, depression, sleep apnea, and corticosteroid withdrawal.[371,372] Sleep apnea is a common problem in sarcoidosis patients, especially those patients who have been treated with glucocorticoids.[372-374] However, even after treatment of sleep apnea, fatigue may persist.[375]

The neurostimulants such as methylphenidate appear to be effective in treating sarcoidosis-associated fatigue.[376] The benefits associated with treatment of fatigue should always be weighed against the risks associated with the side effects of neurostimulants. In a double-blind, placebo-controlled crossover trial of d-methylphenidate, sarcoidosis-associated fatigue was 30% lower during active treatment versus placebo.[221] A limitation of methylphenidate is the short half-life of the drug that often requires an afternoon dose, which may lead to insomnia. Long-acting preparations of methylphenidate may be preferred for this reason. Armodafinil is a neurostimulant-like drug. In a double-blind, placebo-controlled crossover trial, armodafinil was found to reduce fatigue significantly more than placebo.[375]

SMALL FIBER NEUROPATHY

Small fiber neuropathy is common with sarcoidosis,[377] and there is a relationship between small fiber neuropathy and fatigue.[378] Several agents have been used with varying success in sarcoidosis-associated small fiber neuropathy. Although drugs for neuropathic pain are often the initial medications of choice, these agents have limited efficacy, and anti-TNF therapy and intravenous gamma globulin have been found to be more effective.[377,379]

MYCETOMA

Fungal infections, especially aspergillomas, are complications of advanced fibrotic sarcoidosis usually associated with immunosuppressive therapy.[6,187,380-382] Aspergillomas may be associated with fatal hemoptysis. The risks and benefits of medical and surgical therapy vary with the manifestations of disease and the patient's pulmonary status. Therefore, the approach to therapy must be individualized. For the acute management of massive hemoptysis, bronchial artery embolization may be effective, at least in the short term.[383] In patients with good pulmonary function, surgical resection is offered to prevent or treat potentially life-threatening hemoptysis, and it is usually curative. The

medical treatment of aspergillomas includes azole therapy.[6,384,385] The evidence regarding the efficacy of long-term antifungal therapy for chronic cavitary pulmonary aspergillosis is based on small case series and open-label, noncomparative studies.[384,386] Limited data suggest that intracavitary amphotericin may be effective on a short-term basis in treating selected cases of aspergillomas in sarcoidosis patients.[387]

BONE HEALTH

Because sarcoidosis patients often have high levels of 1,25-$(OH)_2$ vitamin D_3 there usually is no reason for supplementation of vitamin D.[388] However, osteopenia or osteoporosis may improve with bisphosphonates.[389]

Key Points

- Sarcoidosis is characterized by an enhanced granulomatous response to an unknown antigen or antigens, although autoimmunity related to molecular mimicry may also be involved.
- Although many patients with sarcoidosis have resolution of their disease within 2 years, a significant proportion will have chronic disease—with roughly a quarter of all patients still requiring systemic therapy more than 2 years after diagnosis.
- The diagnosis of sarcoidosis relies on recognition of a clinical pattern consistent with disease, exclusion of other conditions that can cause granulomatous inflammation and, in most cases, a biopsy demonstrating granulomas.
- Identification of extrapulmonary disease is important not only to identify other potential causes of morbidity in sarcoidosis but also to help bolster confidence in the diagnosis.
- Quality of life and functional status are more important issues for patients than quantitative measures of organ function. Fatigue, chest discomfort, and depression are conditions that lead to poor quality of life for patients with chronic sarcoidosis.
- Systemic treatment of sarcoidosis, usually initially with glucocorticoids, is indicated when the patient has symptoms. Steroid-sparing agents are most useful for patients with chronic disease or those encountering toxicity with glucocorticoids.
- Treatment of sarcoidosis also includes therapy for any nongranulomatous aspects of disease, including fatigue, small fiber neuropathy, and pulmonary hypertension.

KEY POINTS

INTRODUCTION

Diffuse alveolar hemorrhage (DAH) is a life-threatening condition characterized by widespread intra-alveolar hemorrhage originating from the pulmonary microcirculation (arterioles, capillaries, and venules). DAH can arise as a complication of many disease states and often as the initial manifestation. Unlike the more common forms of pulmonary bleeding resulting from focal lesions (e.g., necrotizing pneumonia, bronchitis, bronchiectasis, malignancy, pulmonary infarction, arteriovenous malformation), DAH involves the majority of the alveolar capillary surface. DAH is a medical emergency that often results in acute respiratory failure and death. Pulmonologists must be prepared to identify DAH promptly, diagnose the underlying disease causing it, and institute appropriate medical therapy. DAH is defined on clinical grounds, including radiographic findings of diffuse pulmonary opacities, varying degrees of respiratory failure, a falling hemoglobin level, and progressively bloody return (increasing red blood cell counts) on sequential *bronchoalveolar lavage* (BAL) specimens.

CLASSIFICATION

There is no consensus classification schema for DAH, although clinical, histopathologic, and etiologic approaches have all been suggested.[1,2] One approach is presented here (Table 94.1). The various causes of DAH are diverse; any source of injury to the alveolar microcirculation may contribute. The most common causes of DAH are the systemic vasculitides, in particular *granulomatosis with polyangiitis* (GPA) (Fig. 94.1). Other vasculitides are also implicated, including *microscopic polyangiitis* (MPA) and isolated pulmonary capillaritis. A review of 34 cases of DAH found that vasculitis accounted for about one-half of the cases, followed by *anti–glomerular basement membrane disease* (anti-GBM disease, formerly Goodpasture syndrome) (13%), *idiopathic pulmonary hemosiderosis* (IPH; 13%), and connective tissue disease (13%).[3]

CLINICAL PRESENTATION

The clinical presentation of DAH includes hemoptysis, alveolar opacities on chest radiograph, and anemia.[1] However, some cases show only one or two of these features; the absence of classic features does not exclude DAH. In up to 33% of cases, hemoptysis is initially absent.[4] Other symptoms are nonspecific (e.g., dyspnea, cough, chest pain, fever), although, in some cases, disease-specific symptoms (e.g., sinusitis, rash, arthritis) may be present. In general, symptoms are usually of short duration, manifest from days to several weeks, and may be recurrent. The lung examination is nonspecific, with inspiratory crackles common but not universal. There may also be physical findings suggesting a systemic disease.

LABORATORY FINDINGS

Laboratory evaluation usually reveals anemia and leukocytosis. Serum creatinine levels may be elevated. BAL reveals a bloody return that, with each aliquot obtained from the same location, becomes progressively bloodier (Fig. 94.2). BAL shows increased sequential red blood cell counts even in patients who do not report hemoptysis. The reason for this increasing red blood cell count is not known, but it may be caused by increased sampling with each aliquot of the bleeding at the most distal area of the lung; bleeding at a more proximal site (e.g., bronchial bleeding) may instead be diluted with each aliquot. On examination of the BAL sediment, there is a predominance of red blood cells and hemosiderin-containing macrophages.

RADIOLOGIC FEATURES

The chest radiograph in DAH shows varying degrees of diffuse alveolar opacities (Fig. 94.3; see also eFigs. 87.3A,

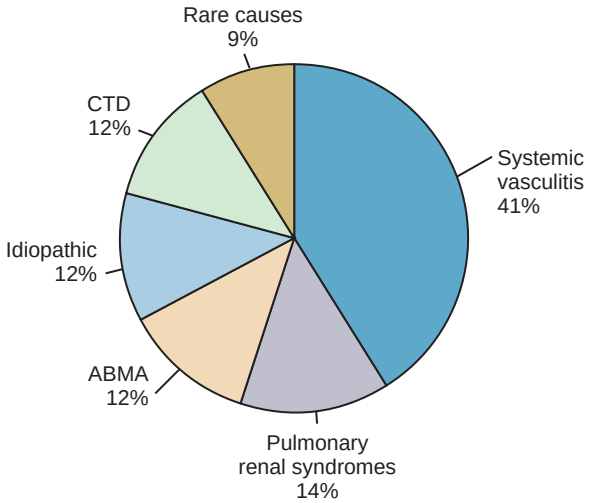

Figure 94.1 Causes of diffuse alveolar hemorrhage. A retrospective review of 34 cases of diffuse alveolar hemorrhage found systemic vasculitis to be the most common cause (14 cases: 5 definite granulomatosis with polyangiitis, 6 probable, and 3 unclassifiable), followed by unclassifiable pulmonary renal syndromes (5 cases), anti–glomerular basement membrane disease (Goodpasture syndrome; 4 cases), idiopathic (4 cases), *connective tissue disease* (CTD; 4 cases: 2 systemic lupus erythematosus, 1 rheumatoid arthritis, 1 juvenile rheumatoid arthritis), and other rare causes (3 cases: 2 idiopathic glomerulonephropathy, 1 immunoglobulin A nephropathy). ABMA, anti–glomerular basement membrane antibody. (Data from Travis WD, Colby TV, Lombard C, Carpenter H. A clinicopathologic study of 34 cases of diffuse pulmonary hemorrhage with lung biopsy confirmation. *Am J Surg Pathol.* 1990;14:1112–1125.)

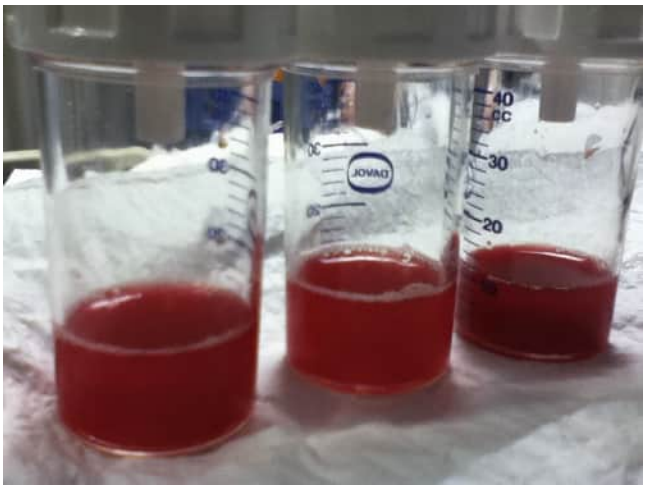

Figure 94.2 Sequential bronchoalveolar lavage specimens showing increasing bloody appearance diagnostic of diffuse alveolar hemorrhage. These bronchoalveolar lavage specimens, sequential in order from left to right, were obtained from the same location of the lung in a patient with granulomatosis with polyangiitis. (Courtesy Dr. Sixto Arias, Johns Hopkins University.)

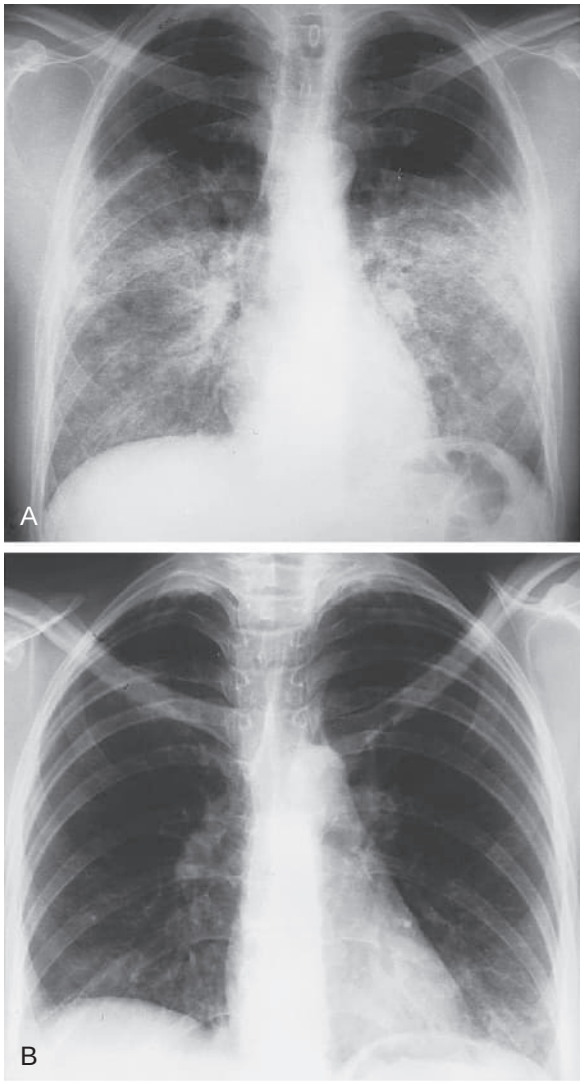

Figure 94.3 Diffuse alveolar hemorrhage. Chest radiographs show diffuse alveolar opacities in a patient with microscopic polyangiitis (A) and in a patient with granulomatosis with polyangiitis (B).

87.9A, and 87.10A).[5] *High-resolution computed tomographic* (HRCT) imaging is more sensitive for radiographic abnormalities and generally shows bilateral ground-glass opacities or patchy consolidation and occasionally centrilobular nodules. Nonetheless, it is important to recognize that the HRCT appearance of pulmonary hemorrhage is variable and not specific for a particular cause or for DAH itself (Fig. 94.4; see also eFigs. 87.3B–E, 87.9B–E, and 87.10B–E, and Fig. 125.4). With recurrent and chronic disease, reticulation may appear, providing evidence of interstitial fibrosis. Interlobular septal thickening (Kerley B lines) (eFig. 94.1) may occasionally be present in cases of mitral stenosis and *pulmonary veno-occlusive disease* (PVOD).

PHYSIOLOGIC FEATURES

When measured, there are features of a restrictive lung disease with gas exchange abnormalities. In acute DAH, an increase in the diffusing capacity for carbon monoxide can be present, attributed to the increased binding of carbon monoxide to intra-alveolar hemoglobin.[6] This will generally resolve in 48 to 72 hours, as hemoglobin is degraded

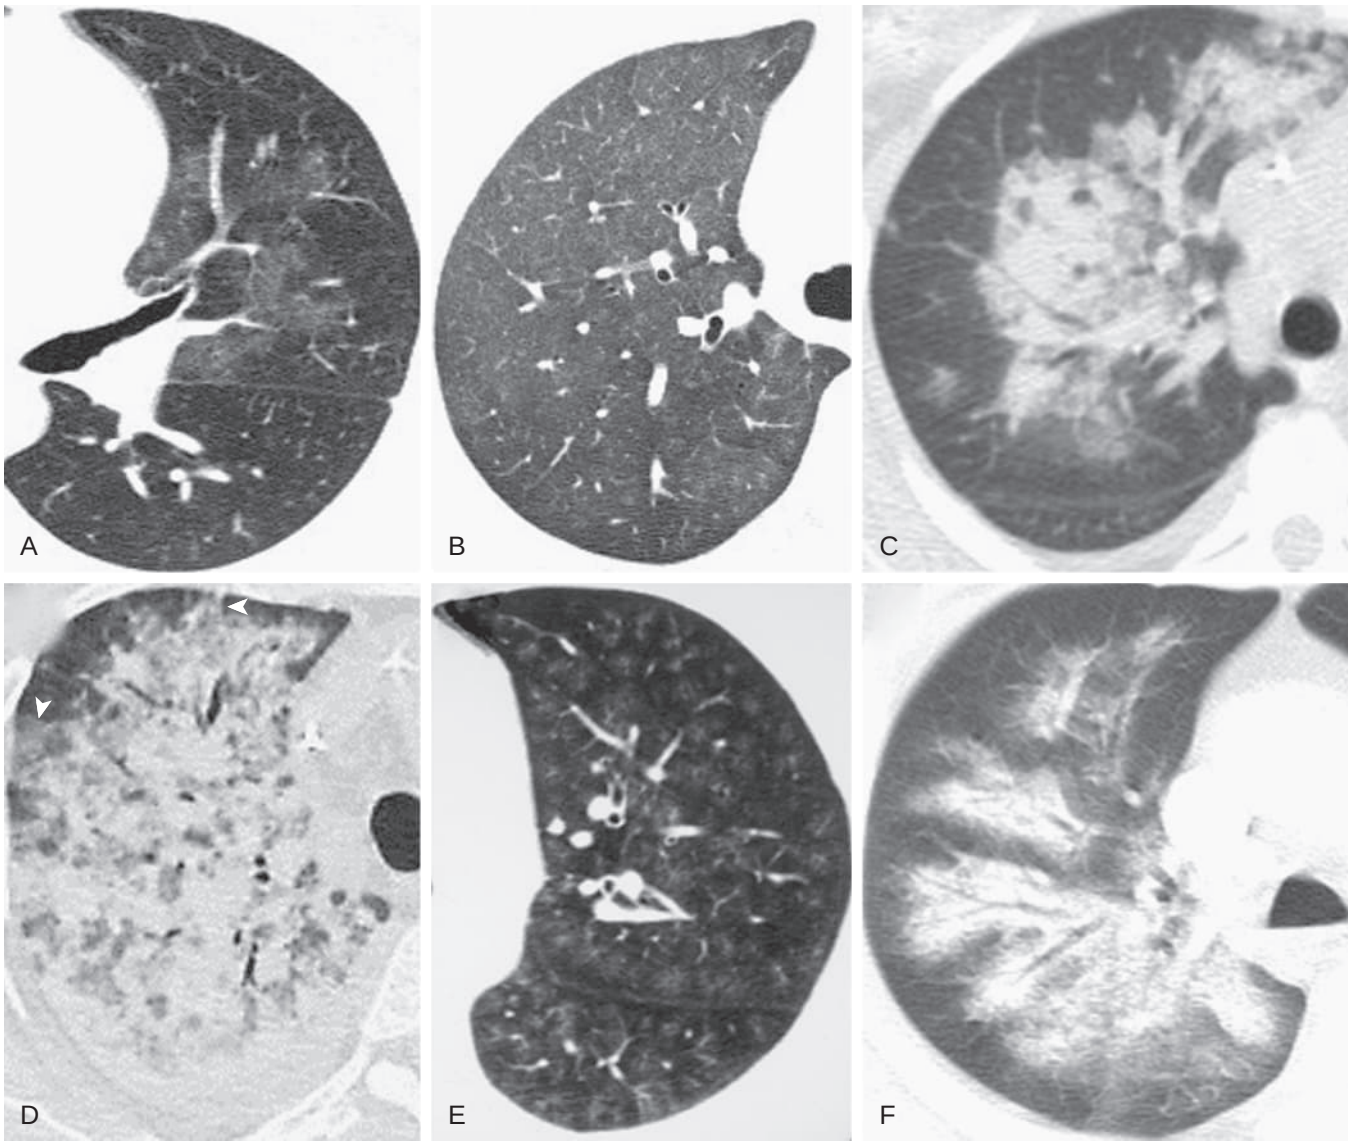

Figure 94.4 High-resolution computed tomographic appearance of diffuse alveolar hemorrhage. Axial chest computed tomographic images in different patients with various causes of diffuse alveolar hemorrhage showing the variable computed tomographic manifestations of pulmonary hemorrhage. The features of diffuse alveolar hemorrhage on high-resolution computed tomography are nonspecific and can be seen with any cause. (A) Patchy, geographic ground-glass opacity in a patient with granulomatosis with polyangiitis. (B) Vague, extensive multifocal ground-glass opacity in a patient with systemic lupus erythematosus. (C) Dense consolidation with air bronchograms in a patient with microscopic polyangiitis. (D) Consolidation and ground-glass opacity with a background of linear opacities representing interlobular septal thickening (*arrowheads*) in an overly anticoagulated patient undergoing antiplatelet therapy. (E) Hazy ground-glass opacity in a patient with hemosiderin-laden macrophages on bronchoalveolar lavage, with presumed idiopathic pulmonary hemosiderosis. (F) Extensive peribronchovascular thickening and peribronchial consolidation and ground-glass opacity in a patient with granulomatosis with polyangiitis. Solid centrilobular nodules can also be manifestations of pulmonary hemorrhage. (Courtesy Michael B. Gotway, MD.)

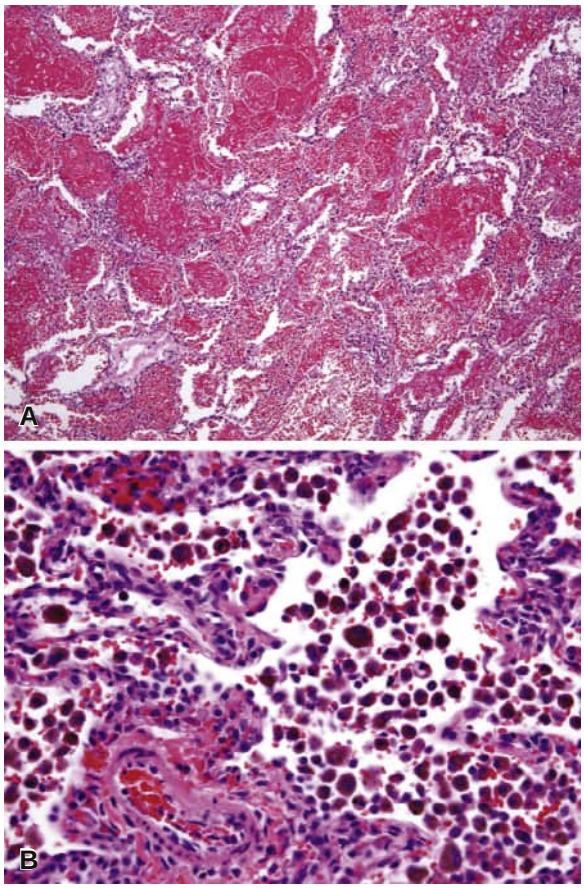

Figure 94.5 Histopathologic findings of diffuse alveolar hemorrhage. (A) In acute diffuse alveolar hemorrhage, the alveoli show filling and distention by red blood cells admixed with fibrin. (B) Chronic alveolar hemorrhage shows numerous hemosiderin-filled macrophages within air spaces. The alveolar septa may show mild fibrosis. (Courtesy Dr. Kirk Jones, University of California, San Francisco.)

into hemosiderin.[7] Varying degrees of hypoxemia result from the ventilation-perfusion abnormalities produced by the alveolar hemorrhage, and patients often require ventilatory support.

HISTOPATHOLOGIC FEATURES

The pathologic process is characterized by the intra-alveolar accumulation of erythrocytes (Fig. 94.5). There is often histologic evidence of previous bleeding represented by the accumulation of intra-alveolar hemosiderin-containing macrophages, erythrophagocytosis, and loci of free interstitial hemosiderin,[3,8,9] findings that help distinguish DAH from acute biopsy-related bleeding. Other histologic features of DAH include hyperplasia of the alveolar epithelial type 2 cells, intra-alveolar organization as seen in organizing pneumonia, mononuclear cell infiltration of the alveolar interstitium, and small thrombi in the alveolar capillaries and venules.[3,8–11]

Patients with DAH may demonstrate neutrophilic inflammation of the alveolar interstitium known as pulmonary or alveolar capillaritis (Fig. 94.6).[12] Capillaritis represents a small vessel vasculitis of the lung and is central to the pathogenesis of many cases of DAH. The

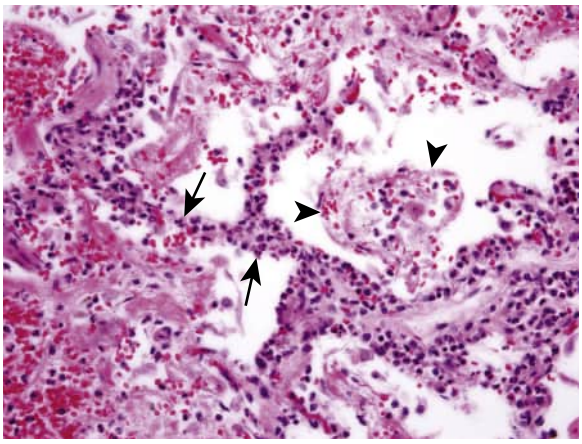

Figure 94.6 Histopathologic findings of diffuse alveolar hemorrhage accompanied by pulmonary capillaritis. Capillaritis is identified by accumulation of neutrophils (*arrows*) within alveolar septa with accompanying fibrinoid necrosis and adherent alveolar fibrin within air spaces (*arrowheads*). (Courtesy Dr. Kirk Jones, University of California, San Francisco.)

small vessel injury and necrosis lead to the loss of integrity of the shared epithelial-endothelial alveolar basement membrane, resulting in endothelial edema, injury, localized fibrinoid necrosis, and extravasation of red blood cells into the alveolar lumina.[10] Characteristically, there is infiltration of the alveolar septa with neutrophils, many of which are undergoing leukocytoclasis and appear fragmented and pyknotic. Fragmentation of these cells leads to accumulation of nuclear dust in the lung parenchyma.

The pathogenesis of DAH due to capillaritis is thought to result from one of the following scenarios: (1) the direct effects of autoantibodies on the alveolar capillary endothelium, as in GPA or MPA; (2) the effects of antibody directed against the alveolar basement membrane (e.g., anti-GBM disease); (3) immune complex–mediated injury (e.g., *systemic lupus erythematosus* [SLE], Henoch-Schönlein purpura); or (4) direct alveolar injury.[13]

DAH can also result from all causes of *diffuse alveolar damage* (DAD) (i.e., cytotoxic drug, allogeneic [bone marrow transplantation]) as well as from bland (noninflammatory) injuries (i.e., mitral stenosis, coagulation disorders).

DIAGNOSIS OF DIFFUSE ALVEOLAR HEMORRHAGE

The diagnostic considerations for patients presenting with DAH are broad. A thorough history and physical examination looking for evidence of potential associated conditions (e.g., connective tissue disease, symptoms/signs of systemic vasculitis, anticoagulant medications) are essential, and initial studies should include an HRCT scan of the chest, complete blood count, and examination of the urine sediment. If DAH is suspected, fiberoptic bronchoscopy should be performed immediately.

Bronchoscopy with BAL is essential to the accurate identification of DAH. Sequential BAL specimens should be obtained and sent for cell count and differential, with an increasing red blood cell count considered consistent with the diagnosis. BAL specimens should be obtained after

the bronchoscope is wedged into a terminal bronchus; the selection of site does not matter because this is a diffuse condition throughout all segments of the lung. Sterile saline is then instilled through the bronchoscope in 30- to 60-mL aliquots to achieve a 20-mL return after each instillation. Qualitative evaluation by the performing clinician can often differentiate those samples, which become progressively bloodier, and is adequate to diagnose DAH. However, samples can also be sent in the nonheparinized sample tubes to the laboratory to evaluate cell counts in each sample to determine the degree or presence of serial red blood cell elevation in the samples.

Quantitative scoring of the hemosiderin concentration in alveolar macrophages obtained by BAL cytologic examination also has sensitivity for the diagnosis of DAH.[14] Importantly, BAL serves to rule out other diagnostic considerations such as infection, acute eosinophilic pneumonia, and pulmonary alveolar proteinosis.

DIAGNOSIS OF UNDERLYING ETIOLOGY

Once DAH is identified, the underlying cause is sought. Table 94.2 summarizes the differential clinical and laboratory features of some of the more common causes of DAH. In some cases, the cause is clear (e.g., history of SLE, drug exposure). In others, a detailed laboratory evaluation is required.

The presence of proteinuria and abnormal urinary sediment (red blood cells and red blood cell casts) suggests underlying glomerulonephritis consistent with the diagnosis of systemic vasculitis, anti-GBM disease, connective tissue disease or, rarely, infection.[15]

Vasculitis is often associated with the presence of *antineutrophil cytoplasmic antibodies* (ANCAs) directed against either proteinase 3 (*cytoplasmic ANCA* [c-ANCA]) or myeloperoxidase (*perinuclear ANCA* [p-ANCA]).[16] Elevation of the c-ANCA level is seen in GPA, whereas elevation of p-ANCA is seen with MPA, pauci-immune glomerulonephritis, eosinophilic GPA, and sometimes isolated pulmonary capillaritis.[17]

The diagnosis of anti-GBM disease is established by the presence of serum anti-GBM antibodies. DAH caused by SLE is accompanied by reduced serum complement levels as well as the presence of antinuclear and native anti-DNA antibodies in the serum. Henoch-Schönlein purpura is characterized by the formation of immunoglobulin A immune complexes present in the circulation and also bound to tissue.[18]

ROLE OF SURGICAL LUNG BIOPSY AND RENAL BIOPSY

To establish the presence of DAH, BAL is generally sufficient. For identifying the underlying cause of the DAH, clinical and confirmatory serologic findings are usually sufficient.[3] Surgical biopsy of the lung may be useful but is often nonspecific; it should be strongly considered when a patient has isolated DAH without an obvious cause because treatment is based on the etiology of the hemorrhage. For patients with DAH without positive serologic findings and with an echocardiogram excluding mitral valve stenosis, a lung biopsy should be strongly considered if the clinical scenario allows. For instance, lung biopsy is required for the diagnosis of isolated pulmonary capillaritis and PVOD, and treatment differs in these conditions.

When serologic findings are equivocal and vasculitis or anti-GBM disease is under consideration, renal biopsy may be appropriate because these conditions are more easily confirmed on renal tissue, even in the absence of clinically apparent involvement.[19] Moreover, renal biopsy may provide useful information regarding the activity and chronicity of renal involvement that may help guide therapy.

Table 94.2 Clinical Differentiation of Common Diffuse Alveolar Hemorrhage Syndromes

Syndrome	Renal	Arthritis	Skin	ANA	dsDNA	C	ABMA	c-ANCA (PR3)	p-ANCA (MPO)	Histopathology; IF
Granulomatosis with polyangiitis	+	+	+	±	±	Nl	–	+	–	Capillaritis; ± granular IF
Microscopic polyangiitis	+	+	+	±	±	Nl	–	–	+	Capillaritis; no IF deposits
Isolated pulmonary capillaritis	–	–	–	–	–	Nl	–	–	±	Capillaritis; no IF deposits
Anti-GBM disease (Goodpasture syndrome)	+	–	–	–	–	Nl	+	–	–	Bland or capillaritis; linear IgG
Systemic lupus erythematosus	+	+	±	+	+	Low	–	–	–	Bland or capillaritis; granular IgG
Idiopathic pulmonary hemosiderosis	–	–	–	–	–	Nl	–	–	–	Bland; no IF deposits

ABMA, anti–glomerular basement membrane antibody; ANA, antinuclear antibody; C, complement; c-ANCA (PR3), cytoplasmic antineutrophil cytoplasmic antibody (anti–proteinase 3); dsDNA, anti–double-stranded DNA antibody; GBM, glomerular basement membrane; IF, immunofluorescence; IgG, immunoglobulin G; Nl, normal; p-ANCA (MPO), perinuclear antineutrophil cytoplasmic antibody (anti-myeloperoxidase).

THERAPEUTIC APPROACH

The first steps in management are to identify the underlying cause and begin specific treatment. Initial treatment may include stopping suspected drugs or exposures, treating infection, and reversing excess anticoagulation. Patients with severe hemoptysis require general supportive therapy based on the degree of bleeding. Finding an underlying capillaritis is paramount because mortality in these groups without appropriate therapy is very high. Picard and colleagues[20] validated a clinical scoring system to evaluate risk for immune-mediated DAH that can help guide early clinical decisions.

Systemic glucocorticoids, with additional immunosuppressive therapy including plasma exchange therapy, are the mainstays of therapy for the DAH syndrome associated with systemic vasculitis, connective tissue disease, anti-GBM disease, and isolated pulmonary capillaritis. The common approach is to begin intravenous pulse methylprednisolone (500 to 1000 mg in divided doses daily) for up to 5 days followed by gradual tapering and then maintenance on an oral preparation. The decision to add immunosuppressive therapy (e.g., cyclophosphamide, azathioprine, or rituximab) is dependent on the severity of the illness, the responsiveness to glucocorticoids, and the underlying disease.

Plasma exchange has typically been used in the treatment of DAH associated with anti-GBM disease, vasculitis syndromes, or connective tissue disease if patients require intensive care unit level care or are initially refractory to intravenous corticosteroid administration.[21–25] The role of intravenous immunoglobulin or rituximab in patients with DAH remains to be defined; however, these therapeutic interventions have been shown to have significant success in patients with SLE-related DAH and rheumatoid arthritis–related DAH.[26–30] Recombinant activated factor VII has been given intravenously, by nebulizer, or via bronchoscopy in refractory DAH with variable success.[31–36]

The role of advanced cardiopulmonary support such as *extracorporeal membrane oxygenation* (ECMO) has been explored successfully in a few patients with DAH. However, the use of ECMO in this disease state remains controversial given the need for anticoagulation in current ECMO circuits and the subsequent risk of worsening the underlying hemorrhage. Several centers have reported their success in treating refractory DAH with typical ECMO circuits.[37,38] Of note, a single center reported their experience supporting a patient with DAH in a circuit without systemic anticoagulation.[39] Given the reversibility of many of the causes of DAH, ECMO as a supportive measure or salvage therapy should be considered early in the disease course, and clinicians should facilitate transfer of patients with life-threatening DAH to ECMO-capable centers.

SPECIFIC CAUSES

VASCULITIS (See Chapter 87)

Granulomatosis With Polyangiitis

GPA is a systemic vasculitis that commonly involves the upper and lower respiratory tracts and kidneys. Other organs (e.g., eyes, skin) may be involved. The typical histologic features of GPA are granulomatous inflammation, small and medium vessel vasculitis, and parenchymal necrosis in a geographic pattern (e.g., involving areas sharply demarcated from other uninvolved areas). DAH secondary to pulmonary capillaritis can either complicate an established case of GPA or represent the initial manifestation of the disease. Surgical lung biopsy specimens from 87 patients with GPA revealed pulmonary capillaritis in 31%, but only in three patients was it an isolated finding.[11] In another series, capillaritis was present in 17% of 35 patients, but never as an isolated finding.[40] In a postmortem study of 22 patients, capillaritis was the sole histologic feature in three patients and was seen in conjunction with the more typical granulomatous vasculitis in seven cases.[41] When DAH is present alone (see eFig. 87.3), without the characteristic histologic features, sinusitis (see eFig. 87.7), or nodular or cavitary lung lesions (see eFigs. 87.1, 87.2 and 87.4), differentiation from MPA is difficult.

The specific diagnosis depends on the ANCA pattern, with c-ANCA suggesting the diagnosis of GPA. If the cytoplasmic pattern of ANCA immunofluorescence is present, most laboratories will perform reflex testing for the specific *immunoglobulin G* (IgG) class ANCA directed at the proteinase 3 of neutrophils and monocytes because proteinase 3 positivity is also more typical of GPA.[42] The characteristic histologic and clinical features of GPA may appear months to years after the initial presentation of DAH and capillaritis.[43]

Alveolar hemorrhage is often subclinical and recurrent in GPA (as well as in MPA), suggested by the presence of hemosiderin-laden macrophages on BAL. This pattern of frequently recurring DAH is more typical of the ANCA-associated vasculitides and SLE than of nonvasculitic diseases such as rheumatoid arthritis.[44]

More than 40 cases of GPA with only DAH and pulmonary capillaritis without the other features of GPA have been described. Early mortality is 37% and is most often the result of acute respiratory or renal failure.[11,40,41,43,45,46] Renal disease in the form of focal segmental necrotizing glomerulonephritis (Fig. 94.7), cutaneous leukocytoclastic vasculitis, and arthritis often accompanies the DAH.

Treatment with high-dose corticosteroids and cyclophosphamide or rituximab has been the recommended

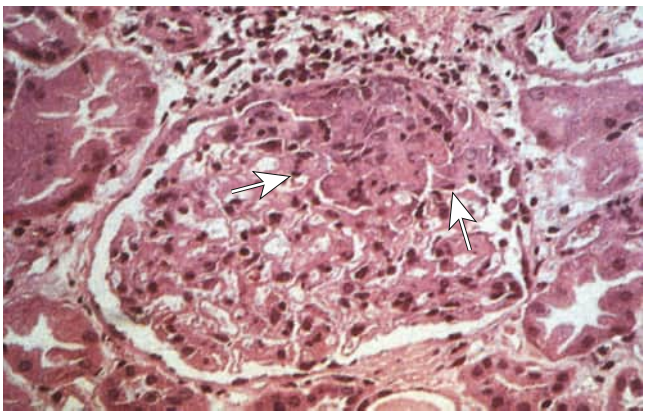

Figure 94.7 Granulomatosis with polyangiitis. Histopathologic findings of a renal biopsy specimen demonstrate focal segmental necrotizing glomerulonephritis. The focal lesion represents an area of fibrinoid necrosis (*arrows*) (×40 original magnification).

initial therapy for GPA with DAH.[47–52] Therapeutic plasma exchange is typically initiated for patients with DAH with impaired oxygen exchange or patients requiring mechanical ventilation, as well as cases of GPA with renal failure, typically followed by rituximab therapy.[22–25] In a large randomized controlled trial of plasma exchange for induction therapy in ANCA-associated vasculitis with renal disease, plasma exchange was not associated with benefit.[53] However, because this trial was not expressly designed to evaluate the role of plasma exchange in ANCA-associated pulmonary hemorrhage, plasma exchange remains a mainstay of therapy in ANCA-associated DAH.[53]Azathioprine may be substituted for cyclophosphamide after remission.[54]

Exacerbations of DAH and other disease manifestations with tapering treatment are to be expected. Disease activity can be monitored by erythrocyte sedimentation rate, ANCA level, serial diffusing capacity for carbon monoxide determination, and microscopic urine examination. As previously stated, in the setting of DAH, the differentiation of GPA from MPA is at times difficult because the clinical presentation, lung histologic features (e.g., capillaritis), and serologic findings can be identical.[55] In fact, the response to treatment and the tendency to recurrence are similar. The differentiation can be established only after the development of the more typical upper airway disease and pathologic features of GPA.

Microscopic Polyangiitis

MPA is distinguished from GPA by the absence of granuloma formation and is typified by a necrotizing vasculitis. When present, it is a frequent cause of pulmonary capillaritis and DAH (see eFig. 87.10).[10,12,43,56–59]

The most consistent pathologic feature in MPA is a focal segmental necrotizing glomerulonephritis, the renal lesion common to all systemic vasculitides. The lungs are involved by capillaritis in 20–30% of cases.[31] The alveolar hemorrhage tends to be severe and is often life-threatening. Other manifestations include fever, weight loss, cutaneous vasculitis, myalgias, arthralgias, diarrhea, and gastrointestinal bleeding from mucosal vasculitis (often visible by direct examination), peripheral neuropathy, and, in a few cases, sinusitis.[59,60,61]

As with other vasculitides, the erythrocyte sedimentation rate is elevated, and nonspecific increases of serum rheumatoid factor and antinuclear antibody levels are possible. Although circulating immune complexes are present in 45% of cases, tissue localization of these complexes is difficult to detect (i.e., pauci-immune). Anti-DNA antibodies and hypocomplementemia, findings suggestive of SLE, are absent. A positive serum p-ANCA result supports the diagnosis, and serology is typically notable for positivity to ANCA myeloperoxidase.[42] Antibodies to hepatitis B and C antigens are present in 33% of cases.[62]

Treatment consists of either oral or intravenous corticosteroids combined with cyclophosphamide or rituximab.[54,47–52] Adjuvant treatment with therapeutic plasma exchange is recommended for patients with MPA who are experiencing hypoxemic respiratory failure or renal failure.[59,53] In one reported case of uncontrolled DAH, intravenous factor VIIa was used successfully with dramatic effects.[63]

Outcome with early initiation of therapy for MPA is generally good, with a 65% rate of 5-year survival. However, the presence of DAH contributes to an early mortality rate of 25%.[10,12,43,56–59] There is a tendency to recurrence with tapering of the medications.

The transition to pulmonary fibrosis and restrictive ventilatory impairment after recurrent DAH has been described,[7] and fibrotic lung disease has been reported as the presenting manifestation of MPA.[64] There have been three cases of persistent, severe, irreversible airway dysfunction after recurrent episodes of DAH that complicated MPA.[65]

Isolated Pulmonary Capillaritis

Isolated pulmonary capillaritis is a small vessel vasculitis confined to the lungs and without concomitant systemic involvement.[66] There are two forms: one with serum p-ANCA positivity and the other without positive serologic testing.[66,67] In one series, the latter type was the most frequent cause of pulmonary capillaritis and DAH.[66] In that series, results of direct immunofluorescence studies of the lungs in these patients were negative (pauci-immune). Although respiratory failure necessitating ventilator support was frequent, response to corticosteroids and cyclophosphamide was good, and only one of eight patients died. Recurrences appeared in two subjects. In another series, patients with biopsy-proven isolated pulmonary capillaritis were followed for a median duration of 116 months; during that follow-up period, no clinical or serologic evidence for a systemic vasculitis or connective tissue disease appeared, and all patients achieved remission following immunosuppressive therapy.[68] There have been case reports of successful treatment of this condition with rituximab after failure of traditional glucocorticoid and cyclophosphamide regimens.[69]

Isolated forms of pulmonary capillaritis causing DAH must be distinguished from IPH, which is not associated with pulmonary capillaritis, as well as from lung-limited forms of anti-GBM disease, initial presentations of a collagen vascular disease, primary antiphospholipid antibody syndrome, and mitral stenosis. Thus, all patients who present with unexplained DAH should have an echocardiogram and, if possible, undergo surgical lung biopsy to differentiate these possible causes.

Mixed Cryoglobulinemia

Mixed cryoglobulinemia is a systemic vasculitis recognized by the presence of purpura, arthritis, hepatitis, and glomerulonephritis. It is thought to be an immune complex–induced disease, with most cases linked to hepatitis C (and less commonly hepatitis B) viral infection. Cutaneous vasculitis appearing as raised purpura is the clinical hallmark of this disease. Histologically, a perivascular polymorphonuclear infiltration with tissue extravasation and fragmentation in the dermis termed leukocytoclastic vasculitis are noted. The renal disease is a proliferative glomerulonephritis with positive granular immunofluorescence. Interstitial lung disease consisting of inflammation and fibrosis of the alveolar walls is the most common pulmonary manifestation.[70] There are two published cases of DAH with pulmonary capillaritis that complicated mixed cryoglobulinemia.[71,72] DAH associated with mixed cryoglobulinemia is treated with an immunosuppressive strategy combining

high-dose steroids with intravenous rituximab, which has shown efficacy in treating the underlying condition.[31,73,74]

Behçet Syndrome

Behçet syndrome is a chronic relapsing illness characterized by oral and genital ulceration, iridocyclitis, thrombophlebitis, and a multisystem disease consisting of a cutaneous vasculitis, arthritis, and meningoencephalitis.[72] Immune complexes have been identified in the serum of active cases as well as in the lung and other organs.[75,76]

The thorax is involved in 5–10% of cases of Behçet syndrome. The pulmonary disease is typically a small vessel vasculitis affecting capillaries, venules, and arterioles. The renal disease is a focal segmental necrotizing vasculitis, as is seen in other systemic vasculitides. Immune complexes composed of IgG and complement have been identified in small pulmonary vessels in several cases.[75,76] In addition to alveolar hemorrhage, involvement of larger vessels can lead to aneurysms of the pulmonary (eFig. 94.2) and bronchial arteries, the latter potentially eroding into bronchi, thereby causing massive pulmonary hemorrhage and death.[77,78] Another potential cause of pulmonary hemorrhage in Behçet syndrome is pulmonary arterial occlusion with infarction.[76] A review of 28 cases of pulmonary involvement in Behçet syndrome emphasized two points: pulmonary signs and symptoms consisting of cough, hemoptysis, chest pain, and fever were more common in men than in women, and 39% of patients died of pulmonary hemorrhage, usually within 6 years of the first episode of hemoptysis.[79] Other studies have confirmed the seriousness of this complication regardless of its cause.[77,78] Treatment consists of corticosteroids and immunosuppressive therapy.[80] Treatment with intravenous anti–tumor necrosis factor therapy has shown dramatic results in case reports and is supported in systemic manifestations of Behçet syndrome by European society guidelines.[81,82]

Henoch-Schönlein Purpura

Henoch-Schönlein purpura, primarily a disease of children, can also be seen in adults.[83] Adults typically present with palpable purpura caused by leukocytoclastic vasculitis and glomerulonephritis.[18] The joints and gastrointestinal tract are commonly involved. Pulmonary involvement is unusual. In several large series, pulmonary disease, except for transient chest radiographic opacities, was not mentioned.[18] There have been documented cases of DAH with pulmonary capillaritis in patients with Henoch-Schönlein purpura.[84–86] In one case, immunoglobulin A immune complexes were present in the alveolar septa.[84] It is postulated that immunoglobulin A immune complexes, which are present in the serum and kidneys of these patients, are responsible for the tissue damage that results in the clinical syndrome.[87] Corticosteroids were used in both cases and are generally recommended.

Pauci-Immune Glomerulonephritis

Pauci-immune glomerulonephritis is one of three types of vasculitides with renal predominant manifestations associated with DAH (the other two being immune complex–mediated glomerulonephritis and anti-GBM disease). Pauci-immune glomerulonephritis lacks any immunoreaction product (i.e., no antibody is detected in serum or on histologic examination except for the minimal accumulation of fibrin). The glomerulonephritis is histologically and immunologically similar to that of MPA and GPA and is considered to represent a form of renal-limited vasculitis.[43] Up to 50% of affected patients develop pulmonary capillaritis and DAH, and a smaller number will develop a full-blown systemic vasculitis indistinguishable from MPA. Another indication that pauci-immune glomerulonephritis represents a limited form of vasculitis is the presence of serum p-ANCA. Because clinical manifestations are often limited to the lung and kidney, the disorder can be confused with anti-GBM disease.[43,87] Pauci-immune glomerulonephritis is distinguished by the absence of circulating basement membrane antibodies in the serum and by the negative findings on renal immunofluorescence studies. Treatment with high-dose corticosteroids and immunosuppressive therapy with cyclophosphamide is recommended. In patients who present with hypoxemic respiratory failure or require intensive care unit admission, treatment should also consist of therapeutic plasma exchange given the possibility of an unidentified plasma antibody.[88]

IMMUNOLOGIC DISORDERS

Anti–Glomerular Basement Membrane Disease (Goodpasture Syndrome)

Whether the case reported by Goodpasture in 1919[89] describes the syndrome that bears his name is questionable. He described an 18-year-old man who died 6 weeks after an influenza infection and was found to have DAH, pleuritis, glomerulonephritis, splenic infarctions, and vasculitis of the small intestines. In 1965, an *anti–glomerular basement membrane antibody* (ABMA)—now identified as an antibody against the NC1 domain of the α3 chain of type IV collagen—was identified in the kidneys and lungs of some patients with DAH and glomerulonephritis.[90,91] The diagnosis of anti-GBM disease is reserved for cases of DAH and glomerulonephritis in which this antibody appears in the serum and is seen to bind to kidney and/or lung basement membranes in a linear manner by immunohistochemical staining.[43,92]

The level of ABMA is not generally considered an accurate index of disease activity, although higher levels have been associated with more severe renal disease. In 60–80% of cases, the lung and renal disease appears simultaneously; in 5–10%, only the lung is affected; and in the remainder, renal disease exists by itself.[93,94] It is clear that ABMA is pathogenic; however, the stimulus for its production remains unknown. The clinical onset of anti-GBM disease has been temporally related to infection with influenza A2 as well as other respiratory infections, hydrocarbon exposure, and tobacco use.[95–97] The presence of histocompatibility human leukocyte antigens DRw2 and B7 (90% and 60%, respectively) in patients with anti-GBM disease indicates that susceptible individuals are predisposed to disease.[98,99] In some experimental models, the introduction of ABMA produced renal but not pulmonary disease; for the antibody to deposit in the lung, an additional injury was required that increased alveolar-capillary permeability.[100,101]

Men are more commonly affected (60–80% of patients), with the highest incidence between the ages of 20 and

30 years.[102,103] In older patients, the sex distribution is equal, and the disease tends to be limited to the kidney.[96] Interestingly, DAH is more common in patients who smoke.[96] The alveolar permeability is increased in most smokers, which is thought to be an important factor leading to DAH.[95] In one study, 100% of smokers with anti-GBM disease developed both DAH and glomerulonephritis, whereas only 20% of nonsmokers developed DAH.[96] Resumption of cigarette smoking by patients who are in remission can result in recurrent episodes of DAH. Exposure to volatile hydrocarbons (e.g., petroleum products, turpentine, toluene, and pesticides) is associated with initiation and exacerbations of DAH.[93,94,104,105]

Symptoms most often refer to the lungs and consist of hemoptysis, cough, and dyspnea. Fatigue caused by iron-deficiency anemia and renal failure may predominate. Microscopic hematuria, proteinuria, and increases in the serum creatinine level are often present, but gross hematuria with hypertension is unusual. The diffusing capacity may be increased during periods of active bleeding and is considered to be a useful monitor of new or recurrent DAH.[106] An increase of 30% above baseline is highly suggestive of an intra-alveolar hemorrhage, and this increase may precede pulmonary symptoms or radiographic changes.

Chest radiography often reveals patchy air space abnormalities (eFig. 94.3A–B). Computed tomographic scanning (see eFig. 94.3C) typically shows ground-glass opacities and consolidation and is more sensitive for DAH than is chest radiography.[107]

The usual histologic appearance is bland pulmonary hemorrhage, although pulmonary capillaritis is present in some cases.[105] Alveolar wall necrosis, which is seen with systemic vasculitis, is not a feature of anti-GBM disease. The renal histologic findings consist of a focal segmental necrotizing glomerulonephritis with crescent formation. The major distinction between anti-GBM disease and the other rapidly progressive glomerulonephritides is the presence of an uninterrupted linear deposition of immunoglobulin and complement along the glomerular basement membrane (Fig. 94.8). Identical findings are present on alveolar basement membranes.[108] Even when DAH dominates the clinical picture (i.e., there is no evidence of renal disease), renal biopsy usually reveals the typical linear staining.[109]

If there is no evident renal involvement, DAH responds to oral or intravenous corticosteroids. However, if glomerulonephritis is present, the hemorrhage associated with anti-GBM appears resistant to corticosteroid monotherapy. The combination of therapeutic plasma exchange, corticosteroids, and cytotoxic drugs is effective, particularly in patients who do not have anuria and do not require dialysis.[110–114] The combination of cyclophosphamide or azathioprine with corticosteroids leads to a dramatic fall in circulating ABMA, and oliguric dialysis-dependent subjects have responded to the point at which dialysis could be discontinued.[114,115] However, anuric patients do not respond well to this combination therapy, and dialysis and renal transplantation are often necessary.[115] Case reports of successful treatment of refractory, life-threatening anti-GBM disease with mycophenolate mofetil and rituximab have been reported.[116,117]

The survival rate in anti-GBM disease has improved from 80% mortality at 6 months, with one-half of patients dying of DAH and the rest dying of renal insufficiency, to approximately 50% at 2 years.[103] With the aggressive treatment approach described previously, it is estimated that the 5-year survival rate exceeds 80%, and less than 30% of patients require long-term dialysis. DAH is the usual cause of death, often precipitated by a concomitant infection.[94] There has been spontaneous remission in patients without clinical evidence of renal disease, although this is not usual.[118] The most useful prognostic information comes from the kidney. Clinically, oliguric or anuric renal failure reduces the survival rate to 50% at 6 months. Histopathologically, less than 30% involvement of the glomeruli on biopsy predicts significant therapeutic response and improved survival. When 70% or more of glomeruli have formed crescents in conjunction with renal insufficiency, renal failure is progressive and often unresponsive to therapy, and patients eventually require dialysis.[115]

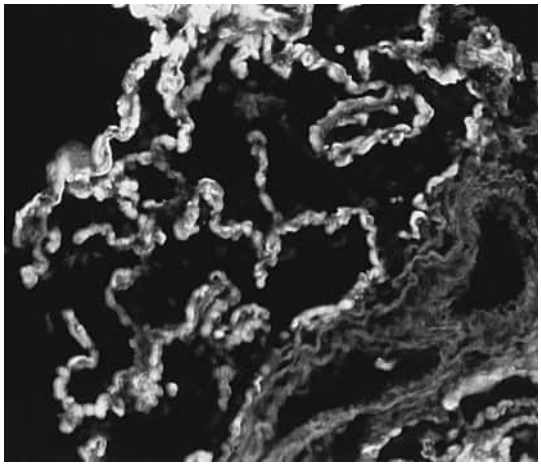

Figure 94.8 Anti–glomerular basement membrane disease (formerly Goodpasture syndrome). Immunofluorescence study demonstrates linear staining of immunoglobulin G in the alveolar walls in a patient with anti–glomerular basement membrane disease (×10 original magnification).

Connective Tissue Disease

Systemic Lupus Erythematosus. Among the connective tissue diseases, SLE is the most common cause of DAH (eFig. 94.4).[43,119–121] It is unusual for DAH to be the initial pulmonary manifestation of SLE; the more common initial manifestation is acute lupus pneumonitis.[122,123] Most patients with DAH have active lupus nephritis.[120] The onset of alveolar hemorrhage can be dramatic, producing severe gas exchange abnormalities and necessitating mechanical ventilation. Reduced complement levels and increased serum titers of serum antinuclear antibodies confirm the diagnosis.

DAH must be distinguished from other causes of hemoptysis in SLE, specifically acute lupus pneumonitis. Acute lupus pneumonitis manifests with fever, cough, and dyspnea and, in 50% of cases, this is the initial manifestation of SLE.[123] It is an inflammatory condition characterized histologically by organizing pneumonia, DAD, cellular nonspecific interstitial pneumonia, and occasionally intra-alveolar hemorrhage. Although hemoptysis may accompany acute lupus pneumonitis, significant reductions of the hemoglobin level are not expected. Unlike in DAH, pleural and pericardial effusions

are common in acute lupus pneumonitis. Other diagnostic considerations in the patient with suspected DAH include infectious pneumonias and pulmonary infarction associated with pulmonary emboli with or without a circulating lupus anticoagulant.[124,125]

Histopathologic examination of the lung in patients with DAH resulting from SLE generally reveals capillaritis, but bland pulmonary hemorrhage and DAD have been described.[123,126] Granular deposits of IgG and complement (C3) are commonly found in the alveolar interstitium and within the walls of intra-alveolar blood vessels (Fig. 94.9).[119,126–128] Capillaritis and immune complex deposition do not necessarily overlap. In one series of four patients with SLE and massive DAH associated with pulmonary capillaritis, only two demonstrated immune complexes by light and electron microscopic techniques.[129]

Treatment of DAH caused by SLE includes high-dose intravenous corticosteroids as well as azathioprine or cyclophosphamide. Rituximab has been shown to be an effective treatment strategy; in some cases, it limits the need for high-dose steroids or other typical chemotherapy regimens.[26–29] Recombinant activated factor VII administered by the local intrapulmonary route may also be an effective treatment option for DAH in patients with SLE.[32] Therapeutic plasma exchange has been combined with chemotherapy in some cases,[22] but its utility is not as clear as in the ANCA-associated vasculitidies.[120,130] Broad-spectrum antibiotic coverage is recommended because of some evidence that infection may trigger the hemorrhage.[120] DAH is associated with a 50% mortality rate in SLE and can be recurrent in survivors.[122,126–129,131] Death is caused by massive hemorrhage, concurrent infection, or renal or central nervous system disease.

Antiphospholipid Syndrome. *Antiphospholipid syndrome* (APS) can manifest as a primary disorder; however, it is commonly seen in the setting of other underlying autoimmune diseases such as SLE. The DAH seen in APS is commonly typified by a diffuse capillaritis (eFig. 94.5)[132]; however, this was seen in only 50% of biopsy specimens in one series.[133] The presence of anticardiolipin antibodies, anti–β_2-glycoprotein 1, and/or a lupus anticoagulant is consistent with APS.[134] The diagnosis of APS is generally made by the presence of one of the aforementioned antibodies in the clinical setting of vascular thrombosis or pregnancy morbidity; however, an atypical manifestation such as DAH may be the initial presenting feature of APS.[135] These patients typically respond to high doses of glucocorticoids, although the role of other steroid-sparing agents or long-term options for remission induction or maintenance remains unclear.[135] DAH in APS remits following corticosteroids in nearly one-half of patients, whereas the other half require a steroid-sparing agent such as cyclophosphamide or rituximab.[133]

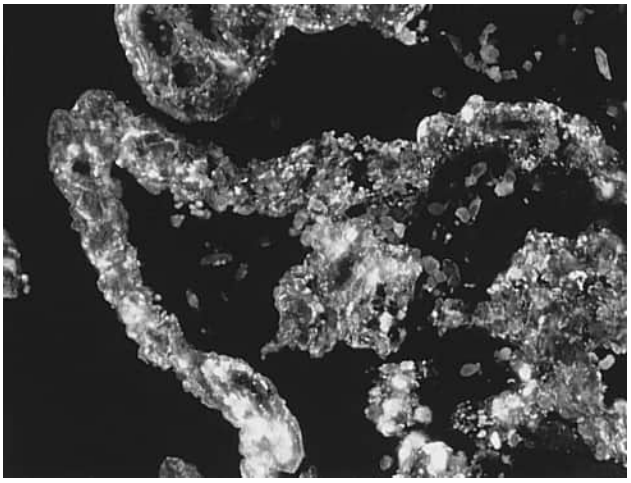

Figure 94.9 Systemic lupus erythematosus. Immunofluorescence study demonstrates granular deposition of immunoglobulin G in the alveolar walls of a patient with systemic lupus erythematosus and diffuse alveolar hemorrhage (×40 original magnification).

Other Connective Tissue Diseases. Other connective tissue diseases such as rheumatoid arthritis, polymyositis, dermatomyositis, scleroderma, and mixed connective tissue disease can cause DAH but are much less common causes than are APS and SLE.[136–142] Isolated DAH with capillaritis has been described in polymyositis, rheumatoid arthritis, and mixed connective tissue disease.[143,144] In polymyositis, DAH was the presenting manifestation and, in rheumatoid arthritis and mixed connective tissue disease, DAH and capillaritis followed the primary diagnosis by 2 to 20 years.[143,144] The therapeutic approach in these cases is similar to that used in the management of SLE, with the use of high-dose corticosteroids with a second agent such as cyclophosphamide or rituximab.

Immune Complex–Related Crescentic Glomerulonephritis

Immune complex–related crescentic glomerulonephritis is rarely accompanied by capillaritis and DAH.[3,145] Although the kidneys demonstrate granular immune deposits, immune complexes are not found in lung tissue.

Acute Pulmonary Allograft Rejection

Pulmonary capillaritis and DAH have been reported after lung transplantation and may represent an acute vascular rejection.[146] The capillaritis can develop weeks to months after the transplantation and may be the only histopathologic manifestation of allograft rejection. This condition represents a serious immunologic complication that threatens survival. In addition to standard anti-inflammatory therapy with corticosteroids and cytotoxic agents, therapeutic plasma exchange may be effective.

COAGULATION DISORDERS

Coagulation disorders associated with DAH include disseminated intravascular coagulation,[147] idiopathic thrombocytopenic purpura,[148] thrombotic thrombocytopenic purpura,[149] and acquired vitamin K deficiency.[150]

All anticoagulant medications have been associated with DAH, including warfarin and its derivatives,[151–153] thrombolytic agents,[154–156] agents targeting the platelet glycoprotein IIb/IIIa,[157–159] and clopidogrel[160] as well as direct oral anticoagulant therapies.[161,162] In most iatrogenically anticoagulated patients, correction of the coagulation defect resolves the DAH. It has been suggested that patients using coumarin with confirmed DAH are at risk for the development of fibrosing interstitial pneumonitis.[163]

DAH can be seen in patients with acute leukemia who have undergone induction chemotherapy and are thrombocytopenic (eFig. 94.6).[164–166] Although thrombocytopenia surely contributes to the DAH, these patients also have evidence of DAD resulting from chemotherapy, oxygen toxicity, and infection that likely plays a central role.

IDIOPATHIC PULMONARY HEMOSIDEROSIS

IPH is predominantly a disease of children, but adults represent about 20% of cases.[165,166] It is a diagnosis of exclusion,[167,168] and efforts to rule out other causes of DAH are essential. Among adults, men are more often affected, and there are reports of familial cases.[169]

The pathogenesis of IPH is not understood. Some cases may be secondary to environmental exposures, such as exposure to *Stachybotrys chartarum,* a toxigenic fungus that has been potentially linked to several cases of otherwise idiopathic alveolar hemorrhage.[170] There are reports of an association between IPH and celiac disease, which is referred to as Lane-Hamilton syndrome. As can be seen with celiac disease, serum immunoglobulin A levels are increased in 50% of cases.[171,172] Serologic testing for immunoglobulin A anti–tissue transglutaminase should be undertaken, and then dietary avoidance of gluten should be initiated to prevent DAH recurrence because some series show total remission of DAH in these cases.[162,173–175]

Recurrent hemoptysis resulting from DAH is the rule, ranging from intermittent blood-streaked sputum to life-threatening hemorrhage. Fever, cough, substernal chest pain, and fatigue secondary to iron-deficiency anemia are also reported. In selected pediatric cases, lymphadenopathy and hepatosplenomegaly are found. Renal disease is absent. In chronic recurrent disease, progressive dyspnea, finger clubbing, inspiratory crackles, and pulmonary fibrosis appear.

Pulmonary function testing reveals a restrictive ventilatory defect with an increase in the diffusing capacity for carbon monoxide during periods of active bleeding. Chest imaging reveals diffuse ground-glass opacity (eFigs. 94.7 and 94.8) and ill-defined centrilobular nodules, the typical appearance of pulmonary hemorrhage of any cause.[176]

In adult cases, lung tissue is required to exclude the entity of isolated pulmonary capillaritis. Histologic examination of the lung in IPH reveals bland alveolar hemorrhage with hemosiderin accumulation.[168,177] There is hyperplasia of alveolar epithelial type 2 cells with capillary dilation and tortuosity. The iron content of the lung is increased, and it is the hemosiderin deposition in the interstitium that is thought to be the basis for collagen proliferation and parenchymal fibrosis. Electron microscopic studies indicate degeneration of alveolar epithelial type 1 cells with exposure of and breaks in the basement membrane and discontinuity of the alveolar capillary structure.[170,176] Although nonspecific, these findings indicate a form of DAD.

Clinical benefit and recovery from the acute hemorrhage after corticosteroid therapy have been reported, but long-term benefit is unlikely.[168,178] Azathioprine has been successful in several cases.[177,179,180] Approximately 25% of patients are free of disease after the initial episode. Another 25% are free of active disease but have persistent dyspnea and anemia, and another 25% have persistent disease activity that leads to fibrosis and severe restrictive lung disease. The rest have unresponsive disease with continued hemorrhage and death from respiratory failure. In patients with persistent disease, the average survival is 3 to 5 years.[168,178] Adults have a better prognosis than children. Lung transplantation is controversial in this disease because IPH has been reported to recur after bilateral lung transplantation.[181]

MISCELLANEOUS CAUSES

Drugs and Toxins

There are many drugs that have been reported to cause DAH.[182] Anticoagulant agents have been discussed previously. Most cases of DAH resulting from drugs or toxins are associated with DAD. This has been reported with abciximab, amiodarone, azathioprine, carbamazepine, cyclosporine, cytosine arabinoside, dextran, docetaxel, fludarabine, hydralazine, methotrexate, radiographic contrast media, retinoic acid, sirolimus, tumor necrosis factor-α, and valproate.[183]

A few drugs have been associated with DAH and capillaritis, including tretinoin, propylthiouracil, phenytoin, and mitomycin.[184–188] DAH resulting from these drugs may also be associated with crescentic glomerulonephritis and elevated ANCA levels.

Penicillamine can result in DAH and an immune complex–mediated glomerulonephritis. Glomerular capillaries display a granular (as opposed to a linear) immunofluorescent pattern for IgG and complement (C3).[189–191] Cases have appeared after as much as 20 years of treatment. Treatment with immunosuppressive therapy and even plasma exchange may be required.[192]

Trimellitic anhydride, used for the manufacture of paints, epoxy resins, and plastics, has caused DAH after the inhalation of fumes or dry powder, generally during spraying of this product on heated surfaces.[193–195] Antibodies to trimellitic anhydride in the serum and a latent period of 1 to 3 months both support an immunologic basis for this syndrome. Long-term physiologic impairment is unusual if further exposure is avoided.

Cocaine inhalation is associated with acute pulmonary toxicity, referred to as "crack lung."[196–198] Crack lung reflects a constellation of findings associated with DAD and hemorrhagic vasculitis, which, in autopsy series, has been associated with DAH.[199] The inhaled particulates used as cocaine adulterants or cocaine-induced acute pulmonary vasoconstriction likely play roles in the acute presentation of DAH in cocaine users. In addition to supportive care, cocaine-related DAH is treated mainly by avoidance of further exposure to cocaine; there are case reports of successful treatment of DAH with glucocorticoids.[200] Vaping and marijuana use have also been reported to cause DAH.[200a,200b]

Diffuse Alveolar Damage

DAD is the underlying histopathologic feature of acute lung injury, and it has a variety of causes (Table 94.3). In DAD, the interstitium of the lung becomes edematous, and the alveolar epithelial type 1 cells are sloughed. There is neutrophilic inflammation and fibroblastic proliferation, but the neutrophilic inflammation in DAD-associated DAH is not as intense as it is in pulmonary capillaritis. Hyaline

Table 94.3 Causes of Diffuse Alveolar Damage

ACUTE RESPIRATORY DISTRESS SYNDROME
Sepsis
Pneumonia (e.g., bacterial, viral, *Pneumocystis jirovecii*)
Trauma
Aspiration
Massive transfusion
Drugs (e.g., cytotoxic/chemotherapeutic agents, antibiotics)
CONNECTIVE TISSUE DISEASE
DIFFUSE LUNG DISEASE
Acute interstitial pneumonia
Acute exacerbation of idiopathic pulmonary fibrosis
RADIATION THERAPY
TOXIC INHALATION
Smoke
Ozone
Heavy metal fumes

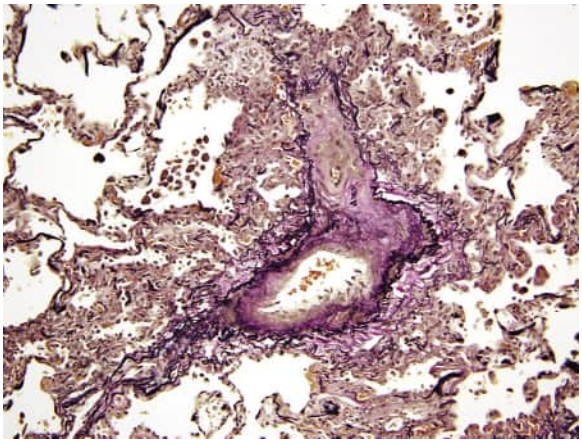

Figure 94.10 Histopathologic findings of pulmonary veno-occlusive disease. An elastic tissue stain (elastic van Gieson) shows marked intimal sclerosis with venous narrowing. These cases may show mild interstitial chronic inflammation and air space accumulation of hemosiderin-filled macrophages (hemosiderosis). (Courtesy Dr. Kirk Jones, University of California, San Francisco.)

membranes consisting of eosinophilic strands of necrotic cells, protein, and fibrin develop adjacent to the injured alveolar walls. In severe cases, the injury to the alveolar-capillary interface leads to leakage of red blood cells into alveolar space that results in DAH.

Mitral Stenosis

Mitral stenosis can be clinically silent and, over time, can result in substantial pulmonary venous hypertension. In some cases, this can lead to the development of DAH.[201] The presentation can be dramatic, with massive hemoptysis arising from the rupture of engorged bronchial varicosities that develop as a result of long-standing left atrial hypertension. Less severe DAH may be recurrent and is often misdiagnosed, leading to chronic interstitial fibrosis. Radiographic findings consist of central ground-glass abnormalities and, in chronic cases, reticular abnormalities (eFig. 94.9).[202] Repair or replacement of the stenotic mitral valve prevents recurrence.

Pulmonary Veno-occlusive Disease

PVOD is a rare cause of *pulmonary hypertension* (PH) resulting from fibrous obliteration of small pulmonary veins and venules. PVOD affects men and women equally and involves all age groups, most commonly children and young adults.[203–205] Patients with PVOD present with dyspnea, syncope, and, when severe, physical findings suggestive of right ventricular overload or failure. Because PVOD is a postcapillary cause of PH, paroxysmal nocturnal dyspnea, orthopnea, and DAH can be seen.

Right-sided heart catheterization cannot easily distinguish PVOD from precapillary PH because the pulmonary capillary wedge pressure is measured in veins distal to the obstructive process, and is generally normal. Chest imaging shows signs of PH; in some cases, interstitial opacities with septal thickening (see Fig. 84.2) suggesting congestion, as well as ground-glass abnormality from alveolar hemorrhage, may be seen. Pleural effusions are common.

Pulmonary function studies reveal a reduced diffusing capacity for carbon monoxide with preservation of lung volumes, a physiologic picture similar to that found in other causes of PH.

Definitive diagnosis is achieved by lung biopsy, which demonstrates fibrous intimal obliteration of small pulmonary veins and venules, acute or recanalized thrombi, and hemosiderosis (Fig. 94.10).

PVOD is usually idiopathic, but it has been reported after chemotherapy (e.g., carmustine, mitomycin, bleomycin), after bone marrow transplantation, and in association with connective tissue disease.[206–213] A mutation in the *bone morphogenic protein receptor II gene* (*BMPR2*), a gene associated with many cases of primary PH, has been identified in a patient with idiopathic PVOD, suggesting an etiologic role.[214]

The use of pulmonary vasodilators in the treatment of PVOD is complicated and potentially harmful. Modest improvements with nifedipine and epoprostenol have been reported, but there have also been cases of these agents precipitating massive pulmonary edema and death.[215,216] Any trial of vasodilator therapy should be performed during right-sided heart catheterization in an appropriate hospital setting. A few patients have had clinical responses to prednisone and azathioprine.[217,218] Anticoagulation for PVOD has been recommended based on the potential role of thrombosis in the pathogenesis of PVOD and on limited data suggesting efficacy in patients with primary PH. However, anticoagulant agents should generally be avoided in patients who have had DAH.

Pulmonary Capillary Hemangiomatosis

Pulmonary capillary hemangiomatosis (PCH) is a rare cause of PH that can be associated with severe and recurrent DAH.[219–221] It is seen across ages and sexes. Patients universally present with dyspnea, often with evidence of right-sided heart failure. Hemoptysis develops in roughly one-third of cases during the course of the disease.[219]

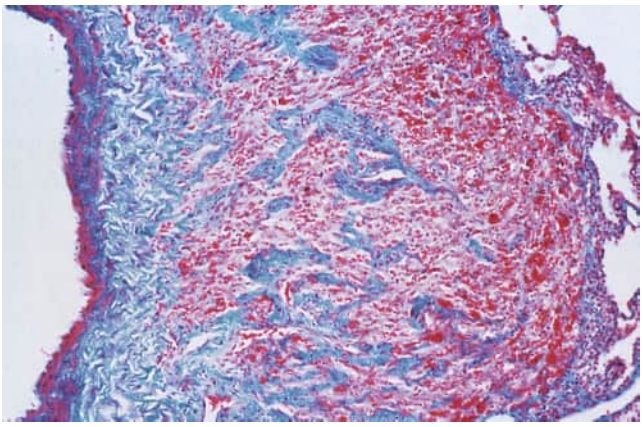

Figure 94.11 Histopathologic findings of pulmonary capillary hemangiomatosis. There is capillary proliferation in the wall of this large pulmonary vein (×100 original magnification).

Chest imaging findings are nonspecific. Chest radiography often shows nonspecific diffuse or bibasilar predominant reticular (eFig. 94.10A) and nodular opacities, with interlobular septal thickening less common than seen with PVOD. Chest computed tomography may show multifocal or diffuse, poorly defined centrilobular ground-glass opacities (eFigs. 94.10B–E and 94.11) and evidence of PH.

Pulmonary function test results are mixed, with both obstructive and restrictive changes described.[219] As with PVOD, right-sided heart catheterization generally reveals a normal pulmonary capillary wedge pressure.

Histologically, PCH is characterized by a proliferation of pulmonary capillaries, which infiltrate the interstitial, bronchial, and vascular structures of the lung (Fig. 94.11).[220] The exact mechanism of PH and DAH is unclear, but mechanical rupture of hemangiomatous vessels in the setting of pulmonary arterial and venous occlusion and/or thrombosis is likely responsible.

Treatment of PCH with pulmonary vasodilators is generally contraindicated because worsening pulmonary edema and death have been reported.[222,223] In a few reports, treatment with recombinant interferon-alfa-2a may have led to stabilization or improvement.[219,224] Mean survival after diagnosis is usually 3 years, although successful treatment with lung transplantation has been reported.[219]

Lymphangioleiomyomatosis and Tuberous Sclerosis

Lymphangioleiomyomatosis and tuberous sclerosis share common pathobiologic features involving proliferation of smooth muscle in pulmonary interstitial, lymphatic, bronchial, and vascular structures (see Chapter 97 for a full discussion of these diseases).[225–227] Involvement of the pulmonary vasculature commonly results in episodes of alveolar hemorrhage. This alveolar bleeding is often focal; DAH is unusual. Pathologic specimens of the lung in lymphangioleiomyomatosis and tuberous sclerosis typically demonstrate focal areas of hemorrhage and hemosiderin deposition.

Key Points

- Diffuse alveolar hemorrhage is a medical emergency that often results in acute respiratory failure and death.
- The classic clinical presentation of diffuse alveolar hemorrhage includes dyspnea, hemoptysis, alveolar opacities on chest radiograph, and anemia. Importantly, in as many as one-third of patients with diffuse alveolar hemorrhage, hemoptysis may not be a presenting symptom.
- Many of the disorders causing diffuse alveolar hemorrhage appear to be immunologically mediated, either through injury to the capillary basement membrane by specific autoantibodies or through deposition of immune complexes.
- Bronchoscopy with serial bronchoalveolar lavage showing a sequential increase in red blood cell counts or bloody appearance is essential to confirm diffuse alveolar hemorrhage.
- Many cases of diffuse alveolar hemorrhage demonstrate neutrophilic inflammation of the alveolar interstitium known as capillaritis.
- The presence of proteinuria and an abnormal urinary sediment (red blood cells and red blood cell casts) suggests underlying glomerulonephritis consistent with the diagnosis of systemic vasculitis or anti–glomerular basement membrane disease (formerly Goodpasture syndrome).
- Accurate diagnosis is essential because, in some of the causes of diffuse alveolar hemorrhage, aggressive treatment with corticosteroids, cytotoxic agents, rituximab, and plasma exchange (alone or in combination) is often helpful.

INTRODUCTION

Histiocytic disorders are associated with organ infiltration and inappropriate activation of myeloid cells belonging to the monocyte-macrophage and dendritic cell lineage.[1] Individual histiocytic syndromes vary widely in natural history and clinical behavior.[1] *Langerhans cell histiocytosis* (LCH) is a subgroup of the histiocytic syndromes characterized by organ infiltration with myeloid cells expressing surface CD1a and intracellular Birbeck granules.[1] In adults, LCH may affect the lungs in isolation (as pulmonary LCH) or as part of a multisystem disease.[2]

PULMONARY LANGERHANS CELL HISTIOCYTOSIS

EPIDEMIOLOGY

Pulmonary Langerhans cell histiocytosis (PLCH) is an uncommon cause of diffuse lung disease and represents approximately 3% of all cases referred for evaluation of interstitial lung disease.[3] The disease is seen principally in adults between the ages of 20 and 40 years.[2,4] Men and women are affected in equal proportion.[2,5] PLCH, particularly when isolated to the lung, is a smoking-related lung disease.[2,5-10] At least 90% of adults with isolated PLCH are active or former smokers,[2] and cigarette smoking has been reported to precipitate the onset of PLCH in adolescents previously in remission from disease earlier in childhood, a finding suggesting that smoking may be a critical factor in disease induction.[6] The role of smoking is less clear when LCH arises in the context of a multisystem disease.

PATHOLOGY

Inspection of the surface of the lungs at the time of autopsy or during surgery reveals cysts. When the lung is sectioned, nodules of varying sizes (0.1 to 1.5 cm) may be seen.[11] In advanced disease, the predominant finding may be bullous and cystic destruction of the middle and upper lung regions.[5,11,12] In early-stage disease, PLCH is an inflammatory type of bronchiolitis with varying degrees of interstitial infiltration.[5,11,13] Some patients have extensive alveolar macrophage infiltration in the air spaces.[14] In addition to bronchiolar, interstitial, and varying degrees of alveolar involvement, some cases may be associated with extensive vascular infiltration.[5,15-17] An appreciation of the different pulmonary compartments that the disease involves is important because the extent of airway, interstitial, and vascular involvement may vary greatly from one patient to another, and it helps to explain the variability observed in clinical findings and lung function testing.[2]

Histologic examination of lung biopsy samples shows loose cellular nodules adjacent to small airways and scattered throughout the lung parenchyma.[5,11,18] The nodules consist of a mixed population of inflammatory cells including T lymphocytes, monocytes, plasma cells, eosinophils, and myeloid cells, which share morphologic features with cutaneous antigen-presenting cells known as Langerhans cells (identifiable by typical morphologic features on light microscopy and surface CD1a staining).[5,11,19,20] The histologic findings may sometimes be confused with respiratory bronchiolitis or desquamative interstitial pneumonia because of the extent of macrophage accumulation in small airways and alveolar and interstitial spaces.[11,14] The bronchiolocentric lesions often form symmetrical stellate shapes with central scarring.[11]

The stage of evolution of the process influences the pathologic findings. In early stages, numerous cells accumulate adjacent to terminal or respiratory bronchioles, thus resulting in the destruction of the bronchiolar wall and the adjacent alveolar structures. In more advanced disease, cellularity may diminish considerably, and fibrotic changes predominate.[11]

Cystic lesions are characteristic of PLCH. These lesions do not represent necrosis of the nodules but rather progressive dilation of the small airways and eventual fibrosis as the peribronchial lesions destroy the bronchiolar walls.[11,13] Injury to the small airways with subsequent dilation and scarring leads to the formation of irregular parenchymal cystic lesions.

PATHOGENESIS

The cell believed to be primarily responsible for disease pathogenesis is a myeloid cell that shares several morphologic features with cutaneous Langerhans cells.[1] Given their location and close association to airway epithelial cells, it is very likely that these myeloid cells are recruited, or possibly develop in situ, in response to epithelial signals that arise in the context of certain inhalational challenges such as cigarette smoking.

Accumulation of CD1a-expressing myeloid cells in a subepithelial distribution is postulated to be the earliest lesion to develop in the natural history of PLCH.[21] Cigarette smoking may lead to recruitment of these cells through the induction of certain cytokines and chemokines such as tumor necrosis factor-α, *granulocyte-macrophage colony-stimulating factor* (GM-CSF), and transforming growth factor-β from airway epithelial cells.[22,23] These putative mechanisms of myeloid cell accumulation in subepithelial regions are supported by immunohistochemical techniques that identify abundant GM-CSF protein expression in the epithelium of bronchioles affected by the inflammatory lesions of PLCH, which colocalizes with the presence of numerous $CD1a^+$ myeloid cells in proximity.[21] A pathogenic role for GM-CSF is further suggested by the observation that the expression of GM-CSF is substantially lower in bronchioles not affected by disease.[21] In addition to epithelial cells, alveolar macrophages and other lung cells may be important sources of secreted factors that recruit myeloid as well as other inflammatory cells that ultimately lead to nodular lesions.

Although the link between smoking and PLCH appears strong, the disease develops in a very small percentage of smokers, thereby indicating that in addition to exogenous factors, there must be some inherent host genetic (or additional environmental) factors that lead to PLCH. Extensive analyses have failed to identify candidate viruses.[24,25] It is possible that somatic mutations affecting the *mitogen-activated protein kinase* (MAPK) pathway may be the critical endogenous factor that predisposes smokers to PLCH development.[26]

Whether PLCH is a reactive or a clonal neoplastic process has been a subject of debate.[27] The low frequency of mitotic figures or cytogenetic abnormalities in the lesional $CD1a^+$ myeloid cells, reports of "spontaneous" resolution, and the inflammatory nature of the nodules were considered arguments favoring a reactive immune granulomatous reaction. Conversely, the occasionally aggressive natural course of PLCH in some patients with progressive disease and the efficacy of chemotherapy in certain severe forms of PLCH favored a neoplastic mechanism. The argument was fueled further by discordant findings in two molecular studies: one supported a clonal nature of infiltrating lesional $CD1a^+$ myeloid cells,[28] whereas another study reported a polyclonal process in most cases.[27]

The identification of recurrent genetic abnormalities in the lesional $CD1a^+$ cells provides the strongest argument to date in support of the neoplastic nature of PLCH.[29] Both *B-raf proto-oncogene* (BRAF) and *neuroblastoma RAS viral oncogene* (NRAS) mutations have been found in PLCH lesions and in circulating myeloid $CD1a^+$ cells.[30,31] The $BRAF^{V600E}$ mutation results in a modified kinase domain of the protein that leads to constitutive activation of the MAPK pathway.[29] This mutation is found in 35–50% of people with PLCH.[31,32] Although at least one-half of PLCH patients have a wild-type BRAF status, evidence of activation of the MAPK pathway by immunohistochemical studies can be shown in all patients.[29] This finding implies additional mechanisms for MAPK pathway activation in the absence of $BRAF^{V600E}$ mutations. At this time, and although strongly supportive of a neoplastic biology, the clinical significance of MAPK pathway mutations in PLCH is not fully known. Additional studies are needed to evaluate the impact of MAPK mutations and the associated clinical phenotype, as well as the potential for these mutations to guide individualized treatment approaches with targeted inhibitors of the MAPK pathway.[26]

RADIOGRAPHIC FINDINGS

The chest radiograph is abnormal except in mild or very early disease (Fig. 95.1). Nodular and reticulonodular opacities predominate in early disease, whereas cystic abnormalities and hyperinflation are typical in advanced disease.[33] Unusual findings on chest radiographs include discrete pulmonary nodules[34] and pleural effusions.

High-resolution computed tomography (HRCT) scans should be obtained in every patient suspected of having PLCH. As with the chest radiograph, abnormalities described on HRCT vary depending on when it is obtained relative to the natural course of the disease. In disease of recent onset, nodules are very common: these vary in size from a few millimeters to up to 2 cm in size, and they may show central cavitation.[35] In more advanced disease, lung cysts tend to predominate.[36] The combination of nodular and cystic changes may result in a highly characteristic radiographic appearance (see Fig. 95.1). The lung cysts often vary in size, have thin walls, and tend to be pleomorphic (unlike the more uniform-appearing cysts reported in lymphangioleiomyomatosis and described in Chapter 97 and Fig. 97.3).[2,37]

PLCH lesions are frequently fluorodeoxyglucose avid, and positron emission tomography scanning may be helpful to determine the extent of thoracic disease activity, as well as to detect occult extrapulmonary disease, present in approximately 10–15% of patients.[38]

PULMONARY FUNCTION TESTING

Results of pulmonary function testing may be normal in up to 20% of patients at the time of diagnosis.[2] The most

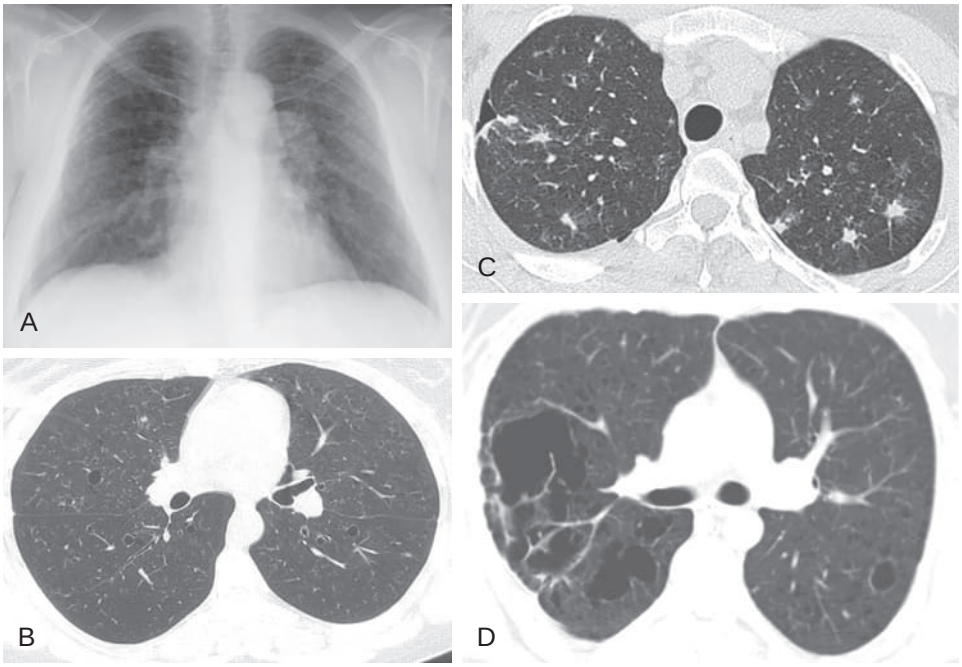

Figure 95.1 Pulmonary Langerhans cell histiocytosis. (A) Chest radiograph from a 48-year-old woman with biopsy-proven *pulmonary Langerhans cell histiocytosis* (PLCH) showing diffuse interstitial opacities with an upper lobe predominance and prominent pulmonary arteries resulting from coexistent secondary pulmonary hypertension. (B) Representative high-resolution chest *computed tomography* (CT) image from a 23-year-old woman with biopsy-proven PLCH showing discrete, thin-walled cysts in both upper lobes. (C) Representative chest CT image from the upper lobes of a 35-year-old woman with PLCH. Several nodules can be appreciated in both lungs. A tiny, right-sided pneumothorax and focal area of consolidation along a suture line are present in the right upper lobe laterally, at the site of recent surgical lung biopsy. (D) Representative chest CT image from a 50-year-old patient with PLCH showing pleomorphic cystic changes, particularly in the right lung.

common abnormality at the time of diagnosis is a reduction in *diffusing capacity for carbon monoxide* (DL_{CO}).[2,5] Lung function testing may also reveal obstructive, restrictive, or mixed physiologic abnormalities.[2,5] The various patterns of lung function abnormalities are manifestations of the different degrees of interstitial, airway, and vascular involvement in PLCH. In a series of 23 patients with presumed early disease, lung function testing showed normal or restrictive physiology,[39] whereas another cohort reported restriction in 37 of 81 patients (46%) at the time of diagnosis.[2] Obstructive physiology manifested by increased lung volumes, air trapping, and diminished *forced expiratory volume in 1 second* (FEV_1) relative to the *forced vital capacity* (FVC), is present in at least one-third of patients at the time of diagnosis and becomes more prevalent later in the natural course of disease.[2,14,40]

CLINICAL FEATURES AND DIAGNOSTIC EVALUATION

Two-thirds of patients have symptoms at the time of presentation, usually cough and dyspnea.[2] Chest pain secondary to pneumothorax can happen in 10–20% of patients, and it may be recurrent.[41,42] Complications of PLCH include pneumothorax, hemoptysis, and pulmonary vascular disease.

Physical examination of the pulmonary system is usually unremarkable. Auscultation of the chest may be normal or may reveal evidence of airflow limitation. There are no diagnostic blood tests, and most patients have normal hematologic indices.

PLCH should be suspected in any smoker with diffuse lung opacities. HRCT of the chest should be obtained in all patients suspected of having PLCH. In asymptomatic patients or those with mild disease, HRCT may be sufficient to enable a provisional diagnosis. Further evaluation and definitive diagnosis with lung biopsy should be pursued when the HRCT findings are consistent with, but not highly suggestive of, PLCH, and whenever treatment is contemplated. The yield of transbronchial lung biopsy is relatively low,[5,43,44] and the identification of greater than 5% $CD1a^+$ *bronchoalveolar lavage* (BAL) cells has high specificity but low sensitivity and is infrequently used as a diagnostic test.[45-49]

Surgical lung biopsy may establish the diagnosis if transbronchial lung biopsy is nondiagnostic. In patients with multisystem LCH, the diagnosis may be established by biopsy of other involved sites, such as bone or skin. With the recognition of specific mutations associated with LCH, and the potential for these mutations to guide treatment decisions, biopsy confirmation of disease is recommended whenever possible. Although a provisional diagnosis may be established on the basis of clinical features and consistent imaging findings, analysis of biopsy tissue for specific mutations should be considered whenever possible.

MANAGEMENT

The management of PLCH should be individualized. Active smokers should be offered the best current smoking cessation approaches. Abstinence from smoking leads to stabilization of symptoms in many patients, and it may be the only medical intervention necessary

for sustained remission.[10,50] Unfortunately, the lung function of patients may not improve or even stabilize following smoking cessation. In addition, some patients are unable to quit smoking and develop progressive disease. Because the decline in FEV_1 and D_{LCO} predict adverse outcome,[2,40] a practical approach to detect patients at risk of progressive disease is to establish longitudinal follow-up every 3 to 6 months with pulmonary function testing.

Oral corticosteroids are often prescribed for PLCH, but there is limited evidence in support of their use.[7,51-53] The presumed efficacy of corticosteroids, as suggested by retrospective studies, is difficult to ascertain because of the confounding effect of smoking cessation, which may in itself lead to objective improvement. Given the potential for side effects and limited evidence to support efficacy, as well as the availability of alternative therapies, it is now quite uncommon to use corticosteroid therapy for the treatment of PLCH.

Various chemotherapy agents have been reported to induce disease remission in patients with isolated progressive pulmonary disease or multisystem LCH with lung involvement.[54-58] Cladribine, a purine nucleoside commonly used in the treatment of hairy cell leukemia, seems to have efficacy in both multisystem and isolated PLCH.[55,59-61] Of interest have been anecdotal reports of responses to cladribine associated with reduction in the dimension of lung cysts.[62] However, the long-term bone marrow toxicity of cladribine in young patients is not well defined, and treatment with this agent should be undertaken only by specialized centers.

Another treatment option for patients with mutated $BRAF^{V600E}$ is the use of the targeted inhibitors of the BRAF/MAPK/MEK pathways, vemurafenib and tramatenib.[63] Use of these agents should be restricted to patients with documented $BRAF^{V600E}$ mutation and only in those with progressive disease despite smoking cessation. One report suggested that in patients who have BRAF wild type and have progressive disease, use of inhibitors of the downstream MEK pathway may also be a potential alternative therapy.[64] The role of these agents in the management of isolated PLCH is not well established at this time and, given their potential toxicity, they should be used only after careful consultation with centers that have expertise in managing rare histiocytic disorders.

The management of PLCH also includes screening for *pulmonary hypertension* (PH) by transthoracic echocardiography, particularly in patients with dyspnea that seems out of proportion to measured pulmonary function, or in patients with progressive decline in D_{LCO}. In patients with signs of possible PH, it is recommended to proceed to right-sided heart catheterization to confirm the presence and severity of the PH and to measure the hemodynamic response to a vasodilator trial (see Chapter 83).[16]

Lung transplantation is an option for patients with severe respiratory impairment and should be considered in the patient with rapidly declining lung function or with a severe limitation unresponsive to smoking cessation or a trial of immunosuppressive therapy.[65-68a] It is imperative that patients stop smoking before lung transplantation because the disease may recur in the transplanted lung if smoking is resumed.[69] There are also reports of recurrence in the transplanted lung in spite of presumed abstinence from tobacco use.[57,70,71]

OUTCOMES AND PROGNOSIS

The overall prognosis is good for most patients, particularly if they stop smoking early in the course of disease. Factors associated with a worse prognosis include multisystem involvement, extensive cysts, markedly reduced D_{LCO}, low FEV_1/FVC ratio, and a high ratio of residual volume to total lung capacity.[2,40,72] As mentioned, some patients develop progressive disease. It is difficult to determine how many patients with PLCH progress to respiratory failure because some of these patients have associated emphysema caused by long-standing tobacco abuse.

Pregancy in women with PLCH appears to be safe. One study reported that 10 healthy children were delivered by a cesarean section in eight women with PLCH.[73] In that cohort, pregnancy did not significantly influence pulmonary function or the distance and arterial oxygen saturation in the 6-minute walk test.[73] One patient did experience bilateral pneumothorax in the third trimester. Accordingly, although limited data exist, pregnancy does not appear to trigger deterioration of pulmonary function in PLCH.[73] Anecdotally, complete remission of cutaneous and lymph node involvement by LCH during pregnancy has been reported.[74] Although PLCH is not a contraindication to pregnancy, patients with PH require very careful monitoring and counseling.[75]

PLCH patients also appear to have an increased risk of secondary malignant diseases, including lymphoma, multiple myeloma, myelodysplastic syndrome, and other cancers.[2] These cancers may either predate or follow the diagnosis of LCH. It is important for clinicians to recognize this association because of the implications in follow-up and counseling of these patients.

RARE INFILTRATIVE DISORDERS OF THE LUNG

This is a collection of diseases with very low incidence, associated with different genetic mechanisms and characterized by multisystemic involvement, including the lungs. In most of these disorders, no clear treatment options are recognized. Most affected individuals tend to be young, and appropriate recognition and diagnosis are essential. In many instances, given the relatively young age of persons affected by these rare infiltrative disorders, lung transplantation referral should be considered.

NEUROFIBROMATOSIS

Neurofibromatosis (NF) is a genetic condition characterized by multiorgan involvement with compromise of skin, central and peripheral nervous system, bone, and eyes. The more common form is NF type 1 (NF1), formerly known as von Recklinghausen disease. It is an autosomal dominant disorder; however, 50% of cases arise sporadically from spontaneous mutations. The *NF1* gene is located on the long arm of chromosome 17 (at locus 17q11.2). Its protein product, neurofibromin, is a negative regulator of the proto-oncogene Ras, which could explain the higher

incidence of neoplasia,[76] with reported coexistence of different malignant tumors in the same patient,[77,78] along with rare cases of primary lung carcinosarcoma[79] and primary lung rhabdomyosarcoma.[80] The loss of neurofibromin protein accelerates the production of Ras proteins, which play a central role in cell differentiation and growth, resulting in the development of benign neurofibroma-type tumors, and perhaps interstitial lung disease, potentially because of increased fibroblast proliferation.[81] Moreover, proliferation and migration of endothelial cells cause pronounced pulmonary arterial remodeling and uniform wall thickening in cases associated with PH.[82]

The most common manifestations include café au lait macules, neurofibromas, Lisch nodules (present in 95% of patients), and axillary or inguinal freckling (present in 70% of patients). NF is fully penetrant in adults, but many manifestations of the disease increase in frequency and severity with age, with full criteria eventually recognized by the age of 10 years.[83]

Abnormal chest CT findings are documented in 15% of patients with NF1.[84] The more common abnormal radiologic findings are subcutaneous and skin nodules, with rates of cystic changes and emphysema approximately 15% and 18%, respectively.[84,85] The presence of emphysema seems to be related to a positive smoking history.[84,86] Cysts and bullous disease are common, particularly in the upper lobes, with sizes ranging between 8 and 25 mm; some of these cystic and bullous lesions may have thicker and more sharply defined walls than similar lesions observed in cases of smoking-related emphysema (Fig. 95.2).[84-86] Mediastinal masses are present in 15% of cases; 50% correspond to neurofibromas, and others are malignant peripheral nerve sheath tumors, meningoceles, and other causes.[84,87,88] Positive radiologic findings were related to symptoms and abnormal pulmonary function test results in most of the patients in two small case series.[85,86]

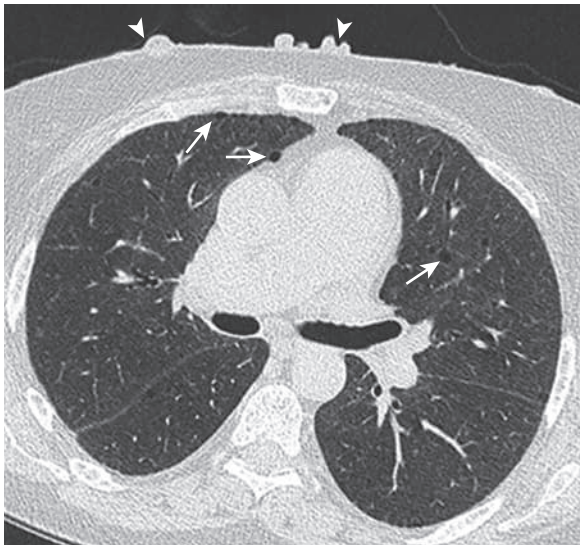

Figure 95.2 Neurofibromatosis. Axial computed tomography image of the chest demonstrates a few small (2- to 3-mm) lung cysts *(arrows)* with a random pattern of distribution in this patient with neurofibromatosis type 1. Also note cutaneous neurofibromas in the anterior and posterior chest walls *(arrowheads)*.

An additional complication is PH, categorized as group 5 (unclear and/or multifactorial mechanisms). The described cases to date have shown female predominance and presentation late in the course of NF, with median age at diagnosis of 57 years. Most patients have severe functional impairment (New York Heart Association functional class III or IV) at the time of diagnosis, with average mean pulmonary arterial pressure values of 49 mm Hg. There are no clear recommendations for this group for the use of PH-approved drugs.[82,89,90] Evidence of capillary hemangiomatosis has been described, and questions about a relatively high prevalence of pulmonary veno-occlusive disease have been raised, given the development of respiratory failure following the initiation of vasodilators.[91] The limited response to specific PH therapies and the poor prognosis of PH associated with NF1 indicate the need for prompt referral to lung transplantation centers following diagnosis.[90]

HERMANSKY-PUDLAK SYNDROME

Hermansky-Pudlak syndrome (HPS) is a rare autosomal recessive genetic disorder characterized by oculocutaneous albinism, bleeding diathesis, and granulomatous colitis. Ten subtypes have been recognized; among them, HPS-1, HPS-2, and HPS-4 are associated with pulmonary fibrosis and generally manifest with more severe disease.[91a] HPS affects approximately 500,000 to 1 million people worldwide. Puerto Rico has the highest prevalence, with 1 in 1800 in the northwest of the island, representing 50% of cases globally, most of them subtypes 1 and 3.[92,93]

The HPS genes encode proteins that form complexes termed *biogenesis of lysosome-related organelles complexes* (BLOCs), which are critical regulators of protein trafficking to lysosome-like organelles, such as melanosomes and platelet dense granules, thus explaining many of the syndrome manifestations. The *HPS1* gene product is a component of BLOC3, and *HPS1* mutations cause highly penetrant pulmonary fibrosis.[92,93] Evidence indicates that macrophage-mediated inflammation precedes pulmonary fibrosis.[93]

The diagnosis of HPS, regardless of the type, includes albinism and a functional platelet disorder resulting from a storage pool deficiency. Other manifestations include strabismus, nystagmus, and transillumination of the iris. *Idiopathic pulmonary fibrosis* (IPF) and HPS-related pulmonary fibrosis share the *usual interstitial pneumonia* (UIP) pattern but, in HPS, it is characterized by giant lamellar body formation in alveolar epithelial type 2 cells.[94] Virtually all patients with HPS-1 develop pulmonary fibrosis, typically around the fourth decade of life (in contrast to IPF, which usually manifests after the age of 60 years), with an average survival following the onset of pulmonary fibrosis of 10 years. Although the pattern of the fibrosis associated with HPS shares some similarities with IPF, there are distinct differences, particularly a greater frequency of ground-glass opacities, more common subpleural thickening, and generally less honeycombing (Fig. 95.3).[95] There are no Food and Drug Administration–approved treatments for HPS pulmonary fibrosis. Whether antifibrotic therapies such as pirfenidone or nintedanib have efficacy in HPS-associated pulmonary fibrosis is not well established at this time.[96] Despite the bleeding diathesis, patients with HPS-associated IPF have undergone lung transplantation successfully. Given the potential need

for lung transplantation in their future, patients should be managed with care to avoid alloimmunization from platelet transfusions that could prevent finding a suitable match.[97]

DYSKERATOSIS CONGENITA

Dyskeratosis congenita (DC) is a congenital premature aging syndrome and bone marrow failure disorder characterized by abnormal skin pigmentation, nail dystrophy, and oral leukoplakia. These abnormalities are secondary to short telomeres; in fact, telomere-mediated diseases were initially identified in the context of DC.[98] More recently, similar telomere mutations have been documented in adults with IPF.[99] These telomere-mediated disorders are now recognized as syndromes of telomere shortening, characterized by manifestations in multiple organs with the highest morbidity and mortality related to failure of the bone marrow, liver, and lung; indeed, the coexistence of bone marrow, liver, and lung dysfunction should alert clinicians to this diagnosis.[98,100,101]

Pulmonary fibrosis develops in a proportion of patients with DC, and lung function decline may be detected early in life, usually associated with cytopenias and the onset of bone marrow failure. Certain genotype abnormalities are linked with bone marrow failure, and studies are ongoing to determine whether these correlations also link with pulmonary complications, thus suggesting a possibility for early detection.[101] Histopathologic findings on lung biopsy include interstitial fibrosis with pneumocyte hypertrophy, intra-alveolar foamy macrophages, and honeycombing. Radiologic findings have been characterized as atypical UIP with frequent involvement of middle and upper lobes (Fig. 95.4).[101,102] Pulmonary involvement is usually progressive (eFig. 95.1). Rarely, lung disease may be complicated by the hepatopulmonary syndrome.[103] There are no known effective therapies for the interstitial lung disease in DC, and early referral for lung transplantation should be considered.

NIEMANN-PICK AND GAUCHER DISEASES

Niemann-Pick (NP) disease and Gaucher disease are rare lysosomal storage diseases, inherited in an autosomal recessive manner, that result in accumulation of lipid compounds in various organs. NP disease is associated with acid sphingomyelinase deficiency, and Gaucher disease is associated with deficient activity of the lysosomal enzyme glucocerebrosidase; these diseases cause accumulation of sphingomyelin and glucocerebroside, respectively. In both disorders, lipid-laden macrophages (called NP or Gaucher cells for the respective eponymous disorder) accumulate in different organs, including liver, spleen, bone marrow, brain, and lung.

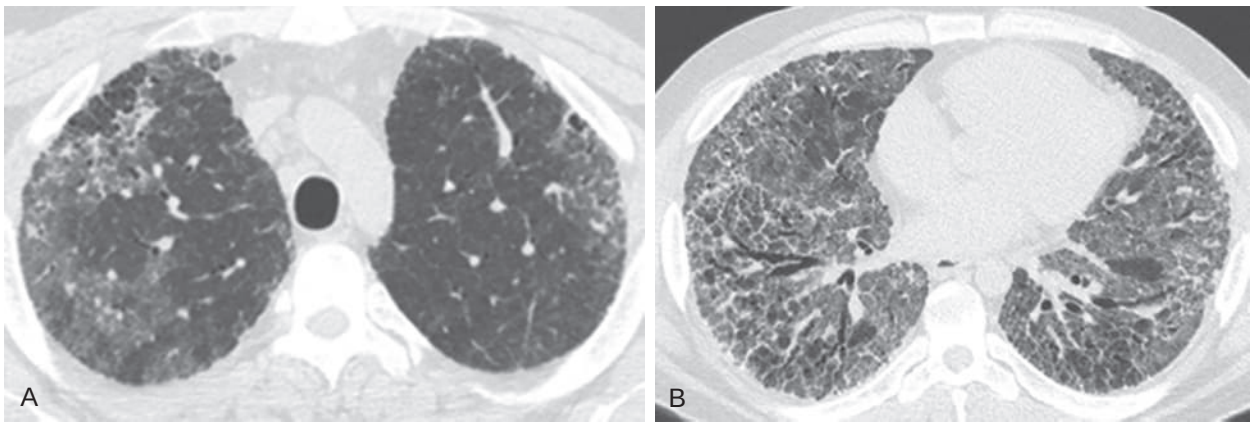

Figure 95.3 Hermanksy-Pudlak syndrome. Axial computed tomography images of the chest at the level of the (A) upper and (B) lower lobes demonstrate extensive reticulation, bronchiectasis, and ground-glass opacities with lower lobe predilection and with no definite honeycombing.

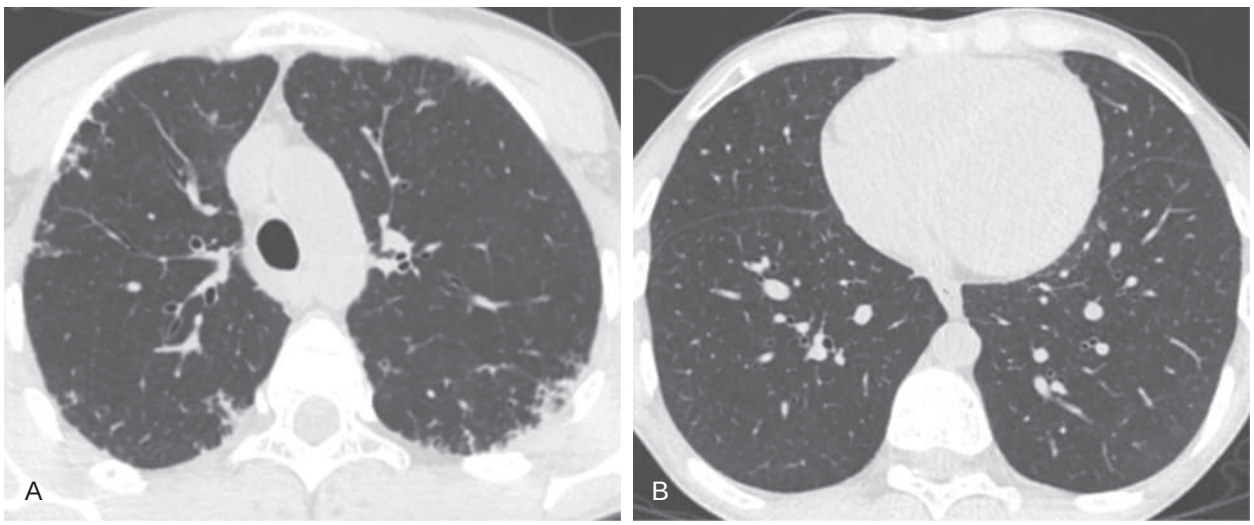

Figure 95.4 Dyskeratosis congenita. Axial computed tomography images of the chest at the level of the (A) upper and (B) lower lobes demonstrate subpleural reticulation with an upper lobe predilection and with no honeycombing.

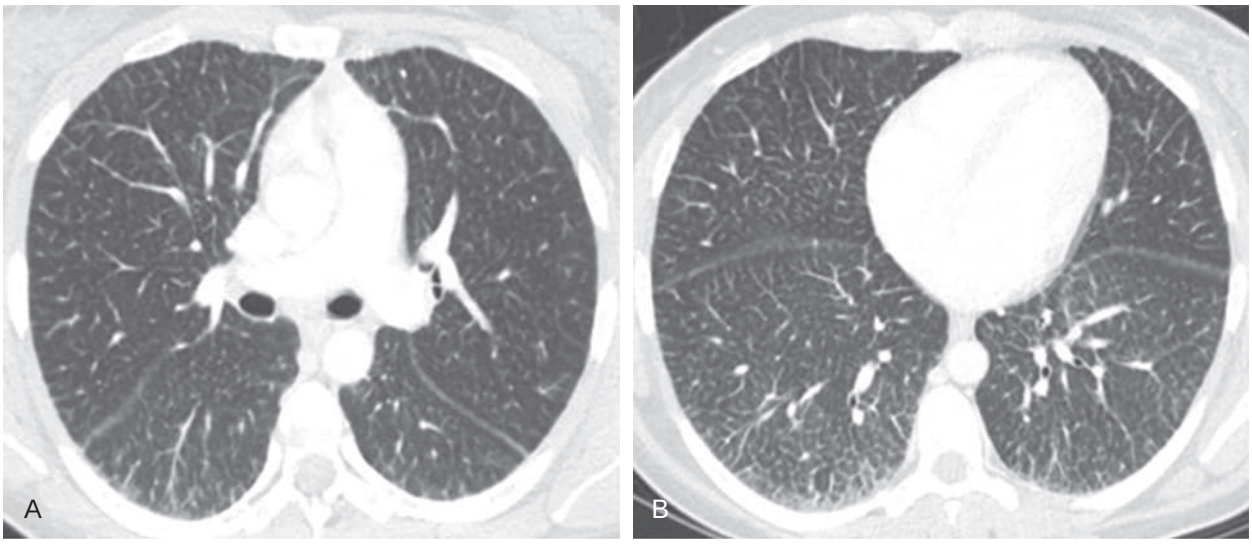

Figure 95.5 Niemann-Pick disease. Axial computed tomography images of the chest (A) immediately below the level of the carina and (B) lower lobes demonstrate interlobular septal thickening and ground-glass opacities, predominantly at the lung bases.

Each disease has different recognized subtypes. In NP disease, A and B subtypes are associated mostly with neurologic involvement. The A subtype is fatal during infancy, whereas the B subtype is associated with milder disease. The lung can be involved in all subtypes, but it is more common in type B, which causes chronic lung and bone marrow compromise without significant neurologic manifestations. Pulmonary involvement is detected mostly in adults, sometimes incidentally with an abnormal chest CT (Fig. 95.5 and eFig. 95.2) although, in some cases, it can progress to respiratory failure.[104,105] Of the three recognized subtypes of Gaucher disease, pulmonary disease is seen in type 1, usually in the more severe form of the disease. In both NP and Gaucher diseases, recurrent pulmonary infections are common.[106-108]

PH and hepatopulmonary syndrome have been documented in both NP and Gaucher diseases but seem to be more prevalent in the latter. The hepatopulmonary syndrome usually develops in the setting of long-standing liver disease and is associated with intrapulmonary shunting (intrapulmonary vascular dilations), with invariable association with splenomegaly. PH is not consistently related to the severity of the disease because it has been reported in cases of mild Gaucher disease.[110]

A presumptive diagnosis can be established in the setting of clinical symptoms, abnormal radiologic findings, and associated hepatosplenomegaly. The diagnosis of NP disease may be confirmed by genetic testing or determination of sphingomyelinase activity in peripheral blood leukocytes or cultured skin fibroblasts.[81,104] Analysis of bone marrow biopsy specimens may also reveal accumulations of lipid-filled macrophages.[109] BAL reveals lipid-laden macrophages. Lung biopsy shows foamy histiocytes in the alveolar space and interstitial tissue.[104] The diagnosis of Gaucher disease is confirmed by the finding of reduced glucocerebrosidase activity, usually in peripheral leukocytes, or detection of relevant mutations in peripheral blood cells.

Management is challenging and should include the usual supportive measures (vaccination, treatment of hypoxemia, pulmonary rehabilitation). Enzyme replacement therapy can ameliorate some of the manifestations, and cases of successful lung transplantation have been reported.[111]

PULMONARY ALVEOLAR MICROLITHIASIS

Pulmonary alveolar microlithiasis (PAM) is a rare autosomal recessive disorder characterized by widespread intraalveolar accumulation of calcium phosphate deposits called microliths. The disorder is linked to mutations in the type IIb sodium-dependent phosphate cotransporter, which results in an inability of alveolar epithelial type 2 cells to clear phosphorus ions from the alveolar space, thus leading to microlith or calcospherite formation in the extracellular fluid.[112,113]

The average age at the time of diagnosis is 40 years. There is no sex predilection. It is seen in all continents, but mostly in Europe and Asia, and particularly in Turkey and China.[114] Most patients are asymptomatic, with PAM diagnosed incidentally on the basis of radiologic findings. Slow progression follows in most cases (usually 10 to 20 years), with subsequent development of dyspnea, dry cough, chest pain and, in some cases, weight loss. Clubbing is present in most patients with advanced disease, and pneumothorax has been seen as a complication.[114]

Clinicoradiologic dissociation is an important characteristic, with minimal symptoms in the setting of abnormal or advanced radiologic changes. The *sandstorm sign* is characteristic of PAM. It is seen in both chest radiography and chest CT and consists of diffuse, scattered, bilateral areas of micronodular calcifications, involving the dependent portions of the lung, followed by the middle and upper areas (eFig. 95.3). The vascular tree and borders of the heart and diaphragm are often obscured ("vanishing heart" phenomenon).

A linear radiolucency at the pleural boundaries abutting the heart, diaphragm, and pleura on HRCT is also characteristic, and it has been named the *black pleural sign.* This characteristic imaging finding is likely secondary to the development of subpleural cystic changes, as reported in cross-sectional imaging and pathologic specimens.[112]

Figure 95.6 Pulmonary alveolar microlithiasis. (A) Chest radiograph showing the widespread intraalveolar deposition of calcium-containing microliths, with a lower lobe predominance. (B–C) Axial computed tomography images of the chest at the level of the (B) upper and (C) lower lobes demonstrate extensive alveolar granular calcifications in both lungs. Note the subpleural sparing giving the appearance of a "black pleura" sign, characteristic of alveolar microlithiasis.

This pattern can also be observed in mediastinal window images because calcification is present along the interlobular septa. One of the main differential diagnoses is miliary tuberculosis, given its similar radiologic appearance (Fig 95.6).[113-115]

At autopsy, the lungs are enlarged, heavy, and nonbuoyant, with a granular appearance of the pleural surface. The microliths are periodic acid–Schiff positive and form calcareous concentric lamellae around a central nucleus[113,114] (eFig. 95.4). The diagnosis is usually established in the setting of a characteristic radiologic appearance. Microliths can be isolated from BAL and even from sputum. Lung biopsy can be considered as well; transbronchial biopsy may be sufficient to provide the diagnosis.[116]

Currently, there is no recognized medical or gene therapy. Calcium-chelating agents, diphosphonates, and serial BAL have been ineffective. Lung transplantation should be considered.[114,117,118]

Key Points

- *Pulmonary Langerhans cell histiocytosis* (PLCH) is a smoking-induced diffuse lung disease that usually affects young adults and may cause varying degrees of bronchiolar, interstitial, and pulmonary vascular dysfunction.
- Analyses of PLCH tissues have identified activating mutations, particularly *BRAF*^{V600E}. For that reason, and because it can respond to chemotherapeutic agents such as cladribine, PLCH is currently considered a myeloid neoplasm with inflammatory characteristics.
- The natural history of PLCH is unpredictable: many patients have remissions or stabilize following smoking cessation, whereas others develop progressive lung disease.
- Smoking cessation is essential but not sufficient for all patients with PLCH. For a select subgroup, additional therapy with chemotherapy or *BRAF* inhibitor therapy may be necessary.
- Lung transplantation may extend life expectancy and improve quality of life in advanced PLCH, as well as in other rare infiltrative disorders discussed in this chapter, and it should be considered in patients with severe pulmonary involvement.
- Given the rarity of these disorders, referral to specialized centers and participation in clinical trials are recommended.
- Pulmonary hypertension group 5 (unclear and/or multifactorial mechanisms) may complicate the course of PLCH, neurofibromatosis, Niemann-Pick disease, and Gaucher disease.
- Hepatopulmonary syndrome can develop in patients with dyskeratosis congenita, Niemann-Pick disease, and Gaucher disease.

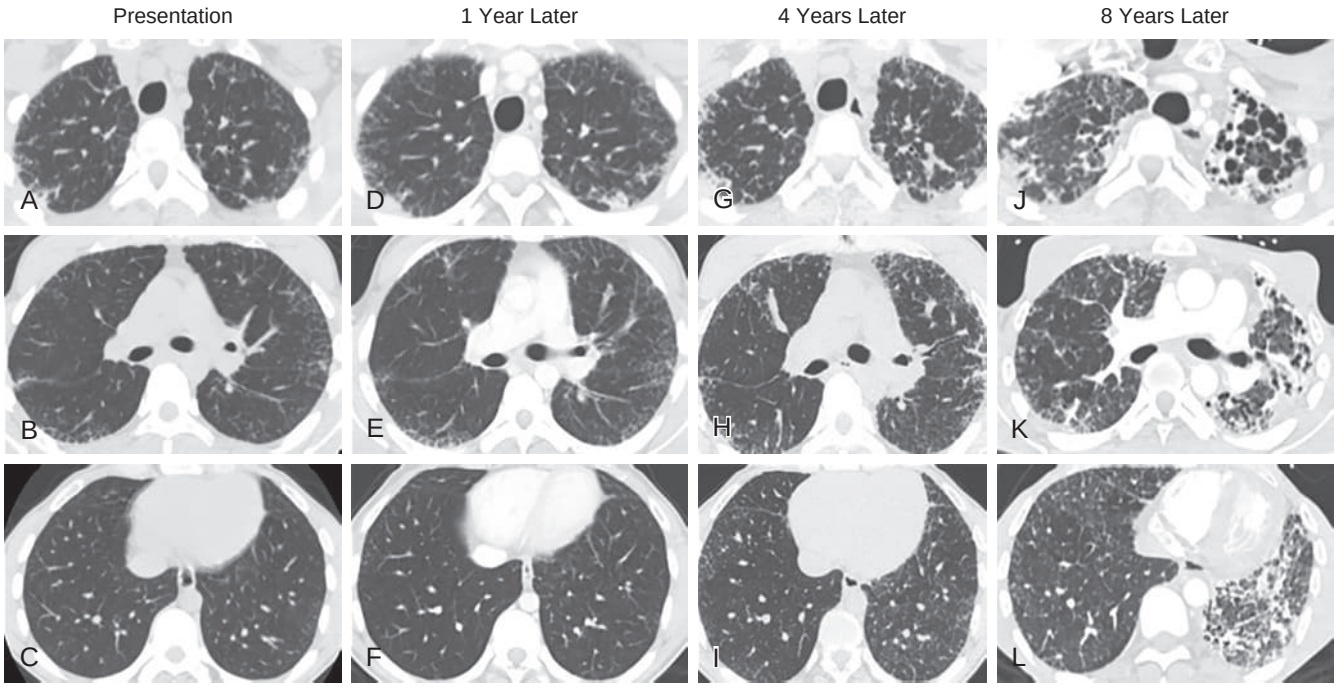
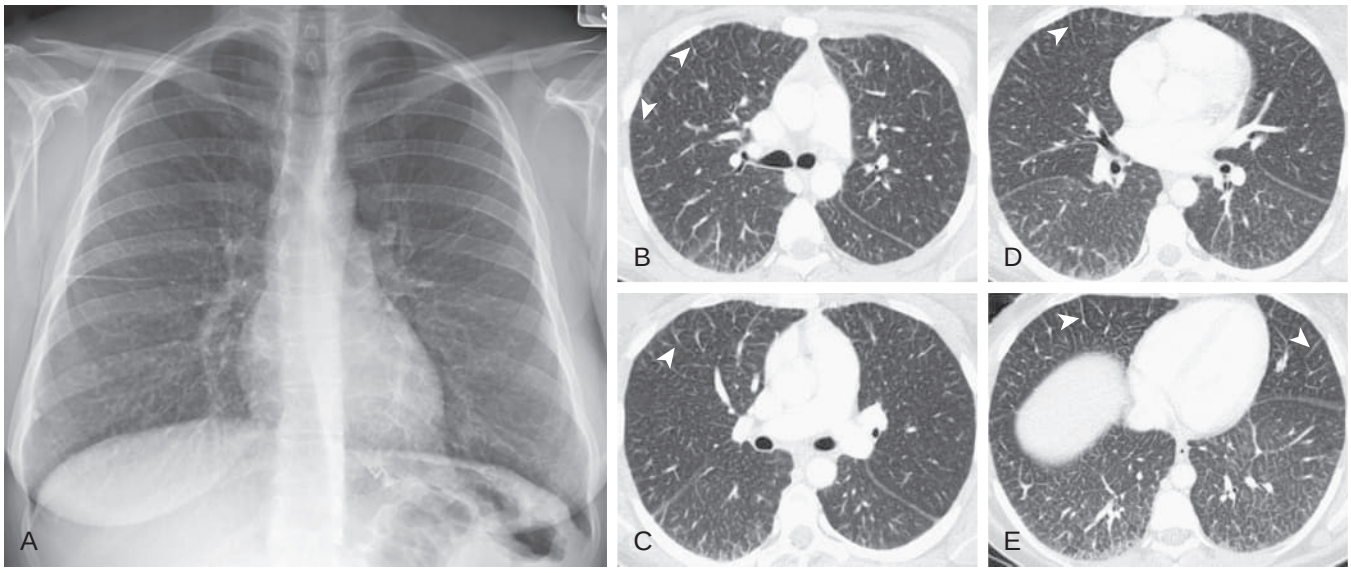
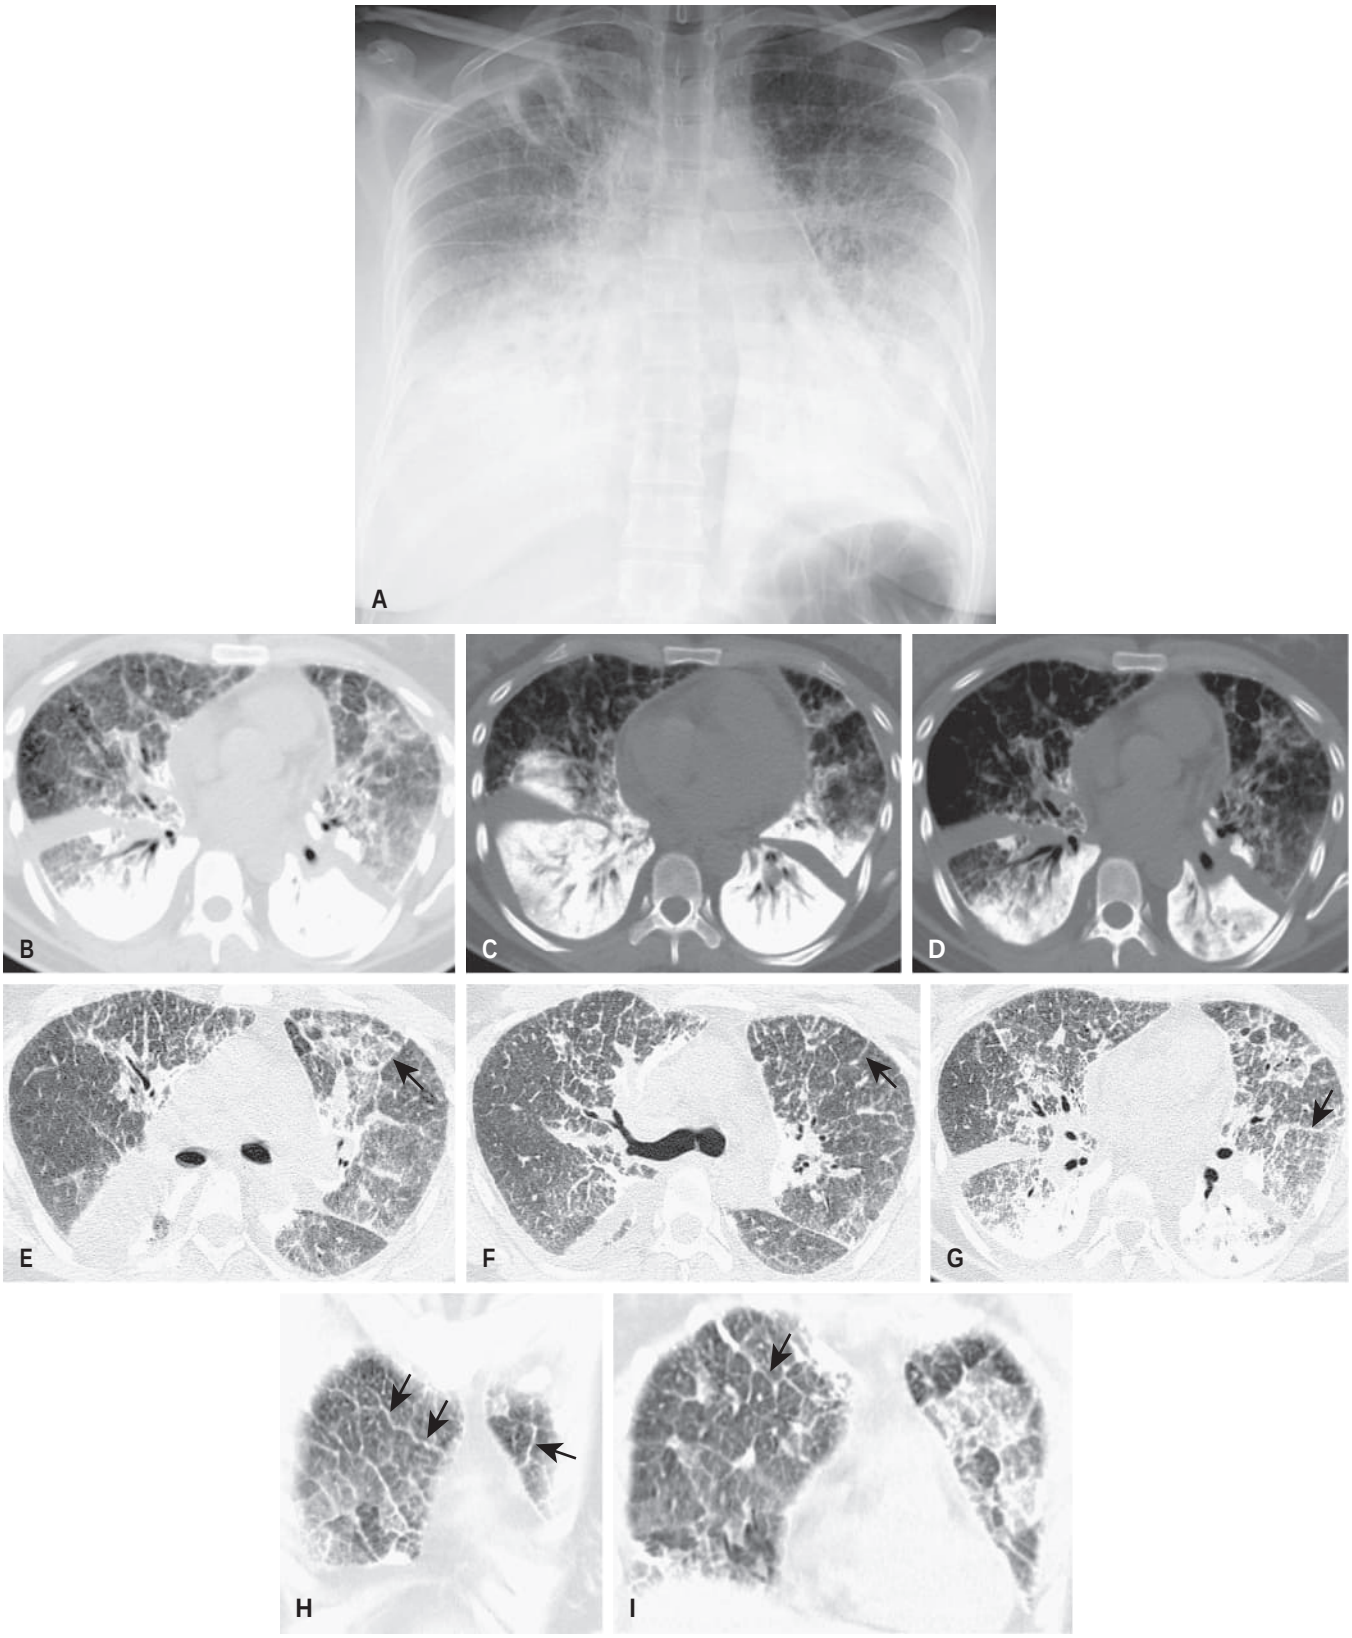
eFIGURE IMAGE GALLERY



eFigure 95.1 Fibrotic lung disease secondary to dyskeratosis congenita. (A–C) Axial chest *computed tomography* (CT) through the (A) upper, (B) middle, and (C) lower lungs in a 30-year-old man at presentation shows upper lobe peripheral reticulation without honeycombing; only mild architectural distortion is present. (D–F) Axial chest CT through the (D) upper, (E) middle, and (F) lower lungs 1 year following presentation shows slightly more apparent upper lobe predominant reticulation. (G–I) Axial chest CT through the (G) upper, (H) middle, and (I) lower lungs shows progression 4 years after presentation. (J–L) Axial chest CT through the (J) upper, (K) middle, and (L) lower lungs 8 years after presentation shows severe upper lobe fibrotic disease with frank honeycombing in the left apex. Fibrosis at the bases, particularly the left, has also worsened, but the abnormalities remain most severe in the upper lobes. (Courtesy Michael B. Gotway, MD.)



eFigure 95.2 Niemann-Pick disease: chest radiographic and chest computed tomography findings. (A) Frontal chest radiograph in a 34-year-old patient with Niemann-Pick disease type B shows fine, symmetrical, basal-predominant reticulation. Lung volumes are normal, and no pleural disease is evident. (B–E) Axial chest computed tomography displayed in lung windows shows smooth interlobular septal thickening *(arrowheads),* becoming particularly pronounced in the bases bilaterally. (Courtesy Dr. Eric A. Jensen, Mayo Clinic, AZ, and Michael B. Gotway, MD.)



eFigure 95.3 Pulmonary alveolar microlithiasis: chest radiographic and chest computed tomography findings. (A) Frontal chest radiograph shows bilateral, extensive, hyperattenuating basal consolidation associated with extensive linear opacity radiating from the hila. A right apical cavity (a finding unrelated to pulmonary alveolar microlithiasis) is present. (B–D) Axial chest *computed tomography* (CT) displayed in (B) lung and (C–D) bone windows shows calcified basal consolidation. Extensive interlobular septal thickening, in some areas hyperattenuating, is present. (E–G) Axial high-resolution chest CT displayed in lung windows shows extensive interlobular septal thickening *(arrows),* which is also seen to advantage in the coronal reformatted images (H–I; *arrows).* (From Panse PM, Jensen EA, Gruden JF, Gotway MB. Pulmonary parenchymal consolidation at thoracic CT: clues to a specific diagnosis. *Clin Pulm Med.* 2014;21:104-106.)

INTRODUCTION

The eosinophilic lung diseases are a group of disorders characterized by the presence and presumed pathogenetic role of eosinophils. They are mainly represented by the eosinophilic pneumonias, defined by a prominent infiltration of the lung parenchyma by eosinophils, which respond dramatically to corticosteroid treatment and generally heal without significant sequelae. The other eosinophilic lung diseases mainly involve the airways, as in the allergic bronchopulmonary mycoses and hypereosinophilic obliterative bronchiolitis. The eosinophilic endotype of asthma is not discussed in this chapter (see Chapter 60).

EOSINOPHIL BIOLOGY

PHYSIOLOGIC ROLE OF EOSINOPHILS

Identification of the multifunctional properties of the eosinophil has changed the view of eosinophils from terminal effector cells in allergic airway diseases to being involved in the initial stages of nonimmune and immune responses and disease.[1,2] Eosinophils are leukocytes implicated in innate and adaptive immunity, including numerous inflammatory reactions to parasitic helminth, bacterial, and viral infections.[3,4] They have been credited with a beneficial role against migratory nematode larvae in parasitic infestation through a strong *type 2 T-helper* (Th2) lymphocytic immune response and a non–antigen-specific host defense response mediated by group 2 innate lymphoid cells expressing *interleukin* (IL)-5.[5] In addition to their role in host protection, eosinophils have a role in tissue regeneration and repair after injury, metabolic homeostasis, immune homeostasis, angiogenesis, fibrosis, steady-state development of intestine and mammary gland, and tumor rejection.[1]

Many biologic properties of the eosinophil are directed by Th lymphocytes, but the eosinophil interacts in many allergic or inflammatory processes with other cells, including mast cells and basophils, endothelial cells, macrophages, platelets, and fibroblasts.[1,3,4,6] Eosinophils are

capable of regulating mast cell function and histamine release. Activated eosinophils express the major histocompatibility complex II protein *human leukocyte antigen* (HLA)-DR and possess the ability to participate in numerous immune functions, including antigen presentation and secretion of an array of cytokines capable of promoting effector T cell proliferation. Eosinophils are implicated in the regulation of Th1/Th2 balance through the synthesis of IL-4; the promotion of IL-4, IL-5, and IL-13 secretion by $CD4^+$ T cells; and the synthesis of indoleamine 2,3-dioxygenase (indirectly promoting Th1 apoptosis) (see also Chapters 15 and 16).

DIFFERENTIATION AND RECRUITMENT OF EOSINOPHILS TO THE LUNG

The eosinophil[3,4,6] matures in the bone marrow under the action of cytokines and especially of IL-5 (involved in the differentiation of eosinophil precursors), and, to a lesser extent, IL-3 and *granulocyte-macrophage colony-stimulating factor* (GM-CSF), the receptors of which use a common beta-chain, and the activation of transcription factors, including Δdbl-GATA-1. The eosinophil then circulates in the blood for about 1 day before being attracted into tissues by complex processes, including adhesion and chemoattraction, diapedesis, and chemotaxis, where it undergoes apoptosis unless survival factors are present. Recruitment of the eosinophil to the lung mostly implicates IL-5 and the eotaxin subfamily of chemokines (eotaxin is regulated by the Th2 cell–derived IL-13 cytokine).[7] IL-5 is mainly produced by Th2 cells but also by group 2 innate lymphoid cells implicated in the homeostatic homing of eosinophils to tissues, including the lungs.[8–10]

RELEASE OF PREFORMED PROTEINS

The release of proteins stored in intracellular granules is a major function of eosinophils and contributes to dysfunction and tissue damage.[11] Crystalline core-containing granules can release toxic cationic granule proteins (especially eosinophil peroxidase and eosinophil major basic protein-1[3]) and lipid mediators.[12] Granules also contain preformed cytokines that can be secreted by classical exocytosis, piecemeal degranulation, or cytolysis with granule release in a process that is rapid, stimulus dependent, and highly specific in terms of which cytokines are secreted.[1] For example, stimulation of eosinophils by eotaxin-1 leads to the rapid and specific release of granule-stored IL-4.[13] Vesicle-associated membrane proteins are implicated in the regulation of granule fusion in eosinophils.[6]

In addition to eosinophil-specific cationic proteins and cytokines, eosinophils release arachidonic acid–derived mediators, enzymes, reactive oxygen species, and matrix metalloproteases. They express a variety of surface proteins, including adhesion molecules, apoptotic signaling molecules, chemokines, complement receptors, chemotactic factor receptors, cytokine receptors, and immunoglobulin receptors.

The release of toxic substances contributes to the pathophysiology of eosinophilic disorders.[3] Eosinophilic cationic proteins have direct toxicity to the heart, brain, and bronchial epithelium.[11] Activated, degranulated eosinophils and cationic proteins can be found in the *bronchoalveolar lavage* (BAL)[14,15] and the lung tissue[16–18] of patients with eosinophilic pneumonia, and in cardiac lesions in the hypereosinophilic syndrome or in tropical eosinophilia.[19,20] Eosinophil-derived neurotoxin can be found in the urine in patients with active eosinophilic disease.[21,22]

Although histopathologic lesions in eosinophilic pneumonias are largely reversible with treatment, there may be tissue damage and remodeling with fibrosis partly through the release by eosinophils of transforming growth factor-β, especially in the bronchial mucosa, as in allergic bronchopulmonary aspergillosis and in *eosinophilic granulomatosis with polyangiitis* (EGPA).

TARGETING THE EOSINOPHIL CELL LINEAGE

Corticosteroids are the most effective agents for dramatically reducing eosinophilia in the blood and tissues by shortening the half-life of cytokines, such as eotaxins, and by inhibiting the cytokine-dependent survival of eosinophils; however, corticosteroids lack specificity.[23] Because IL-5 is involved at all stages of eosinophil differentiation, priming, activation, degranulation, and mediator secretion, monoclonal antibodies targeting the IL-5 pathway have been developed to target this cell lineage selectively,[24] first in humans with asthma[25–28] and later in various eosinophilic disorders.[29,30] Several other biologic therapies are already licensed to suppress type 2 inflammation via *immunoglobulin* (Ig)E and IL-4 receptor α.[31] Other targets for therapy more specific for eosinophils are being investigated, including eotaxins, which drive eosinophil recruitment into tissues, CD2-binding protein, and eosinophil surface-expressed inhibitory receptors,[1] especially Siglec-8.[32]

GENERAL FEATURES OF EOSINOPHILIC PNEUMONIAS

HISTORICAL PERSPECTIVE

In 1952, Reeder and Goodrich[33] published a series of cases describing pulmonary "infiltration with eosinophilia," including probable *idiopathic chronic eosinophilic pneumonia* (ICEP) and EGPA. In the same year, Crofton and coworkers[34] published a series of 16 cases of "pulmonary eosinophilia" with a review of 450 cases from the literature and proposed a classification of clinical presentations, including a description of simple pulmonary eosinophilia (Loeffler syndrome), defined by mild symptoms and transient opacities and, of interest, they mentioned "a continuum from the Loeffler syndrome to the severe and often fatal manifestations of polyarteritis nodosa." Churg and Strauss had reported in 1951[35] the eponym syndrome of "allergic granulomatosis, allergic angiitis, and periarteritis nodosa," now EGPA, and Carrington and colleagues[36] described in 1969 the syndrome of ICEP. McCarthy and Pepys[37] later reported 27 cases of "cryptogenic pulmonary eosinophilias," two of which developed systemic vasculitis. Idiopathic acute eosinophilic pneumonia was described by Davis and colleagues

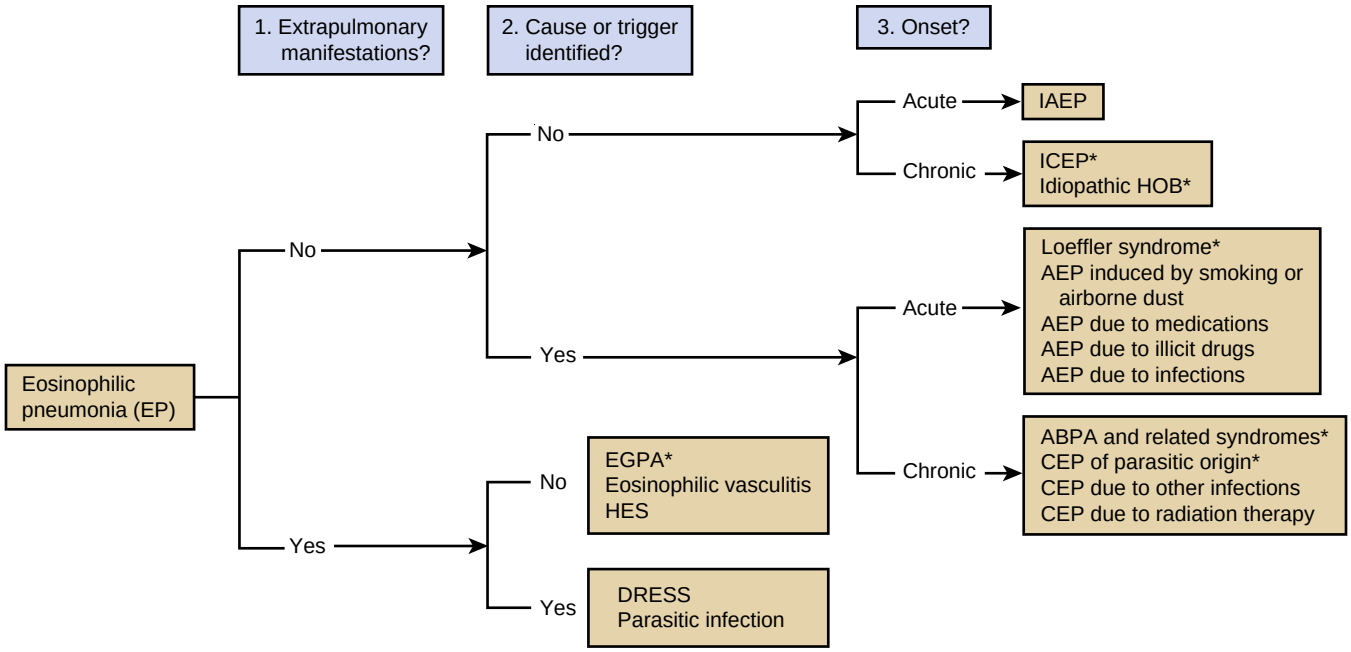

Figure 96.1 Diagnostic algorithm for eosinophilic pneumonia. The initial diagnostic question is whether there are extrapulmonary manifestations. *Conditions commonly associated with asthma or airflow obstruction. ABPA, allergic bronchopulmonary aspergillosis; AEP, acute eosinophilic pneumonia; CEP, chronic eosinophilic pneumonia; DRESS, drug reaction with eosinophilia and systemic symptoms; EGPA, eosinophilic granulomatosis with polyangiitis; HES, hypereosinophilic syndrome; HOB, hypereosinophilic obliterative bronchiolitis; IAEP, idiopathic acute eosinophilic pneumonia; ICEP, idiopathic chronic eosinophilic pneumonia.

in 1986,[38] then by Badesch and colleagues[39] and Allen and colleagues in 1989.[40] Hypereosinophilic bronchiolitis[41] and EGPA limited to the lung[42] were described recently.

CLINICAL PRESENTATION

Eosinophilic pneumonia is a pneumonia in which, on histopathologic examination, eosinophils are the most prominent inflammatory cells. Other inflammatory cells, especially lymphocytes and neutrophils, are often associated, but eosinophils clearly predominate. In clinical practice, eosinophilic pneumonias may be separated into two main etiologic categories: (1) those in which a definite cause is found or (2) those of undetermined origin (idiopathic), with the eosinophilic pneumonia being either solitary or included in a systemic disorder such as EGPA. A definite cause must be carefully investigated in any patient with eosinophilic pneumonia because it has practical consequences (e.g., stopping a drug responsible for iatrogenic eosinophilic pneumonia or treating a parasitic infection) (Fig. 96.1).

PATHOLOGY

Histopathologic studies of eosinophilic pneumonia have mainly been done in patients with ICEP,[36,43,44] which was initially diagnosed by open-lung biopsy. The pathologic features described in ICEP may be considered as a common denominator of all categories of eosinophilic pneumonias, whatever their origin. Additional features may be seen in other conditions, such as a distinctive distribution of lesions (e.g., bronchocentric distribution in *allergic bronchopulmonary aspergillosis* [ABPA], angiocentric distribution in EGPA), the presence of causal agents such as parasites or fungal hyphae, or necrotizing vasculitis in EGPA.[42]

In ICEP, the alveolar spaces are filled with eosinophils (Fig. 96.2A). Macrophages are also present, with some multinucleated giant cells scattered in the infiltrate; these may contain eosinophilic granules or *Charcot-Leyden crystals*, which are microscopic crystals composed of the eosinophil protein galectin-10.[36] An associated proteinaceous and fibrinous exudate and an interstitial inflammatory cellular infiltrate consisting of eosinophils, lymphocytes, plasma cells, and histiocytes are present. Some eosinophilic microabscesses may be observed as foci of necrotic intra-alveolar eosinophils surrounded by macrophages or epithelioid cells with palisading arrangement. The global architecture of the lung remains intact.

Organization of the alveolar inflammatory exudate is common,[36] suggesting some possible overlap between ICEP and organizing pneumonia. However, in ICEP, intraluminal organization in the distal air spaces is only sparse and never prominent and mucus plugs obstructing the small airways may be present.[36] A mild *non-necrotizing* vasculitis involving both small arteries and venules is common, with perivascular cuffing and a few cells infiltrating the arterial media (see Fig. 96.2B). The hilar lymph nodes associated with ICEP contain many eosinophils, and lymphoid hyperplasia is present.[36]

In *idiopathic acute eosinophilic pneumonia* (IAEP), the pathologic pattern includes intra-alveolar and interstitial eosinophilic infiltrates, diffuse alveolar damage, intra-alveolar fibrinous exudates, organizing pneumonia, and non-necrotizing vasculitis (Fig. 96.3).[45]

DIAGNOSIS

In clinical practice, the diagnosis of eosinophilic pneumonia is suspected in patients presenting with respiratory

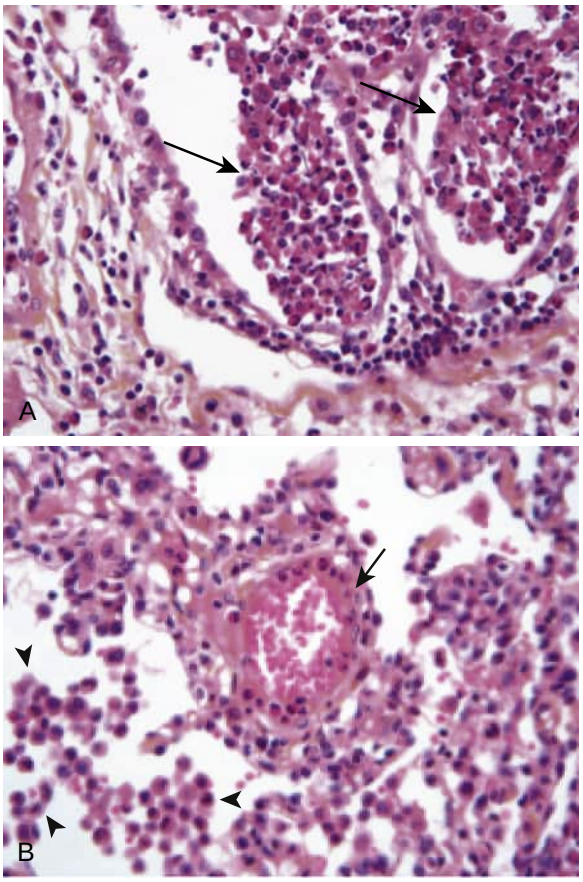

Figure 96.2 Eosinophilic pneumonia. (A) There is an accumulation of eosinophils (*arrows*) within the alveoli. (B) Eosinophils have infiltrated the arteriolar wall (non-necrotizing vasculitis) (*arrow*) and are present within the alveoli (*arrowheads*). (Courtesy Françoise Thivolet-Béjui, MD, Department of Pathology, Louis-Pradel Hospital and Claude Bernard University, Lyon, France.)

symptoms (dyspnea, cough, or wheezing), pulmonary opacities on chest imaging, and the demonstration of eosinophilia in the peripheral blood or, preferably, in the lung. Of importance, *blood eosinophilia* is defined by an eosinophil blood count greater than 0.5×10^9/L (500/μL) and *hypereosinophila* by an eosinophil blood count greater than 1.5×10^9/L (1500/μL) on two examinations at least 1 month apart, and/or tissue hypereosinophilia.[46]

Lung biopsy is seldom necessary to confirm the diagnosis of eosinophilic pneumonia. Transbronchial forceps lung biopsy may show characteristic features, but the small size of the specimen usually does not allow morphologic evidence of a possible etiologic process. Transbronchial cryobiopsy may be useful in difficult cases.[47,48]

BAL is recommended to confirm the diagnosis of eosinophilic pneumonia in most cases. BAL is a widely accepted noninvasive surrogate of lung biopsy for the diagnosis in a patient with *high-resolution computed tomography* (HRCT) features of eosinophilic pneumonia, although no study has definitely established a correlation between increased eosinophils at BAL and the finding of eosinophilic pneumonia at lung pathology. In normal subjects, BAL eosinophils comprise less than 1% of cells.[49,50] In contrast, BAL eosinophilia greater than 40% is found mainly in patients with chronic eosinophilic pneumonia, whereas BAL eosinophilia from 3–25% (and especially from 3–9%) may be found in various conditions, such as idiopathic pulmonary fibrosis, interstitial lung disease associated with connective tissue disorders, hypersensitivity pneumonitis, sarcoidosis, radiation pneumonitis, asthma, pneumoconioses, and infection.[51]

A conservative cutoff of 40% of eosinophils in the BAL has been adopted for the diagnosis of ICEP in clinical studies,[52,53] and a cutoff of 25% has been proposed for the diagnosis of IAEP.[54] For clinical practice, a diagnosis of eosinophilic pneumonia is supported by alveolar eosinophilia when the eosinophils (1) are the predominant cell population (macrophages excepted) and (2) represent more than 25% of the differential cell count in the BAL.[50]

Although BAL is usually useful and safe in patients with suspected eosinophilic pneumonia, it may not always be mandatory in typical cases with both pulmonary opacities on imaging and markedly elevated peripheral blood eosinophilia (>1×10^9/L and preferably 1.5×10^9/L [1500/μL]). However, BAL also contributes to alternative diagnoses in cases of bacterial or parasitic pneumonia or when pulmonary opacities are related to Hodgkin disease. BAL is generally omitted in Loeffler syndrome. Conversely, peripheral blood eosinophilia may be missing in patients who have already received systemic corticosteroids, and it is often absent at presentation in IAEP.

Once the diagnosis of eosinophilic pneumonia has been made, a thorough evaluation is necessary to investigate possible causes, such as parasitic infection or drug or toxic exposure, and to classify the case into one of the possible clinical entities (see Fig. 96.1).

IDIOPATHIC CHRONIC EOSINOPHILIC PNEUMONIA

CLINICAL FEATURES

ICEP was first described in detail by Carrington and colleagues[36] in a series of nine patients and further confirmed and detailed by several series.[44,52,55–59] It is the most frequent cause of eosinophilic pneumonia is Western countries. Current diagnostic criteria of ICEP are listed in Table 96.1.

ICEP is characterized by a progressive onset of symptoms over a few weeks or months with cough, increasing dyspnea, malaise, and weight loss. ICEP arises predominantly in women (with a 2:1 female/male ratio). It is rare before the age of 20 years,[60] and incidence is highest in the fourth decade.[44,52] A vast majority of patients are nonsmokers.[44,52,56,58] A prior history of atopy is found in about half of the patients, with allergic rhinitis in 12%[44] to 24%,[52] drug allergy in about 10%,[44,52] nasal polyps in 5–13%,[44,52] urticaria in 10%,[52] and eczema in 5%.[52]

Prior asthma is present at diagnosis of ICEP in two-thirds of the patients, develops concomitantly with the diagnosis of ICEP in 15% of patients, and can develop after ICEP in 13%.[53] The presentation of ICEP is similar in asthmatic and nonasthmatic patients, with the exception of higher total IgE in asthmatics.[53] Allergic desensitization is not considered to trigger ICEP. Asthma often gets worse after the development of ICEP and requires long-term oral corticosteroid

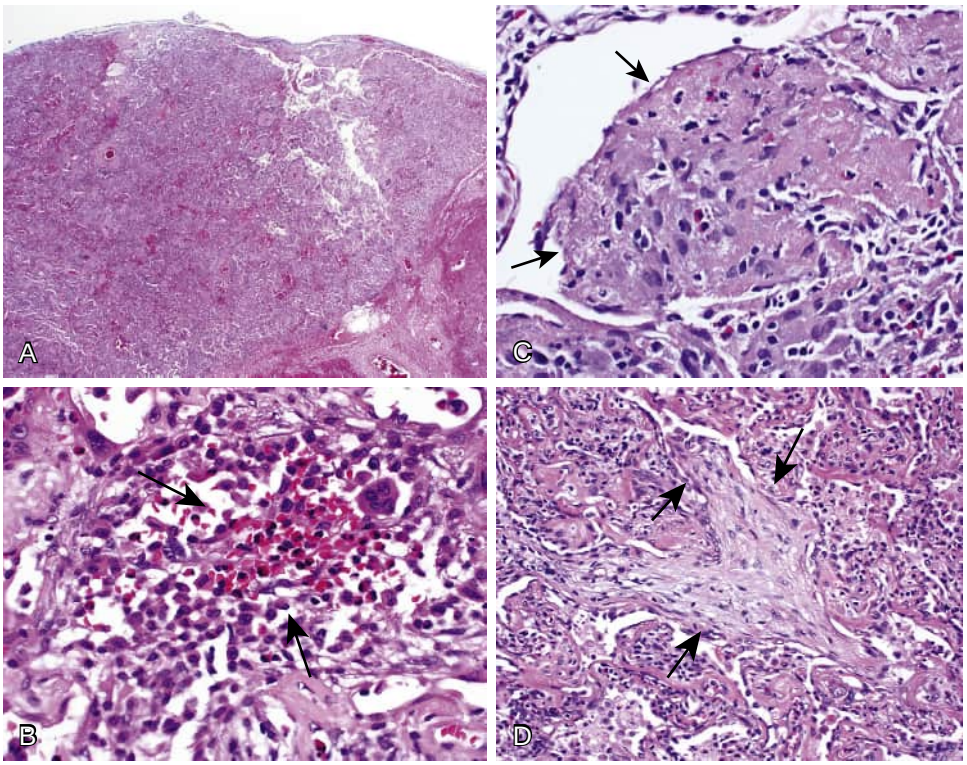

Figure 96.3 Acute eosinophilic pneumonia. (A) In acute eosinophilic pneumonia, the alveolar spaces are diffusely filled with eosinophils and plump eosinophilic macrophages, sometimes with an associated mild interstitial pneumonia. In this low-power view, multiple alveolar spaces are completely filled, up to the pleural surface. (B) Eosinophilic microabscesses (*arrows*) may be present. (C) Fibrinous air space exudates (*arrows*) are commonly present, typically with admixed eosinophils, as seen in this specimen. (D) Organizing pneumonia pattern with repair may also be seen (*arrows*). (From Leslie KO, Wick MR. *Practical Pulmonary Pathology: A Diagnostic Approach: A Volume in the Pattern Recognition Series.* ed 2. Philadelphia: Elsevier; 2011.)

Table 96.1 Distinctive Features of Idiopathic Chronic Eosinophilic Pneumonia and Idiopathic Acute Eosinophilic Pneumonia

	Idiopathic Chronic Eosinophilic Pneumonia	Idiopathic Acute Eosinophilic Pneumonia
Onset	>2–4 wk	<1 mo
History of asthma	Yes	No
Smoking history	10% are smokers	Two-thirds are smokers; often recent initiation
Respiratory failure	Rare	Usual
Initial blood eosinophilia	Yes	Often no (typically delayed)
BAL eosinophilia	>25%	>25%
Chest imaging	Homogeneous peripheral air space consolidation	Bilateral patchy areas of ground-glass attenuation, airspace consolidation, interlobular septal thickening, bilateral pleural effusion
Relapse	Yes	No
Diagnostic criteria	1. Diffuse pulmonary alveolar consolidation with air bronchogram and/or ground-glass opacities at chest imaging, especially with peripheral predominance 2. Eosinophilia at BAL differential cell count ≥ 40% (or peripheral blood eosinophils ≥ 1000 /mm^3) 3. Respiratory symptoms present for at least 2–4 wk 4. Absence of other known causes of eosinophilic lung disease (especially exposure to drug susceptible to induce pulmonary eosinophilia)	1. Acute onset with febrile respiratory manifestations (≤1 mo, and especially ≤7 days' duration before medical examination 2. Bilateral diffuse opacities on imaging 3. Pa_{O_2} on room air ≤ 60 mm Hg (8 kPa), or Pa_{O_2} /F_{IO_2} ≤ 300 mm Hg (40 kPa), or oxygen saturation on room air <90% 4. Lung eosinophilia, with ≥25% eosinophils at BAL differential cell count (or eosinophilic pneumonia at lung biopsy when done) 5. Absence of determined cause of acute eosinophilic pneumonia, including infection or exposure to drugs known to induce pulmonary eosinophilia. Recent onset of tobacco smoking or exposure to inhaled dusts may be present

BAL, bronchoalveolar lavage; F_{IO_2}, fractional concentration of oxygen in inspired gas; IAEP, idiopathic acute eosinophilic pneumonia; ICEP, idiopathic chronic eosinophilic pneumonia; kPa, kilopascal; Pa_{O_2}, arterial P_{O_2}.

treatment even in the absence of recurrence of the eosinophilic pneumonia.[53]

The onset of ICEP is progressive, with a mean interval between the onset of symptoms and the diagnosis of several weeks, and up to 4 months in one series.[52] However, the disease may be severely symptomatic at the time of diagnosis, and the definition of "chronic" may create some ambiguity. Fever, weight loss (>10 kg in about 10%), asthenia, malaise, fatigue, anorexia, weakness, and night sweats are also common.[52,58] The most common respiratory symptoms

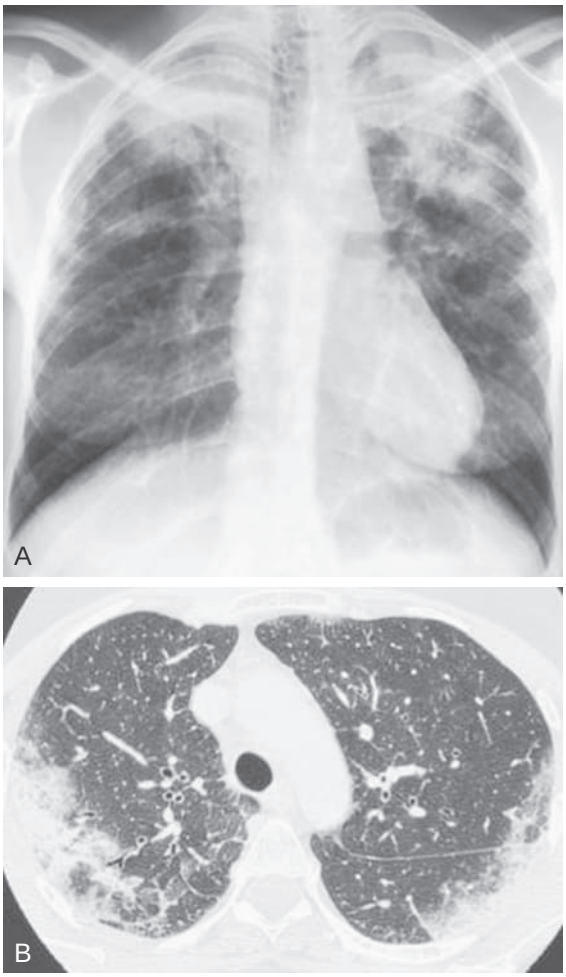

Figure 96.4 Idiopathic chronic eosinophilic pneumonia. (A) Chest radiograph of a patient with idiopathic chronic eosinophilic pneumonia shows bilateral alveolar opacities predominating in the upper lobes. (B) Axial chest computed tomography scan of a patient with idiopathic chronic eosinophilic pneumonia shows bilateral symmetrical peripheral alveolar opacities.

are cough, dyspnea, and chest pain.[44,52] Dyspnea is usually not severe initially, although respiratory failure has been reported.[61,62] Hemoptysis is rare (<10% of cases).[44,52] Wheezes at physical examination are found in one-third of patients[44] and crackles in 38%.[52] Upper respiratory tract symptoms of chronic rhinitis or sinusitis are present in about 20% of patients.[52]

IMAGING

The imaging features of ICEP are characteristic, although they may overlap with those found in cryptogenic organizing pneumonia. Peripheral opacities on chest radiography are present in almost all cases[36,44,52] and are migratory in a one-fourth of the cases.[52] They usually consist of alveolar opacities with ill-defined margins, with a density varying from ground-glass to consolidation (Fig. 96.4A, eFig. 96.1). The classic pattern of "photographic negative or reversal of the shadows usually seen in pulmonary edema,"[63,64] which is highly suggestive of ICEP,[63] is seen in only one-fourth of patients.[44]

The characteristic imaging features of ICEP are better described at HRCT (see Fig. 96.4B). Whereas the opacities are bilateral in at least 50% of cases at chest radiography,[44,56] the proportion of bilateral opacities may increase up to 97.5% at HRCT.[52] Characteristic opacities predominate in the upper lobes[44,52,65] and are peripheral, with generally coexisting ground-glass and consolidation opacities (Video 96.1).[52,66–69] Midzone distribution of opacities and centrilobular nodules are present in less than 20% of cases.[68] Lower lung zone involvement is infrequent.[58] Consolidation with segmental or lobar atelectasis may be seen.[66] Septal line thickening is common (see Video 96.1).[67] On corticosteroid treatment, consolidation and ground-glass opacities rapidly show a decrease in size and extent (eFig. 96.2), with possible change from consolidation to ground-glass opacities or inhomogeneous opacities and later to streaky or bandlike opacities parallel to the chest wall.[66] Cavitary lesions are extremely rare and should lead to reconsideration of the diagnosis. Contrary to organizing pneumonia, the reverse halo or atoll sign (i.e., central ground-glass opacity surrounded by denser consolidation in a crescentic circle or ring) is rare. Mediastinal lymph nodes are enlarged in 15–20%.[52,58] Compared with IAEP, in which pleural effusions are seen in the majority (see later), small pleural effusions are present in only 10% of cases of ICEP at HRCT.

LABORATORY STUDIES

Peripheral blood eosinophilia is almost always present, with the exception of cases where treatment has been initiated before the test. The mean percentage of blood eosinophils at differential count is generally greater than 20%,[44] and the mean blood eosinophilia is often greater than 5×10^9/L (5500/μL).[52,58] C-reactive protein level is elevated.[44,52,56] Total blood IgE level is increased in about half of cases and is greater than 1000 IU/mL in 15% (normal < 100 IU/mL) but lacks specificity.[52] Fractional exhaled nitric oxide is increased in ICEP and has been proposed as a way to monitor eosinophilic parenchymal inflammation.[70] Measurement of urinary excretion of eosinophil proteins and leukotrienes has been proposed for monitoring disease activity[21,71]; however, it is not widely available.

BRONCHOALVEOLAR LAVAGE

BAL is generally recommended for the diagnosis of ICEP. Alveolar eosinophilia is always present, with a differential cell count greater than 25% (mean value, 38% and 58% in two large series). A value greater that 40% is considered most consistent with a confident diagnosis of ICEP in the appropriate clinical setting.[52,58] Alveolar eosinophilia may also be associated with an increased percentage of neutrophils, mast cells, and lymphocytes.[52] BAL eosinophil cell count drops within a few days under corticosteroid treatment.[72] Sputum eosinophilia may also be present.[34,57]

Eosinophils with features of degranulation, activation and suppression of apoptosis (defined by in vitro studies), and eosinophil cationic proteins and various mediators are present in BAL fluid[15,73–88] and lung tissue[89] of patients

with ICEP. Of note, BAL lymphocytes are characterized by an accumulation of $CD4^+$ T cells that express activation surface antigens of memory T cells ($CD45RO^+$, $CD45RA^-$, $CD62L^-$)[90] and may present clonal rearrangement of the T cell receptor repertoire.[91,92]

DIFFERENTIAL DIAGNOSIS

Parasitic infection and drug-induced lung disease must be excluded. Although ICEP is not a systemic disease, isolated and moderately severe extrapulmonary manifestations, including arthralgias, repolarization (ST-T) abnormalities on the electrocardiogram, pericarditis, altered liver biologic tests, or eosinophilic lesions at liver biopsy, have been reported occasionally.[36,52] More significant manifestations, such as mononeuritis multiplex, skin nodules, or eosinophilic enteritis, suggest misclassification or overlap between ICEP and EGPA. Because eosinophilic pneumonia similar to ICEP may be a presenting feature of EGPA,[93–95] a thorough clinical evaluation is warranted, especially for clinically silent cardiac or renal involvement by EGPA, particularly in patients who have already received corticosteroids, which might prevent the development of overt systemic vasculitis.

PULMONARY FUNCTION TESTS

Pulmonary function tests (PFTs) in ICEP show an obstructive ventilatory defect in about half the patients[44,52] and a restrictive ventilatory defect in the other half.[52] An arterial partial pressure of oxygen of 75 mm Hg or less was present in 64% of patients in one series.[52] *Diffusion capacity for carbon monoxide* (D_{LCO}) may be decreased due to restrictive physiology, but the transfer coefficient (D_{LCO}/unit alveolar volume) is impaired in only one-fourth of cases.[52] An increased alveolar-arterial oxygen tension difference has been reported in 90% of cases.[44]

With treatment, PFTs normalize rapidly in most patients.[44] However, asthma frequently gets worse after the diagnosis of ICEP and may require long-term oral corticosteroids.[53] A persistent obstructive ventilatory defect may develop over time in one-third of patients,[58] especially those with a markedly increased BAL eosinophilia[96] or with airflow obstruction[58] at initial evaluation.

TREATMENT AND PROGNOSIS

Because ICEP is generally symptomatic, most patients are treated, although spontaneous resolution has been reported.[44,52] Response to oral corticosteroids is dramatic and rapid, with symptomatic improvement within 48 hours in about 80% of cases.[52] Death directly resulting from ICEP is exceedingly rare. Pulmonary opacities on chest radiography clear rapidly (eFig. 96.3), within 1 week of treatment in the majority of patients.[52]

The initial dose of corticosteroids usually varies between 20 and 60 mg/day. In an open-label, parallel group study, patients with ICEP were randomized to receive oral prednisolone for either 3 months or 6 months, with an initial dose of prednisolone of 0.5 mg/kg/day, which was then tapered and discontinued at either 3 or 6 months.[97] The primary end point was relapse during the follow-up period. No significant difference was found in the cumulative rate of relapse, and all relapses improved rapidly upon resumption of prednisolone. Our group starts with 0.5 mg/kg/day of prednisone, with slow tapering down to 5 to 10 mg/day over 3 months based on clinical evaluation and blood eosinophil cell count.

The clinical series in which follow-up is reported clearly show that most patients need very prolonged corticosteroid treatment due to the high frequency of relapse (>50%) below a daily dose of 10 to 15 mg/day of prednisone, or after stopping the corticosteroid treatment.[44,52,55] Relapses respond well to resumed corticosteroid treatment; a dose of 20 mg/day of prednisone is usually sufficient to treat the relapses.

Respiratory symptoms may be due to asthma or to a relapse of ICEP. Relapses of ICEP may be less frequent in patients with asthma, possibly because they often receive inhaled corticosteroids after stopping oral corticosteroids.[52,53] Inhaled corticosteroids might thus help in reducing the maintenance dose of oral corticosteroids, although they are not sufficient when given as monotherapy.[98] Alternate-day oral prednisone may reduce the adverse effects of systemic glucocorticoids. Long-term steroid use may lead to osteoporosis.

Omalizumab, a recombinant humanized monoclonal antibody against IgE, has been suggested in case reports to prevent recurrence of ICEP and to spare oral corticosteroids[99–101]; however, caution must be exerted given recent reports of omalizumab-associated EGPA.[102,103]

Successful off-label use of mepolizumab,[104,105] a monoclonal antibody against IL-5, and benralizumab,[47,104,106] an IL-5 receptor antagonist, were reported in case reports of ICEP. Because of the exquisite sensitivity of ICEP to corticosteroids, medications targeting the IL-5 pathway should be used with caution in patients with ICEP, pending further studies. Cases considered refractory to corticosteroids should lead the clinician to reconsider the diagnosis of ICEP.

IDIOPATHIC AND SMOKING-RELATED ACUTE EOSINOPHILIC PNEUMONIA

IAEP differs from ICEP by its acute onset; the severity of hypoxemia; the usual lack of increased blood eosinophils at presentation, contrasting with frank eosinophilic alveolitis at BAL (BAL differential count with ≥25% eosinophils); and the absence of relapse after clinical recovery.[38–40,45,54,57,107–109] Because fever and bilateral opacities on chest radiograph are present in nearly all patients, IAEP is often misdiagnosed as infectious pneumonia, and its frequency may therefore be underestimated[54] (see Table 96.1).[110]

CLINICAL FEATURES

IAEP presents acutely in previously healthy young adults,[111–113] with an average age at presentation of 30 years.[54,109,114,115] It is very rare in children.[116] A second peak has been reported in individuals age 60 years or older.[117] In contrast with ICEP, IAEP predominates in men,[112,115,118] and most patients have no prior asthma history.[57]

Symptoms at presentation consist of acute onset of cough, dyspnea, fever, and chest pain. IAEP may also develop subacutely over a few weeks (up to 1 month).[45,109] Abdominal complaints and also myalgias have been reported.[54] At physical examination, tachypnea and tachycardia are present, with crackles or, less often, wheezes on auscultation.

EXPOSURE AND TRIGGERS

AEP can be due to identifiable causes, including medications (see later) and inhalational exposures, especially cigarette smoke. Most patients diagnosed with IAEP seem to have been exposed to dust or cigarette smoke within the days before onset of disease,[119–123] and challenge with cigarette smoking was positive in some of them.[119–124] Tolerance may develop in patients who resume smoking.[120–122] Flavoring components of smoked cigars have been suspected.[125] Recent alterations in smoking habits within the previous month (e.g., beginning to smoke, restarting, or increasing the number of cigarettes smoked daily) is a frequent trigger.[112,115,123,126,127] Passive smoking has also been reported to cause AEP.[128] It is likely that inhalation of tobacco smoke or of other nonspecific injurious agents may initiate or contribute to the development of IAEP in individuals intrinsically prone to develop eosinophilic reactions to inhaled nonspecific causative agents. Increased levels of β(1→3)-D-glucan, a major component of the cell wall of most fungi and also one of the components of cigarette smoke, have been reported in BAL fluid of patients with IAEP,[129] suggesting that inhaled β(1→3)-D-glucan may be involved in the mechanisms of pulmonary inflammation in patients with IAEP.

Some patients reported peculiar prior outdoor activities, such as cave exploration, plant repotting, wood pile moving, smokehouse cleaning, motocross racing in dusty conditions, indoor renovation work, gasoline tank cleaning, and exposure to an exploding tear gas bomb,[54,109] which may explain why IAEP predominates in young patients during the summertime.[117] IAEP was reported in military personnel exposed to airborne dust and recent onset of tobacco smoking.[111–113,130–133] One case was also reported in a New York City firefighter exposed to World Trade Center dust.[134]

IMAGING

The chest radiograph shows bilateral opacities, with mixed alveolar or interstitial opacities (eFig 96.4A–B, G).[54,107–109] In contrast with ICEP, bilateral pleural effusion and Kerley B lines are common.[54] The chest radiograph returns to normal within 3 weeks (see eFig. 96.4L),[54,107] with pleural effusions being the last abnormality to disappear.[54]

At chest CT imaging, ground-glass opacities and air space consolidation are the most common patterns of parenchymal lesions, with poorly defined nodules and interlobular septal thickening seen in a majority of patients; pleural effusion is present in at least two-thirds of patients and is usually bilateral (see eFig. 96.4C–F, H–K).[54,107,109,113,135,136] Bilateral pleural effusion and interlobular septal thickening are highly characteristic of IAEP in a patient with eosinophilic pneumonia; in addition, they should raise the suspicion of IAEP in a patient considered to have infectious pneumonia.

LABORATORY STUDIES

In contrast with ICEP, the white blood cell count at presentation usually shows an increased leukocyte count with a predominance of neutrophils, with eosinophils only rarely higher than 0.3×10^9/L (300/μL). The eosinophil count often rises to high values later during the course of disease,[54,57,109,113] a retrospective finding suggestive of IAEP. Compared with medication-related and idiopathic AEP, smoking-related AEP is less likely to be associated with peripheral eosinophilia at presentation.[137] Eosinophilia is also present in the pleural fluid[113,121] and sputum.[57] Patients with peripheral blood eosinophilia[131,133,137] at onset or high BAL eosinophilia[133] may have milder disease.

The serum level of IgE may be increased,[113] and the serum level of IgG may be decreased,[138] but both lack specificity. Serum biomarkers were proposed[114,139–149] but with uncertain clinical relevance.

BRONCHOALVEOLAR LAVAGE

Given the usual lack of initial blood eosinophilia, BAL is the key to the diagnosis of IAEP,[115] showing an average percentage of 37%[54] to 65%[114] eosinophils on the differential cell count, with sterile bacterial cultures. Lymphocyte and neutrophil counts can be moderately increased. Eosinophilia greater than 25% at BAL establishes the diagnosis of AEP and obviates the need for lung biopsy. Bronchoscopy may show inflamed mucosa of the trachea.[127] A careful search for a cause of AEP is mandatory, and infectious agents must be sought for in BAL fluid by cultures and appropriate staining.[150–154] Drug-induced AEP must also be carefully excluded.

PULMONARY FUNCTION TESTS

Hypoxemia may be severe and refractory to breathing 100% oxygen, suggesting right-to-left shunting.[40,109] A majority of patients fit the definition of acute respiratory disease syndrome.[155] More than half of patients present with acute respiratory failure.[112] Noninvasive ventilation or mechanical ventilation is necessary less frequently in recent series[112,113,115,133,137] than in earlier reports.[54,109] In contrast with acute respiratory disease syndrome, shock is extremely unusual,[156,157] and extrapulmonary organ failure is not seen. Within a few hours of steroid treatment, it may be possible to decrease the fractional concentration of oxygen in inspired gas in many patients initially requiring oxygen.[54]

When performed in less severe cases, PFTs have shown a restrictive ventilatory defect, reduced D_{LCO},[45,109,111,116] and increased alveolar-arterial oxygen tension difference.[54] PFTs performed after recovery are normal in most patients, with possible ventilatory restriction in some of them.[54,158]

LUNG BIOPSY

When BAL is performed, lung biopsy is seldom necessary. When done, lung biopsies show acute and organizing

diffuse alveolar damage together with interstitial alveolar and bronchiolar infiltration by eosinophils, intra-alveolar eosinophils, and interstitial edema.[45,54,59,156]

TREATMENT AND PROGNOSIS

Recovery without corticosteroid treatment has been reported.[109,114] However, most patients diagnosed with IAEP receive corticosteroid treatment, with a starting dose of 40 to 60 mg of oral prednisone. For those with respiratory failure, intravenous methylprednisolone (60–125 mg every 6 hours) is given until respiratory failure resolves.[112] The patient generally responds to corticosteroids within 3 days (see eFig. 96.4L)[112] and can be rapidly weaned from the ventilator and from oxygen supplementation. The chest radiograph normalizes within 1 week in 85% of patients, but mild pulmonary opacities and pleural effusion may still be present on chest CT at 2 weeks.[112] A treatment duration of 2 weeks is sufficient.[112] Fatal cases are very rare,[111,156] and therefore prognosis is far better than that of acute respiratory disease syndrome.

The disease does not relapse after corticosteroid treatment is stopped, in contrast with ICEP. Identification of causative tobacco or environmental exposures is crucial to preventing rare recurrences that, in most cases, are due to resumption of cigarette smoking after smoking cessation.

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS

HISTORY AND NOMENCLATURE

Although the first cases were reported by Lamb in 1914,[159] and by Rackemann and Greene in 1951,[160] J. Churg and A. Strauss[35] described the syndrome, mainly from autopsied cases. They described characteristic pathologic features consisting of granulomatous extravascular lesions, as well as necrotizing, inflammatory, and granulomatous vascular changes, with an inflammatory exudate rich in eosinophils. The most frequent site of inflammation was the heart. In approximately half of the cases, a pneumonic process was found.

In 2012, the disease was renamed eosinophilic granulomatosis with polyangiitis at the International Chapel Hill Consensus Conference.[161] EGPA is a systemic disease associated with asthma, blood eosinophilia, and eosinophil-rich and granulomatous inflammation involving the respiratory tract and a small-vessel, necrotizing, small- to medium-sized vessel necrotizing vasculitis.[161] Because EGPA is associated in about 30–40% of cases with *antineutrophil cytoplasmic antibodies* (ANCA) positivity, it belongs to the group of ANCA-associated vasculitides, together with granulomatosis with polyangiitis and microscopic polyangiitis.[161] Yet, in most cases, circulating ANCAs are absent,[162,163] and robust criteria of documented systemic vasculitis (polyangiitis) are not always present.[164] (See also Chapter 87.)

PATHOLOGY

Because the diagnosis is now made earlier in the course of disease, lung biopsy is seldom necessary, and patients may receive corticosteroids before overt vasculitis has developed. The pathologic lesions of EGPA currently observed[165–167] only rarely comprise all the characteristic features on a single biopsy from one organ. When typical features are present, both vasculitis (necrotizing or not, involving mainly the medium-sized pulmonary arteries) and granulomatous eosinophilic infiltration are seen (Fig. 96.5A–B).[42] The extravascular granuloma consists of palisading histiocytes and giant cells (see Fig. 96.5C). Diffuse pulmonary hemorrhage with capillaritis can develop (see Fig. 96.5D). When present, the eosinophilic pneumonia in EGPA is similar to ICEP. The early (prevasculitic) phase of EGPA is characterized by eosinophilic infiltration of the tissues without vasculitis (perivascular eosinophils are commonly found).

CLINICAL FEATURES

EGPA predominates in the fourth or fifth decade, with no gender predominance,[163,164,168–178] which contrasts with allergic asthma predominating earlier in life and in women. EGPA also presents earlier in life than other ANCA-associated vasculitides. It has occasionally been reported in children and adolescents.[179–185]

Asthma, generally severe and corticosteroid dependent, presents at a mean age of about 35 years.[169] It may precede the onset of vasculitis by 3 to 9 years.[169–172] However, the interval between asthma and the onset of vasculitis may be much longer in rare cases,[172] or they may be contemporaneous.[170] Asthma severity, however, may attenuate after the onset of the vasculitis,[169,172,186] possibly due to the effect of systemic glucocorticoids prescribed for vasculitic manifestations.[186–188]

Chronic rhinitis is present in about three-fourths of cases of EGPA[169,189,190] and is often accompanied by relapsing paranasal sinusitis and/or polyposis,[163,186,191,192] with eosinophilic infiltration seen on histopathology.[193–195] Crusty rhinitis may be present, but the rhinitis in EGPA is distinctly much less severe than in granulomatosis with polyangiitis, with septal nasal perforation being rare. Mild to moderate hearing impairment is frequent.[191]

Asthenia, weight loss, fever, arthralgias, and myalgias often herald the development of the extrapulmonary manifestations of vasculitis.

Heart damage, which may be severe and lead to cardiac failure with long-term sequelae or sudden death,[169-173,196–198] results especially from eosinophilic myocarditis[196] and much less commonly from coronary arteritis[199–201] or endomyocarditis.[202] It is often insidious and asymptomatic and thus may be recognized only when left ventricular failure and dilated cardiomyopathy have developed. Heart failure may require heart transplantation.[203] Because marked improvement may be obtained with corticosteroid treatment without resolving the cardiac risks, any patient suspected of having EGPA should undergo a systematic cardiac evaluation,[204] including electrocardiogram, echocardiography, and serum levels of troponin I and N-terminal pro–brain natriuretic peptide. In case of clinical suspicion, cardiac *magnetic resonance imaging* (MRI) is the preferred method to confirm heart involvement, by demonstrating late enhancement of the myocardium[197,198,204–209]; however, it remains difficult to differentiate irreversible lesions representing scarring from active inflammation requiring intense

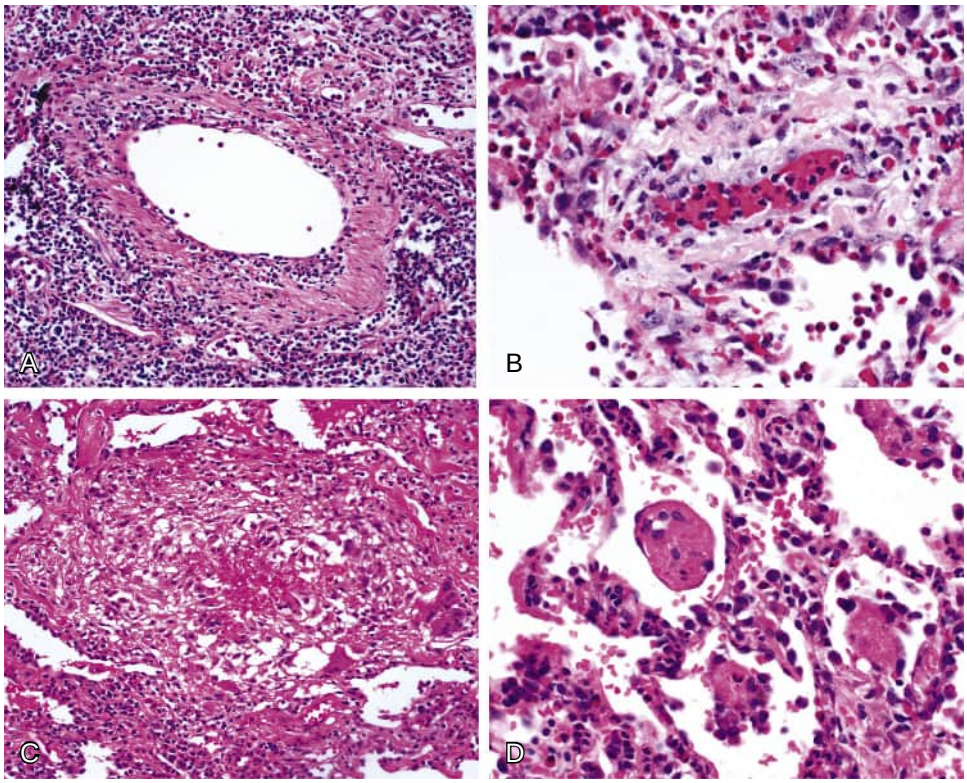

Figure 96.5 Eosinophilic granulomatosis with polyangiitis. (A) Vasculitis. A medium-sized artery infiltrated by eosinophils and scattered lymphocytes. (B) Vasculitis. A venule infiltrated by eosinophils. Note fibrin and eosinophils in surrounding air spaces. (C) Eosinophilic granulomas. Characteristic "allergic granuloma" is readily apparent. Note the vaguely palisaded histiocytes at the periphery of eosinophilic necrosis (*center*). Multinucleate giant cells may be present and typically have a brightly eosinophilic cytoplasm. (D) Pulmonary hemorrhage. Diffuse pulmonary hemorrhage with capillaritis can be seen in eosinophilic granulomatosis with polyangiitis. Capillaritis is demonstrated here, associated with aggregated air space fibrin and eosinophils. (From Leslie KO, Wick MR. *Practical Pulmonary Pathology: A Diagnostic Approach: A Volume in the Pattern Recognition Series.* ed 2. Philadelphia: Elsevier; 2011.)

immunosuppression.[197,205,210–212] The combination of cardiac MRI with positron emission tomography may be useful but deserves further study.[213] Pericarditis with limited effusion at echocardiography is common, but tamponade is rare.[214] In contrast with the idiopathic hypereosinophilic syndrome, endomyocardial involvement is not a common feature. Patients with EGPA are at increased risk of venous thromboembolic events,[215,216] in part through activated eosinophils.[217–219]

Virtually all organs may be involved with varying frequency.[220] Peripheral neurologic involvement consists mainly of sudden onset of mononeuritis multiplex, present in three-fourths of patients.[163,221–224] Cranial nerve palsies and central nervous system involvement are rare.[225] Gastrointestinal tract involvement is present in 31% of cases[163] and usually manifests as isolated abdominal pain, but intestinal or biliary tract vasculitis may be present. Other gastrointestinal manifestations include diarrhea, ulcerative colitis, gastroduodenal ulcerations, perforations (esophageal, gastric, intestinal), digestive hemorrhage, and cholecystitis.[226] Cutaneous lesions, which present in about half of patients,[163] mainly consist of palpable purpura of the extremities, subcutaneous nodules (especially of the scalp and extremities), erythematous rashes, and urticaria. Renal involvement presents in one-fourth of cases and is usually mild,[163,171,227,228] in contrast with the other ANCA-associated vasculitides. Alveolar hemorrhage is rare.[163,229–233]

IMAGING

Pulmonary opacities corresponding to eosinophilic pneumonia represent the most typical abnormalities present in 37–72% of cases on chest radiograph.[169,234] The chest radiograph may be normal throughout the course of the disease. The pulmonary opacities usually consist of ill-defined opacities, sometimes migratory, transient, and of varying density.[169,172,235–237] Pulmonary cavitary lesions are extremely unusual. Pleural effusion (usually mild) and phrenic nerve palsy may be observed.

The abnormalities on thin-section chest CT may predominate in the airspaces or in the airways, corresponding to eosinophilic pneumonia, or to bronchiolar and bronchial involvement, respectively.[185,237,238] Airspace abnormalities consist of ill-defined opacities, with a density varying from ground-glass attenuation to airspace consolidation (Fig. 96.6). They typically predominate in the lung periphery and upper zones of the lung, or have a random distribution, and can be migratory as in ICEP.* Airway abnormalities include centrilobular nodules, bronchial wall thickening, and occasionally bronchiectasis or a tree-in-bud pattern.[68,135,186,237] Interlobular septal thickening, mediastinal lymphadenopathy, and pleural or pericardial effusion (eFig. 96.5) can rarely be observed.[68,235,237,239,242]

LABORATORY STUDIES AND BRONCHOALVEOLAR LAVAGE

Peripheral blood eosinophilia is a major feature of EGPA and usually parallels the activity of the vasculitis. Blood eosinophils are generally between 5 and 20 × 10^9/L (5000–20,000/μL), but they may reach higher values.[163,169,186] Blood eosinophilia often disappears

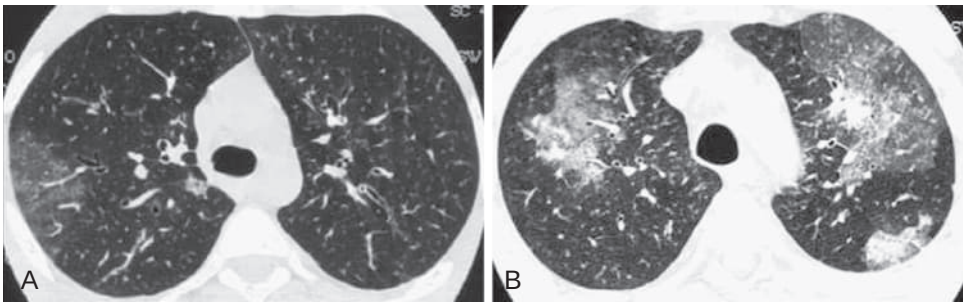

Figure 96.6 Eosinophilic granulomatosis with polyangiitis. Axial chest computed tomography scan of patients with eosinophilic granulomatosis with polyangiitis shows ground-glass opacity of the right upper lobe (A) and bilateral central and peripheral opacities with varying density (B).

dramatically after the initiation of corticosteroid treatment. Eosinophilia, sometimes greater than 60%, is found on BAL differential cell count[186,243] and in pleural fluid when present.[244] The bronchial mucosa may look macroscopically inflammatory at bronchoscopy, with occasional whitish granulations[186,245–247] reminiscent of what is seen in hypereosinophilic bronchiolitis.[41]

Serum IgE levels are increased[186] but lack specificity for the diagnosis. The C-reactive protein level is increased, and anemia is common. Rheumatoid factor may be associated with more frequent gastrointestinal lesions.[180] None of the proposed biomarkers has been validated.[22,248–258]

ANTINEUTROPHIL CYTOPLASMIC ANTIBODIES

The ANCAs reported in 30–40% of patients are mainly *perinuclear antineutrophil cytoplasmic antibodies* (p-ANCAs) with myeloperoxidase.[162,164,170,171,259,260] ANCA status characterizes two distinct clinical phenotypes in EGPA, although with some overlap.[162,163,259–262] Patients *with* ANCA, representing approximately 40% of patients, have a *vasculitic phenotype* of disease, with more frequent glomerular renal disease, peripheral neuropathy, palpable purpura, and biopsy-proven vasculitis. Conversely, patients *without* ANCA have a *tissue* phenotype of disease, with more frequent cardiac (eosinophilic myocarditis), fever, and pulmonary involvement (eosinophilic pneumonia). The latter might conceivably represent a variant of the hypereosinophilic syndrome with systemic manifestations.[263] A genetic predisposition may affect the phenotype of EGPA.[264–266] ANCAs have been found in the sputum of patients with EGPA, including in some without circulating ANCAs.[267] However, measurement of ANCAs in the sputum is not recommended in clinical practice.

PATHOGENESIS

Deciphering the pathogenesis of EGPA is challenging due to its dual categorization as a hypereosinophilic condition and an ANCA-associated systemic vasculitis.[268] It is unclear whether the two subsets of EGPA have unique pathogenic mechanisms.[268]

EGPA, when associated with ANCAs, is considered an autoimmune process involving a Th2-mediated inflammatory response.[269–271] A genetic predisposition to EGPA has been demonstrated in patients carrying the major histopathology complex DRB4 and the DRB1*04 and *07 alleles[264] and perhaps in certain families.[272] Genetic predisposition may affect the presence of ANCA and the clinical phenotype of disease.[266,273,274] In patients with EGPA without ANCA, IL-10 promoter polymorphisms have been found to be associated with increased serum levels of IL-10 (a cytokine that inhibits the Th1-type T cell response).[265]

Possible defects have been identified in regulatory T cell lymphocytes.[275,276] Also, dysregulation of Th17,[269] clonal expansions of $CD8^+/V\beta^+$ T cells with effector memory phenotype expressing markers of cytotoxic activity, and rearrangement of the *T cell antigen receptor (TCR)-γ* gene[277–279] and *T-cell receptor-C β* gene have been reported.[280] The pathogenic relevance of these observations is unclear. The hypothesis of defective apoptosis pathways in eosinophils has not been confirmed.[281]

Exogenous and environmental risk factors were suspected to play a role in the pathogenesis of EGPA, including vaccines, allergens, desensitization, medications,[282,283] some infections *(Aspergillus,* allergic bronchopulmonary candidiasis, *Ascaris*), or exposure to silica,[284] birds, or smoked cocaine. Evidence of allergy (demonstration of specific IgE with corresponding clinical history) is present in less than one-third of patients with EGPA, mainly consisting of perennial allergies, especially to *Dermatophagoides*.[285]

Drug-induced eosinophilic vasculitis with pulmonary involvement has been reported in the past with sulfonamides used together with antiserum[286] and later with diflunisal,[287] macrolides,[288] diphenylhydantoin,[289] mesalazine,[290] propylthiouracil,[291] masitinib,[292] and immune checkpoint inhibitors.[293] The association between leukotriene-receptor antagonists (montelukast, zafirlukast, pranlukast) and EGPA is generally considered to be related to reducing oral or inhaled corticosteroids, allowing them to unmask smoldering EGPA,[170,294–301] although a direct causal relationship cannot be totally excluded.[262,294,296,302,303] It is probably wise to avoid these medications in any asthma patient with eosinophilia or suspected EGPA. EGPA has also been reported in asthmatic patients treated with inhaled corticosteroids[304] or with omalizumab, an anti-IgE antibody, probably through better control of asthma manifestations, allowing a reduction in corticosteroids.[103,305–310]

DIAGNOSIS

The evolution of EGPA usually follows three stages: asthma and rhinitis, tissue eosinophilia (such as a pulmonary disease resembling ICEP), and extrapulmonary eosinophilic disease with vasculitis. Diagnostic difficulties thus largely depend on the stage of disease at which the patient is seen. Exceptional cases without asthma have been described[311,312]; however, no lung function was reported.

Table 96.2 Cottin and Cordier[316,317] Diagnostic and Classification Criteria of Eosinophilic Granulomatosis With Polyangiitis

Asthma
Peripheral blood eosinophilia > 1500 /mm^3 and/or alveolar eosinophilia > 25%
Extrapulmonary clinical manifestations of disease (other than rhinosinusitis), with at least one of the following: ■ Systemic manifestation typical of the disease: mononeuritis multiplex, cardiomyopathy confidently attributed to the eosinophilic disorder, or palpable purpura ■ Any extrapulmonary manifestation with histopathologic evidence of vasculitis as demonstrated especially by skin, muscle, or nerve biopsy ■ Any extrapulmonary manifestation with evidence of ANCA with antimyeloperoxidase or antiproteinase 3 specificity

When a single extrarespiratory manifestation attributable to the systemic disease is present, disease may be called a forme fruste of EGPA syndrome.
ANCA, antineutrophil cytoplasmic antibodies; EGPA, eosinophilic granulomatosis with polyangiitis.

Although systemic disease is necessary to consider a diagnosis of EGPA, it is extremely important that the diagnosis be established before severe organ involvement (especially cardiac) is present. In addition, *formes frustes* of EGPA[313,314] or EGPA limited to a single organ,[313] including the lungs, have been described.[42,315]

Diagnostic and classification criteria for EGPA are present in Table 96.2, including pragmatic criteria taking into account the presence of ANCA[316,317]; additional criteria are included in eTable 96.1. Of importance, the classification criteria of the American College of Rheumatology[318] are applicable only in a patient with proven systemic vasculitis.

A pathologic diagnosis of EGPA is desirable, but not mandatory, in patients with characteristic clinical features and marked eosinophilia. The skin, nerve, and muscle are the most common sites where a pathologic diagnosis of vasculitis may be obtained. Biopsy of the cutaneous lesions is the most common and simple procedure to obtain pathologic evidence of vasculitis. Lung biopsy is seldom done. Transbronchial biopsies usually do not show vasculitis or granulomata.

Idiopathic systemic eosinophilic vasculitis[319] is a recently described entity. Pathologically, the vasculitis, which may be necrotizing or not, is without granulomas. By definition, patients do not have a history of asthma. The lung may be involved,[320] although this has not yet been described in detail. Although idiopathic systemic eosinophilic vasculitis appears distinct from EGPA, it may be part of a common spectrum.[320]

Cases of EGPA overlapping with ICEP,[36,93,94] ABPA,[321–324] granulomatosis with polyangiitis,[325–328] polyarteritis nodosa,[329] temporal arteritis,[330–335] IgA glomerulonephritis,[336] unclassified systemic eosinophilic disease, idiopathic hypereosinophilic syndrome,[337,338] and infections[339] have been described. Rare infections can masquerade as EGPA.[340,341] Careful clinical analysis, the presence of ANCA, serology for *Aspergillus*, the finding of a vasculitis and granulomas on biopsy, and molecular biologic analysis (in the cases of idiopathic hypereosinophilic syndrome) help in determining the final diagnosis.

TREATMENT AND PROGNOSIS

Glucocorticoids are the mainstay of treatment and are sufficient to control the disease in the majority of cases. Oral prednisone is initiated at a dose of 1 mg/kg/day for 3 to 4 weeks, then tapered to reach 5 to 10 mg/day by 12 months of therapy. Initial methylprednisolone bolus (15 mg/kg/day for 1–3 days) may be indicated in the most severe cases,[342] especially in case of myocardial involvement. Management should be multidisciplinary,[343] avoiding any delay which may impact prognosis.[344]

For remission induction, the immunosuppressant cyclophosphamide (three intravenous infusions of 0.6 g/m^2 each at day 1, 15, 30; then three additional infusions of 0.7 g/m^2 every 3 weeks)[345–347] should be added to glucocorticoids in patients with features of poor prognosis (so-called five-factor score: i.e., cardiomyopathy, severe gastrointestinal involvement, renal insufficiency with serum creatinine greater than 150 μmol/L [1.7 mg/dL], proteinuria > 1 g/day, central nervous system involvement).[348,349] (The dose of cyclophosphamide may be reduced to 500 mg fixed-dose intravenous pulses, every 2 to 3 weeks, in individuals older than 65 years.[352])

Predictors of poor prognosis have been updated and now include age older than 65 years, cardiac symptoms (based on easily detectable clinical parameters), gastrointestinal involvement, renal insufficiency, and absence of ear, nose, and throat symptoms.[163,350,351] In addition, severe alveolar hemorrhage, eye involvement (e.g., scleritis), and/or fulminant mononeuritis multiplex also warrant the prescription of immunosuppressants. In the absence of criteria of poor prognosis, corticosteroids alone are sufficient and, in a randomized placebo-controlled trial, azathioprine failed either to increase remission rate or prevent relapses.[353]

Once remission has been achieved, prolonged maintenance therapy is necessary to prevent relapses. In the absence of criteria of poor prognosis, maintenance generally consists of glucocorticoids alone, with tapering doses.[354] Immunosuppressive therapy, especially azathioprine or methotrexate, is occasionally used as a corticosteroid-sparing agent in this situation, particularly in subjects who require 10 mg/day of prednisone or more; however, it may now be less frequently used due to availability of eosinophil-targeted therapy. In patients with poor prognostic criteria, maintenance therapy is generally based on azathioprine for 18 to 24 months. Mycophenolate mofetil may be less effective than azathioprine to prevent relapses.[355] Methotrexate, 0.25 mg/kg/week, is an alternative to azathioprine.[356]

Mepolizumab, a human monoclonal antibody that binds to IL-5 and prevents its interaction with its receptor on the eosinophil surface, consistently reduces eosinophil cell counts in peripheral blood, and improves severe eosinophilic asthma.[26,27,357–359] After promising preliminary results in isolated cases,[29,360,361] the efficacy and safety of mepolizumab was evaluated in a Phase III randomized trial as add-on therapy versus placebo in subjects with relapsing or refractory EGPA,[30] in many patients due to difficult to control asthma. Compared to placebo, mepolizumab (300 mg every 4 weeks) led to an increased proportion of patients achieving remission, an increased duration of remission, a lower rate of relapse, and a lower average daily dose of oral corticosteroids.[30] Mepolizumab is indicated as adjunctive

eTable 96.1 Variously Published Diagnostic and Classification Criteria of Eosinophilic Granulomatosis With Polyangiitis

LANHAM AND COLLEAGUES[169]
Asthma
Eosinophilia
Evidence of vasculitis involving at least two organs
AMERICAN COLLEGE OF RHEUMATOLOGY*[318]
Asthma
Eosinophilia > 10%
Mononeuropathy or polyneuropathy
Pulmonary infiltrates, nonfixed
Paranasal sinus abnormality
Extravascular eosinophil infiltration on biopsy findings
2012 CHAPEL HILL CONSENSUS CONFERENCE DEFINITION[161]
Eosinophil-rich and necrotizing granulomatous inflammation, often involving the respiratory tract ■ *and* necrotizing vasculitis predominantly affecting small to medium vessels ■ *and* associated with asthma and eosinophilia
ANCA is more frequent when glomerulonephritis is present
DIAGNOSTIC CRITERIA USED IN TRIAL NCT02020889[30]
History or presence of asthma plus eosinophilia ($1.0 \geq 10^9$/L and/or >10% of leukocytes) plus at least two of the following additional features of EGPA: ■ A biopsy showing histopathologic evidence of eosinophilic vasculitis, perivascular eosinophilic infiltration, or eosinophil-rich granulomatous inflammation ■ Mononeuropathy or polyneuropathy (motor deficit or nerve conduction abnormality) ■ Pulmonary infiltrates, nonfixed ■ Sinonasal abnormality ■ Cardiomyopathy (established by echocardiography or MRI) ■ Glomerulonephritis (hematuria, red cell casts, proteinuria) ■ Alveolar hemorrhage (by bronchoalveolar lavage) ■ Palpable purpura ■ ANCA-positive (MPO or PR3)

*Diagnosis is probable when four of the six criteria are present (sensitivity of 85%, specificity of 99.7%); these are classification criteria that may be used when the diagnosis of systemic vasculitis has been established by histopathology.

ANCA, antineutrophil cytoplasmic antibodies; EGPA, eosinophilic granulomatosis with polyangiitis; MPO, myeloperoxidase; MRI, magnetic resonance imaging; PR3, proteinase 3.

therapy in subjects with relapsing or refractory EGPA; however, many questions remain regarding its optimal use and timing in EGPA. It is anticipated that it may also be beneficial in cases with persistent severe asthma when the vasculitis is in remission.

Reslizumab, another monoclonal antibody against IL-5, is beneficial in uncontrolled asthma with peripheral blood eosinophilia[362,363] but has not been studied in EGPA. Benralizumab, a monoclonal antibody directed against the α-subunit of IL-5 receptor, has demonstrated a sparing effect of oral glucocorticoids in severe asthma,[364] especially eosinophilic asthma[365]; its potential effect in EGPA[366–369] remains to be determined in prospective trials.

Other treatments have been used successfully in a few cases refractory to glucocorticoids, including omalizumab,[370–373] subcutaneous interferon-α,[374–377] high-dose dose intravenous immunoglobulins,[378,379] cyclosporine-A,[380] tacrolimus,[381] tumor necrosis factor-α inhibitors,[382] and rituximab.[383–395] These treatments, however, are not routinely used. Whether rituximab may reduce the need for cyclophosphamide in patients with severe forms of EGPA, especially those with ANCAs,[393] or to reduce the risk of relapse,[396] is currently being evaluated; however, severe bronchospasm has been reported after the first infusion.[397] Plasma exchanges are not beneficial.[398,399]

The 5-year overall survival in EGPA is currently greater than 90%.[163,176] Most deaths during the first years of treatment are due to cardiac involvement,[163,400] gastrointestinal bleeding, renal insufficiency, or central nervous system involvement.[348,350]

Distinguishing relapse or persistence of so-called difficult asthma from relapse or persistence of EGPA requires precise evaluation, with consideration of the levels of blood eosinophils (generally <1000/μL in asthma without EGPA relapse)[349] and occasionally new systemic manifestations. Nearly half of patients experience at least one episode of disease worsening, consisting of asthma exacerbation with peripheral eosinophilia (two-thirds of cases), or of new-onset systemic manifestations (one-fourth to one-half of patients).[163,186,351,354] The risk of relapse of the vasculitis is higher in patients with ANCA[163] and lower in patients with baseline eosinophils greater than 3×10^9/L (>3000/μL).[351]

Because most patients continue to take oral corticosteroids over the long term, treatment-related side effects cause significant morbidity.[176,186,401] In addition, persistent airflow obstruction due to uncontrolled asthma is present despite corticosteroids in nearly half the patients during follow-up.[186–188,401–404] In the future, treatment indications based on phenotypes, endotypes, and possibly genotypes may help tailor the choice of medications and reduce the risk of adverse events associated to corticosteroids.[186,405]

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS AND RELATED SYNDROMES

ABPA is distinct from the other pulmonary manifestations caused by the fungus *Aspergillus*, such as invasive pulmonary aspergillosis developing in immunocompromised patients,[406] aspergilloma developing in preexistent pulmonary cavities,[407] or *Aspergillus fumigatus*–associated asthma.[408,409] However, ABPA may be associated with chronic necrotizing aspergillosis.[410]

PATHOGENESIS

ABPA is characterized by asthma, eosinophilia, and bronchopulmonary manifestations with bronchiectasis secondary to a complex allergic and immune reaction to the presence of *Aspergillus* colonizing the airways in susceptible hosts who are unable to clear the respiratory epithelium of inhaled fungal spores.[411] ABPA presents almost exclusively in subjects with a prior history of chronic bronchial disease. ABPA develops in approximately 2.5% of adults with previous asthma[412,413] and in up to 7–10%[414,415] of patients with cystic fibrosis. ABPA is exceedingly rare in patients with COPD despite their impaired mucociliary clearance.[416–418] ABPA has also been reported in Kartagener syndrome,[419] in hyper-IgE syndrome,[420] in Crohn disease,[421] in workers in the bagasse-containing sites in sugar cane mills,[422] in sarcoidosis after infliximab therapy,[423] and, rarely, in the absence of asthma or bronchial lung disease.[424]

Persistence of *A. fumigatus* is hypothesized to be caused partly by defects in innate and adaptive immunity.[409,425] The immunologic response in ABPA includes an early allergic response mediated by IgE antibodies and late-phase lung injury in response to repeated exposure to *Aspergillus* antigens with the participation of IgG and IgA antibodies, and of a Th2 $CD4^+$ T cell–mediated immune response accompanied by sustained IL-17 expression.[426–428] The Th2 response causes a profound inflammatory reaction with influx of neutrophils and eosinophils and synthesis of IgE (total and *A. fumigatus*–specific). A defect in regulatory T cell response has been documented.[429] Over time, the associated inflammatory reaction, with secretion of a variety of inflammatory cytokines and recruitment of inflammatory cells, results in damage to the bronchial epithelium, submucosa, and adjacent pulmonary parenchyma.[425,430,431]

Interaction of luminal eosinophils with *A. fumigatus* causes cytolysis of eosinophils, leading to the release of filamentous chromatin fibers and the creation of extracellular traps. Eosinophil extracellular traps are composed of stable and condensed chromatin fibers and thus might contribute to the high viscosity of eosinophilic mucus.[427] Eosinophils accumulated in the airways release toxic cationic proteins, as seen by the presence of Charcot-Leyden crystals,[432] causing epithelial damage and further decreasing mucus clearance. Airway mucus plugging, a hallmark of ABPA, is therefore key to the pathogenesis of this condition.

Genetic susceptibility to ABPA has been well demonstrated[425] and includes mutations and polymorphism in a variety of genes coding for HLA DR4, DR5, DR7, DR2, DR2/DR5, DRB1*1501, DRB1*1503, DRB1*0701, DQB1*0602, DQB1*0201, mannose-binding lectin (10q11.2-q21), surfactant protein A2 (10q22.3), toll-like receptor 9 (3p21.3), IL-4Ra (16p12.1-p11.2), IL-10 (13q13), transforming growth factor-β (19q13.1, 13.2), cystic fibrosis transmembrane regulator (7q31.2), and chitinase 1 (1q31–32)[433–437] (as previously reviewed).[425,438] Familial cases may represent up to 5%.[439]

CLINICAL FEATURES AND DIAGNOSIS

Patients with ABPA experience chronic cough, dyspnea, expectoration of brown or tan sputum plugs, low-grade fever, and chronic rhinitis, with a chronic course of disease and repeated exacerbations.[440] The current staging system of ABPA includes seven stages: stage 0: asymptomatic; stage 1: acute (with or without mucoid impaction); stage 2: response; stage 3: exacerbation; stage 4: remission; stage 5a: treatment-dependent ABPA; stage 5b: glucocorticoid-dependent asthma; and stage 6: advanced ABPA.[425] Pulmonary opacities or peripheral blood eosinophilia may be present only during the acute phase or recurrent exacerbations of the disease.

Diagnostic criteria, which encompass the spectrum of disease manifestations, can be found in Table 96.3.[425] Finger clubbing is rare.[425] A high index of suspicion should be maintained in patients with particularly severe asthma.

PFTs may show airflow obstruction; however, normal spirometry results do not exclude ABPA.[441] Bronchial provocation with *Aspergillus* antigens is not recommended.[425]

ABPA may be associated with allergic *Aspergillus* sinusitis, which has been considered as a sinus equivalent of ABPA and results in a syndrome called *sinobronchial allergic aspergillosis.*[442–453] Diagnosis is based on demonstration of eosinophilic mucin and fungal hyphae in the specimens obtained from the paranasal sinuses[449] and of hyperattenuating mucus and/or bony erosion on a paranasal CT scan. Hyperattenuation (increased attenuation on CT images and decreased signal intensity on T1- and T2-weighted MR images) is a feature of *Aspergillus* infection due to the fixation of calcium by the organism and to the high protein and low free water content in mucin, along with the presence of air and paramagnetic metals (iron, magnesium, manganese).[453a–c]

LABORATORY STUDIES

The total IgE level is particularly high in ABPA, indicating that a normal serum IgE (in the absence of systemic corticosteroid therapy) generally excludes active ABPA. However, no consensus cutoff value exists, and different units may be used.[425] The IgE level generally increases during exacerbations of ABPA. Peripheral eosinophilia greater than 1000/μL is present in fewer than half the patients at diagnosis,[454] and a normal blood eosinophil count does not rule out ABPA.

An immediate cutaneous hypersensitivity to *A. fumigatus* antigens, as demonstrated by a skin prick test, is the hallmark of ABPA, and denotes the presence of IgE specific for *A. fumigatus*. An elevated level of IgE antibodies specific to *A. fumigatus* is considered a characteristic finding of ABPA,[441] more sensitive than prick tests,[455,456] however, also lacking specificity because it may be found in patients with *Aspergillus* sensitization or severe asthma with fungal sensitization.[425] Specific IgE to recombinant antigens rAsp f4 and rAsp f6 have better reproducibility, consistency, and specificity compared to antibodies against crude antigens.[457] They may differentiate ABPA from asthma with *Aspergillus* sensitization[458–461] or infection.[462] High levels of *Aspergillus* IgG are more suggestive of chronic pulmonary aspergillosis than of ABPA.[463] Serum levels of thymus- and activation-regulated chemokine were proposed for identification and monitoring of ABPA because of animal studies linking an antifungal immune response with the promotion of Th2-mediated hypersensitivity to *A. fumigatus*.[464,465]

Sputum and expectorated plugs contain eosinophils and Charcot-Leyden crystals.[466] Sputum cultures are positive for *A. fumigatus* in only 40–60% of cases with ABPA,[467] despite the presence of detectable *Aspergillus* DNA in the sputum or in mucus plugs.[468] Increasing the number of specimens examined may increase the rate of positive results.[425]

Table 96.3 Diagnostic Criteria for Allergic Bronchopulmonary Aspergillosis

MINIMAL ESSENTIAL DIAGNOSTIC CRITERIA OF ABPA[488]	
Patients with asthma and central bronchiectasis	1. Asthma 2. Central bronchiectasis (inner two-thirds of chest CT field) 3. Immediate cutaneous reactivity to *Aspergillus* 4. Total serum IgE concentration > 417 IU/mL (1000 ng/mL) 5. Elevated serum IgE—*Aspergillus fumigatus* and/or IgG—*A. fumigatus* (opacities on chest radiograph and serum precipitating antibodies to *A. fumigatus* may be present but are not minimal essential diagnostic criteria)
Patients with asthma (ABPA-seropositive)	■ Patients with the above criteria 1, 3, 4, 5 (opacities on chest radiograph may be present but are not a minimal essential diagnostic criteria)
Patients with cystic fibrosis	■ Clinical deterioration (increased cough, wheezing, exercise intolerance, increase sputum, decrease in pulmonary function) ■ Immediate cutaneous reactivity to *Aspergillus* or presence of IgE—*A. fumigatus* ■ Total serum IgE concentration ≥ 1000 IU/mL ■ Precipitating antibodies to *A. fumigatus* or serum IgG—*A. fumigatus* ■ Abnormal chest radiograph (opacities, mucus plugging, or a change from earlier films)
NEWLY PROPOSED DIAGNOSTIC CRITERIA[425]	
Predisposing conditions	■ Bronchial asthma ■ Cystic fibrosis
Obligatory criteria (both should be present)	■ Type I *Aspergillus* skin test positive (immediate cutaneous hypersensitivity to *Aspergillus* antigen) or elevated IgE levels against *A. fumigatus* ■ Elevated total IgE levels (>1000 IU/mL)*
Other criteria (at least two of three)	■ Presence of precipitating or IgG antibodies against *A. fumigatus* in serum ■ Radiographic pulmonary opacities consistent with ABPA† ■ Total eosinophil count > 500 cells/μL in steroid naïve patients (may be historical)

*If the patient meets all other criteria, an IgE value <1000 IU/mL may be acceptable.

†The chest radiographic features consistent with ABPA may be transient (i.e., consolidation, nodules, tram-track opacities, toothpaste/finger-in-glove opacities, fleeting opacities) or permanent (i.e., parallel line and ring shadows, bronchiectasis and pleuropulmonary fibrosis).

ABPA, allergic bronchopulmonary aspergillosis; CT, computed tomography; IgE, immunoglobulin E; IU, international units.

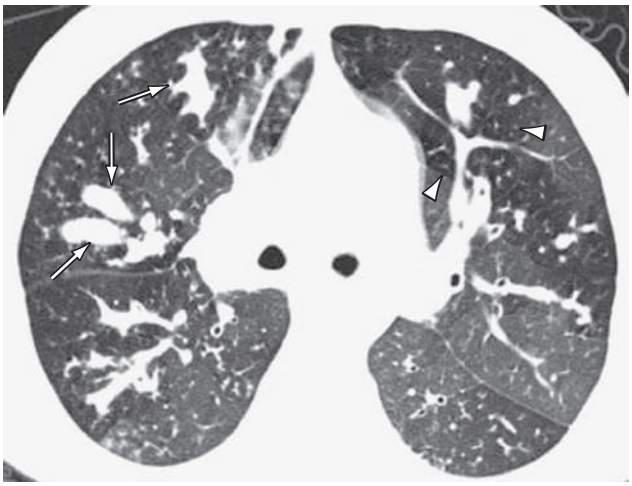

Figure 96.7 Allergic bronchopulmonary aspergillosis. Axial computed tomography scan of a patient with allergic bronchopulmonary aspergillosis shows central bronchiectasis with mucoid impaction (*arrows*), representing the "finger-in-glove" appearance typical of this disease. Diffuse bilateral inhomogeneous lung opacity is present, with areas of low attenuation throughout the pulmonary parenchyma (*arrowheads*) representing mosaic perfusion resulting from a combination of large and small airway inflammation. (Courtesy Michael B. Gotway, MD.)

Infection with nontuberculous mycobacteria may be seen with increased frequency in patients with ABPA.[469] Sputum cultures are often positive for *Pseudomonas aeruginosa* and *Staphylococcus aureus*, especially in individuals with bronchiectasis.

IMAGING

The initial stage of ABPA is characterized on imaging by either fleeting opacities due to eosinophilic pneumonia or mucus plugging with ensuing segmental, lobar, or even whole-lung atelectasis and bronchial wall damage.[470] Mucoid bronchial impaction is typically characterized by a V-shaped lesion with the vertex pointing toward the hilum and by atelectasis.[471,472] High-attenuation mucus defined as mucus visually denser than paraspinal skeletal muscle is considered pathognomonic for ABPA (see eFig. 69.5).[473–477] MRI is a promising technique to identify mucoid impaction.[478]

Proximal bronchiectasis predominates in the upper lobes on chest CT[479–482]; however, it lacks both specificity and sensitivity, especially in early disease.[425] Bronchiectasis may extend to the periphery of the lung.[441,480,482] Mucoid impaction of high attenuation, mosaic attenuation, centrilobular nodules, and tree-in-bud opacities are also commonly seen (Fig. 96.7 and eFig. 69.5). In asthmatic patients, the presence of bronchiectasis affecting three or more lobes, centrilobular nodules, and mucoid impaction on CT scan is highly suggestive of ABPA.[135,483] The CT imaging pattern may be classified as serologic ABPA (without bronchiectasis), ABPA with bronchiectasis, ABPA with high-attenuation mucus, and ABPA with pleuropulmonary fibrosis.[425] However, central bronchiectasis does not always develop during follow-up.[484]

Features of bronchiolitis are common, with centrilobular nodules with a tree-in-bud pattern.[441,483] Although surgery is seldom warranted, eosinophilic pneumonia may be found in resected specimens from patients with asthma and ABPA with chronic pulmonary consolidation or masses.[479,485–487]

TREATMENT

In addition to conventional treatment of severe asthma (i.e., high-dose inhaled corticosteroids and long-acting bronchodilators), the treatment of ABPA mainly relies on oral corticosteroids during exacerbations, with long-term corticosteroids maintained only in patients with frequent symptomatic attacks or evidence of progressive lung damage. Treatment is initiated at 0.5 mg/kg/day of prednisone for 1 or 2 weeks, then tapered over a total duration of about 12 weeks (short regimen),[488] or at 0.75 mg/kg/day for 6 weeks, then tapered over a total duration of 6 to 12 months (long regimen).[441,489] Treatment of episodes of pulmonary consolidation may prevent the progression of ABPA to the fibrotic end stage.[490] Inhaled corticosteroids may reduce the need for long-term oral corticosteroids.

Antifungal therapy to attenuate the fungal load in the airways is a useful adjunct to corticosteroids. However, prednisolone alone is more effective than itraconazole monotherapy in the acute stage of treatment-naïve ABPA.[491] Oral itraconazole reduces the doses of corticosteroids[492–495] and decreases sputum eosinophils, sputum eosinophil cationic protein levels, serum IgE levels, serum IgG levels to *A. fumigatus,* and the number of exacerbations. Uncontrolled studies further suggest that itraconazole is potentially useful in ABPA patients with cystic fibrosis.[496,497]

The duration of itraconazole therapy is not standardized; however, treatment is generally continued for a minimum of 4 to 6 months.[425] Serum levels of itraconazole should be monitored. Itraconazole interacts with many medications and may also induce adrenal insufficiency.[498,499] To reduce interactions, oral prednisone and inhaled beclomethasone or ciclesonide are preferred to oral methylprednisolone and budesonide or fluticasone.[497] Measuring the total serum IgE level may be helpful for monitoring therapy. Clinical and radiologic improvement along with a 25% or greater decline in serum total IgE level signifies a satisfactory response to therapy.[425]

Treatment with the anti-IgE recombinant antibody omalizumab may be useful,[500–504] with possibly fewer episodes of exacerbation and with a reduction of steroid dose. The appropriate dosing, however, is unknown in the setting of ABPA with IgE levels that exceed 1000 IU/mL. Pulses of intravenous corticosteroids have also been used to treat exacerbations.[505–508] Mepolizumab, benralizumab,[509–519] and dupilumab[520] have been used successfully in isolated cases. Bronchoscopy to remove mucus plugs may improve symptoms and lung function.[521]

Experience with the newer agents, voriconazole[522–531] and posaconazole,[527,532–534] is still moderate in ABPA, with cases reported especially in cystic fibrosis. In an open-label, randomized trial, voriconazole was as effective as oral corticosteroids in patients with acute ABPA.[523] In the absence of proven benefit compared with itraconazole, these medications are indicated in patients intolerant to itraconazole or in itraconazole failures.[425] Sustained improvement has been reported after administration of nebulized liposomal amphotericin B in patients with ABPA that was difficult to control using the standard treatment regimen.[535,536]

OTHER ALLERGIC BRONCHOPULMONARY MYCOSES

A similar syndrome of allergic bronchopulmonary disease may be produced by other fungi or yeasts.[537–540] The diagnosis is difficult due to the necessity to document sensitization to the specific fungi. The frequency of this condition is far less than that of ABPA, which may be due to the small size (3–6 μm) of the conidia of *A. fumigatus*,[541] their high dispersibility due to their remarkable hydrophobicity,[542,543] induction of the *MUC5AC* gene and mucus production in bronchial epithelial cells,[544] and higher serine protease activity, which activates membrane-bound tumor necrosis factor-α–converting enzyme and transforming growth factor-α, stimulating epidermal growth factor receptors.[544,545]

BRONCHOCENTRIC GRANULOMATOSIS

Bronchocentric granulomatosis described by Liebow[546] is defined pathologically as an inflammatory and destructive process beginning within the bronchiolar walls and further extending into the surrounding parenchyma.[547] The granulomatous inflammatory process destroys both the mucosa and the walls of the bronchioles, and the necrotic areas resulting from the destroyed bronchioles are often surrounded by palisading histiocytes and a dense inflammatory infiltrate, mostly composed of eosinophils. Scattered fungal hyphae may be demonstrated by the Grocott silver stain. Vascular inflammation and mucoid impaction may be present.[547,548]

About half the patients are asthmatics, who present with fever and cough. A peripheral blood eosinophilia is common, generally greater than 1000/μL.[547,548] The radiographic features consist of masses (eFig. 96.6), alveolar opacities or pneumonic consolidation, or reticulonodular opacities, which predominate in the upper lobes and are unilateral in a majority of patients.[470,549] Most of these patients fulfill the criteria for ABPA, and those treated with corticosteroids have an excellent prognosis, although recurrences are common.[547] Eosinophilia is usually not conspicuous.

HYPEREOSINOPHILIC SYNDROMES

DEFINITION AND CLASSIFICATION

Since the historical description of "idiopathic" *hypereosinophilic syndrome* (HES) by Hardy and Anderson,[550] then by Chusid and colleagues,[551] the definition of HES has been refined,[552] although it remains a heterogeneous entity. After a consensus statement,[46] the diagnosis of HES is now considered in patients with (1) absolute eosinophil count of 1500/μL or greater and clinical manifestations attributable to eosinophilia or (2) tissue hypereosinophilia with blood eosinophilia (eosinophil count above the upper limit of normal for the reference laboratory). HES is further divided into six clinical variants[553,554]: myeloid variant HES (myeloproliferative HES), lymphocytic variant HES, overlap HES corresponding to eosinophilic disease restricted to a single organ (including ICEP or IAEP) or defined eosinophilic syndromes (including EGPA), HES associated with a known cause (including infection with helminths, drug reactions, and immunodeficiency), familial HES, and idiopathic HES. This section reviews, especially, pulmonary manifestations associated with myeloproliferative HES or lymphocytic HES (so-called primary HES).

PATHOGENENESIS

In contrast with common hypereosinophilia, which is usually a reactive nonclonal process (as in parasitic disorders), several studies demonstrated that HES may result from the clonal proliferation of the eosinophil cell lineage itself (myeloproliferative HES, including the *chronic eosinophilic leukemia*) or from a clonal proliferation of lymphocytes producing eosinophilopoietic chemokines (lymphocytic HES).[554] The term *idiopathic* HES or HES of unknown significance[554,555] is used in cases that cannot at present be classified in either category despite appropriate diagnostic tools, including the quantitative assessment of the *Wilms tumor (WT1)* gene transcript (a molecular marker useful for the detection of clonal myeloid disorders) in peripheral blood.[556]

Myeloproliferative HES (or chronic eosinophilic leukemia), considered to account for 20–30% of cases, is caused primarily by a constitutively activated tyrosine kinase fusion protein created by fusion of the genes *FIP1-like 1 (FIP1L1)* and *platelet-derived growth factor receptor-α* (*PDGFRA-α)* as a consequence of an interstitial chromosomal deletion in 4q12. The fusion gene *FIP1L1-PDGFRA* is not detectable by karyotype analysis but can be demonstrated by reverse transcriptase polymerase chain reaction analysis[557,558] or by fluorescence in situ hybridization on peripheral blood or peripheral bone marrow aspirate.[559] The tyrosine kinase of PDGFRA is constitutively activated in the fusion protein, transforms hematopoietic cells, and is inhibited by imatinib.[557] Clonal eosinophilia in patients presenting with clinical features of HES can also be related to other uncommon, imatinib-sensitive *PDGFR* fusions, including *KIF5B-PDGFRA* and *ETV6*-PDGFRB[560–562] and to point mutations in *PDGFRA*.[563] Clonal eosinophilia has been described in chronic eosinophilic leukemia–not otherwise specified, in *D816V KIT*–positive systemic mastocytosis,[564] and in mixed lymphoid/myeloid neoplasms with rearrangements of *FGFR1* or *JAK2*.[565–567] Hepatomegaly, splenomegaly, mucosal ulcerations, severe cardiac manifestations resistant to corticosteroid treatment, anemia, thrombocythemia, increased serum vitamin B_{12}, leukocyte alkaline phosphatase and serum tryptase level, atypical mast cells, and circulating leukocyte precursors are common and suggestive of the diagnosis, whereas cutaneous manifestations are infrequent.[567–569]

Lymphocytic HES,[570,571] which may account for up to 30% of patients with HES, results from the production of chemokines, especially IL-5, by clonal Th2 lymphocytes bearing an aberrant immunologic phenotype, such as $CD3^-$ $CD4^+$.[570,572–578] Lymphocyte phenotyping should be performed on peripheral blood (or bone marrow) to detect a phenotypically aberrant T cell subset by flow cytometry and analysis of the rearrangement of the *TCR* genes in search of T cell clonality. The observation of increased IL-5 expression from cultured T cells can also demonstrate that the observed eosinophilia is caused by an expanded population

of T cells.[559] There is no sex predominance. Patients present with a high prevalence of skin and soft tissue manifestations, elevated serum IgE (as a consequence of IL-4 and IL-13 production by Th2 lymphocytes),[570,579] and thymus- and activation-regulated chemokine levels.[580] Most reported patients are recruited from dermatology clinics and have papules or urticarial plaques. The disease may progress to overt lymphoma or leukemia in 5–25% of cases.[570,576,581]

CLINICAL AND IMAGING FEATURES

The pulmonary involvement in HES has not been studied extensively in cases classified according to the previously discussed variants. Clinical manifestations mainly comprise fatigue, weight loss, and nonrespiratory involvement, especially targeting the skin, mucosa, heart, and nervous system.[573,582] In older series, nonspecific respiratory manifestations, such as cough and dyspnea, present in up to 40% of patients, and patchy ground-glass attenuation, consolidation, and small nodules are seen at chest imaging.[551,583,584]

In more recent studies using current diagnostic standards, respiratory manifestations are generally of mild severity, with rare eosinophilic pneumonia, if any.[585] Chest CT may show pleural effusion, pulmonary emboli, small nodules with or without a halo of ground-glass attenuation, and focal areas of ground-glass attenuation mainly in the lung periphery.[135,586,587] Chronic dry cough can be remarkable and may be a presenting or the only feature.[588–590]

Cardiovascular involvement is a major cause of morbidity and mortality.[591–593] Fibrotic thickening of the endocardium by collagen-rich connective tissue (endomyocardial fibrosis) is characteristic of cardiac disease in HES,[583,594] which differs from the cardiac involvement seen in EGPA. Endomyocardial fibrosis is preceded by an initial acute necrotic stage followed by a thrombotic process[595,596] (eFig. 96.7). Cardiac manifestations include dyspnea, congestive heart failure, mitral regurgitation, and cardiomegaly.[583,597,598] Echocardiography demonstrates mural thrombus, ventricular apical obliteration, and involvement of the posterior mitral leaflet.[599]

TREATMENT AND PROGNOSIS

In myeloproliferative HES, imatinib, a tyrosine kinase inhibitor, is the first-line therapy when the *FIP1L1-PDGFRA* fusion protein or rearrangement of *PDGFRB* is present.* Imatinib should be started together with corticosteroids. Testing for the presence of *FIP1L1-PDGFRA* is recommended every 3 to 6 months in patients on a stable imatinib dose because of possible relapses.[603] Imatinib can be stopped without relapse in some patients, whereas in others, low-dose imatinib is necessary to maintain long-term remission.[555,569] Alternative tyrosine kinase inhibitors may be used in case of imatinib resistance.[567]

In lymphocytic HES, corticosteroids are the first-line therapy (with response in only about half of the patients); however, doses of 30 to 60 mg of prednisone per day may be required.[567] Imatinib may also be beneficial in lymphocytic HES.[604] The anti–IL-5 antibody mepolizumab has been shown to be beneficial as a corticosteroid-sparing agent in HES patients negative for the *FIP1L1-PDGFRA* fusion gene.[25,605–609] Other treatments include chemotherapeutic agents (hydroxyurea, vincristine, etoposide), cyclosporin A,[584,591,595] and interferon-α either as monotherapy[610–614] or in association with hydroxyurea, particularly in the myeloproliferative variant.[615,616] A detailed description of treatment can be found elsewhere.[567]

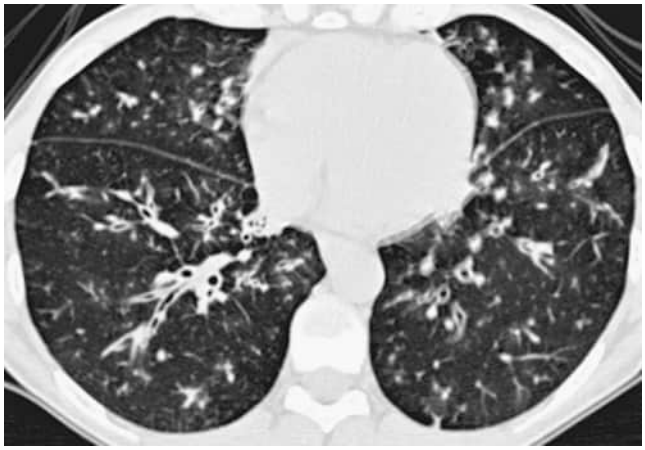

Figure 96.8 Idiopathic hypereosinophilic obliterative bronchiolitis. Axial chest computed tomography scan of a patient with idiopathic hypereosinophilic bronchiolitis shows bronchial wall thickening, peripheral tree-in-bud and branching pattern, and central bronchiectasis with mucoid impaction.

IDIOPATHIC HYPEREOSINOPHILIC OBLITERATIVE BRONCHIOLITIS

Hypereosinophilic obliterative bronchiolitis is a distinct entity defined by the following provisional working criteria: (1) blood eosinophil cell count greater than 1×10^9/L (>1000/μL) and/or BAL eosinophil count greater than 25%, (2) persistent airflow obstruction despite high-dose inhaled bronchodilators and corticosteroids, and (3) eosinophilic bronchiolitis at lung biopsy, and/or direct signs of bronchiolitis (centrilobular nodules and branching opacities) on chest CT[41] (Fig. 96.8). Before this description, some biopsy-proven isolated cases of eosinophilic bronchiolitis had been reported,[617–620] and a few cases have been reported since then.[621,622] The blood eosinophil cell count is elevated (with a mean of 2.7×10^9/L (2700/μL), and the mean eosinophil differential percentage at BAL was 63% in our series.[41] Airflow obstruction is often severe but reversible with oral corticosteroid therapy in all cases. Whitish tracheal and bronchial granulations or bronchial ulcerative lesions can be present with prominent eosinophilia at bronchial biopsy.[41] Clinical and functional manifestations often recur when oral prednisone is tapered to less than 10 to 15 mg/day. It is hypothesized that unrecognized and/or smoldering hypereosinophilic obliterative bronchiolitis might be a cause of irreversible airflow obstruction in chronic eosinophilic respiratory diseases. In addition to the idiopathic presentation, a similar condition of hypereosinophilic obliterative bronchiolitis can be encountered in patients with asthma, ABPA, or EGPA or may be induced by drugs, especially minocycline[41] or sulfasalazine.[623] Mepolizumab may be beneficial.[624]

EOSINOPHILIC PNEUMONIAS OF PARASITIC AND INFECTIOUS ORIGIN (See Also Chapter 58)

The eosinophilic pneumonias related to parasite infestation[625–627] probably represent the most common cause of eosinophilic pneumonia in the world and in travelers and refugees.[628–630] Parasitic eosinophilic pneumonia arises mainly in humans after infection by helminths (large multicellular worms) and especially nematodes (roundworms). The parasites may or may not be found at pathologic examination of the lung when performed. Due to frequent chronic infection, echocardiography is advised to assess endomyocardial and valvular disease.[631]

TROPICAL PULMONARY EOSINOPHILIA

Tropical pulmonary eosinophilia,[632–635] caused by the filarial nematodes *Wuchereria bancrofti* and *Brugia malayi,* is endemic in the tropical and subtropical areas of Asia and Africa. It presents mainly in young adults, with a male predominance.[630,632,636–639] Presenting manifestations include dry, hacking cough exacerbated at night and often associated with dyspnea and expiratory wheezing masquerading as asthma.[640] Associated fever, weight loss, and anorexia are common. Eosinophils, and sometimes Charcot-Leyden crystals, are present in the sputum. Clinical features of lymphatic filariasis (e.g., adenolymphangitis or dermatolymphangioadenitis) are usually absent because tropical pulmonary eosinophilia results from an immune response of the host to the parasites trapped in the lung vasculature.

The chest radiograph can reveal patchy bilateral opacities and small nodules (see Fig. 58.2 and eFig. 58.2).[639] Prominent blood eosinophilia is high at the early stage (<2 weeks) of pulmonary disease[634] but may be missing.[641] Eosinophilic pneumonia with eosinophilia at BAL[20,642] is seen later (1–3 months). Cases left untreated for 5 years or more eventually show pulmonary fibrosis with histiocytic infiltration, with possible restrictive and reversible obstructive ventilatory defects.[643,644]

Because microfilariae are not detectable in the blood, the diagnosis is made by the combination of cough worse at night, residence in a filarial endemic area, and laboratory features, including blood eosinophilia persisting for weeks with an absolute eosinophil count in the blood greater than 3×10^9/L (3000/μL), IgE levels exceeding 4200 IU/mL (normal < 100 IU/mL), and markedly increased antifilarial IgG. Diagnosis is further supported by a clinical and hematologic response to diethylcarbamazine,[645] which is the only effective drug. Corticosteroids in addition to diethylcarbamazine may be beneficial.

ASCARIS PNEUMONIA

Ascaris lumbricoides is the most common helminth infecting humans, especially children, in tropical and subtropical areas. The disease is transmitted through food or water contaminated by human feces. The infective larvae formed within eggs develop in the small intestine, penetrate through the intestinal wall, and migrate via the venous circulation to the lungs, where they break out into the alveoli. They then migrate through the bronchi and trachea, are swallowed, and mature into adult worms in the small intestine.

Pulmonary manifestations develop during larval migration to the lungs. Usually, pulmonary symptoms are mild, with cough and wheezing, transient pulmonary opacities (Loeffler syndrome), and blood eosinophilia that can be higher than 20×10^9/L (20,000/μL).[646] There may be transient fever and pruritus. Symptoms spontaneously resolve in a few days, whereas blood eosinophilia may remain elevated for several weeks. The diagnosis may be made by finding larvae in the sputum or gastric aspirates but is more usually made by the delayed finding of the worm or ova in the stool within 3 months of the pulmonary manifestations. Intestinal ascariasis is treated with oral mebendazole, 100 mg twice a day for 3 days, or albendazole, 400 mg once, or ivermectin.[647]

EOSINOPHILIC PNEUMONIA IN LARVA MIGRANS SYNDROME

Visceral larva migrans[635,648] is a zoonotic infection caused in humans by *Toxocara canis,* a parasite infecting dogs and found in all areas of the world. Children playing in areas contaminated by infected dogs may become infected, especially when they practice geophagia.[649] Ingested eggs hatch in the intestine, migrate through the portal circulation, and invade the liver, lung, and other organs. However, in humans, the development of the parasite is blocked at the larval stage.

Visceral larva migrans presents predominantly in children, the majority of whom remain asymptomatic and undiagnosed. When symptomatic, patients may present with fever, fatigue, pulmonary manifestations, and seizures. Pulmonary manifestations in about 80% of cases consist of cough, wheezes, and dyspnea; pulmonary opacities on chest radiography are present in approximately half the patients with pulmonary symptoms.[635] Although uncommon in adults, toxocariasis may be severe.[650–652] Blood eosinophilia may be present initially or may develop only in the following days.[653] Eosinophils are increased in the BAL differential cell count.

The diagnosis of toxocariasis is difficult because a positive serodiagnosis may be caused by residual antibodies that do not have any diagnostic significance. IgM antibodies can be found throughout the course of helminthiasis and are not diagnostic of recent infection.[654] Visceral larva migrans usually requires only symptomatic treatment, with the use of antihelminthics being controversial. Corticosteroids seem beneficial in cases with severe pulmonary involvement.[650]

STRONGYLOIDES STERCORALIS INFECTION

Strongyloides stercoralis is an intestinal nematode that may cause severe autoinfection in immunocompromised patients. It is widely distributed in the tropics and subtropics and is especially diagnosed in travelers returning from tropical countries.[655–658] Human infection is acquired through the skin by contact with the contaminated soil. Eosinophilia is usually present in recently infected

patients, but it is often absent in disseminated disease.[659] *S. stercoralis* infection may persist for years and give rise to severe disseminated strongyloidiasis, which may affect all organs (hyperinfection syndrome),[659,660] especially after treatment with corticosteroids or with immunosuppression from any cause.[661]

Loeffler syndrome develops when larvae migrate through the lungs after acute infection.[659] Rhabditiform larvae may be recovered by BAL or bronchial washing (eFig. 96.8A)[662,663] or in the sputum.[664] Diagnosis of strongyloidiasis depends on the demonstration of larvae in the feces or in sputum or BAL fluid (see Fig. 58.1C). Immunodiagnostic assays by enzyme-linked immunosorbent assay may be useful for diagnosis and screening. All infected patients should be treated when diagnosed (ivermectin, 200 µg/kg daily for 2 days and repeated 2 weeks later).

EOSINOPHILIC PNEUMONIAS IN OTHER PARASITIC INFECTIONS

In early acute schistosomiasis, due to either *Schistosoma haematobium* or *Schistosoma mansoni* (see eFig. 96.8B), patients may develop transient, multiple, small pulmonary nodules on chest radiography (best seen on chest CT scan) and eosinophilia.[628,665,666] Chronic infection can cause pulmonary hypertension. Eosinophilic pneumonitis resulting from parasitic antigen release may follow treatment.[667]

The dog hookworm *Ancylostoma brasiliense*, the human hookworms *Ancylostoma duodenale* and *Necator americanus*, the filarial parasite of dog *Dirofilaria immitis*[635] (the pulmonary fluke) (eFig. 96.8C, see Fig. 58.3), *Paragonimus westermani*[668] (see Fig. 58.4 and eFig. 58.3), *Trichomonas tenax*,[669] *Capillaria aerophile*,[670] and *Clonorchis sinensis*[671] are other possible causes of Loeffler syndrome or other pulmonary manifestations with eosinophilia.

EOSINOPHILIC PNEUMONIAS OF OTHER INFECTIOUS CAUSES

Pulmonary infection with eosinophilia has been reported with the fungi *Coccidioides immitis*, *Bipolaris australiensis*, *Aspergillus niger*, and *Bipolaris spicifera*. BAL eosinophilia has been reported in *Pneumocystis jirovecii* pneumonitis in patients with acquired immunodeficiency syndrome. Bacterial or viral pulmonary infection (e.g., tuberculosis, brucellosis, respiratory syncytial virus, influenza infection), or the ingestion of *Ulomoides dermestoides* larvae ("Chinese beetles")[672] may occasionally be a cause of eosinophilic pneumonia.

DRUG-, TOXIC AGENT-, AND RADIATION-INDUCED EOSINOPHILIC PNEUMONIAS

MEDICATIONS AND ILLICIT DRUGS (see also Chapter 99)

An iatrogenic cause must be systematically considered in patients with eosinophilic pneumonia.[673] More than 80 drugs have been reported to cause eosinophilic pulmonary opacities and especially acute eosinophilic pneumonia. However, the cause has not been established in many case reports, and thus the number of drugs that can reliably be considered as a common cause of drug-induced eosinophilic pneumonia is much smaller.

Drugs causing eosinophilic pneumonia are mainly nonsteroidal anti-inflammatory drugs, antibiotics, and cardiac medications.[674,675] The online database www.pneumotox.com is a reliable reference in the evaluation of suspected cases. All the drugs taken in the weeks or months preceding the clinical syndrome must be carefully recorded in any patient presenting with eosinophilic pneumonia, including illicit drugs such as cocaine, crack, heroin; marijuana/cannabis use (i.e., smoking, vaping, eating, or dabbing),[674,676–679] the intake of which is often denied by the patient; and noncigarette smoking products, including vaping and water pipe smoking.[680–682] Historical toxic causes also include the eosinophilia-myalgia syndrome, related to the intake of contaminated preparations of L-tryptophan in 1989 in the United States,[683–686] and the toxic oil syndrome, a scleroderma-like disorder that affected about 20,000 people in Spain in 1981.[687]

Drug-induced eosinophilic lung disease may present in three scenarios: (1) patients taking a drug for several months (or years) who develop symptoms, (2) asymptomatic patients who are found to have incidental imaging abnormalities, and (3) patients who present with acute respiratory manifestations, sometimes severe.

Presentation of eosinophilic drug-induced pneumonia is generally nonspecific, including manifestations of simple pulmonary eosinophilia (Loeffler syndrome); chronic eosinophilic pneumonia with the association of pleural effusion and extrapulmonary manifestations, including cutaneous rash, which is suggestive of drug-induced pneumonia; and acute eosinophilic pneumonia, with possible overlap in presentation.[688] Associated extrapulmonary manifestations, especially cutaneous rashes, fever, or nausea, may be present. Severe cases may present as *drug reaction with eosinophilia and systemic symptoms* (DRESS),[689,690] which consists of a multiorgan sensitivity reaction to an eliciting drug with a genetic predisposition, together with an antiviral immune response to reactivated human herpesvirus-6 in the majority (>70%) of these patients.[691–693] Drug-induced systemic eosinophilic vasculitis involving the lung has also been reported (see earlier).

The regression of eosinophilic lung disease after stopping the drug is the best clue for an iatrogenic reaction. However, this may take a long time and, therefore, in many reported cases, corticosteroids have been given concomitantly with drug withdrawal, so the responsibility of the drug cannot be definitely established. The only absolute proof of the drug responsibility would be obtained by its reintroduction with ensuing relapse of pneumonia, but this may be dangerous and thus is strongly discouraged.

RADIATION THERAPY

Chronic eosinophilic pneumonia may develop after radiation therapy for breast cancer.[694] It was seen in women with a history of asthma or allergy, at a median time of

3.5 months and up to 10 months after completion of radiotherapy for breast cancer (one case was reported 6 years after completion of radiation therapy).[695–697] Dyspnea and cough were the main presenting symptoms, with pulmonary opacities at imaging being unilateral (involving the irradiated lung) or bilateral and possibly migratory. All patients had blood eosinophilia of 1.0×10^9/L (1000/μL) or greater and/or eosinophilia greater than 40% on the BAL differential cell count. Patients rapidly improved with oral corticosteroids without sequelae, but some patients relapsed after treatment withdrawal. Cases have also been reported after radiation therapy for lung cancer.[698,699]

This syndrome is similar to the organizing pneumonia syndrome primed by radiation therapy to the breast,[700] with eosinophilic pneumonia developing preferentially in patients with asthma or atopy. Eosinophilic pneumonia may also develop on radiation therapy preferentially in patients with a preexisting Th2-oriented lymphocyte response,[694,701,702] together with yet unidentified additional factors.

EOSINOPHILIC BRONCHITIS

Eosinophilic bronchitis is distinct from bronchial asthma. Eosinophilic bronchitis (without asthma) with a high percentage of eosinophils (about 40%) in sputum is a cause of chronic cough responsive to corticosteroid treatment, with normal lung function and absence of bronchial hyperreactivity.[705–711] It is not accompanied by eosinophilic pneumonia. The observed values of sputum eosinophils and of various chemokines are often much higher in eosinophilic bronchitis than in asthma,[707,712] although levels of IL-5 in sputum and pathologic findings are comparable.[713,714] Chest imaging is normal.[715] The *FIP1L1-PDGFRA* fusion gene has been reported in some patients with eosinophilic bronchitis.[588,589] Bronchoscopy may show diffuse nodules in the tracheobronchial mucosa causing obstruction that does not respond to bronchodilators.[716] Rare cases may be due to drugs[717] or occupational exposure to acrylates,[718] welding fumes and formaldehyde,[719] isocyanate, or flour.[720]

Treatment is based on inhaled corticosteroids.[706,721–723] Treatment with an antagonist of the eotaxin tissue receptor CCR3, the receptor for eotaxin and other chemokines, may be beneficial.[724] It generally is a benign condition,[725,726] although it may in rare cases evolve to irreversible airflow obstruction without asthma or to genuine asthma.[727–729]

See ExpertConsult.com for a discussion of other lung diseases associated with eosinophilia, including hypereosinophilic asthma, idiopathic interstitial pneumonias, and pulmonary Langerhans cell histiocytosis.

Key Points

- Eosinophilic lung disease may manifest clinically with varying severity, ranging from chronic or transient opacities with mild symptoms to the acute severe eosinophilic pneumonia resembling acute lung injury or acute respiratory distress syndrome and necessitating mechanical ventilation.
- Blood eosinophilia greater than 1×10^9 eosinophils/L (and preferably $>1.5 \times 10^9$/L or 1500/μL) is of considerable help for suggesting the diagnosis. However, blood eosinophilia may be absent (as in the early phase of idiopathic acute eosinophilic pneumonia or when patients are already taking corticosteroids).
- On bronchoalveolar lavage, high eosinophilia (>25%) may be considered diagnostic of an eosinophilic pneumonia in a compatible setting.
- Inquiry concerning drug intake must be meticulous (www.pneumotox.com), and any suspected drug should be withdrawn.
- Consideration of parasitic causes must consider the travel history or residence and the epidemiology of parasites.
- When present, extrathoracic manifestations raise the suspicion of a systemic eosinophilic disease, such as eosinophilic granulomatosis with polyangiitis or hypereosinophilic syndrome.
- Airflow obstruction can be found in hypereosinophilic asthma, allergic bronchopulmonary aspergillosis, idiopathic chronic eosinophilic pneumonia, eosinophilic granulomatosis with polyangiitis, or in hypereosinophilic obliterative bronchiolitis.
- Corticosteroids remain the cornerstone of symptomatic treatment for eosinophilic disorders, with a generally dramatic response, but relapses are common when tapering the doses or after stopping treatment. Cyclophosphamide is necessary in patients with eosinophilic granulomatosis with polyangiitis and poor prognostic factors.
- Medications targeting the interleukin-5 pathway play an increasing role in eosinophilic lung diseases.
- Imatinib, a tyrosine kinase inhibitor, has proved effective in the treatment of myeloproliferative hypereosinophilic syndrome.

HYPEREOSINOPHILIC ASTHMA

Eosinophilic inflammation in asthma is beyond the scope of this chapter. However, some patients present with asthma and important blood hypereosinophilia (i.e., >1 and especially >1.5 × 10^9/L (1500/μL) or alveolar eosinophilia (>25% and especially >40%), a condition tentatively labeled hypereosinophilic asthma.[703,704] Hypereosinophilic asthma is generally severe, frequently requires high-dose inhaled or even oral corticosteroids, and may progress to EGPA, ABPA, or ICEP. To what extent hypereosinophilic asthma differs from the eosinophilic endotype of asthma has not been formally studied.

IDIOPATHIC INTERSTITIAL PNEUMONIAS

Organizing pneumonia may have imaging features that closely mimic ICEP, especially with migrating alveolar opacities. Organizing pneumonia can also overlap with ICEP pathologically, with foci of organizing pneumonia in ICEP, and eosinophils in organizing pneumonia.[36,730,731] In some cases, organizing pneumonia may represent the evolution of an untreated CEP.[732] Cryptogenic organizing pneumonia may also have eosinophilia in BAL, but it is usually less than 20% at differential cell count.

The other idiopathic interstitial pneumonias, including idiopathic pulmonary fibrosis[733–735] and nonspecific interstitial pneumonia,[736] may exhibit mildly increased levels of eosinophils in BAL and/or focal lesions of eosinophilic pneumonia at biopsy. In series of pulmonary fibrosis that predated the current definitions, increase of BAL eosinophils was associated with a poor outcome,[737–740] which may reflect eosinophil-fibroblast interaction.[741] Desquamative interstitial pneumonia may show eosinophilia at BAL[742,743]; however, peripheral blood eosinophilia is unusual.

PULMONARY LANGERHANS CELL HISTIOCYTOSIS

The pulmonary pathologic lesions of Langerhans cell histiocytosis (also designated as eosinophilic granuloma) consist of nodules composed of Langerhans cells with variable numbers of eosinophils, plasma cells, and lymphocytes. Eosinophils usually present in the initial active stage of disease contribute to the eosinophilic granuloma. Numerous in about one-fourth of cases, they are usually situated at the periphery of the lesions.[744] The eosinophils are rare or absent at the chronic stage of disease. Blood eosinophilia is generally absent.

OTHER CONDITIONS

In lung transplant recipients, eosinophilic alveolitis may be indicative of acute rejection[745] or may result from drugs or infectious agents such as *Aspergillus, Pseudomonas,* or coxsackievirus. BAL eosinophilia of 2% or greater is associated with a poor outcome in lung transplantation.[746] In patients with graft-versus-host disease after hematopoietic stem cell transplantation, the significance of eosinophilia at BAL is unclear.[747]

In sarcoidosis, blood eosinophilia and tissue eosinophilia may be present but are usually mild.[748,749] Pulmonary eosinophilia developed in two patients after transplantation for sarcoidosis, with bronchiolitis obliterans syndrome developing after resolution of pulmonary eosinophilia.[750] Eosinophilic pneumonia was reported as a paraneoplastic manifestation in patients with colon adenocarcinoma,[751] and in gastric cancer producing GM-CSF and IL-5.[752]

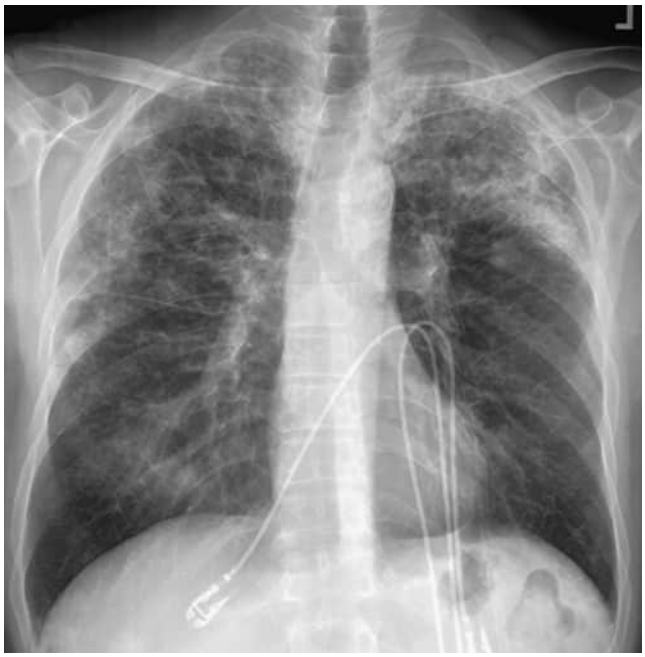
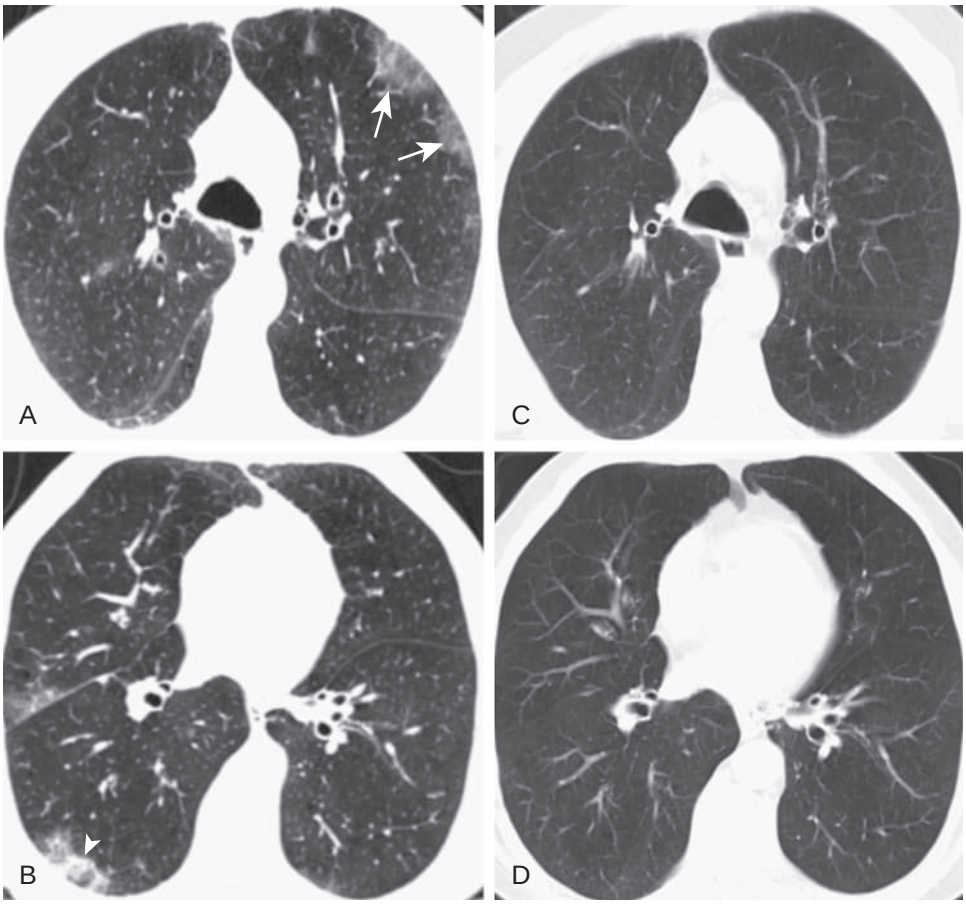
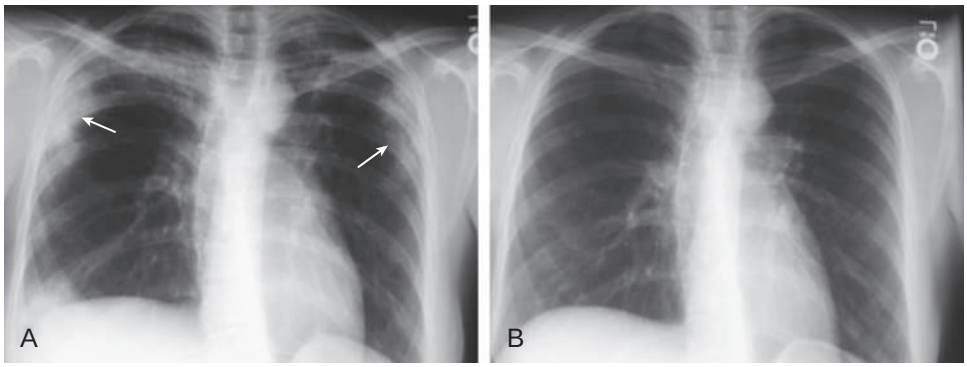
eFIGURE IMAGE GALLERY



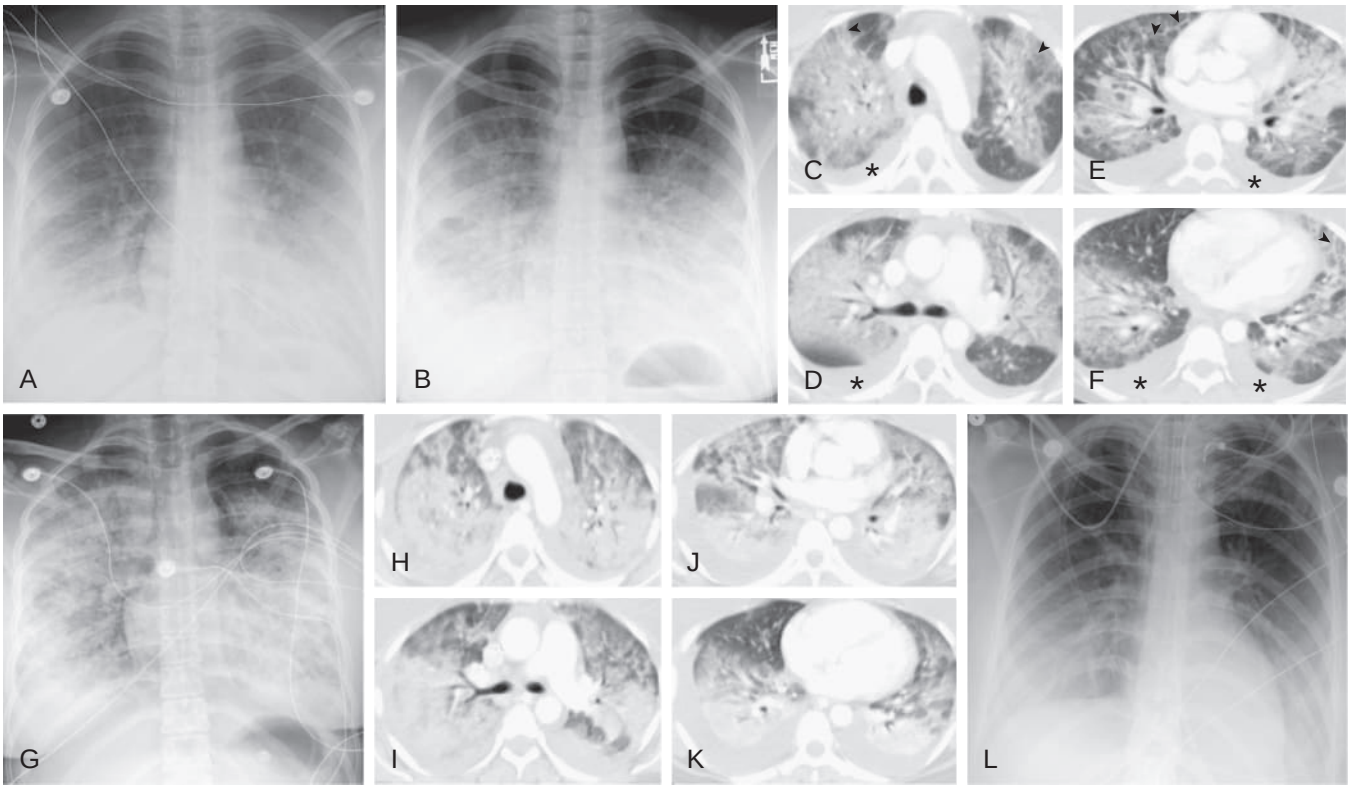
eFigure 96.1 Idiopathic chronic eosinophilic pneumonia: chest radiographic findings. Frontal chest radiograph in a patient with chronic eosinophilic pneumonia shows bilateral, upper lobe predominant peripheral consolidation and bronchovascular thickening (see Video 96.1 for chest computed tomography for this patient). (Courtesy Michael B. Gotway, MD.)



eFigure 96.2 Idiopathic chronic eosinophilic pneumonia: clearing after corticosteroid therapy at chest *computed tomography* (CT). (A–B) Axial chest CT in a patient with chronic eosinophilic pneumonia, displayed in lung windows, shows patchy, bilateral areas of subpleural ground-glass opacity (*arrows*) and consolidation (*arrowhead*). (C–D) Axial chest CT displayed in lung windows after corticosteroid therapy shows resolution of the areas of ground-glass opacity and consolidation. (Courtesy Michael B. Gotway, MD.)

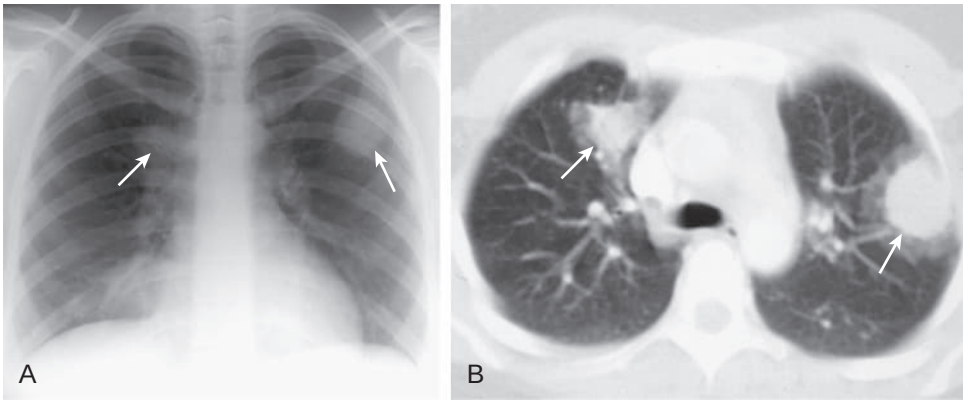


eFigure 96.3 Idiopathic chronic eosinophilic pneumonia: clearing after corticosteroid therapy at chest radiography. (A) Frontal chest radiograph in a patient with chronic eosinophilic pneumonia shows the typical appearance of upper lobe, bilateral, subpleural consolidation (*arrows*). (B) Frontal chest radiography after corticosteroid therapy shows clearing of the consolidation. (Courtesy Michael B. Gotway, MD.)

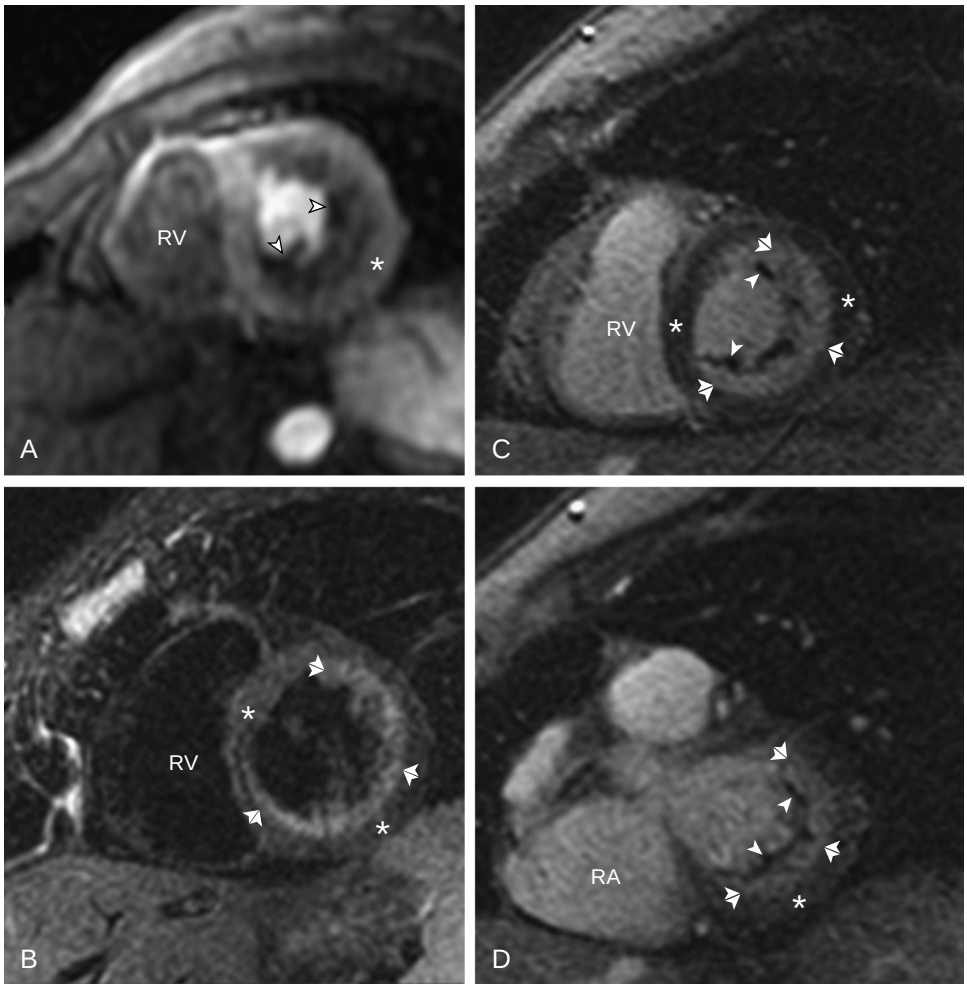


eFigure 96.4 Idiopathic acute eosinophilic pneumonia: chest radiographic and chest *computed tomography* (CT) findings with evolution. (A) Frontal chest radiograph in a 31-year-old previously healthy, immunocompetent, nonsmoking woman performed on the first day of hospitalization shows bilateral, symmetrical, middle and lower lung–predominant opacities with preserved lung volumes, normal mediastinal width, and no clear pleural effusions. The patient initially reported cough and was treated with broad-spectrum antibiotics, but her condition worsened and she developed shortness of breath and fever. (B) Frontal chest radiograph performed on the second day of hospitalization shows progression of the bilateral pulmonary opacities. (C–F) Axial chest CT displayed in lung windows on the third hospital day shows symmetrical, bilateral, diffuse air space consolidation and ground-glass opacity with a background of smooth interlobular septal thickening (*arrowheads*). Small symmetrical bilateral pleural effusions (*asterisks*) are seen. (G) Frontal chest radiograph on the third hospital day shows continued progression in bilateral and now extensive air space consolidation. (H–K) Axial chest CT displayed in lung windows after the patient developed profound oxygen desaturation, which required transfer to the intensive care unit and intubation, shows progression in the bilateral ground-glass opacity and consolidation with slight enlargement of the pleural effusions. (L) Frontal chest radiograph performed 6 days after hospitalization, after administration of corticosteroids initiated after bronchoscopy with bronchoalveolar lavage revealed eosinophilia, shows marked clearing of the bilateral air space opacities. The patient remains intubated, but her respiratory status continued to improve rapidly. She was subsequently extubated and discharged home 5 days later. (From Gotway MB, Conomos PJ. Rapidly progressive pulmonary opacities on thoracic imaging studies. *Clin Pulmon Med.* 2008;15:300–303. Courtesy Paul Conomos, MD, Arizona Pulmonary Specialists, Phoenix.)

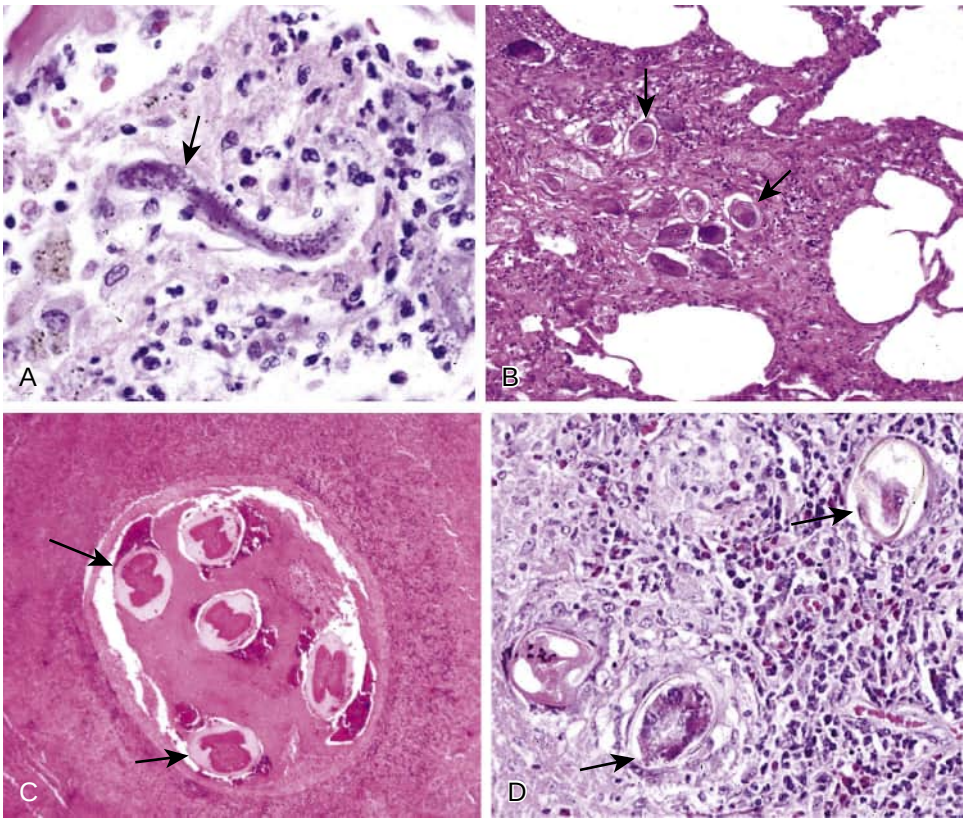
eFigure 96.5 Eosinophilic granulomatosis with polyangiitis. Axial chest computed tomography scan of a patient with eosinophilic granulomatosis with polyangiitis, with lung consolidation and ground-glass opacities corresponding to eosinophilic pneumonia. In addition, pericardial effusion and bilateral pleural effusions are present due to cardiomyopathy.



eFigure 96.6 Bronchocentric granulomatosis: chest radiographic and chest computed tomography findings. (A) Frontal chest radiograph performed in a 20-year-old nonsmoking woman with pleuritic chest pain shows bilateral, upper lobe pulmonary nodules and masses (*arrows*). (B) Axial chest computed tomography displayed in lung windows shows the lesions at chest radiography to be somewhat poorly defined, with faint, surrounding ground-glass opacity halos (*arrows*). Percutaneous biopsy of the dominant left upper lobe lesion showed only necrotizing granulomatous inflammation without evidence of malignancy. Surgical lung biopsy was performed and showed bronchocentric granulomatosis. The patient's symptoms and lesions resolved after corticosteroid therapy, and she had no recurrences during 5 years of follow-up. (Courtesy Michael B. Gotway, MD.)



eFigure 96.7 Cardiac involvement in hypereosinophilic syndrome. Cardiac magnetic resonance imaging findings showing the characteristic three-layered appearance of endomyocardial fibrosis. (A) Short-axis, first-pass perfusion image shows extensive low-signal, nonenhancing thrombus (*arrowheads*) within the left ventricle, adjacent to the enhanced left ventricular cavity, internal to the left ventricular muscle (*asterisk*). (B) Short-axis triple inversion recovery image (a fluid and inflammation-sensitive sequence) shows diffuse high signal involving the severely thickened endomyocardium (*double arrowheads*) internal to the normal-appearing, intermediate signal left ventricular musculature (*asterisk*). (C–D) Short-axis, inversion–recovery-prepared, fast-gradient echo late gadolinium enhancement images (obtained 10 minutes after the intravenous administration of gadolinium) at the base of the heart show the hypointense thrombus (*single arrowheads*) associated with extensive enhancement of the inflamed (and possibly fibrotic) and markedly thickened endomyocardium (*double arrowheads*), interposed between the low-signal thrombus (*single arrowheads*) and normal-appearing left ventricular muscle (*asterisk*). **RA, right atrium; RV, right ventricle.** (Courtesy Philip A. Araoz, MD, Department of Radiology, Mayo Clinic, and Michael B. Gotway, MD.)



eFigure 96.8 Parasites in the lung. (A) Filariform larva of *Strongyloides stercoralis* (*arrow*) penetrating into alveolar space with associated inflammation. (B) Schistosome eggs in lung parenchyma (*arrows*). (C) Dirofilarial nodule, with worm remnants (*arrows*) in organizing thrombosed vessel. (D) *Paragonimus westermani* with yellowish refractile eggs (*arrows*) in eosinophil-rich exudates. (Modified from Leslie KO, Wick MR. *Practical Pulmonary Pathology: A Diagnostic Approach: A Volume in the Pattern Recognition Series.* ed 2. Philadelphia: Elsevier; 2011.)

INTRODUCTION

Lymphangioleiomyomatosis (LAM) is a rare neoplastic disease characterized by a genetic association with the neurocutaneous syndrome *tuberous sclerosis complex* (TSC), marked female sex predominance, cystic destruction of the lung, and progressive respiratory failure. Symptoms and signs include dyspnea on exertion, recurrent pneumothoraces, abdominal tumors including renal *angiomyolipomas* (AMLs) and lymphangioleiomyomas, and chylous fluid accumulation in the chest and abdomen.[1]

LAM was first reported in a patient with TSC who presented with bilateral spontaneous pneumothorax in 1918[2] and in a patient without TSC in 1937.[3] In the 1950s and 1960s, solitary case reports or small case series fostered a varied and confusing pathologic nomenclature in the early literature.[4] Since the late 1970s, larger case studies and registry-based studies have better defined the natural history, pathologic classification, and clinical presentation of LAM.[5-16] Moreover, in the past 2 decades, synergistic interactions among pulmonary investigators, TSC geneticists, *Drosophila* biologists, molecular biologists, and patient advocacy groups have resulted in truly remarkable progress in the understanding of the molecular and cellular basis of LAM,[17,18] as well as the development of a diagnostic serum test, clinical practice guidelines, and a targeted therapy.[19]

EPIDEMIOLOGY

LAM is seen both in the setting of TSC (TSC-LAM) and in a sporadic form in patients who do not have germline mutations in TSC genes or the clinical syndrome of TSC (*sporadic LAM* [S-LAM]) (Table 97.1).[1] TSC is an autosomal dominant genetic disorder associated with cognitive impairment, seizures, and the development of hamartomas and dysplastic lesions in several organs, including cortical tubers, giant cell astrocytomas, and subependymal nodules in the central nervous system; angiofibromas, shagreen patches, and ash leaf macules of the skin; and AMLs and cysts of the kidney.[20,21]

The cystic lung changes seen in patients with TSC are typically presumed to be caused by LAM, and several cases of biopsy-proven LAM have been reported in women and men with TSC.[22-24] Lung biopsies are not routinely performed in the TSC population, however, and other causes of cystic change in TSC patients are possible, including smoking,[25] alpha$_1$-antitrypsin deficiency, Sjögren syndrome,[26] and as yet unclassified forms.[27]

In cross-sectional studies from tertiary referral centers, TSC-LAM has been reported in approximately 10% of men and 30% of women with TSC,[28-30] although a screening study suggested that age-dependent development of cystic change in women with TSC results in an estimated LAM prevalence of up to 80% by the age of 40 years.[31] Symptomatic TSC-LAM is almost entirely restricted to women, with a few rare exceptions.[23,24,32]

In S-LAM, lesions of the skin and brain are absent, and manifestations that accompany the pulmonary cystic changes include only renal and extrarenal AMLs, infiltration and obstruction of the lymphatic system, and occasional sclerotic bone lesions.[33] A clinical presentation consistent with S-LAM, including biopsy documentation and negative germline TSC mutation analysis, has been reported in a single male patient without clinical evidence of TSC.[34] However, it is possible that limitations of the genetic

methods available at the time may have precluded identification of underlying *mosaicism* for TSC in this case, whereby there may be two genotypes in the same individual. In support of this notion, mosaicism for *TSC2* mutations has been described in two male patients with apparent S-LAM who did not meet diagnostic criteria for TSC.[35,36]

Careful epidemiologic analyses of the ethnic and racial distribution of LAM have not been performed. Although the biases introduced by the rarity of the illness, the protean presentation, and the disproportionate reporting of patients with LAM in large series from the United States, Europe, and Asia may suggest a predilection of the disease for whites and Asians, it is likely that all races are affected and that countries and populations with the greatest access to health care resources and the Internet are overrepresented in these studies.

Harknett and colleagues[37] determined that LAM was diagnosed in 3.4 to 7.8 women per million across seven different countries. These investigators did not stratify patients by the presence or absence of TSC, but it is likely that both S-LAM and TSC-LAM populations were included in the estimate. Extrapolation of this prevalence range to the approximately 3.8 billion women on Earth results in a predicted global LAM population ranging from 13,000 to 30,000 diagnosed patients.

It is likely that LAM is severalfold more common than these numbers suggest. The live birth prevalence of TSC ranges between 1 in 6000 and 1 in 13,000 persons.[38] TSC affects both sexes equally,[39] and the estimated worldwide prevalence of TSC is approximately 0.6 million to 1.25 million people (assuming a world population of 7.6 billion people), with roughly half of them being women. If one estimates that cystic pulmonary changes consistent with LAM are found in one-third of women with TSC,[28-30] the global prevalence of TSC-LAM is estimated to be approximately 100,000 to 200,000 women.

Although screening of TSC populations identifies a subset of LAM patients who have a range of cystic change in the lung from very mild to severe, the degree of cystic profusion is most often mild or moderate,[31] and pulmonary manifestations appear to reach clinical significance in only approximately 5–10% of patients with TSC-LAM.[40] TSC-LAM is certainly underrepresented in large trials, registries, and databases: patients with TSC-LAM made up only about 14.7% of the 230 patients who enrolled in the *National Heart, Lung and Blood Institute* (NHLBI) LAM Registry.[11] Although TSC-LAM is predicted to be 10-fold more common than S-LAM, most patients with LAM (85–90%) who seek medical attention with adult pulmonary specialists have S-LAM. This observation is consistent with the notion that TSC-LAM identified through screening is often milder than S-LAM, which most typically reaches attention through progressive dyspnea, pneumothorax, or chylothorax. It is also possible that other TSC comorbidities may overshadow the pulmonary manifestations of TSC-LAM and hinder TSC-affected patients from seeking medical care for their lung disease.

GENETIC AND MOLECULAR BASIS OF TUBEROUS SCLEROSIS COMPLEX AND LYMPHANGIOLEIOMYOMATOSIS

INHERITANCE

Approximately two-thirds of new TSC cases arise from de novo mutations that take place during embryogenesis. Familial TSC, which results from inheritance of germline mutations, accounts for one-third of new cases.[41] There have been several reports of familial TSC-LAM,[28,42] but mother-daughter transmission of S-LAM has never been reported.

MOLECULAR PATHOGENESIS

LAM is a neoplastic and metastatic process caused by mutations in TSC genes.[43] Dysregulation of the PI3 (phosphatidylinositol-3)/Akt signaling pathway leading to

constitutive activation of the *mechanistic* (or *mammalian*) *target of rapamycin* (mTOR) complex plays a central role in abnormal LAM cell growth, proliferation, and survival.[18,44] The metastatic and destructive effects of the disease are aided by the combination of abnormal lymphangiogenesis mediated by lymphangiogenic growth factors such as *vascular endothelial growth factors* (VEGF-C and VEGF-D),[45,46] matrix degradation by proteolytic enzymes,[47] antiapoptotic effects of sex steroids such as estrogen,[48] and immune evasion strategies.[49-51]

Tumor Suppressor Proteins Control Cell Growth

Clinicians have long recognized that the cystic lung disease in women with TSC is pathologically indistinguishable from that in women with S-LAM.[4,52] However, the demonstration that S-LAM and TSC-LAM are genetically linked was delayed, in part, by the failure to appreciate that a nonfamilial disease could share a common genetic basis with a heritable disease.[53] There are several precedents for this phenomenon among the class of diseases known as tumor suppressor syndromes (including neurofibromatosis and von Hippel–Lindau disease), of which TSC is a member.

Tumor suppressor proteins regulate orderly cell growth and differentiation by sensing the surrounding environment, transmitting signals to the nucleus, and directly affecting transcription, translation, survival, or cell division. In the classic "two-hit" paradigm,[54] a mutant copy of a tumor suppressor gene is inherited from one parent, and a tumor or dysplastic lesion develops when the second "good" parental copy of the tumor suppressor gene is inactivated through a random, somatic mutation. This first (inherited) hit, often a point mutation or a small insertion or deletion, results in heterozygosity for the allele (i.e., one good copy and one mutant copy). The second mutational event is usually a large deletion, resulting in the loss of a chromosomal segment and *loss of heterozygosity* (LOH) (i.e., two mutant copies). When both copies of a tumor suppressor gene contain damaging mutations, the protein produced by the gene becomes defective or deficient, protein function is lost, and cell growth, survival, and synthetic function become dysregulated.

Tuberous Sclerosis Complex Proteins Regulate Signaling Through the Akt Pathway

TSC is caused by inactivating mutations in either of the two known TSC loci, *TSC1* on chromosome 9q34[55] or *TSC2* on chromosome 16p13.[56] The proteins encoded by *TSC1* and *TSC2* are hamartin and tuberin, respectively. Hamartin has no informative homologies with other proteins in the National Center for Biotechnology Information database, whereas tuberin has a domain with *guanosine triphosphatase* (*GTPase)-activating protein* (GAP) homology.[57]

Until recently, little was known about the function of TSC proteins other than that they modulate cell growth. In 1999, it was reported that the enlarged eye cell phenotype of the mutant fruit fly, *Gigas,* was the result of genetic inactivation of the fly homologue for tuberin.[58] Several laboratories subsequently reported that tuberin and hamartin regulate signaling through the phosphatidylinositol-3-kinase/PKB (Akt)/S6K pathway, which controls cellular size and proliferation.[59-61]

Tuberin and hamartin associate into a complex that functions as a master regulator for mTOR through an intermediate G protein called Rheb.[62,63] The intact tuberin-hamartin complex acts as a GAP for Rheb, thus maintaining the protein in an inactivated, nonphosphorylated state (Rheb–guanosine diphosphate). Phosphorylation of tuberin by Akt inactivates the GAP activity of the tuberin-hamartin complex, increases the abundance of Rheb–guanosine triphosphate, drives association of mTOR with raptor (and mLST8 and PRAS40, not shown) to form the mTORC1 complex, and results in phosphorylation and activation of downstream kinases mTOR, S6K, and the initiation factor *4E-binding protein* (4E-BP1) (Fig 97.1). The association of mTOR with rictor (and mSIN1 and mLST8, not shown) to form mTORC2 results in activation of ROCK and rho kinase, cytoskeletal rearrangement, and cell movement.

Genetic mutations that result in the absence or dysfunction of tuberin or hamartin, such as is seen in patients with TSC and LAM, ultimately cause constitutive activation (phosphorylation) of S6 and eIF4E, two proteins intimately involved in the regulation of protein translation, as well as Rho kinase, which regulates intracellular trafficking, cell adhesion, and cell movement. Constitutive activation of the mTOR pathway causes inappropriate cell growth and proliferation by promoting anabolic metabolism in a pleiotropic fashion, leading to increased protein, lipid, and nucleotide synthesis in a balanced and coordinated manner.[64-68] Disruption of this balance in the anabolic pathway activation may yield a future therapeutic strategy. Multiple mTOR effectors and mTOR itself are found to be highly phosphorylated in tumors of rats,[69] mice,[70] and humans[71] with mutations in TSC genes. Sirolimus, a microbial product that inhibits mTOR activity, extinguishes staining for phosphorylated S6 and causes regression of TSC-deficient rat renal tumors.[69]

Tuberous Sclerosis Complex Mutations Are Found in the Lung and Kidney Lesions of Patients With Sporadic Lymphangioleiomyomatosis

Patients with tuberous sclerosis have germline mutations in TSC genes, but patients with S-LAM do not.[72] Whether patients with S-LAM represent generalized low-level mosaics for TSC gene mutations remains a possibility, at least in some individuals.[35,36] Smolarek and coworkers[43] first implicated TSC genes in the pathogenesis of S-LAM by finding that LOH for *TSC2* was present in the renal AMLs and lymph nodes of patients with S-LAM. Proof that the loss of tuberin function was responsible for lung disease in LAM was provided by Carsillo and colleagues,[53] who demonstrated the presence of missense and protein truncating *TSC2* mutations associated with LOH in the abnormal lung and kidney tissue of patients with S-LAM. Samples taken from the normal regions of lung and the kidney in those patients did not exhibit TSC mutations.[72] These findings were subsequently confirmed in 21 patients by Sato and associates.[73] Whereas both *TSC1* and *TSC2* mutations have been described in patients with TSC-LAM,[28,74] to date only *TSC2* mutations have been described in patients with S-LAM.[53,73,75]

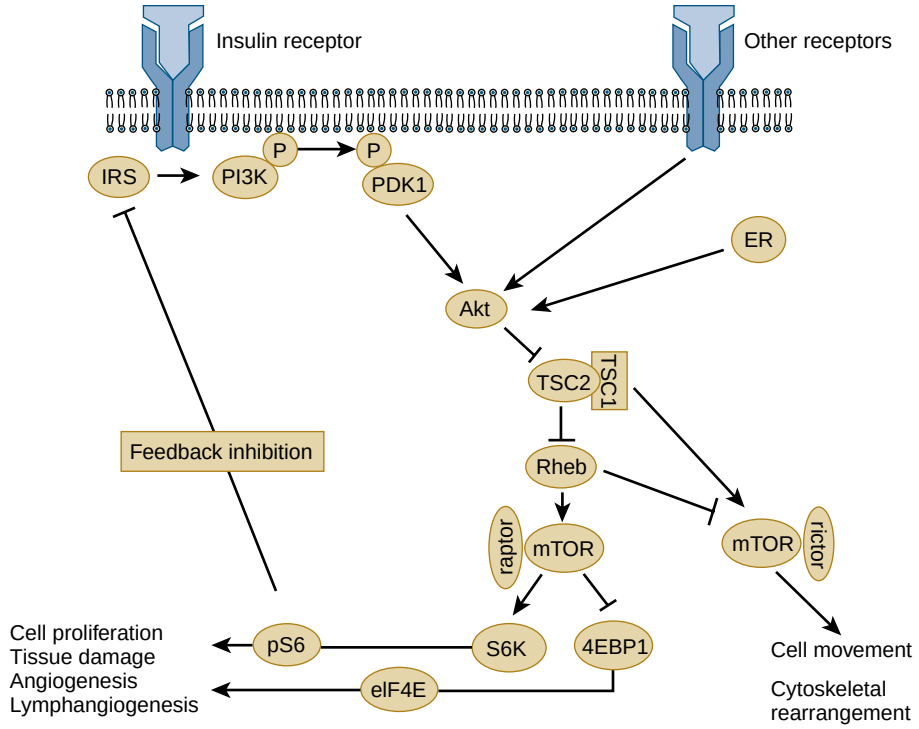

Fig. 97.1 Tuberous sclerosis proteins regulate signaling through the Akt growth and protein translation pathway. The binding of a ligand to a growth factor receptor (e.g., the insulin receptor) activates *phosphatidylinositol-3-kinase* (PI3K) followed by PDK1 and Akt. Activated pAkt phosphorylates *tuberous sclerosis complex-2* (TSC2), which blocks its *guanosine triphosphatase–activating protein* (GAP) activity. When not phosphorylated, TSC2 complexed with TSC1 functions as a GAP for Rheb, thus maintaining Rheb in an inactivated Rheb–guanosine diphosphate state. Activated Rheb (Rheb–guanosine triphosphate [GTP]) is therefore abundant when TSC1 or TSC2 is missing or defective or when TSC2 is phosphorylated. Rheb-GTP activates *mechanistic target of rapamycin* (mTOR) in a manner that is potentiated by the availability of amino acids, phosphatidic acid, and adenosine triphosphate and is blocked by the absence of these substrates or the presence of sirolimus. Activated mTOR complexed with raptor phosphorylates downstream targets S6K and *4E-binding protein* (4E-BP1). pS6K phosphorylates S6, and 4E-BP1 releases eIF4E, which together activate the cellular translational machinery and promote cell growth. S6 also feeds back to inhibit upstream signaling, which restrains cell growth and "malignant" cellular behavior. Activated mTOR complexed with rictor signals through a divergent pathway to control cytoskeletal dynamics and cell movement through Rho kinases. ER, estrogen receptor; IRS, insulin receptor substrates. (Modified from Kwiatkowski DJ. Rhebbing up mTOR: new insights on TSC1 and TSC2, and the pathogenesis of tuberous sclerosis. *Cancer Biol Ther.* 2003;2:471-476.)

GENETIC EVIDENCE SUGGESTS THAT LYMPHANGIOLEIOMYOMATOSIS IS A METASTATIC NEOPLASM

Cornog and Enterline[4] were the first to suggest that, despite their benign appearance, cells that make up the LAM lesion represent a clonal, neoplastic proliferation of smooth muscle cells. The demonstration of LOH in the lung, kidney, and lymph node lesions in patients with LAM 3 decades later proved that their suspicions were correct.[43] Carsillo and colleagues[53] further demonstrated that the mutations present in the cells of the kidney tumor and lung lesion of a given individual with S-LAM were identical, thus suggesting that they arise from a common precursor.

A model for LAM has been proposed in which the lung is infiltrated as a consequence of benign metastasis of LAM cells from a remote and as yet unidentified source such as the lymphatic system,[46] the uterus,[76,77] or AMLs.[78] Reports of recurrence of LAM in the donor lung of patients with LAM who had undergone lung transplantation are also consistent with this metastatic theory[79-82]; in two cases, the source of lung metastases was proven to arise from the recipient by genetic and molecular techniques.[80,83] Cells containing LOH for TSC genes have been isolated from the blood and chylous fluid of patients with LAM,[84,85] a finding consistent with dissemination through the systemic circulation and lymphatics.

ROLE OF LYMPHANGIOGENESIS AND LYMPHATIC SPREAD IN DISSEMINATION OF LYMPHANGIOLEIOMYOMATOSIS

Approximately 30% of patients with LAM have axial abdominal or thoracic lymphadenopathy.[86] In some cases, LAM is restricted to the retroperitoneum, abdomen, or pelvis, with normal lung parenchyma or only a very few lung cysts, consistent with regional spread from a subdiaphragmatic source.[87] Valensi[88] showed that clusters of cells can be found in the chylous pleural fluid of patients with LAM. Itami and coworkers[89] demonstrated that the clusters originated in the dilated lymphatic system and were composed of α-smooth muscle actin–positive spindle cells enveloped by a single layer of endothelial cells (eFig. 97.1). Data from Japan provide additional evidence that the mechanism of spread of LAM may be through the lymphatic circulation.[45,46]

Induction of lymphangiogenesis appears to play an important role in this process, on the basis of abundant expression of lymphatic endothelial markers such as *podoplanin* (D2-40), LYVE-1, *VEGF receptor 3* (VEGFR-3),

VEGF-C, and VEGF-D.[45] Several laboratories have reported that VEGF-D is elevated more than threefold to eightfold in the serum of patients with LAM, a finding useful for distinguishing LAM from other cystic lung diseases and for predicting response to therapy.[90-99]

LAM clusters are found in the lymphatic lumen, in regions between axial lymph nodes (retroperitoneal, mediastinal, and the left venous angle [junction of the left internal jugular and subclavian veins]) that are infiltrated with LAM cells, and in chylous fluid of patients with chylous ascites and chylothorax.[45,46,100,101] LAM cell clusters enter the venous circulation at the insertion of the thoracic duct into the junction of the left internal jugular and subclavian veins and disseminate throughout the pulmonary capillary bed. LAM cell clusters impacted in the lung vasculature proliferate and invade or perhaps establish themselves in the lung by an "invasion-independent" mechanism by which the cluster lodges and becomes enveloped by the capillary wall without actually invading it, a process described by Sugino and colleagues.[102,103]

ROLE OF ESTROGEN IN THE PATHOGENESIS OF LYMPHANGIOLEIOMYOMATOSIS

Estrogen may play a role in LAM cell migration, infiltration, proliferation, survival, or secretion of destructive proteases. Hormonal fluxes during the menstrual cycle and estrogen-containing drugs have been implicated in LAM progression.[104,105] Estrogen regulates the transcription of many genes, and some evidence indicates that estrogen can modulate signaling through the Akt pathway.[106,107] Estrogen-mediated activation of the ERK pathway promotes activation of the late response gene *FRA1*, which is associated with epithelial-mesenchymal transition.[108] Akt activation, in turn, enhances the efficiency of *FRA1* translation through the phosphorylation of the S6K1-dependent eukaryotic translation factor 4B.

Estrogen was shown to promote pulmonary metastases and enhanced survival of TSC2-deficient cells in mice.[48] Prizant and colleagues[109,110] created a uterine-specific Tsc2 knockout mouse model and demonstrated that loss of Tsc2 leads to increased mTORC1 activity that drives uterine myometrial proliferation and pulmonary metastasis. Elimination of sex steroid production by either ovariectomy or aromatase inhibition was shown to decrease mTORC1 activity and inhibit myometrial proliferation. The myometrial growth was restored by addition of estrogen and not progesterone, thus suggesting that estrogen is the major sex steroid regulating myometrial growth and proliferation.[109] Tsc2-null myometrial lesions exhibited increased expression of matrix-degrading proteases such as *matrix metalloproteinases* (MMP-2 and MMP-9), as well as neutrophil elastase, and the expression of these proteases was dependent on estrogen signaling.[110] In another preclinical model of LAM, administration of fulvestrant ([Faslodex] an estrogen receptor antagonist) was shown to reduce estrogen-induced MMP up-regulation and block pulmonary metastasis of Tsc2 null xenograft tumors.[111] Collectively, these data suggest that targeting the estrogen-ERK pathway in combination with the mTORC1 pathway may be an effective combination therapy for LAM.

IMMUNE EVASION AS A MECHANISM FOR LYMPHANGIOLEIOMYOMATOSIS CELL PROLIFERATION

Escaping detection by the host immune system is a key survival mechanism used by a variety of human neoplasms.[112] LAM cell clusters in the lumen of conducting lymphatics and chylous pleural effusions are enveloped by a single layer of (presumably nonmutant) lymphatic endothelial cells, which may shield the mutant LAM cells from immune detection.

Another major modality of immune evasion involves expression of ligands such as PD-L1, PD-L2, and B7-H3 on the surface of neoplastic cells that down-regulate T cell–mediated cellular responses through binding to cognate receptors on the T cell surface, such as *cytotoxic T lymphocyte antigen-4* (CTLA-4), *programmed cell death 1* (PD-1), and *T cell immunoglobulin and mucin receptor 3* (TIM-3). Blocking these interactions through the use of targeted monoclonal antibodies against these receptors or their corresponding ligands (e.g., PD-L1) results in the de-repression of antitumor T cell responses.[113-117] Increased expression of PD-1 on the T cells within LAM nodules, and treatment with anti-PD-1 antibody alone or in combination with anti–CTLA-4 antibody, results in a substantial reduction in tumor burden in an animal model of TSC-LAM.[50] In another study, immunohistochemical analysis revealed evidence of increased PD-L1 expression in LAM nodules, and treatment with anti–PD-1 antibody resulted in prolonged survival in a mouse model of TSC-LAM.[51]

Another common host defense mechanism against tumors involves the *natural killer* (NK) cells, which recognize ligands (NKG2D ligands) such as the *major histocompatibility class* (MHC) *class I chain-related* (MIC) molecules MICA and MICB and the family of UL-16 binding proteins on the surface of neoplastic cells leading to deployment of antitumor defenses such as cytolytic granules. Shedding of soluble NKG2D ligands is a well-characterized decoy mechanism used by tumor cells to evade immune detection. Pulmonary LAM cells were found to express multiple NKG2D ligands by immunohistochemistry, and soluble NKG2D ligands were elevated in the serum of LAM patients. The presence of the NKG2D ligands *UL16 binding protein 2 and 3* (ULBP-2 and ULBP-3) was correlated with the rate of lung function decline.[49] Taken together, these data support the role of immune system evasion in the pathogenesis of LAM and suggest immunotherapy as a potential treatment strategy.

MECHANISMS OF MATRIX REMODELING IN LYMPHANGIOLEIOMYOMATOSIS

Proteases are believed to play a major role in the cystic destruction of the lung parenchyma in LAM. The spectrum of metalloproteinases that are aberrantly expressed in LAM has not been fully characterized, but MMP-2 is the most abundant of those studied to date. Overexpression of MMP-1, MMP-9, MT1-MMP, and MMP-14 has also been reported,[118] and serum levels of MMP-9 are elevated in patients with LAM.[119] MMP-1, MMP-2, and MMP-9 are able to degrade elastin, consistent with the loss and degradation of elastic fibers seen in LAM.[118] Zhe and associates proposed that increased expression of serum response factor

may lead to MMP activation and down-regulation of *tissue inhibitor of metalloproteinase* (TIMP-3) in LAM cells,[120,121] thus resulting in an imbalance of proteases and protease inhibitors.[47,120-122]

Abundant expression of cathepsin K has been reported in LAM, a finding suggesting a possible pathogenic role for this protein in tissue destruction.[123] Extracellular matrix remodeling proteins such as fibronectin, von Willebrand factor, and kallikrein III were found to be differentially expressed in the serum of LAM patients as compared with healthy controls in a small case-control analysis.[124]

Multiple growth factors and cytokines are abundantly expressed in LAM, and they induce proliferation, suppress apoptosis, and support fibrosis. *Basic fibroblast growth factor* (bFGF) is a potent mitogenic factor for smooth muscle cells, myofibroblasts, and fibroblasts. LAM lesions have also been reported to contain abundant tryptase-positive mast cells, which express bFGF and receptors Bek (FGFR-2) and Flg (FGFR-1), as well as chymases, renin, angiotensin-converting enzyme, and angiotensin receptors type I and type II.[125-127] *Insulin-like growth factors* (IGFs) are involved in normal pulmonary development and in the pathogenesis of smooth muscle cell proliferation. IGF-I, IGF-II, IGF-I receptor, *IGF-binding protein* (IGFBP)-1, IGFBP-2, IGFBP-4, IGFBP-5, and IGFBP-6 are expressed in lung tissue of patients with LAM.[128] Carelli and coworkers[129] showed that $TSC2^{-/-}$ human smooth muscle cells derived from AMLs express the apoptosis inhibitor protein, survivin, when exposed to IGF-1. Transforming growth factor-β_1, a profibrotic cytokine, is enriched in highly cellular areas of the LAM lesion.[130] Increased prostaglandin biosynthesis has been reported in preclinical models of LAM, and increased levels of prostaglandin metabolites prostaglandin E_2 and prostacyclin are found in the serum of LAM patients.[131,132] Targeting the systems that promote proteolytic and fibroproliferative responses are possible therapeutic strategies for the future.

CLINICAL FEATURES

LAM usually manifests during the reproductive years, with a mean age at the onset of symptoms in the early to mid-30s.[6,9,14,133] Although new diagnoses of LAM have been reported in patients as young as 12 years,[134,135] documented cases of the disease before menarche are rare. Several reports in the literature describe women in whom the diagnosis was made after menopause and at ages through the ninth decade of life.[6,8,9,136-138] LAM does not appear to be smoking related because most patients in the largest case series were nonsmokers.[8,9,11]

Because LAM is rare and the symptoms are often nonspecific, the diagnosis is often delayed, with a mean interval between the onset of symptoms and diagnosis of 5 to 6 years.[6,8,15,139] Initial incorrect diagnoses typically include bronchial asthma, emphysema, chronic bronchitis, COPD, sarcoidosis, diffuse panbronchiolitis (in Asia), and even idiopathic interstitial pneumonias, including idiopathic pulmonary fibrosis.

The most common reasons for patients with LAM to present for initial evaluation include complaints of dyspnea on exertion, an episode of spontaneous pneumothorax, or an incidental discovery of pulmonary cystic change on imaging performed for unrelated reasons.[10,11,140] During the course of the illness, dyspnea develops in the majority of patients, and pneumothorax happens in approximately two-thirds.[8,14,141] Among patients with a pneumothorax, the first pneumothorax precedes the diagnosis of LAM in 82% of patients; in fact, most patients have two pneumothoraces before the diagnosis is made.[141] Pneumothorax in LAM has a very high (>70%) risk of recurrence.[8,14,141,142]

Other signs and symptoms of LAM, which may be present at the onset or may develop during the course of the disease, include fatigue (frequent and can be disabling), cough (uncommon), hemoptysis (rarely massive), chest pain, and symptoms related to movement of chylous fluid into pleural locations (~20% of patients) and extrapleural locations, such as the peritoneum (chylous ascites) or pericardium (chylopericardium), airway (chyloptysis), and genitourinary tract (chyluria and chylous metrorrhea). Fistulous communication with the gut can result in chyle in stool and protein-losing enteropathy. Chylous pulmonary parenchymal congestion is likely the result of retrograde chylous reflux and manifests with ground-glass opacities or interstitial or reticular changes in the lung. This diagnosis should be considered in LAM patients with crackles and subacute worsening of oxygenation or shortness of breath.[143] It is likely that the chylous complications of LAM result from obstruction of lymphatic channels secondary to infiltration by LAM cells and/or lymphatic remodeling that causes leaking of chylous material into various potential spaces. A history of chylous discharge from visceral organs resulting in such findings as the expectoration of plugs from the bronchi (e.g., plastic bronchitis) or the appearance of white material in urine, stool, or vaginal discharge is often overlooked and should be actively sought in every LAM patient.

AMLs, unusual hamartomas composed of fat, smooth muscle, and abnormal blood vessels, may arise in virtually any location in the chest and abdomen but are most common in the kidney (eFig. 97.2). Approximately 29–33% of patients with S-LAM have renal AMLs, compared with approximately 88–93% of patients with TSC-LAM.[11,28] AMLs are more commonly unilateral and solitary in patients with S-LAM, and they are more commonly bilateral and multiple in patients with TSC-LAM (see eFig. 97.2).[86] Blood vessels in AMLs are often tortuous and aneurysmal and are composed of cells with normal genotype and cells with TSC mutations.[144] Spontaneous hemorrhage into AMLs may produce severe flank or abdominal pain, acute hypotension, and/or anemia, occasionally in association with circulatory collapse.[145]

Renal cysts are seen occasionally in patients with LAM; in TSC-LAM, polycystic kidney disease may develop as a result of a contiguous gene deletion of *PKD1* that is immediately adjacent to *TSC2* on chromosome 16.[146]

Lymphangioleiomyomas (also known as lymphangiomyomas) are tumor-like masses composed of smooth muscle–like LAM cells and endothelial proliferations within lymphatic vessels and lymph nodes in the mediastinum, retroperitoneum, and lung. Not uncommonly, LAM manifests as retroperitoneal masses, including cystic lymphangiomyomas (eFig. 97.3) or lymph nodes with hypodense centers, which mimic necrotizing lymphomas, ovarian or renal cancers, or other malignant tumors.[147,148]

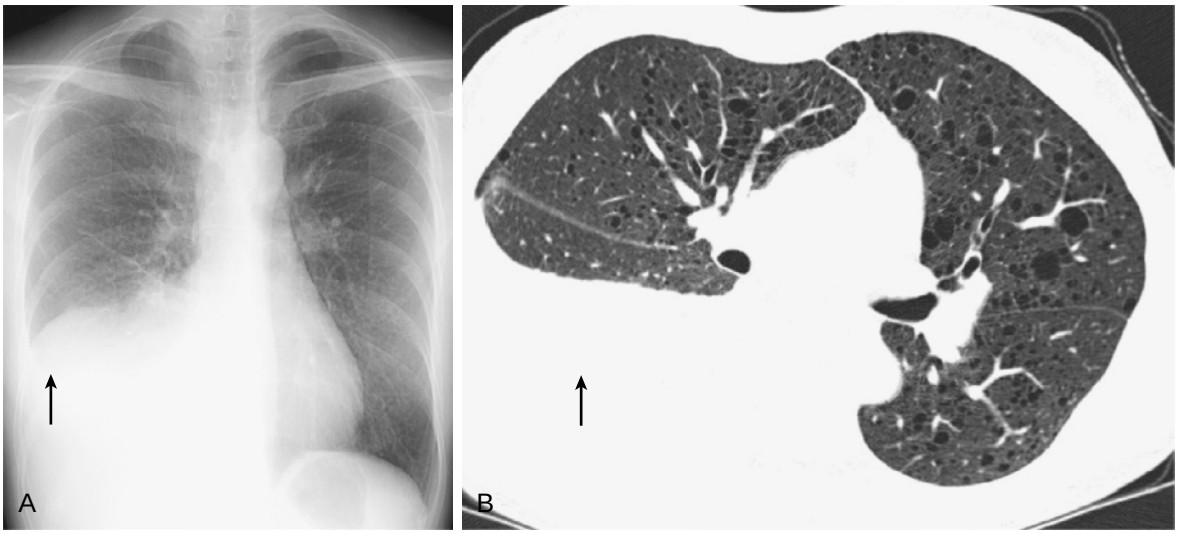

Fig. 97.2 Sporadic lymphangioleiomyomatosis with chylothorax. (A) Chest radiograph and (B) high-resolution computed tomography of a 40-year-old woman with sporadic lymphangioleiomyomatosis. Diffuse cystic changes and right-sided chylothorax *(arrows)* are present.

PHYSICAL EXAMINATION

The physical examination in LAM is often nonspecific. Lung auscultation is usually uninformative but may reveal rhonchi or wheezing in some patients.[8,9,15] Crackles are unusual and, if present, should raise suspicion of chylous pulmonary congestion. Clubbing is not a feature of LAM, even though it was reported in 3% and 5% of patients in two larger case series.[9,15] Physical examination may also reveal evidence of pleural effusion, ascites, or pneumothorax, if present. Careful dermatologic, ocular, and dental surveys should be performed for evidence of TSC, including facial angiofibromas, subungual fibromas, palpable dysplastic cutaneous lesions called shagreen patches, hypomelanotic macules including those with ash leaf or confetti configurations, retinal hamartomas, and dental pitting.[20,21,39]

IMAGING STUDIES

The chest radiograph in patients may appear relatively normal (eFig. 97.4), even late in the disease, or may suggest hyperinflation only. As the disease progresses, the chest radiograph often demonstrates diffuse, bilateral, and symmetrical reticular or nodular opacities (eFig. 97.5), cysts (eFig. 97.6), bullae, or a "honeycomb" or somewhat "pseudofibrotic" appearance (eFig. 97.7).[8,9] Pleural effusion (Fig. 97.2) and pneumothorax (eFig. 97.8) may also be apparent. Preservation of lung volumes in the presence of increased interstitial markings is a radiographic hallmark of LAM that helps distinguish it from most other interstitial lung diseases (see eFigs. 97.4A, 97.5, 97.6A, and 97.7A), in which increased lung elastic recoil decreases lung volumes.

The *high-resolution computed tomography* (HRCT) chest scan is much more sensitive than the chest radiograph in detecting cystic parenchymal disease and is the gold standard radiologic approach to establish the diagnosis of LAM. The typical CT scan shows diffuse round, bilateral, thin-walled cysts of varying sizes ranging from 1 to 45 mm in diameter (see Fig. 97.2; eFigs. 97.2C, 97.3C, 97.4B–D, 97.6B, 97.7B, and 97.8B).[142,149] The numbers of cysts vary in LAM from a few (see eFig. 97.8B) to almost complete replacement of the normal lung tissue (see eFig. 97.6B). The profusion of cysts tends to be milder in patients with TSC-LAM than S-LAM, perhaps explained in part by identification of patients with TSC-LAM earlier in the disease process through screening.[86]

Advances in image analyses enable the quantification of cystic change in patients with LAM,[150-153] and they provide an opportunity to develop imaging-based biomarkers to follow disease progression and treatment response in LAM. For instance, in a post hoc quantitative volumetric analysis of the CT scans obtained during the *Multicenter International Lymphangioleiomyomatosis Efficacy and Safety of Sirolimus* (MILES) trial, Argula and colleagues[151] demonstrated a reduction in CT image–derived residual volume in the sirolimus group and suggested the reduction in air trapping as a potential mechanism for the beneficial physiologic effect of sirolimus. Gopalakrishnan and associates[154] analyzed the pulmonary parenchymal texture on CT scans of LAM patients being evaluated at the NHLBI and identified unique CT-based texture properties that correlated with cyst scores and therapeutic response to sirolimus. Perhaps the greatest barrier to widespread use of serial quantitative CT scans to monitor disease progression and/or treatment response is the risk of cumulative ionizing radiation exposure. Hu-Wang and associates[155] used model-based iterative reconstruction to perform ultralow-dose radiation CT scans on 105 LAM patients at the NHLBI. Radiation exposure was reduced by more than 90%, to levels similar to that of a plain chest film, with sufficient retention of resolution to define the degree of cystic lung destruction.[155] Further validation and widespread clinical availability of these techniques are high-priority future needs in LAM.

The morphology of the cysts is useful in differentiating LAM from other cystic lung diseases (Fig. 97.3). LAM cysts are characterized by their relatively uniform size and thin walls; they also tend to be distributed evenly in a diffuse manner and are separated by normal-appearing lung parenchyma. Blinded expert radiologists can correctly

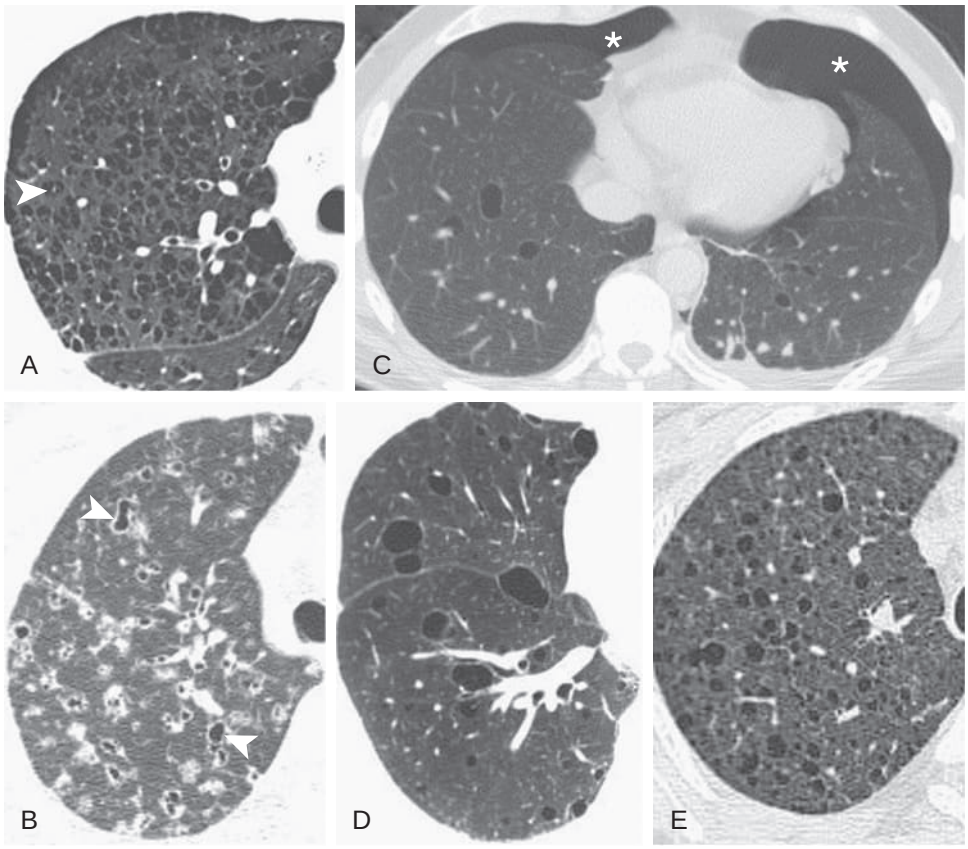

Fig. 97.3 Lymphangioleiomyomatosis cystic lung disease mimics. (A) Centrilobular emphysema—note the lack of a true cyst wall and the presence of the centrilobular artery *(arrowhead)* within the cystic region. (B) Pulmonary Langerhans cell histiocytosis—note unusually shaped cysts *(arrowheads)* and numerous nodules. (C) Birt-Hogg-Dubé syndrome—note lower lobe predominance of cysts. Spontaneous pneumothorax *(asterisks)* is present bilaterally. (D) Lymphocytic interstitial pneumonia—the cysts in this disorder may closely simulate lymphangioleiomyomatosis, particularly when no other infiltrative parenchymal findings coexist. (E) Lymphangioleiomyomatosis, presented for comparison. Note the relatively uniform, thin-walled appearance of the cysts with normal-appearing intervening lung parenchyma. (Courtesy Michael B. Gotway, MD.)

differentiate LAM from other cystic lung diseases approximately 80% of the time when provided with a pool of chest CT scans without accompanying clinical data.[142,149,156,157] Pleural effusions are found on CT in 12% of patients with S-LAM and in 6% of patients with TSC-LAM. Other CT features include linear densities (29%), hilar or mediastinal lymphadenopathy (9%), pneumothorax, lymphangiomyomas (see eFig. 97.3), and thoracic duct dilation.[8,15] Ground-glass opacities (12%) may suggest the presence of interstitial edema secondary to lymphatic congestion (Fig. 97.4). Views that include the abdomen may reveal AMLs.

In patients with TSC, nodular densities on HRCT may represent *multifocal micronodular pneumocyte hyperplasia* (MMPH) or clusters of hyperplastic type 2 pneumocytes[31,158-160] (Fig. 97.5; see also eFig. 80.2). MMPH may be present in male or female patients with TSC in the presence or absence of LAM, but it is typically not seen in patients with S-LAM.[30,161] MMPH is not generally associated with physiologic or prognostic consequences,[162] but one case of respiratory failure from MMPH has been reported.[163]

Chu and associates[15] reported that ventilation-perfusion scans were abnormal in 34 of 35 women with LAM. The most common abnormality was nonspecific diffuse heterogeneity of the ventilation and perfusion scans, with the defects usually grossly matched. These investigators also described an "unusual speckling pattern" on the ventilation scans in 74% of patients, consisting of "small, often peripheral collections of radioisotope" (eFig. 97.9). Using hyperpolarized xenon-129 magnetic resonance imaging ventilation scans on 22 LAM patients, Walkup and colleagues[164] found ventilation abnormalities and alveolar airspace dilation in all subjects, even in patients with normal spirometry; the magnetic resonance imaging abnormalities correlated well with pulmonary function testing. This technology may become useful for identifying the earliest evidence of airway changes in LAM and tracking treatment response. LAM and AML lesions do not typically exhibit increased uptake of ^{18}F-fluorodeoxyglucose on positron emission tomography scanning.[165] Other neoplasms (or sources of inflammation) should therefore be considered

Fig. 97.4 Interstitial pulmonary edema secondary to lymphatic obstruction or congestion. In patients with cystic change seen on high-resolution computed tomography that is otherwise typical for lymphangioleiomyomatosis, the ground-glass appearance *(arrows)*, often together with chylous effusions, lymphadenopathy, and/or lymphangiomyomas, may be indicative of pulmonary lymphatic congestion resulting from chylous reflux.

in known or suspected LAM cases with positive positron emission tomography results.[165]

Abnormalities on abdominal imaging, such as renal AML (Fig. 97.6 and see eFig. 97.2A–B) and enlarged lymphatic structures, are also common in LAM (Fig. 97.7). Fat density within a renal mass is pathognomonic of AMLs (see eFig. 97.2A–B). AMLs are more prevalent and more frequently bilateral and large in patients with TSC-LAM than in patients with S-LAM, and AML size roughly correlates with the prevalence of pulmonary cysts in patients with TSC.[28] Avila and associates[86] reported the results of CT imaging in 256 patients with S-LAM and 67 patients with TSC-LAM who were referred to the National Institutes of Health. Renal AMLs were present in 32% of patients with S-LAM and in 93% of patients with TSC-LAM. Hepatic AMLs (eFig. 97.2A) were present in 2% of patients with S-LAM and in 33% of patients with TSC-LAM. Ascites was uncommon, seen in fewer than 10% of patients with S-LAM and very rarely in TSC-LAM. Abdominal lymphangiomyomas (see eFig. 97.3B), often containing both cystic and solid components, were seen in 29% of patients with S-LAM and in 9% of patients with TSC-LAM.[86]

Central nervous system abnormalities, such as cortical tubers, subependymal nodules, and astrocytomas, are common in patients with TSC, including those with TSC-LAM, but these abnormalities are not found in women with S-LAM. Moss and associates[166] reported that women with S-LAM and TSC-LAM may have an increased incidence of meningioma, but the significance of that finding has been challenged.[167]

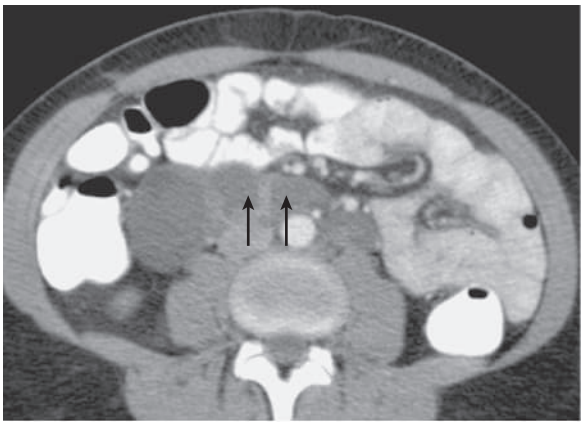

Fig. 97.7 Enlarged lymphatic structures. Abdominal computed tomography of cystic lymphangiomyomas *(arrows)* and retroperitoneal lymphadenopathy in a patient with lymphangioleiomyomatosis.

PULMONARY FUNCTION TESTING

Pulmonary function tests (PFTs) in patients with LAM may be normal or may reveal obstructive, restrictive, or mixed patterns, with obstructive physiology the most common abnormality. Quality-controlled lung function data were collected prospectively by the NHLBI Registry, a 5-year study of patients with LAM in centers around the United States.[11] Spirometry revealed obstructive changes in approximately 57% of patients and normal results in 34%. Restriction, defined as a total lung capacity less than the lower limit of normal, was seen in 11%. Hyperinflation was unusual, present in approximately 6%. The average residual volume was 125% of predicted when measured by plethysmography, but it was only 103% of predicted determined with gas dilution methods, a finding suggesting significant air trapping in noncommunicating air spaces.[11] Approximately 25% of patients with obstructive physiology may demonstrate bronchodilator responsiveness.[13] The obstructive physiologic defect in LAM is primarily attributable to airflow obstruction and, to a lesser degree, to a modest increase in lung compliance.[168]

The earliest and the most common finding on initial PFTs in various case series was abnormal gas transfer, as assessed by the *diffusing capacity for carbon monoxide* ($D_{L_{CO}}$), described in 82–97% of patients.[6,8,9,15] It is not unusual for $D_{L_{CO}}$ to be reduced out of proportion to *forced expiratory volume in 1 second* (FEV_1).[13]

Crausman and colleagues[169] studied the mechanism of exercise limitation in 16 patients with LAM. These investigators concluded that poor exercise performance was primarily the result of airflow obstruction and increased dead-space ventilation caused by pulmonary vascular disease or extensive cystic change. Cardiopulmonary exercise testing in a much larger cohort of patients with LAM revealed a reduced *maximal oxygen consumption* ($\dot{V}O_{2max}$) and anaerobic threshold in 217 patients.[170] Exercise-induced hypoxemia was found even in patients who did not have resting abnormalities in FEV_1 and $D_{L_{CO}}$. In most patients, exercise was thought to be limited by abnormalities in ventilation caused by airflow obstruction and increased dead-space ventilation.

Disease progression is usually accompanied by a progressive obstructive ventilatory defect, and decline in FEV_1 is the most commonly used parameter to monitor disease progression. Although resting pulmonary hypertension appears to be unusual in LAM, pulmonary arterial pressure often rises with low levels of exercise, related in part to hypoxemia.[171] Zafar and colleagues[172] reported an increase in intraparenchymal shunts in dyspneic patients with LAM that may contribute to resting and exercise hypoxemia.

Taveira-DaSilva and coworkers[13] correlated PFTs with lung histologic features in 74 patients. These investigators reported that a positive bronchodilator response was associated with a predominantly solid pattern of LAM lesions, as opposed to a cystic pattern. They also found that the $D_{L_{CO}}$ correlated with the lung histology score, a quantification of the extent of involvement with cystic lesions and LAM cells. FEV_1 and $D_{L_{CO}}$ were the best predictors of $\dot{V}O_{2max}$.

PATHOLOGY

Grossly, LAM lungs are enlarged and diffusely cystic, with dilated air spaces ranging from mild distention of alveolar spaces to bullous lesions of several centimeters in diameter (Fig. 97.8).[7,173] Microscopic examination of the lung reveals foci of smooth muscle cell infiltration of the lung parenchyma, airways, lymphatics, and blood vessels associated with areas of thin-walled cystic change. LAM lesions often contain an abundance of lymphatic channels, forming an anastomosing meshwork of slitlike spaces lined by endothelial cells. LAM cells generally expand interstitial spaces without violating tissue planes, but they have been observed to invade the airways, the pulmonary artery, the diaphragm, aorta, and retroperitoneal fat, to destroy bronchial cartilage and arteriolar walls, and to occlude the lumen of pulmonary arterioles.[7,174,175]

The two major cell morphologic types in the LAM lesion are cuboidal epithelioid cells and small spindle-shaped cells. The cuboidal cells within LAM lesions react with a monoclonal antibody called HMB-45, developed against the premelanosomal protein gp100, an enzyme in the melanogenesis pathway.[176] This immunohistochemical marker is very useful diagnostically because other smooth muscle–predominant lesions in the lung do not react with the antibody.[177] The spindle-shaped cells of the LAM lesion are more frequently proliferating cell nuclear antigen-positive than the cuboidal cells, a finding consistent with a proliferative phenotype.[176] Compared with cigar-shaped normal smooth muscle cells, spindle-shaped LAM cells contain less abundant cytoplasm and are less eosinophilic. In addition to staining for the typical smooth muscle markers such as actin, vimentin, and desmin, LAM lesions also express estrogen and progesterone receptors (Fig. 97.9).[178-180]

LAM lesions express lymphatic markers LYVE-1, PROX1, podoplanin, and VEGFR3.[181] The smooth muscle–like cells of AMLs are morphologically and immunohistochemically similar to LAM cells, with reactivity to antibodies directed against HMB-45 as well as against estrogen and progesterone receptors.[182,183] Unlike the dilated air spaces in emphysema, the cystic spaces found in LAM may be partially lined with hyperplastic type 2 cells in a discontinuous manner.[184]

DIAGNOSIS

The diagnosis of LAM usually follows CT scanning of the chest showing characteristic cystic change (Table 97.2). The differential diagnosis of cystic change on CT scan is broad (Table 97.3 and eFigs. 97.10 to 97.14), and critical review of the radiologic features is central to achieving the correct diagnosis.[1,185,186]

Besides LAM, the most common cystic lung diseases encountered in clinical practice include atypical emphysema, Birt-Hogg-Dubé syndrome (see Fig. 97.3C and eFig. 97.14), pulmonary Langerhans cell histiocytosis, and lymphoid interstitial pneumonia or follicular bronchiolitis typically secondary to underlying Sjögren syndrome or systemic lupus erythematosus. In rare circumstances, LAM and Sjögren syndrome may coexist in the same patient.[26] Typical demographic, clinical, laboratory, radiologic, and pathologic findings of these disorders are presented in Table 97.4.

Typical diffuse, thin-walled cystic change on HRCT is a prerequisite for the diagnosis of pulmonary LAM, but it is not sufficient to establish a definitive diagnosis.[142] Instead, an algorithmic, "least invasive" approach is advised (Fig. 97.10),[142] beginning with a detailed history and physical examination to determine whether TSC is present or absent. Pulmonary cystic change in a nonsmoking woman with TSC that is consistent with LAM does not usually

Table 97.2 Summary of the Joint American Thoracic Society and Japanese Respiratory Society Lymphangioleiomyomatosis Clinical Practice Guidelines

DIAGNOSIS
■ High-resolution chest CT findings should not be used in isolation to establish a confirmed diagnosis of LAM.
■ Serum VEGF-D is a highly specific diagnostic biomarker for LAM, which can obviate the need for more invasive diagnostic procedures.
■ Transbronchial lung biopsy has a >50% diagnostic yield with a reasonable safety profile, and it should be considered before performing surgical lung biopsy.
PHARMACOLOGIC TREATMENT
■ Hormonal agents should not be routinely used to treat LAM.
■ Doxycycline should not be routinely used to treat LAM.
■ Sirolimus is a safe and effective treatment for LAM and should be the first-line treatment for patients with abnormal lung function (FEV_1<70%), symptomatic chylous effusions, rapidly declining lung function (FEV_1 decline rates >90 mL/yr), or substantial disease burden (abnormal D_{LCO}, significant air trapping, resting or exertional hypoxemia).
PLEURAL DISEASE MANAGEMENT
■ Patients with LAM are at a high risk of developing recurrent spontaneous pneumothoraces, and pleurodesis should be offered following the first episode of spontaneous pneumothorax.
■ Prior pleurodesis is not a contraindication to future lung transplantation.

CT, computed tomography; D_{LCO}, diffusing capacity of the lung for carbon monoxide; FEV_1, forced expiratory volume in 1 second; LAM, lymphangioleiomyomatosis; VEGF-D, vascular endothelial growth factor-D.

require biopsy for a clinically confident diagnosis, although some cases of non-LAM cystic disease have been reported in patients with TSC.[25,27]

In the absence of TSC, careful review of the imaging and confirmatory procedures (e.g., thoracentesis to document chylothorax) should be performed to determine whether renal AMLs, chylous fluid collections, lymphadenopathy, or lymphangioleiomyomas are present; any one of these findings can establish the diagnosis in the setting of typical cystic change on HRCT. In the absence of these clinical features, serum VEGF-D levels higher than 800 pg/mL found in approximately 60–70% of the patients with LAM are almost 100% specific for the diagnosis of LAM, thus obviating the need for further invasive testing.[91-93]

Although in most patients (approximately 75–80%) a clinically confident diagnosis of LAM can be made by noninvasive means, the diagnosis is most definitively established by lung biopsy. HMB-45 staining is highly specific for LAM and can be used to differentiate LAM from other causes of smooth muscle proliferation in the lung, including idiopathic pulmonary fibrosis, benign metastasizing leiomyoma, and leiomyosarcoma. Bronchoscopic diagnosis, using transbronchial biopsies with appropriate immunohistochemical staining and expert interpretation, was shown to be safe in small series with a diagnostic yield of 50–60%, and it is recommended before performing surgical lung biopsy.[8,142,187-191] Transbronchial cryobiopsy is an emerging technique for establishing bronchoscopic diagnoses of diffuse parenchymal lung diseases, and it has been successfully used to diagnose LAM in isolated cases.[192-194] Although the diagnostic

NEOPLASTIC
■ Lymphangioleiomyomatosis, sporadic as well as associated with tuberous sclerosis
■ Pulmonary Langerhans cell histiocytosis, and non–Langerhans cell histiocytoses including Erdheim-Chester disease
■ Other primary and metastatic neoplasms (e.g., sarcomas, adenocarcinomas, pleuropulmonary blastoma) (see eFigs. 97.11, 97.12, and 97.13)
GENETIC, DEVELOPMENTAL, OR CONGENITAL
■ Birt-Hogg-Dubé syndrome (see eFig 97.14)
■ Proteus syndrome, neurofibromatosis, Ehlers-Danlos syndrome
■ Congenital pulmonary airway malformation, bronchopulmonary dysplasia, and others
ASSOCIATED WITH LYMPHOPROLIFERATIVE DISORDERS
■ Lymphoid interstitial pneumonia
■ Follicular bronchiolitis
■ Amyloidosis
■ Light chain deposition disease
INFECTIOUS
■ *Pneumocystis jiroveci* pneumonia
■ Staphylococcal pneumonia
■ Recurrent respiratory papillomatosis
■ Endemic fungal diseases especially coccidioidomycosis
■ Paragonimiasis
■ Tuberculous and other nontuberculous mycobacterial disease
ASSOCIATED WITH INTERSTITIAL LUNG DISEASES
■ Hypersensitivity pneumonitis (see eFig 97.10)
■ Desquamative interstitial pneumonia
■ Follicular bronchiolitis/lymphoid interstitial pneumonia associated with connective tissue disorders such as Sjögren syndrome
SMOKING RELATED
■ Pulmonary Langerhans cell histiocytosis
■ Desquamative interstitial pneumonia
■ Respiratory bronchiolitis
OTHER AND MISCELLANEOUS
■ Posttraumatic pseudocysts
■ Fire-eater's lung
■ Hyper-IgE syndrome
CYST MIMICS
■ Emphysema
■ $Alpha_1$-antitrypsin deficiency
■ Bronchiectasis
■ Honeycombing seen in late-stage scarring interstitial lung diseases

Certain diseases have overlapping features and can be classified in more than one category. Pulmonary Langerhans cell histiocytosis is classified both as a neoplasm and a smoking-related cystic lung disease. Similarly, desquamative interstitial pneumonia is classified under the category of interstitial lung disease, as well as a smoking-related cystic lung disease. Although classified as a lymphoproliferative disorder, light chain deposition disease can also be considered under the neoplastic category.

IgE, immunoglobulin E.

Table 97.4 Summary of Demographic, Clinical, Laboratory, Radiologic, and Pathologic Characteristics of the Major Cystic Lung Diseases

	LAM	BHD	PLCH	LIP/FB
Personal history	Pneumothorax, angiomyolipomas, and cortical tubers, seizures, skin lesions if TSC	Pneumothorax, skin lesions, renal tumors	Pneumothorax, smoking	HIV, autoimmune diseases, sicca symptoms, Raynaud phenomenon
Family history	TSC	Pneumothoraces, skin lesions, renal cancers	Not relevant	Not relevant
Sex predilection	Women >> men	Women = men	Women = men	Women > men
Extrapulmonary manifestations and other associations	Renal angiomyolipomas, chylous ascites, TSC manifestations	Renal tumors, skin fibrofolliculomas	Diabetes insipidus, cutaneous and osteolytic bone lesions	SS and other CTDs, HIV, EBV, CVID
Laboratory testing	Elevated serum VEGF-D	Genetic testing for *FLCN* mutations	Serum and urine studies for diabetes insipidus	ANA, SS-A, SS-B, RF, polyclonal dysproteinemia
Typical CT chest findings	Round, thin-walled cysts, distributed uniformly across all lung fields	Round-lentiform thin-walled cysts, predominantly located in the basilar, subpleural areas or abutting the pulmonary vasculature	Both thin-walled cysts and thick-walled cavities and nodules; cysts often have bizarre shapes; findings more prominent in the upper lobes with characteristic costophrenic angle sparing	Cysts of variable size, distributed uniformly across all lung fields with slight lower lobe predominance; cysts often have internal septations or eccentric vessels; may have associated ground-glass attenuation or nodules in the adjacent parenchyma
Diagnostic yield of bronchoscopy (BAL, TBB)	>50%	0	30–50%	Low yield
Consider surgical lung biopsy	Yes	No	Yes	Yes
Pathologic findings	Infiltration by HMB-45–positive LAM cells with smooth muscle phenotype	Intraparenchymal and subpleural cysts abutting interlobular septa and lacking abnormal cell proliferations or significant fibroinflammatory component	S100, CD1a-positive Langerhans cells with intracellular Birbeck granules by electron microscopy; stellate fibrotic scars in late stages	LIP: Diffuse interstitial polyclonal lymphocytic infiltrate FB: Peribronchiolar polyclonal follicular lymphoid hyperplasia with germinal centers
Genetic testing	Germline TSC mutations in TSC-LAM but not S-LAM, usually not clinically indicated	Germline *FLCN* gene mutation	Lesional MAP kinase pathway mutations such as BRAF, NRAS, MAP2K1	No
Inheritance	Autosomal dominant or sporadic	Autosomal dominant	Not inheritable	Not inheritable
Treatment	Sirolimus	None available	Smoking cessation, immunosuppression, cladribine, MEK inhibitors	Corticosteroids and other immunosuppressive agents

ANA, antinuclear antibody; BAL, bronchoalveolar lavage; BHD, Birt-Hogg-Dubé syndrome; CT, computed tomography; CTD, connective tissue disorders; CVID, common variable immunodeficiency; EBV, Epstein-Barr virus; FB, follicular bronchiolitis; HIV, human immunodeficiency virus; LAM, lymphangioleiomyomatosis; LIP, lymphoid interstitial pneumonia; MAP, mitogen-activated protein; MEK, MAP/ER kinase; PLCH, pulmonary Langerhans cell histiocytosis; RF, rheumatoid factor; SS, Sjögren syndrome; SS-A and SS-B, Sjögren syndrome antibodies A and B; TBB, transbronchial biopsy; TSC, tuberous sclerosis complex; VEGF-D, vascular endothelial growth factor-D.

Modified from Gupta N, Vassallo R, Wikenheiser-Brokamp K, McCormack FX. Diffuse cystic lung diseases: part II. *Am J Respir Crit Care Med*. 2015;192:17-29.

yield of transbronchial lung cryobiopsy for LAM should be equivalent or superior to that of traditional transbronchial forceps lung biopsy, the safety of this technique with regard to the risk of pneumothorax and bleeding needs to be more thoroughly investigated before widespread implementation. Video-assisted thoracoscopic lung biopsy remains the gold standard for making the diagnosis of LAM.

Criteria for establishing a confirmed diagnosis of LAM and a proposed diagnostic algorithm are presented in Table 97.5 and Figure 97.10, respectively. Clarity regarding the diagnosis of LAM facilitates discussions on life planning, pregnancy, birth control, pneumothorax management, and candidacy for trials, and it is increasingly important in the era of therapies that are effective but also prone to side effects.

MANAGEMENT

PHARMACOLOGIC TREATMENT

Hormonal Agents

The remarkable sex restriction in LAM, although incompletely explained, provided the rationale for the empirical antiestrogen strategies that had dominated the approach

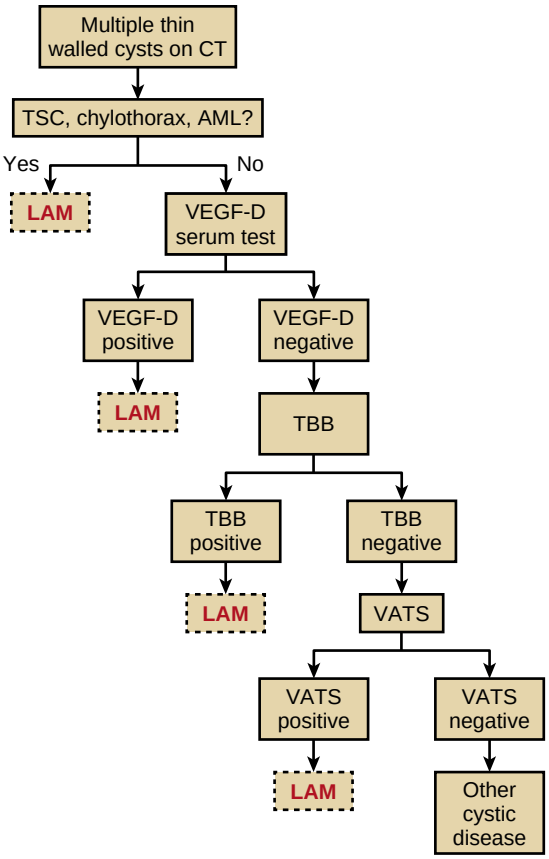

Fig. 97.10 Proposed diagnostic algorithm for lymphangioleiomyomatosis. *Lymphangioleiomyomatosis* (LAM) should be considered in the differential diagnosis of thin-walled multicystic lung disease. In a patient with typical *computed tomography* (CT) changes, a confident clinical diagnosis of lymphangioleiomyomatosis can be made if *tuberous sclerosis complex* (TSC), chylothorax, lymphangiomyoma, or *angiomyolipoma* (AML) is present. For patients without these features, a serum *vascular endothelial growth factor-D* (VEGF-D) level greater than 800 pg/mL is also diagnostic for lymphangioleiomyomatosis. If VEGF-D test results are negative, *transbronchial biopsy* (TBB), cytologic examination of pleural fluid, or thin needle biopsy of abdominal or thoracic masses can be useful for obtaining a pathologic diagnosis without surgery. Biopsy by means of *video-assisted thoracoscopic surgery* (VATS) can be used if the aforementioned approaches are uninformative, and it will distinguish lymphangioleiomyomatosis from other mimics including emphysema, Langerhans cell histiocytosis, and lymphocytic interstitial pneumonitis or follicular bronchiolitis.

to management of LAM for several decades. The results had been generally disappointing and, because proper trials with hormonal therapies have not been conducted, there remain no proven therapies for LAM based on antagonism of estrogen action. Bilateral oophorectomy has not been demonstrated to slow the rate of decline in lung function in LAM.[6,8,9]

Enthusiasm for the use of progesterone, which became the standard of care following a single positive outcome published in a case report in 1987,[180] has similarly waned over time. In a retrospective study of 275 patients, Taveira-DaSilva and associates[139] found that progesterone treatment had no impact on the decline in FEV_1 and was associated with an accelerated rate of decline in D_{LCO} compared with that in untreated patients. This finding was possibly explained by the statistical limitation "confounding by indication"—that is, patients taking progesterone were likely prescribed progesterone therapy because the disease was progressing more rapidly at enrollment.

Table 97.5 Criteria for Establishing a Confirmed Diagnosis of Lymphangioleiomyomatosis

1. Definite diagnosis of LAM can be established if a patient with compatible clinical history and characteristic HRCT of the chest has one or more of the following features:
   - Presence of TSC
   - Renal angiomyolipoma(s)*
   - Elevated serum VEGF-D >800 pg/mL
   - Chylous effusion (pleural or ascites) confirmed by tap and biochemical analysis of the fluid
   - Lymphangioleiomyomas (lymphangiomyomas)*
2. Demonstration of LAM cells or LAM cell clusters on cytologic examination of effusions or lymph nodes
3. Histopathologic confirmation of LAM by lung biopsy or biopsy of retroperitoneal or pelvic masses

*Angiomyolipoma may be diagnosed on the basis of radiographic appearance of characteristic fat-containing lesions either on computed tomography scan or magnetic resonance imaging. Contrast is not typically required unless the vascular characteristics of the tumor need to be analyzed, such as for evaluation of the potential for hemorrhage or planning for embolization. Similarly, lymphangioleiomyomas can typically be diagnosed on the basis of their characteristic radiographic appearance.

HRCT, high-resolution computed tomography; LAM, lymphangioleiomyoma; TSC, tuberous sclerosis complex; VEGF-D, vascular endothelial growth factor-D.

Modified from Gupta N, Finlay GA, Kotloff RM, et al. Lymphangioleiomyomatosis diagnosis and management: official American Thoracic Society and Japanese Respiratory Society clinical practice guidelines: high-resolution chest CT, transbronchial lung biopsy, and pleural disease management. *Am J Respir Crit Care Med*. 2017;196:1337-1348.

In another study, the rate of decline in FEV_1 and D_{LCO} was no different in patients treated with the gonadotropin-releasing hormone agonist triptorelin for 3 years than in a well-characterized cohort of historical control subjects.[195] Other case reports and case series of gonadotropin-releasing hormone agonist treatment have yielded conflicting results.[196-199]

The only randomized controlled trial of hormonal therapy in LAM, a comparison of an aromatase inhibitor versus placebo in postmenopausal women with LAM, demonstrated the safety of this approach but failed to meet the enrollment target needed to assess efficacy.[200] Thus, although there is a strong rationale for the use of hormonal therapy (e.g., aromatase inhibitors, gonadotropin-releasing hormone agonists) for this steroid-responsive neoplasm, this approach is not currently recommended,[201] pending the successful execution of pivotal trials.

Doxycycline

Doxycycline is a tetracycline antibiotic that inhibits the production and activity of several MMPs.[202] On the basis of data demonstrating expression of MMPs in LAM,[47,119,122] and a single case report suggesting dramatic improvement in lung function following administration of doxycycline,[203] there was considerable interest in the potential therapeutic role of doxycycline in patients with LAM. Two uncontrolled studies and an underpowered double-blind clinical trial showed no efficacy in the rate of decline in FEV_1, D_{LCO}, walk distance, or quality of life scores.[204-208] Current guidelines recommend against the routine use of doxycycline for treatment of LAM.[201]

Sirolimus

The discovery of the importance of the mTOR pathway in LAM and preclinical studies in TSC animal models formed the basis for phase I/II trials of sirolimus in patients with tuberous sclerosis and LAM (*Cincinnati Angiomyolipoma Sirolimus Trial* [CAST]; NCT00457964).[209] In CAST, an open-label study, 25 patients with AMLs, including 6 patients with S-LAM, 12 with TSC-LAM, and 7 with TSC alone, were treated for 1 year with sirolimus and followed with serial magnetic resonance imaging studies of the kidneys, chest CT scans, and PFTs. Of the patients still enrolled at 1 year, AML volume shrank by an average of 47% (n = 20). A remarkable and unexpected finding in this study was the improvement in lung function: in 11 of the patients with LAM, the FEV_1 and *forced vital capacity* (FVC) increased by 118 mL and 390 mL, respectively. The residual volume fell by 440 mL, and cyst volume percent, a measurement of the fraction of the pulmonary parenchyma occupied by cysts, tended to decline on therapy.[150] Parameters that did not change included total lung capacity, 6-minute walk distance, and D_{LCO}. There were a number of *adverse events* (AEs) while patients were taking the study agent, including mouth ulcers, cholesterol elevations, and hospitalizations for pneumonia, diarrhea, cellulitis, pyelonephritis, palpitations, and mucositis.[209]

In the second year of the trial, patients were observed off the study agent at 6-month intervals. At the 2-year point, the average AML volume had increased again to 86% of baseline, although, in 25% of patients, tumor volumes remained lower than 70% of baseline. FEV_1 and FVC declined in the observation year but remained 62 mL and 364 mL above baseline, respectively, and residual volume remained 333 mL below baseline, indicative of durable reduction in gas trapping. Similar results were seen in subsequent trials.[210,211]

On the basis of the unexpected lung function improvement in the 11 patients with LAM, and a higher than expected rate of AEs, a pivotal trial was designed to determine the risks and benefits of sirolimus in patients with LAM. The MILES trial was a randomized, double-blind, controlled trial of sirolimus that enrolled 89 women with LAM and abnormal lung function (FEV_1 <70% predicted).[19] During the 1-year treatment period, lung function (FEV_1) stabilized on sirolimus while declining by about 11% in the placebo group. Sirolimus also improved some measures of quality of life and functional performance. In the observation year off therapy, FEV_1 decline resumed in the sirolimus group and paralleled that in the placebo group. At baseline, serum VEGF-D was elevated in both groups. VEGF-D remained stable in the placebo group throughout the study, but it decreased by 50% during the first year on sirolimus. When sirolimus was withdrawn, VEGF-D increased toward baseline again, showing that the effect was temporary, consistent with the known cytostatic action of the drug.[94] The sirolimus-induced decreases in VEGF-D are intriguing in light of the strong lymphangiogenic phenotype observed in LAM and the striking effect of sirolimus on improving chylous effusions and decreasing the volume of lymphangioleiomyomas.[212-214] AEs were common during the treatment period, including acne, mucositis, nausea, diarrhea, hypercholesterolemia, and lower extremity edema, and they were more prevalent in the sirolimus group, especially during the first 3 months on the drug.[95] There was no increase in risk of infection, however, and the frequency of serious AEs was balanced between the groups.[19]

The beneficial effect of sirolimus and another mTOR inhibitor, everolimus, on lung function in LAM has subsequently been replicated in multiple other reports.[215-218] Collectively, these data affirm that treatment with sirolimus provides effective suppression of disease activity and stabilization of lung function in patients with LAM. However, durable disease control requires long-term, perhaps even lifelong, treatment with sirolimus.[217,218] The long-term safety and efficacy of sirolimus in LAM are the subjects of an ongoing, prospective observational study titled *Multicenter International Durability and Safety of Sirolimus in LAM* (MIDAS; NCT02432560). Sirolimus as a treatment of LAM has now been approved by the United States *Food and Drug Administration* (FDA), as well as by regulatory agencies in 39 other countries to date, including Brazil, Japan, Russia, South Korea, Uruguay, and all members of the European Union.

On the basis of the results of the MILES trial,[19] and several other open-label studies,[213,219] the joint *American Thoracic Society* and *Japanese Respiratory Society* (ATS/JRS) guidelines recommend initiation of sirolimus to treat LAM in the following circumstances: FEV_1 lower than 70% predicted, symptomatic chylous effusions, rapidly declining lung function (FEV_1 decline rates ≥ 90 mL/yr), or other parameters that could suggest substantial disease burden, such as abnormal DL_{CO}, air trapping, and exertional or resting hypoxemia[201] (eAppendix 97.1).

The sirolimus dose used in the MILES trial was 2 mg/day, titrated to maintain blood trough levels between 5 and 15 ng/mL, resulting in a mean sirolimus trough level of 7.2 ng/mL.[95] Subsequent open-label data from Japan suggest that lower-dose sirolimus (1 mg/day, blood trough ~2 ng/mL) has similar efficacy.[212] Many physicians around the world have since adopted this low-dose approach.

Serial postbronchodilator spirometry should be obtained at frequent intervals after initiation of sirolimus (every 3 to 4 months for the first 12 months) to assess treatment efficacy and ensure stability of FEV_1. Safety laboratory tests such as trough sirolimus levels, complete blood count, liver and renal function tests, urinalysis, and lipid panel should be monitored periodically, perhaps every month for the first 3 months and every 3 months thereafter.[220] Early administration of long-term, low-dose suppression with sirolimus is an appealing strategy to prevent progression of LAM, and a randomized, placebo-controlled study to determine the safety and efficacy of this approach is ongoing (*Multicenter Interventional LAM Early Disease* [MILED] trial; NCT03150914).

Although sirolimus has been successfully used to treat recurrent LAM after lung transplantation,[221] its use in the immediate postoperative period has been associated with bronchial anastomotic dehiscence,[222] and the FDA has issued a black box warning against sirolimus as first-line immunosuppression postoperatively. Some transplantation centers therefore recommend against the use of sirolimus in listed LAM patients; a practice that has resulted in precipitous lung function decline in some women.[223] On the basis of these experiences, and a review of the evidence that

indicates that most episodes of dehiscence take place more than 6 weeks after surgery, long after the drug would have washed out if stopped on the day of surgery, many centers now allow sirolimus use in patients on the waiting list.[224] In some cases, the therapeutic agent is changed from sirolimus to everolimus, to take advantage of the shorter half-life (11 hours vs. 60 hours) and the faster washout.[225,226]

High serum VEGF-D levels are associated with baseline markers of disease severity, including need for oxygen, bronchodilator responsiveness, and reductions in FVC and D_{LCO}. Higher baseline VEGF-D levels also predict disease progression and treatment response.[94] In the MILES trial, patients with serum VEGF-D levels higher than 600 pg/mL tended to have a faster rate of decline in FEV_1 in the placebo group and better treatment response in the sirolimus group.[94,95] On the basis of these observations, with all other things being equal, a high baseline VEGF-D may tip the balance toward treatment in a patient being considered for sirolimus therapy. Post hoc analysis of the MILES data has shown that sirolimus had a beneficial therapeutic effect regardless of underlying race (Asian vs. white), menopausal status (premenopausal vs. postmenopausal), type of LAM (TSC-LAM vs. S-LAM), bronchodilator responsiveness, or baseline FEV_1.[95]

OTHER THERAPEUTIC CONSIDERATIONS

A trial of bronchodilators should be considered in patients with LAM because up to 17–25% of patients with LAM have bronchodilator-responsive airflow obstruction.[11,15] Oxygen should be administered to maintain oxyhemoglobin saturations at 90% or higher with rest, exercise, and sleep.

All LAM patients should be vaccinated against influenza and against pneumococcus, including both the 13-valent and 23-valent preparations. Patients taking or considering mTOR inhibitors should receive the recombinant shingles vaccine. Live vaccines should be avoided in patients taking mTOR inhibitors (eAppendix 97.2).

Bone densitometry should be considered in all patients who are immobilized and/or receiving antiestrogen therapies, and appropriate therapy should be instituted for osteoporotic patients. Proper attention should be paid to cardiovascular health following natural or induced menopause. Pulmonary rehabilitation was shown to improve exercise capacity, dyspnea, and quality of life in women with LAM in a single-center, parallel-group study in Brazil.[227]

The LAM Foundation, an active patient advocacy organization for LAM, is a useful resource for both patient and provider education (www.thelamfoundation.org). The LAM Foundation also maintains 64 worldwide clinics, including 36 sites within the United States, as a referral network for expert care and access to research studies.

GENERAL RECOMMENDATIONS

SCREENING

Sporadic Lymphangioleiomyomatosis

Spontaneous pneumothorax is the second most common mode of presentation in LAM after dyspnea on exertion. A spontaneous pneumothorax in a woman should prompt consideration of LAM because primary spontaneous pneumothorax is most commonly seen in men who smoke cigarettes. Obtaining a chest CT scan in women presenting with a spontaneous pneumothorax can facilitate a timely diagnosis of LAM and was shown to be cost effective in two separate decision analysis models.[228,229] We recommend HRCT screening in women with spontaneous pneumothorax.

Tuberous Sclerosis–Associated Lymphangioleiomyomatosis

HRCT screening of women with TSC identifies cystic changes in approximately 20% of subjects younger than 30 years of age and in 80% of subjects older than 40 years of age.[31] The Tuberous Sclerosis Alliance[230,231] and the European Respiratory Society[232] recommend a screening chest CT scan in women with TSC after the age of 18 years. For women without pulmonary symptoms, the chest CT scan should be repeated every 5 to 10 years.[231] Once cysts are detected, the pace of TSC-LAM progression should be determined by periodic chest CT screening testing (perhaps every 2 to 3 years, preferably with low–radiation dose algorithms) accompanied by annual PFTs (and in patients with moderate cyst profusion, the 6-minute walk test), at least until trends are established.[231] The percentage of women with TSC and cystic change on CT who become symptomatic because of LAM is generally thought to be small, probably less than 10%, but in a single-center analysis of a large TSC clinic, LAM was found to be the second leading cause of death in the overall clinic population and the leading cause of death in adult women with TSC. These data highlight the importance of vigilance in pulmonary screening and disease management in the TSC population.[32] Although cystic changes consistent with LAM are found in approximately 10% of adult men with TSC,[233,234] symptomatic LAM in men is very rare,[23] and routine screening is not recommended.

PREGNANCY

Patients should be advised that pregnancy has been reported to result in exacerbations of LAM in some cases.[8,235-238a] In a group of 69 patients with sporadic LAM, pulmonary symptoms began during pregnancy in 9 of the 46 patients (20%) with a history of pregnancy before or at the time of diagnosis.[8] In this same group, a marked exacerbation of previously diagnosed LAM was observed in two (14%) patients during pregnancy.[8] In a natural history study of 89 women with LAM in Japan, the frequency of pregnancy was higher in the patients who exhibited a progressive decline in FEV_1 as compared with the subgroup of patients who did not have such a decline.[133] Women in whom LAM is diagnosed during pregnancy have higher rates of pneumothorax, miscarriage, and premature birth.[239] However, risk associated with pregnancy in LAM has not been rigorously studied, and decisions regarding the advisability of pregnancy should be made on an individual basis.[240] Unfortunately, the more pressing question of whether pregnancy accelerates the decline in lung function in LAM may never be rigorously addressed because so few women with a known LAM diagnosis choose to become pregnant, and patients in whom LAM is diagnosed during pregnancy rarely have baseline PFTs available. One recent study addressed this question: in 16 women with LAM, lung function was measured before and after pregnancy. During the pregnancy, pneumothorax was frequent; during

and after the pregnancy, the decline in FEV_1 was also high. The authors conclude that women with LAM should be counseled about the risk of pneumothorax and loss of lung function with pregnancy.[238a] Sirolimus is an FDA pregnancy category C drug and, although there is some experience with use of the drug in pregnant transplant recipients (TransplantPregnancyRegistry.org) and at least one reported LAM patient,[241,242] the safety and efficacy of sirolimus for mother and child have not been well established for pregnant women with LAM.

AIR TRAVEL (see Chapter 106)

Whether patients with LAM are at increased risk for pneumothorax during air travel is controversial. Pollock-BarZiv and coworkers[243] found that 35% of patients with LAM had been advised by their physician to avoid air travel because of the theoretical risk for lung cyst rupture associated with atmospheric pressure changes during flight. In a survey of 276 patients who answered a LAM Foundation questionnaire, there were eight cases of radiographically documented pneumothorax associated with 454 flights. In five cases, however, symptoms that were consistent with pneumothorax may have been present before boarding. Other on-board symptoms and signs noted in 10–20% of flights included anxiety (22%), chest pain (12%), shortness of breath (14%), cyanosis (2%), and hemoptysis (0.4%). The conclusion from the study was that, although there were AEs during flight, air travel is well tolerated by most patients with LAM.

A study of 281 patients with LAM who had routine chest radiographs after traveling to the National Institutes of Health for semiannual study visits identified seven patients with acute pneumothorax. There was no difference in the incidence of pneumothorax in patients who traveled by ground versus air, however. These investigators concluded that pneumothorax with air travel was related to the high incidence of pneumothorax in the disease rather than the air travel itself.[244] Another survey-based study conducted in LAM patients based in Europe revealed 6 episodes of pneumothorax related to air travel from a total of 178 flights. In contrast to prior studies that focused on events in the immediate peritravel period, the European study included any pneumothorax detected within 30 days of air travel as "air travel related."[245]

In summary, the risk of air travel–related pneumothorax in women with LAM is approximately one episode per 100 flights. In advising patients with LAM about air travel, it is reasonable to consider several factors, including a history of frequent or recent pneumothoraces, and the overall extent of cardiopulmonary impairment. Patients with poor cardiopulmonary reserve may tolerate even small pneumothoraces poorly. It is prudent for patients with LAM to seek medical evaluation, including a chest radiograph, before boarding a plane if pleuritic chest pain or unexplained shortness of breath is present. Hypoxemia during flight presents other risks, and patients should consult with their physicians regarding recommendations for on-board oxygen use. In most cases, however, air travel in patients with LAM should not be routinely restricted.

PLEURAL DISEASE (see Chapters 110 and 111)

Pneumothoraces in patients with LAM tend to recur, especially after conservative management such as observation, simple aspiration, or tube thoracostomy (eAppendix 97.3). More than 65% of patients with LAM develop pneumothorax during the course of their illness, averaging 3.5 pneumothoraces per affected patient over a lifetime.[141] The incidence of pneumothorax in LAM has been estimated to be approximately 5% per year following the diagnosis of LAM, and 8% per year following the first onset of symptoms attributable to LAM, compared with an incidence of 0.006% for women in general.[245] Risk of pneumothorax appears to correlate with premenopausal status, age younger than 50 years, and larger size of cysts.[141,246,247]

The ATS/JRS LAM Guideline Committee recommended a pleural symphysis procedure with the first pneumothorax, given the greater than 70% chance of recurrence.[142] Chemical sclerosis, mechanical abrasion, talc poudrage, and pleurectomy have been effective in patients with LAM. However, for reasons that are not well explained, failure rates after pleurodesis are surprisingly high (~35%) compared with other diffuse lung diseases known to be associated with secondary pneumothorax.[141]

Total pleural covering (TPC) is a newer technique from Japan in which the entire visceral pleura is reinforced by sheets of bioabsorbable mesh. This procedure can be accomplished under video-assisted thoracoscopic surgery guidance and does not induce pleural symphysis. In a single-center retrospective analysis involving 43 LAM patients with a spontaneous pneumothorax, TPC reduced the pneumothorax recurrence rate to approximately 25% with an acceptable safety profile.[248] Lack of validation and operator experience with this technique limits its current worldwide applicability; nevertheless TPC holds promise as a minimally invasive way of reducing recurrent pneumothoraces in LAM without creating pleural adhesions, and it warrants future investigation. The role of sirolimus in preventing recurrent pneumothoraces is not clear, but a small case series from China suggested potential benefit.[249]

Chyle does not generally cause pleural inflammation or fibrosis, and small stable chylous effusions are generally well tolerated. Effusions large enough to cause shortness of breath require intervention. The ATS/JRS LAM guidelines recommend treatment with sirolimus as the first-line therapy for symptomatic chylous effusions (see eAppendix 97.3).[201] Although thoracentesis may be required for the relief of acute symptoms, sirolimus therapy has significantly reduced the need for tube thoracostomy and pleural symphysis procedures for control of chylous complications in LAM. It is important to realize that, with sirolimus therapy, complete resolution of chylous effusions and ascites can take up to 6 months.

LUNG TRANSPLANTATION (see Chapter 140)

The first reported lung transplant in a patient with LAM was a combined heart-lung transplant in 1984.[250] Since then, post–lung transplant experience and outcomes in LAM have been reported in various studies from around the world.[8,141,224,226,251-257] Although some estimates suggested that post–lung transplantation survival in LAM was similar to that in other lung diseases,[252,253,256] more recent analyses suggest that LAM patients may fare better.[224,226,258] Khawar and associates[258] analyzed outcomes in 134 LAM patients registered with the *United Network for Organ Sharing* (UNOS) in the United States who underwent lung transplantation

between January 2003 and June 2017. Most patients (109 of 134; 81%) underwent bilateral sequential lung transplantation. The median time spent on the transplant wait list was 257 days, which was reduced to 148 days after the introduction of the lung allocation score in 2005. The median post–lung transplant survival in LAM was 12 years, with 1-, 5-, and 10-year survival rates of 94%, 73%, and 55%, respectively. These survival rates exceed those in patients with other diseases who underwent lung transplantation in the same time frame ($P < 0.0001$).[258] Similar post-transplantation survival outcomes have been reported from a study evaluating 57 LAM patients who underwent lung transplantation in Japan, with 1-, 3-, and 5-year survival rates of 87%, 82%, and 74%, respectively.[226]

Several case reports of recurrence of LAM in the donor allograft have been published.[80-83] The risk of graft compromise from bronchiolitis obliterans and other forms of chronic rejection is much higher than from recurrent LAM, and the latter should not be a dominant factor when judging candidacy for lung transplantation. More than half of patients with LAM who have undergone lung transplantation have a prior history of unilateral or bilateral pleural fusion procedures and, although postoperative bleeding risk is increased, the operative mortality and long-term survival do not appear to be adversely affected.[141,252] According to the ATS/JRS LAM Guidelines and the International Society for Heart and Lung Transplantation Guidelines, a history of prior pleurodesis is not a contraindication to future lung transplantation.[142,259] As with other obstructive lung diseases, referral for lung transplantation should be considered when the FEV_1 falls to less than 30% of the predicted value. Some patients who fail to meet this criterion may qualify on the basis of other factors that profoundly affect quality of life, such as disabling dyspnea or problems maintaining oxygen saturation despite high levels of supplemental oxygen.

ANGIOMYOLIPOMAS

Renal AMLs may require embolization or cauterization for control of bleeding, a complication thought to be more common when the diameter of the tumor exceeds 3 to 4 cm.[260-262] However, the validity of size-based cutoffs to determine bleeding risk in AMLs has been questioned.[263] The extent of aneurysmal change and the rate of growth of AMLs may also influence bleeding risk.[262,264] Serial abdominal imaging should be performed to assess AML size at 6- to 12-month intervals, at least until trends in growth are established. Nephron-sparing partial resections may be considered for very large tumors.[265] Nephrectomy is sometimes required for tumors with intravascular extension or life-threatening hemorrhage, but it is rarely the approach of choice because most AMLs can be managed by less invasive means. The FDA has approved everolimus for the treatment of AMLs.[266] Guidelines for management of AMLs have been published by the Tuberous Sclerosis Alliance.[230,231]

DISEASE PROGRESSION

Progressive airflow obstruction develops in most patients with LAM. In a cohort of patients in the United Kingdom, 10 years after symptom onset, 55% of 77 patients were breathless when walking on flat ground, and 10% were housebound.[267] The average annual rates of decline in FEV_1 and D_{LCO} in 217 patients studied in the NHLBI LAM Registry were 89 ± 53 mL and 0.81 ± 0.20 mL/min/mm Hg, respectively.[12] In other series from Europe, the rate of decline in FEV_1 was considerably higher, estimated at approximately 100 to 120 mL/yr,[8,268,269] whereas the rate of decline in FEV_1 was estimated to be only approximately 50 mL/yr in a natural history analysis in Japan.[133] In the MILES trial, annual loss of FEV_1 in patients in the placebo group was 134 mL, or approximately 11% of their lung function.[19]

There appears to be a clear relationship between menopausal status and the rate of decline in lung function. For instance, the rate of FEV_1 decline was higher in premenopausal women in the NHLBI Registry cohort as compared with postmenopausal women (118 mL/yr vs. 74 mL/yr; $P = 0.003$).[12] Similarly, in the placebo cohort from the MILES trial, the rate of decline in premenopausal patients was fivefold higher than the rate in postmenopausal patients (200 mL/yr vs. 40 mL/yr; $P = 0.003$).[95] A positive bronchodilator response, which was associated with a lower FEV_1, was found to be a predictor of more rapid rate of decline in FEV_1 in some studies,[12,13] but not in the placebo cohort of the MILES trial.[95] Neither a history of pneumothorax nor the total number of pneumothoraces appears to be associated with a higher rate of decline in FEV_1.[12]

Although TSC-LAM is often considered a milder form of disease, after matching for baseline disease severity, the rate of decline in FEV_1 appears to be similar in patients with TSC-LAM as compared with S-LAM.[12,95,270] High baseline VEGF-D also correlates with faster disease progression and better treatment response[92,94,95]; these data indicate that in addition to its utility as a diagnostic tool, serum VEGF-D can be useful for making treatment decisions.

PROGNOSIS

Survival estimates vary widely, appear to be dependent on mode of presentation or ascertainment, and have generally trended upward over the past few decades, probably because of earlier recognition through more widespread use of CT scanning and screening of TSC populations. The data from early, large case series indicated that 38–78% of patients were alive at 8.5 years from the time of disease onset.[6,9] Urban and associates[8] reported a 91% probability of survival at 8.5 years, 79% at 10 years, and 71% at 15 years.

For Japanese patients who presented with pneumothorax as the sentinel event, Hayashida and colleagues[10] reported that 5-, 10-, and 15-year survival probabilities were 95%, 89%, and 89%, respectively, whereas for patients who presented with dyspnea, survival rates were only 85%, 60%, and 47%. Matsui and coworkers[271] found that the actuarial survival rate, based on time from lung biopsy to death or transplantation, was 85% and 71% after 5 and 10 years, respectively. These investigators also developed a lung histology scoring system based on semiquantitative analyses of smooth muscle cell infiltration and cystic change, which correlated with survival. Other negative prognostic indicators include reduced FEV_1/FVC, increased total lung capacity, and predominantly cystic, rather than nodular, histologic features.[9]

In a population-based cohort ascertained by surveying patients registered with the LAM Foundation, the median

survival was 29 years.[140] Gupta and colleagues[12] performed a longitudinal analysis of the NHLBI LAM Registry data set to determine long-term outcomes in patients with LAM. Of the 217 patients who enrolled in the study in the late 1990s, 69 had progressed to death or lung transplantation by the censure date of December 31, 2014. The median transplant-free survival was more than 20 years from the time of diagnosis, with actuarial 5-, 10-, 15-, and 20-year estimates of 94%, 85%, 75%, and 64%, respectively. Postmenopausal status and baseline disease severity as assessed by FEV_1 and D_{LCO}, were the most important determinants of future progression to death or transplantation.[12] These data apply primarily to the presirolimus era (before 2011), and it is not yet clear whether sirolimus will affect mortality or the need for lung transplantation.

Although no robust prognostic data are available for TSC-LAM, the survival of patients identified through screening is almost certainly more favorable than that of patients who present with dyspnea. Zak and associates[32] analyzed long-term outcomes in a large single-center TSC clinic and reported that TSC-LAM is the second leading cause of death overall in the overall TSC population and the leading cause of death among adult women with TSC. The average life expectancy of women with TSC-LAM was 63 years, which was 7.5 years less than women with TSC who did not have LAM.[32]

FUTURE CLINICAL TRIALS

The most tangible and immediate research priorities in LAM include refinement and optimization of the use of mTOR inhibitors by studying the long-term safety and efficacy of sirolimus in LAM (MIDAS; NCT02432560), determining whether early administration of low-dose sirolimus can prevent future disease progression in a prophylactic manner (MILED; NCT03150914), and developing dosing biomarkers that can help personalize mTOR inhibitor-based treatment strategies for individual LAM patients.

Progress in understanding the genetic and molecular basis of LAM has led to several potential candidate therapies beyond allosteric mTOR inhibitors that may be appropriate for single-agent or combination therapy–based testing in clinical trials (eFig. 97.15). Examples of next-generation clinical trials either underway or recently completed include the following: combined hydroxychloroquine and sirolimus (NCT01687179),[272] combined sirolimus and simvastatin (NCT02061397),[273] combined resveratrol and sirolimus (NCT03253913), celecoxib (NCT02484664), imatinib (NCT03131999), and nintedanib (NCT03062943). Other potential promising treatment strategies include phosphatidylinositol-3-kinase pathway inhibitors, Rheb and Rho inhibitors (e.g., farnesyltransferase inhibitors and statins), estrogen antagonists (e.g., gonadotropin-releasing hormone agonists), selective estrogen response modifiers, selective estrogen receptor down-regulators (e.g., fulvestrant [Faslodex]), prolactin axis inhibitors, purine and pyrimidine synthesis inhibitors, angiogenesis inhibitors (e.g., bevacizumab), and lymphangiogenesis inhibitors (e.g., anti–VEGF-D antibody, VEGFR3 antibody, pazopanib). Many agents in these categories have already been approved by the FDA or are in development for other indications.

Key Points

- Lymphangioleiomyomatosis is a progressive cystic lung disease that is most prevalent in women and most commonly manifests with dyspnea on exertion and/or pneumothorax and less commonly with chylothorax, hemoptysis, or incidentally discovered abdominal masses or pulmonary cysts.
- Lymphangioleiomyomatosis is a metastasizing neoplasm, arising from an unknown source, associated with infiltration of lung with benign-appearing smooth muscle–like cells and cystic parenchymal destruction.
- The diagnosis of lymphangioleiomyomatosis can be established on clinical grounds, using consensus guidelines in an algorithmic, least invasive, stepwise approach that comprises abdominal imaging for lymphangioleiomyomatosis-related masses, measurement of the diagnostic biomarker, serum vascular endothelial growth factor-D, transbronchial biopsy, cytologic evaluation of chylous fluid, thin needle aspirates from abdominal lesions, or, less commonly, surgical tissue confirmation.
- Lymphangioleiomyomatosis is associated with tuberous sclerosis complex mutations that activate mechanistic target of rapamycin and promote growth and lymphangiogenesis, whether the mutations are in the germline in the heritable genetic disease tuberous sclerosis complex or exclusively somatic (nongermline) mutations in the sporadic form of the disease.
- Sirolimus is an effective treatment for lymphangioleiomyomatosis that should be considered in patients with abnormal lung function, rapid decline in forced expiratory volume in 1 second or diffusing capacity of the lung for carbon monoxide, recurrence after lung transplantation, or symptomatic chylous complications.
- The clinical course of lymphangioleiomyomatosis is highly variable, but it is generally slowly progressive, with 10-year survival of approximately 80–90% and a median survival after the onset of symptoms approaching 30 years.

eAppendix 97.1

SIROLIMUS PRESCRIBING GUIDE

INITIATION

1. Obtain baseline laboratory tests: complete blood count, comprehensive metabolic profile, lipid profile, urinalysis.
2. Begin drug at 1 to 2 mg daily.

MAINTENANCE

1. Instruct patients to take the drug at the same time every day.
2. After 2 to 4 weeks of treatment, perform a serum trough level. Instruct patients to wait 24 hours (20 to 28 hours) after taking the medication (just before the next dose) before drawing a serum trough level.
3. Check sirolimus level, complete blood count, comprehensive metabolic profile, lipid profile, and urinalysis every month for the first 3 months, and if OK, extend repeat testing to every 3 months.
4. Inquire about other adverse effects such as acne, oral ulcers, or worsening of pulmonary symptoms (to evaluate for drug-induced pneumonitis) at every visit.
5. Encourage patients to have annual influenza vaccinations, recombinant shingles vaccine, as well as pneumococcal prophylaxis, including both *23-valent pneumococcal polysaccharide vaccine* (PPSV) and *13-valent pneumococcal conjugate vaccine* (PCV). Avoid live vaccines while taking sirolimus.
6. Hold drug for at least 1 to 2 weeks before and 1 to 2 weeks after a surgical procedure or injury.

OTHER USEFUL TIPS

1. **Dosing**: We typically begin with low-dose sirolimus (1 mg daily) for most patients, unless disease is rapidly progressive or in an advanced stage. In general, most patients respond well with stabilization of lung function with a trough around 5 ng/mL or less, and caregivers should strive to determine the lowest effective dose to minimize adverse effects, given the need for long-term treatment. For patients with rapidly progressive or advanced disease, it may be better to start at 2 mg per day and titrate downward once stability is ensured.
2. **Oral ulcers**: In general, oral ulcers are uncommon and mild at low sirolimus doses. Corticosteroid-based topical applications are very effective in treating sirolimus-induced oral ulcers. Swish and spit dexamethasone is most effective. For topical gels, fluocinonide or clobetasol is preferred over triamcinolone (Kenalog).
3. **Acne**: Acne is not common in patients taking low-dose sirolimus. Over-the-counter medications such as benzoyl peroxide and salicylic acid are quite effective and are reasonable first-line treatment options for acne.
4. **Hyperlipidemia**: Treatment of hyperlipidemia should follow existing guidelines, including dietary modifications and statins.
5. **Common interactions**:
   a. Over-the-counter medications such as St John's wort
   b. Grapefruit juice
   c. CYP3A4 inducers (e.g., rifampin, carbamazepine, barbiturates, phenytoin)
   d. CYP3A4 inhibitors (e.g., ketoconazole, clarithromycin)

OTHER ADVICE

1. Use sunscreen, hats, and so forth because of the enhanced risk of skin cancer.
2. Do not split tablets.
3. Hold sirolimus for fever requiring antibiotics or for serious infections.
4. Hold sirolimus for any event that requires optimal wound healing, such as an accident with injuries.
5. Spirometry should be obtained at regular intervals that vary on the basis of disease progression, from every 3 months for those with worsening to every year or so for stable patients.
6. Consider obtaining serum vascular endothelial growth factor-D levels at least annually.

eAppendix 97.2

VACCINATIONS IN PATIENTS WITH LYMPHANGIOLEIOMYOMATOSIS

Patients with lymphangioleiomyomatosis (LAM) should maintain appropriate vaccinations. Live vaccines should be avoided in patients taking immunosuppressive agents, so the vaccination recommendations given here differ between LAM patients who are receiving mechanistic target of rapamycin (mTOR) inhibitors and those who are not.

For LAM patients who are *not* taking mTOR inhibitors, we recommend:

1. Annual influenza vaccination with the inactivated vaccine. Flumist (live attenuated influenza vaccine) is not recommended in LAM patients because diffuse lung disease is a relative contraindication.
2. Vaccination against pneumococcus:
   a. All patients should receive 13-valent PCV, one dose in a lifetime; ideally given before 23-valent PPSV, but at least 1 year after 23-valent PPSV.
   b. All patients should receive 23-valent PPSV, one dose every 5 years; given at least 2 months after 13-valent PCV.
3. Shingles (herpes zoster) vaccination:
   a. Shingles (herpes zoster) vaccination with recombinant zoster vaccine (RZV) is preferred over the live attenuated zoster vaccine (ZLV).
   b. RZV is recommended for all LAM patients over the age of 50 years.
   c. It requires a two-dose administration series at zero and 2 to 6 months.
4. Hepatitis (A and B) vaccines are recommended for all patients.
5. Tetanus vaccine is recommended for all patients.

For LAM patients who *are* taking mTOR inhibitors, we recommend:

1. Annual influenza vaccination with the inactivated vaccine. Flumist (live attenuated influenza vaccine) should not be used in immunocompromised LAM patients taking mTOR inhibitors.
2. Vaccination against pneumococcus:
   a. All patients should receive 13-valent PCV, one dose in lifetime; ideally given before 23-valent PPSV, but at least 1 year after 23-valent PPSV.
   b. All patients should receive 23-valent PPSV, one dose every 5 years; given at least 2 months after 13-valent PCV.
3. Shingles (herpes zoster) vaccination with RZV should be given to all LAM patients who are either currently taking or about to start taking mTOR inhibitors, regardless of age.
4. Hepatitis (A and B) vaccines are recommended for all patients.
5. Tetanus vaccine is recommended for all patients.
6. Avoid other live virus vaccines:
   a. Measles, mumps, rubella
   b. Oral polio
   c. Smallpox
   d. Rotavirus
   e. Yellow fever
   f. Rabies

GENERAL COMMENTS

Inactivated or recombinant flu vaccines should not be used in anyone with prior severe allergy without consulting an allergist, and they should be used with caution in patients with moderate or severe acute illness with or without fever, patients with a history of Guillain-Barré syndrome within 6 weeks of previous influenza vaccination, or people with egg allergy.

Minor illnesses (such as diarrhea, mild upper respiratory infection with or without low-grade fever, other low-grade febrile illness) are not contraindications to vaccination. Adults with egg allergy of any severity can receive inactivated vaccines with the same indications as those without egg allergy because the new preparations contain much smaller quantities of egg products.

Contraindications to 23-valent PPSV and 13-valent PCV include severe prior allergic reaction and moderate or severe acute illness. Patients with a documented true allergic reaction (rather than a history of egg allergy) to 13-valent PCV or 23-valent PPSV should seek the advice of an allergist.

eAppendix 97.3

PLEURAL DISEASE IN LYMPHANGIOLEIOMYOMATOSIS

The two most common pleural complications encountered in patients with lymphangioleiomyomatosis (LAM) are (1) spontaneous pneumothorax and (2) chylous pleural effusions.

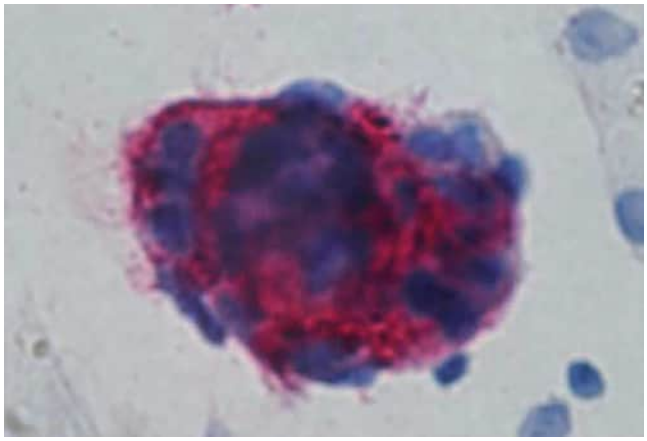
SPONTANEOUS PNEUMOTHORAX

1. Almost two-thirds of women with LAM experience at least one episode of spontaneous pneumothorax in their lifetime.
2. Patients who have a sentinel pneumothorax have a greater than 70% chance of recurrence.
3. Pleurodesis (chemical or surgical) reduces the risk of recurrence to approximately 30%.
4. Because of the high recurrence rate, patients with LAM should be offered pleurodesis after their initial episode of pneumothorax, rather than waiting for a recurrent event.
5. Although the preferred mode of pleurodesis varies among different centers depending on individual practices and experiences, we recommend video-assisted thoracoscopic surgery–guided mechanical abrasion as the preferred modality for pleurodesis, rather than instillation of talc or other sclerosing agents.
6. Whenever possible, pleurodesis should be handled by clinicians experienced in managing pleural complications of LAM.
7. Prior pleurodesis is not a contraindication to future transplantation.
8. All patients should be educated about the signs and symptoms of spontaneous pneumothorax at the time of initial diagnosis and advised to seek immediate medical attention if they experience any of these symptoms.
9. The risk of spontaneous pneumothorax associated with air travel is approximately 1 to 2 episodes per 100 flights. In general, it is safe for LAM patients to undertake air travel. Patients should be advised to seek medical attention and not board an airplane if they experience new or worse pleuritic chest pain and/or dyspnea before undertaking air travel.
10. Although there is no direct evidence, patients with LAM should be advised against scuba diving because of the potential increased risk of spontaneous pneumothorax related to atmospheric pressure changes.

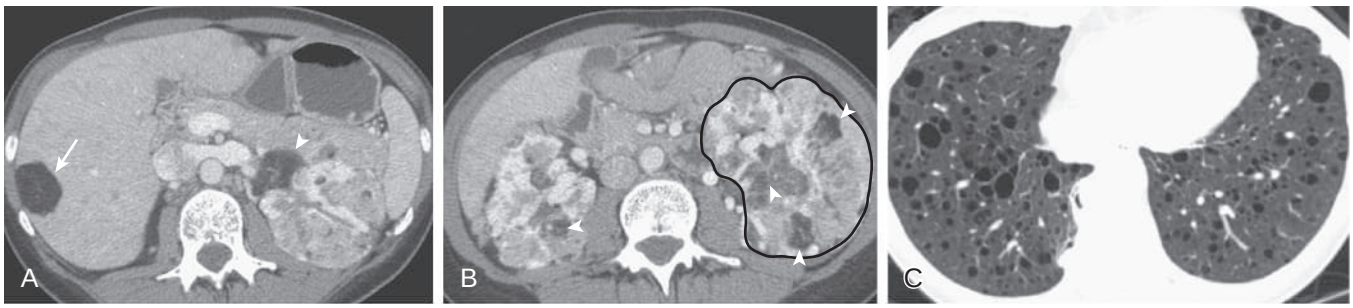
CHYLOUS PLEURAL EFFUSIONS OR CHYLOTHORAX

1. Chylous pleural effusions can be seen in 10–30% of patients with LAM.
2. If large enough to be tapped safely, chylous effusion should be confirmed with diagnostic thoracentesis. The presence of chylous effusion in a patient with characteristic cystic changes on high-resolution computed tomography is diagnostic of LAM. Pleural fluid obtained from diagnostic thoracentesis should be investigated for the presence of LAM cells. The demonstration of LAM cells on pleural fluid cytologic examination further strengthens the diagnosis of LAM.
3. Sirolimus is effective in managing chylous effusion, and it should be the first-line treatment option for patients with chylothorax, as compared with invasive treatment modalities.
4. In patients with persistent chylous leaks, dedicated lymphatic imaging such as heavy T2-weighted magnetic resonance imaging and dynamic contrast-enhanced magnetic resonance lymphangiogram should be performed to study the lymphatic anatomy and to determine if transcatheter embolization is feasible before pursuing invasive options such as pleurodesis.
5. Treatment with sirolimus may take a few months (even up to 6 to 12 months or longer) to be effective in managing chylous effusions. Because chyle does not typically produce pleural inflammation or fibrothorax, it may be prudent to wait for sirolimus to take peak effect before considering invasive treatment options.
6. Invasive management such as thoracic duct embolization should be performed by clinicians who have expertise in managing lymphatic complications in patients with LAM.

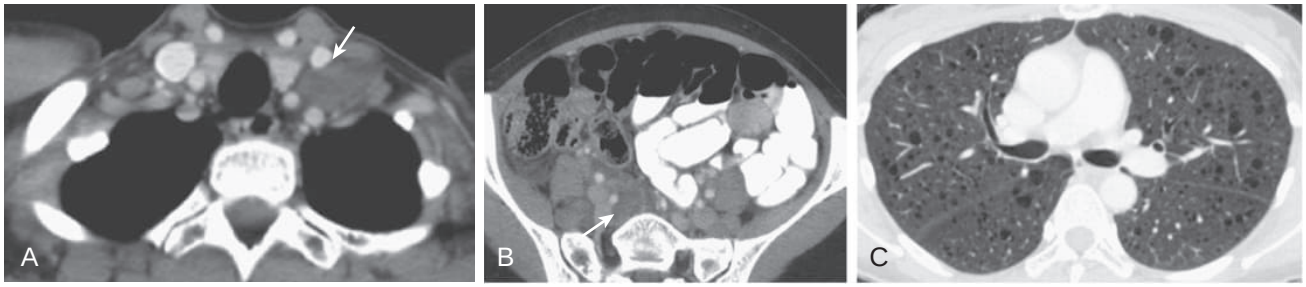
eFIGURE IMAGE GALLERY



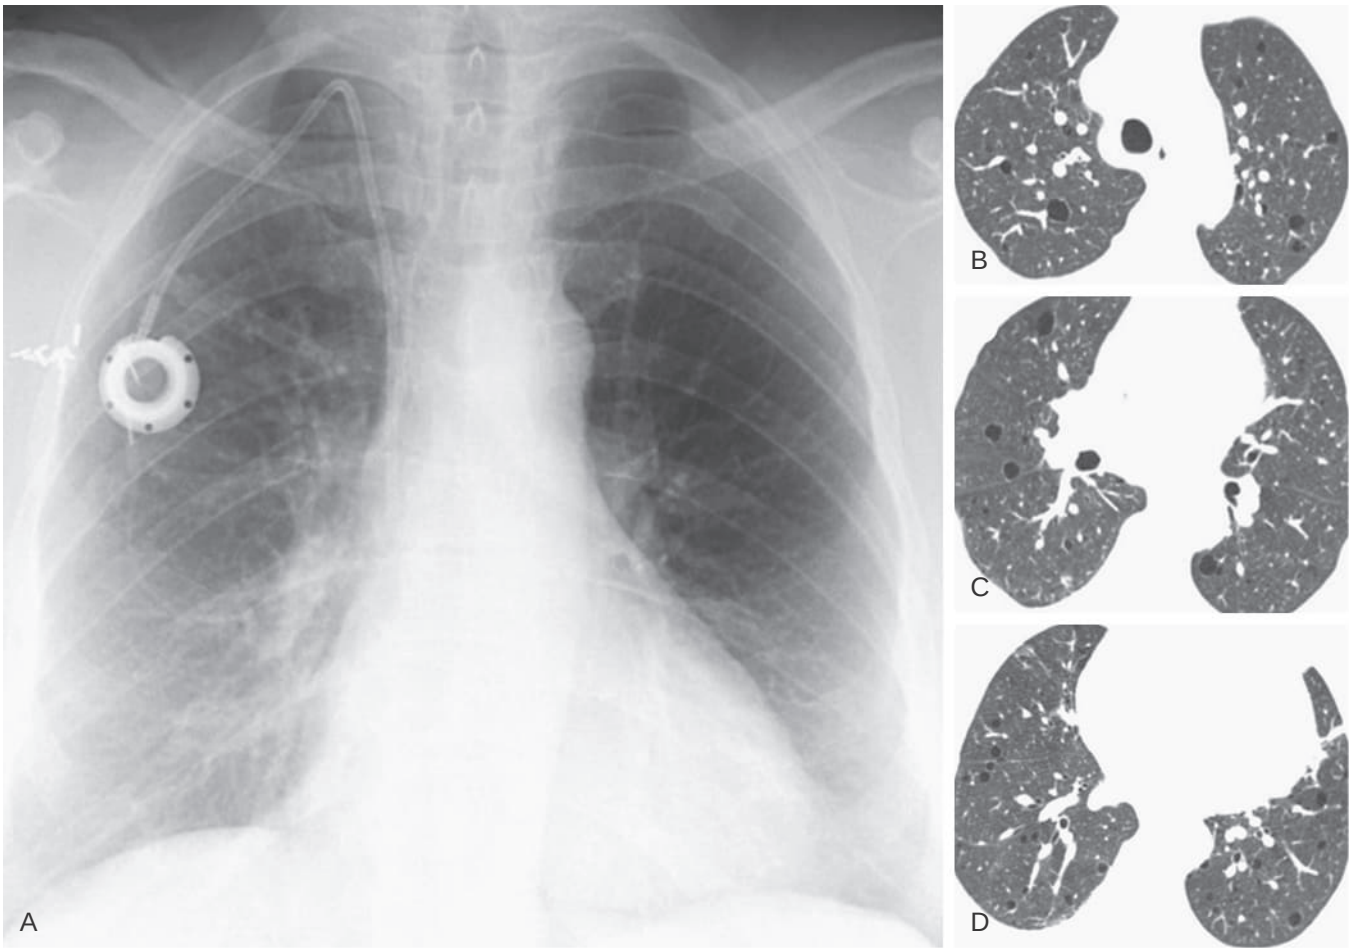
eFigure 97.1 Immunocytochemistry for *lymphangioleiomyomatosis* (LAM) cell cluster in chylous effusion. LAM cells in the clusters were strongly positive for α-smooth muscle actin, but the thin, flat cells surrounding the LAM cells were negative. (Smear; ×3400 original magnification.) (From Kumasaka T, Seyama K, Mitani K, et al. Lymphangiogenesis-mediated shedding of LAM cell clusters as a mechanism for dissemination in lymphangioleiomyomatosis. *Am J Surg Pathol.* 2005;29:1356-1366.)



eFigure 97.2 Angiomyolipomas in lymphangioleiomyomatosis. (A–B) Axial contrast-enhanced chest computed tomography through the upper abdomen shows bilateral renal enlargement (left kidney outlined in B). Numerous areas of fat density (*arrowheads,* A and B) representing angiomyolipomas are present. Hepatic angiomyolipomas (*arrow*, A) are also evident. (C) Axial chest computed tomography displayed in lung windows shows numerous bilateral, uniform-appearing, thin-walled cysts with relatively normal-appearing intervening lung, findings typical of lymphangioleiomyomatosis. (Courtesy Michael B. Gotway, MD.)

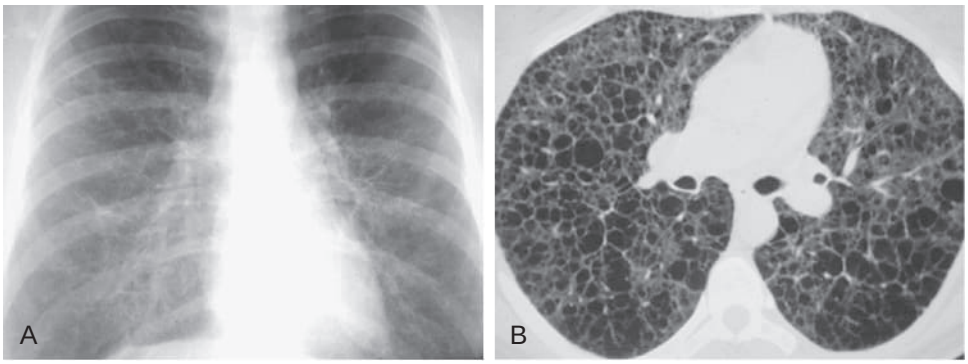


eFigure 97.3 Lymphangiomyomas in lymphangioleiomyomatosis. Axial chest computed tomography through (A) the upper thorax and (B) the pelvis show circumscribed, faintly septated, low-attenuation structures *(arrows)* representing lymphangiomyomas. (C) Axial chest computed tomography displayed in lung windows shows numerous bilateral, uniform-appearing, thin-walled cysts with relatively normal-appearing intervening lung, typical of lymphangioleiomyomatosis. (Courtesy Diego Ruiz, MD, Palo Alto Medical Clinic, Palo Alto, CA.)

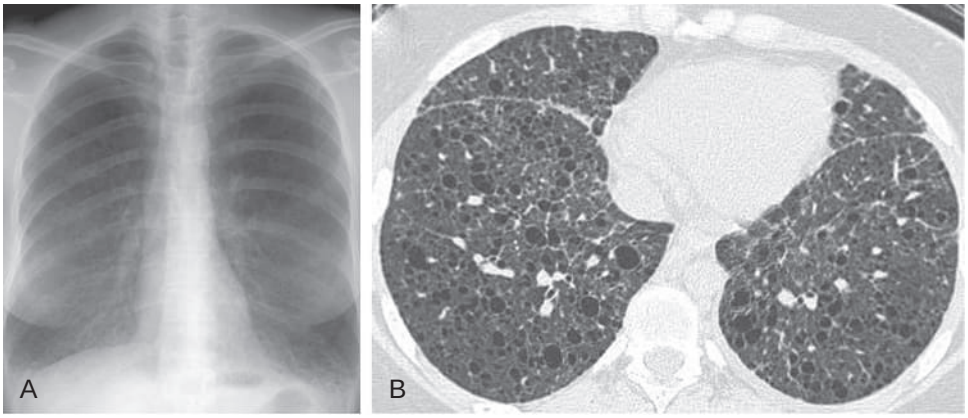


eFigure 97.4 Relatively unremarkable chest radiographic appearance in *lymphangioleiomyomatosis* (LAM). (A) Frontal chest radiograph in a patient with LAM shows relatively few abnormalities, with no findings specifically suggesting the diagnosis of LAM. Nonspecific mild right perihilar linear and reticular opacities are present. (B–D) Axial chest computed tomography displayed in lung windows shows bilateral, uniform-appearing, thin-walled cysts with relatively normal-appearing intervening lung, typical of LAM. The presence of comparatively fewer and smaller cysts in this patient likely contributes to the understated nature of the appearance on the chest radiograph (compare with eFigs. 97.5, 97.6A, and 97.7A). (Courtesy Michael B. Gotway, MD.)

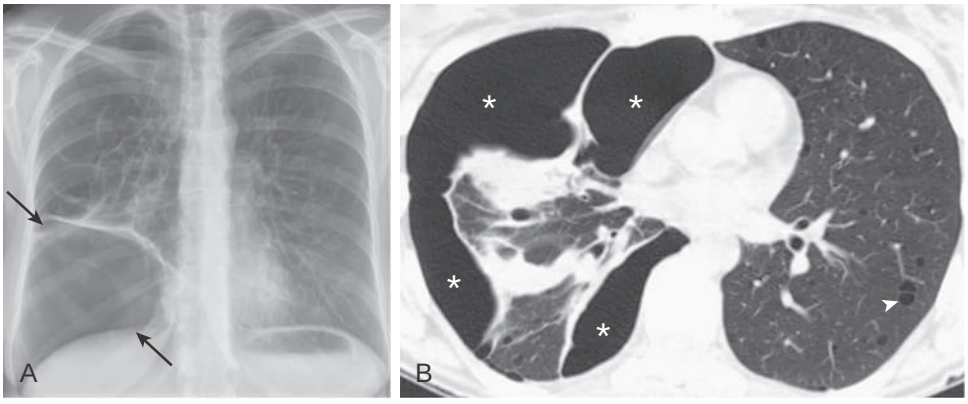
eFigure 97.5 *Lymphangioleiomyomatosis* (LAM)—linear or reticular appearance on chest radiograph. Frontal chest radiograph in a patient with LAM shows diffuse, bilateral, symmetrical linear and reticular opacities suggesting a disorder infiltrating the pulmonary interstitium. The appearance of interstitial lung disease on chest radiograph in patients with LAM may result from superimposition of the walls of the cysts characteristic of this disorder, in addition to actual interstitial space expansion resulting from lymphatic dilation and diffuse nodular proliferation of alveolar type 2 cells. (Courtesy Michael B. Gotway, MD.)



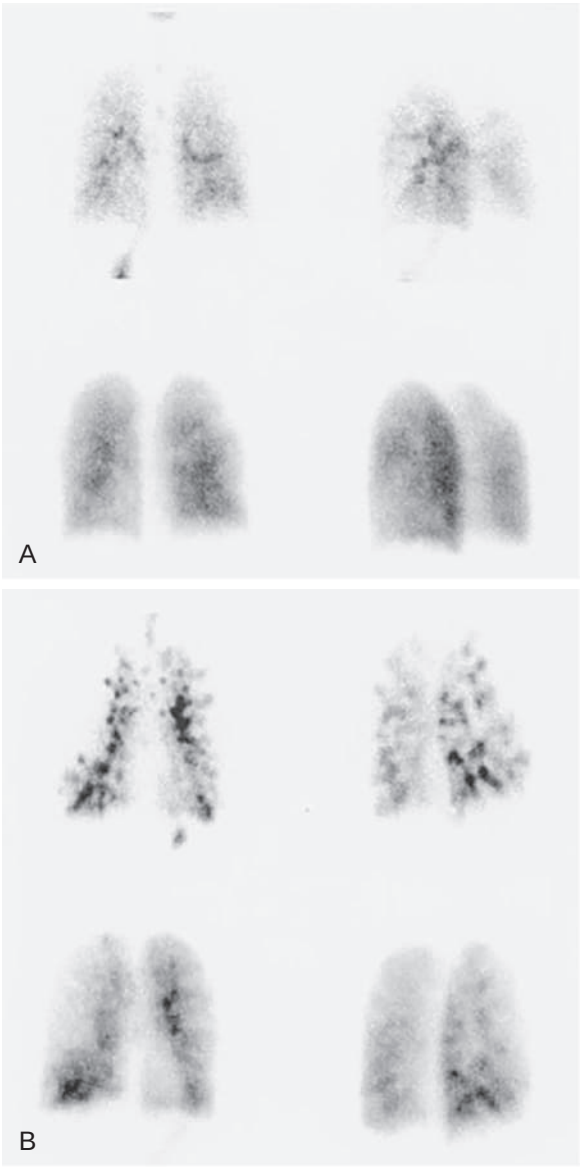
eFigure 97.6 *Lymphangioleiomyomatosis* (LAM)—typical imaging appearance. (A) Frontal chest radiograph in a patient with LAM shows increased lung volumes associated with bilateral linear and reticular opacities, faintly seen to represent the walls of the cysts typical of LAM. (B) Axial chest computed tomography shows numerous bilateral, uniform-appearing, thin-walled cysts with relatively normal-appearing intervening lung, typical of LAM. (Courtesy Michael B. Gotway, MD.)



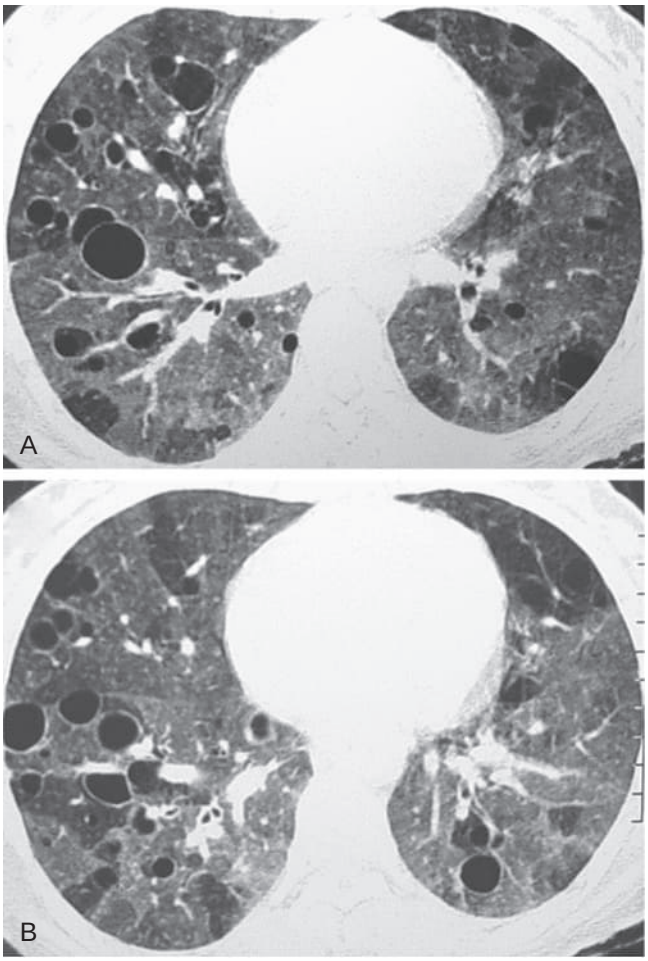
eFigure 97.7 "Honeycomb" or "pseudofibrotic" appearance of lymphangioleiomyomatosis at imaging. (A) Frontal chest radiograph shows bilateral linear and reticular opacities, somewhat resembling interstitial or fibrotic lung disease, especially in the bases. The large lung volumes, however, strongly argue against fibrotic interstitial pneumonia. (B) Axial chest computed tomography displayed in lung windows shows numerous bilateral, uniform-appearing, thin-walled cysts with relatively normal-appearing intervening lung, typical of lymphangioleiomyomatosis. The numerous overlapping cyst walls contribute to the "interstitial" appearance on radiography. This appearance in the bases can superficially resemble fibrotic lung disease. (Courtesy Michael B. Gotway, MD.)



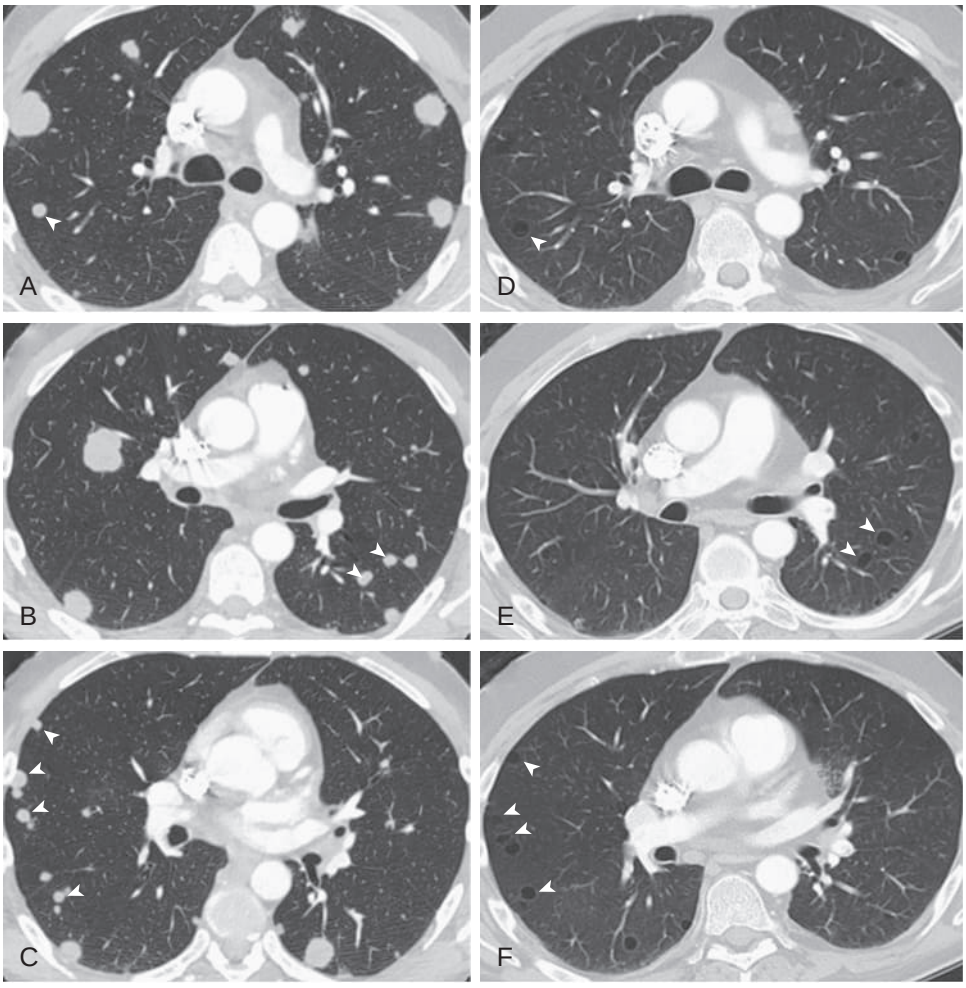
eFigure 97.8 Spontaneous pneumothorax in lymphangioleiomyomatosis. (A) Frontal chest radiograph shows a basal predominant right-sided pneumothorax *(arrows).* (B) Axial chest computed tomography displayed in lung windows shows the pneumothorax *(asterisks);* thin-walled left lower lobe cysts *(arrowhead),* typical of lymphangioleiomyomatosis, are present. (Courtesy Michael B. Gotway, MD.)



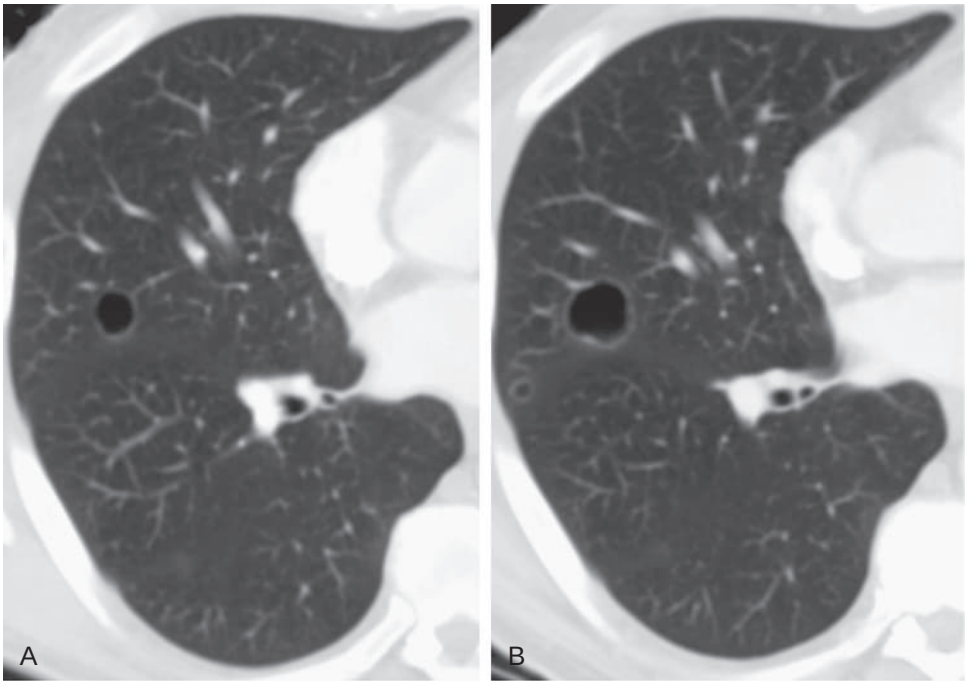
eFigure 97.9 Ventilation-perfusion scans of two patients with lymphangioleiomyomatosis. (A) Mild speckling. Posterior *(left)* and left posterior oblique *(right)* views of ventilation *(upper)* and perfusion *(lower)* scans show diffuse mild heterogeneity with mild speckling. A moderate amount of central clumping is also seen on the ventilation images. (B) Severe speckling. Anterior *(left)* and right posterior oblique *(right)* views of ventilation *(upper)* and perfusion *(lower)* scans show severe speckling and a significant degree of heterogeneity throughout. (From Chu SC, Horiba K, Usuki J, et al. Comprehensive evaluation of 35 patients with lymphangioleiomyomatosis. *Chest.* 1999;115:1041-1052.)



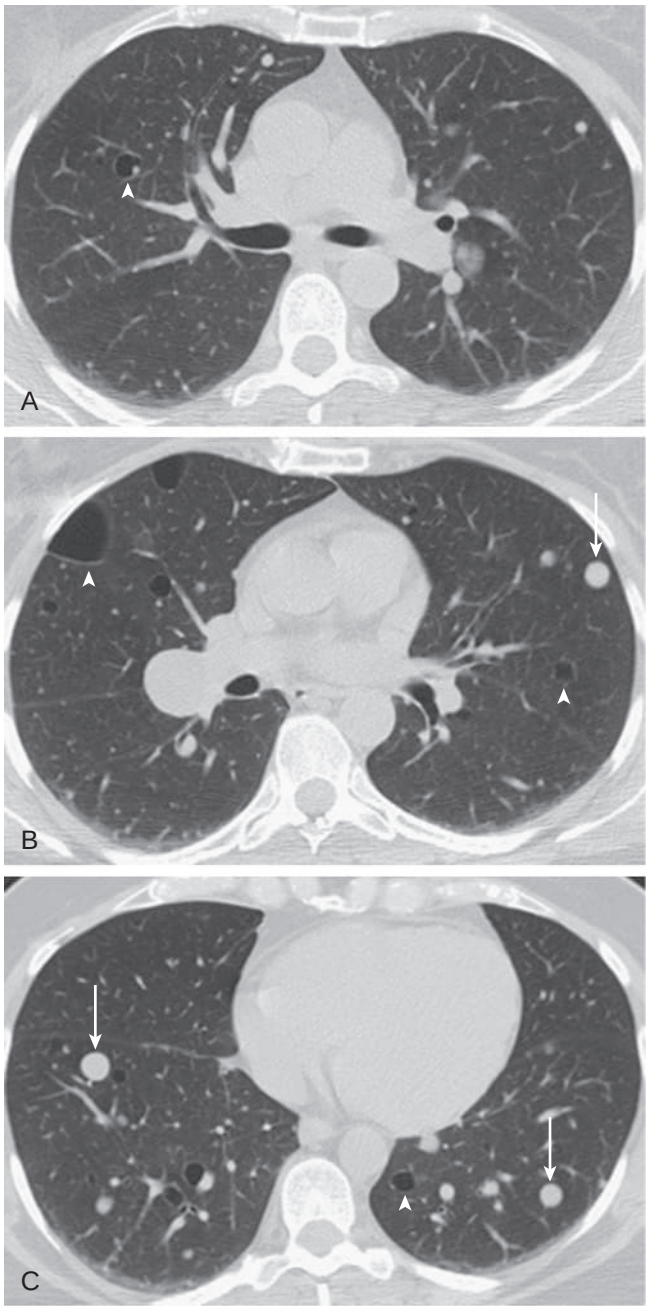
eFigure 97.10 Thin-walled cystic lung disorders simulating lymphangioleiomyomatosis: diffuse cystic lung disease in hypersensitivity pneumonitis. (A–B) Axial chest computed tomography displayed in lung windows shows patchy areas of ground-glass opacity associated with numerous thin-walled cysts in a patient with proven hypersensitivity pneumonitis. (Courtesy Alejandro Gómez-Gómez, Faculty of Medicine, Dr. Ignacio Morones Prieto Central Hospital, San Luis Potosí, Mexico.)



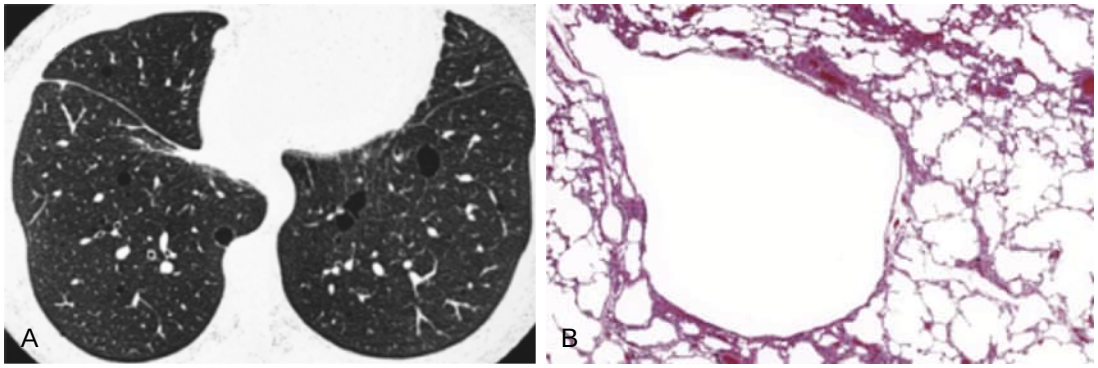
eFigure 97.11 Thin-walled cystic lung disorders simulating lymphangioleiomyomatosis: cystic metastatic disease. (A–C) Axial chest computed tomography displayed in lung windows at diagnosis shows numerous, variably sized, bilateral solid lung nodules *(arrowheads),* representing pulmonary metastatic disease from testicular carcinoma. (D–F) Axial chest computed tomography following therapy for metastatic testicular carcinoma shows many of the solid nodules have evolved into thin-walled cysts *(arrowheads).* Although the appearance at follow-up (D–F) may simulate more common causes of diffuse cystic lung disease, such as lymphangioleiomyomatosis and lymphocytic interstitial pneumonia, the clinical context (particularly the sex in this particular circumstance) and serial evolution from nodular lung disease readily provide differentiation from typical cystic lung disorders. (Courtesy Michael B. Gotway, MD.)



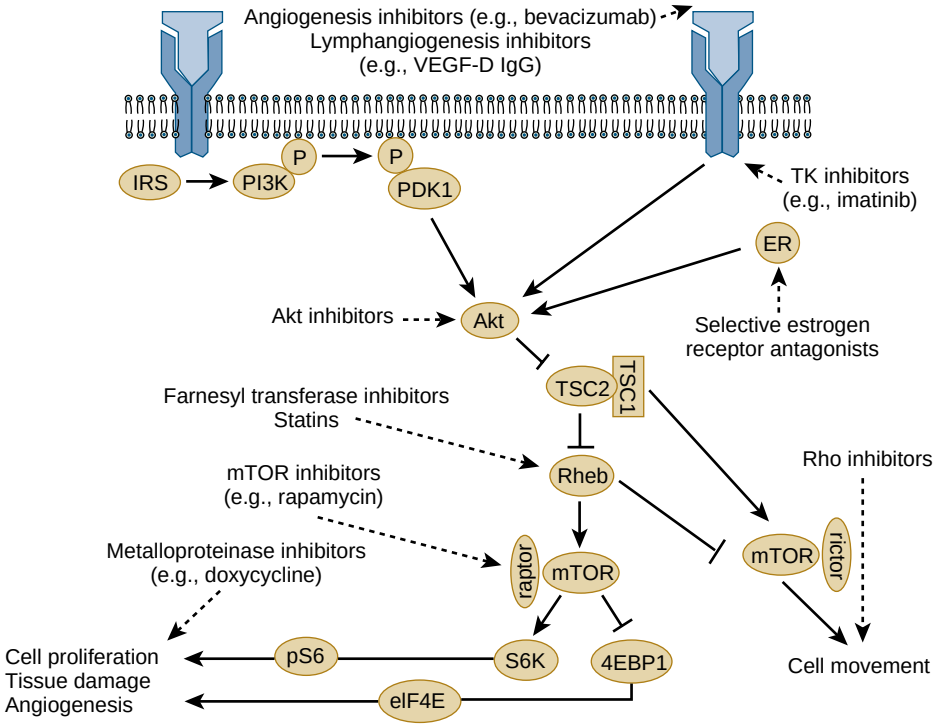
eFigure 97.12 Thin-walled cystic lung disorders simulating lymphangioleiomyomatosis: cystic metastatic disease. (A–B) Axial chest computed tomography displayed in lung windows in a patient with metastatic angiosarcoma shows several thin-walled cysts, ultimately shown to reflect metastatic angiosarcoma. (Courtesy Diego Ruiz, MD, Palo Alto Medical Clinic, Palo Alto, CA.)



eFigure 97.13 Thin-walled cystic lung disorders simulating lymphangioleiomyomatosis: cystic benign metastasizing leiomyoma. (A–C) Axial chest computed tomography displayed in lung windows shows several bilateral thin-walled cysts *(arrowheads)* and solid, circumscribed nodules *(arrows)*. The cysts evolved from solid nodules on serial examinations. Biopsy showed benign metastasizing leiomyoma. (Courtesy Michael B. Gotway, MD.)



eFigure 97.14 Birt-Hogg-Dubé syndrome. (A) High-resolution computed tomography and (B) histopathologic presentation of the lung cysts. (B, Hematoxylin and eosin stain.) This 58-year-old patient had repeated bilateral pneumothoraces and a family history of pneumothorax in a brother, son, and daughter. In the cyst wall, there is a lack of smooth muscle infiltration. (Courtesy Dr. Takashi Ogura, Kanagawa Cardiovascular and Respiratory Center, Kanagawa, Japan; and Tamiko Takemura, Japanese Red Cross Medical Center, Tokyo, Japan.)



eFigure 97.15 Future therapeutic targets for lymphangioleiomyomatosis. Knowledge of the signaling pathways that are dysregulated in patients with lymphangioleiomyomatosis has revealed several promising molecular targets for intervention. The constitutive activation of mechanistic target of rapamycin (mTOR) drives the inappropriate phosphorylation of S6 (pS6) when the *TSC1* or *TSC2* gene is missing or defective, as is seen in patients with lymphangioleiomyomatosis. pS6 (and eIF4E) drives protein translation and inappropriate cellular proliferation, but it also feeds back to inhibit the activation of immunoreactive secretin (IRS) and the downstream effector Akt. This feedback loop control can be defeated by the activation of Akt through other routes, such as the *platelet-derived growth factor* (PDGF) and estrogen receptor pathways (which may partly explain the sex restriction in lymphangioleiomyomatosis). In this regard, *tyrosine kinase* (TK) inhibitors such as imatinib and selective estrogen antagonists may have special utility in lymphangioleiomyomatosis to block alternative activation of Akt. mTOR inhibitors such as sirolimus and everolimus block mTOR signaling, and statins and farnesyl transferase inhibitors block Rheb translocation to the membrane by inhibiting the lipid modification of the protein. Patients with lymphangioleiomyomatosis express elevated levels of the lymphangiogenic growth factor, *vascular endothelial growth factor-D* (VEGF-D), which is currently being studied as a target in metastatic malignancy trials. Angiogenesis inhibitors such as bevacizumab and anti–VEGF-D or VEGF receptor 3 (VEGFR-3) antibody may block blood and lymphatic vessel recruitment required for tumor maintenance, respectively, and metalloproteinase inhibitors such as doxycycline may block lung matrix degradation that plays a role in tumor implantation, spread, and tissue destruction. Cell migration, infiltration, and metastasis are controlled by a rapamycin-insensitive mTOR pathway, but they may be susceptible to inhibition by rho kinase inhibitors. eIF4E, eukaryotic translation initiation factor 4E; ER, estrogen receptor; IgG, immunoglobulin G; PI3K, phosphatidylinositol-3-kinase; PDK, phosphoinositide-dependent kinase; S6K, ribosomal protein S6 kinase; TSC, tuberous sclerosis complex; 4EBP1, 4E-binding protein.

KEY POINTS

INTRODUCTION

Pulmonary alveolar proteinosis (PAP) is a rare syndrome characterized by abnormal alveolar surfactant accumulation and hypoxemic respiratory insufficiency presenting in a heterogeneous group of mechanistically distinct diseases usefully divided into disorders of surfactant clearance or surfactant production.[1–3] The *clearance* disorders can be further divided into primary PAP, caused by disruption of *granulocyte-macrophage colony-stimulating factor* (GM-CSF) signaling, and secondary PAP, caused by another disease or condition that disrupts alveolar macrophage surfactant clearance. The *production* disorders include *pulmonary surfactant metabolic dysfunction* (PSMD) disorders, caused by mutations in genes encoding surfactant proteins or genes encoding proteins involved in surfactant production.

Recent advances, including reports of several large cohorts,[4–7] have greatly improved our understanding of PAP pathogenesis, epidemiology, clinical subtypes, prognosis, and natural history and have resulted in new methods to diagnose, evaluate, and treat patients (see review[8]). Of importance, research on this rare and fascinating syndrome has uncovered the critical role of GM-CSF in alveolar macrophage ontogeny, pulmonary surfactant homeostasis, alveolar structural integrity, lung function, host defense, pulmonary and systemic inflammation, and autoimmunity. Further, studies involving GM-CSF–deficient mice have identified new treatment approaches for common diseases, such as asthma, rheumatoid arthritis, and others. This chapter reviews the pathogenesis, classification, epidemiology, presentation, and therapy of PAP and focuses on the disorders of surfactant clearance. These produce the characteristic pattern of PAP in adults. The disorders of surfactant production are mostly, but not exclusively, in children and only occasionally produce a proteinosis pattern.

PATHOGENESIS

SURFACTANT COMPOSITION AND HOMEOSTASIS

Surfactant is a complex mixture of roughly 80% phospholipids, 10% cholesterol, and 10% surfactant proteins that functions at the air-liquid–alveolar wall interface to reduce surface tension, thereby preventing alveolar collapse. It is produced in alveolar epithelial type 2 cells, secreted into the alveolar space, and cleared either by recycling or catabolism in type 2 cells or by uptake and catabolism by alveolar macrophages. Surfactant composition, production, and homeostasis are reviewed in Chapter 3. Studies in animals and humans have identified GM-CSF as a critical regulator of surfactant homeostasis (Fig. 98.1).

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR

GM-CSF is a 23-kD cytokine that signals via cell surface receptors comprising a GM-CSF–binding, low-affinity α chain (CDw116) and a nonbinding, affinity-converting β chain (CD131).[9,10] Although neither chain has intrinsic signaling activity,[9] the β chain constitutively binds *Janus activating kinase* (JAK),[11] a tyrosine kinase involved in cytokine signaling.

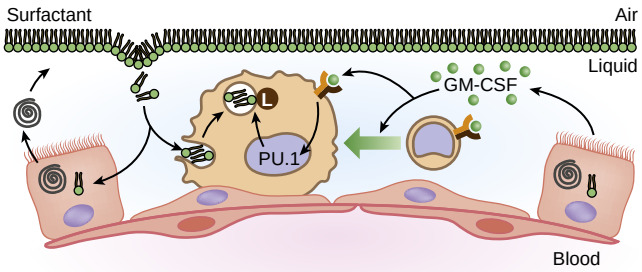

Figure 98.1 Schematic of pulmonary surfactant homeostasis within an alveolus of a healthy individual. Surfactant lipids and proteins are synthesized in alveolar epithelial type 2 cells and secreted into the intra-alveolar space. Extracellular surfactant contributes to the surfactant layer present at the air-liquid-tissue interface, which plays a critical role by reducing surface tension within the alveolus. Surfactant lipids and proteins are removed from the extracellular surfactant by uptake and recycling in type 2 cells or by uptake and catabolism in alveolar macrophages. *Granulocyte-macrophage colony-stimulating factor* (GM-CSF), a critical regulator of surfactant catabolism in alveolar macrophages, functions by binding to heterologous receptors on alveolar macrophages and stimulating surfactant catabolism via the transcription factor PU.1. GM-CSF is also critical for stimulating the terminal differentiation of precursors into mature alveolar macrophages (via *large green arrow*).

Ligand binding causes the formation of αβJAK2 multimers and the activation of JAK2, resulting in phosphorylation of α[12] and β chains, activation of other kinases,[11] and initiation of signaling via multiple pathways,[11,13] including the *signal transducer of activation and transcription-5* (STAT5).[14]

MURINE MODELS OF DISORDERED SURFACTANT HOMEOSTASIS

Abnormal Surfactant Clearance

GM-CSF–deficient (*Csf2*KO) mice provided the first clue to PAP pathogenesis. Although neither production of surfactant by alveolar epithelial type 2 cells nor its uptake by alveolar macrophages was altered,[15,16] surfactant clearance by alveolar macrophages was impaired.[17] Pulmonary GM-CSF,[18,19] acting via the transcription factor PU.1,[20] coordinately regulated surfactant catabolism; expression of Fc receptors, mannose receptors, and other receptors; phagocytosis; bacterial killing; and toll-like receptor-4 signaling[20] and identified pulmonary GM-CSF as a critical regulator of the terminal differentiation of alveolar macrophages in mice.

Mice deficient in either the GM-CSF receptor α chain (*Csf2ra*KO) or the β chain (*Csf2rb*KO) develop PAP indistinguishable from that observed in GM-CSF–deficient mice.[21] Transplantation of wild-type bone marrow corrected PAP in these mice, identifying myeloid cells and not lung epithelial cells as the cellular site of pathogenesis.[22] A biomarker of PAP in these mice (increased serum GM-CSF) suggested the means that led to identification of hereditary PAP caused by *CSF2RA* and *CSF2RB* mutations in children.[23–25] Of importance, *Csf2ra*KO and *Csf2rb*KO mice and children with *CSF2RA* or *CSF2RB* mutations develop a lung disease that is identical in every respect, including lung pathology (surfactant-filled alveoli, preserved architecture), cytopathology (oil-red-O–stained macrophages, cell debris), alveolar macrophage biomarkers (reduced messenger RNA for PU.1, *peroxisome proliferator-activated receptor* (PPAR)-γ, *ATP-binding cassette G subfamily1* (ABCG1), bronchoalveolar lavage biomarkers (increased surfactant proteins/lipids, turbidity), cytokines (GM-CSF, *macrophage colony-stimulating factor* [M-CSF], monocyte chemoattractant protein-1), and clinical course (progressive surfactant accumulation). Studies in these mice have identified pulmonary macrophage transplantation as a novel therapeutic approach for hereditary PAP.[26]

A more recent development has been the demonstration of a murine model of autoimmune PAP, using the *Rasgrp1*-deficient mouse. RasGRP1 is a guanine exchange factor expressed by B and T cells that activates *Ras* downstream of antigen receptor stimulation; mice deficient in RasGRP1 are prone to autoimmune features. *Rasgrp1*-deficient mouse lungs display the characteristic histopathology of PAP and reduced lung compliance.[27]

Mice deficient in ABCG1, a transmembrane protein mediating cellular cholesterol efflux, accumulate cholesterol in alveolar macrophages and alveolar epithelial type 2 cells and develop pulmonary lipidosis, indicating ABCG1 may be important in surfactant homeostasis.[28] Of importance, ABCG1 expression is decreased in alveolar macrophages from GM-CSF–deficient mice and patients with autoimmune PAP,[29] and from GM-CSF receptor–deficient mice and patients with hereditary PAP (unpublished data). Conditional disruption of *PPAR-γ* (a known transcriptional regulator of ABCG1), specifically in alveolar macrophages, also disrupts surfactant clearance.[30]

Together, murine studies suggest the pathogenesis of autoimmune and hereditary PAP may involve disruption of a pathway, including GM-CSF, PU.1, PPAR-γ, and ABCG1, that is essential for surfactant clearance by alveolar macrophages.

Several models have shed light on the pathogenesis of secondary PAP. In one, reduction of alveolar macrophage numbers by chemical depletion increased surfactant pool size.[31] In another, inhalation of respirable silica resulted in extensive alveolar proteinosis.[32] These models both support the concept that decreasing the number and/or functions of alveolar macrophages can cause the development of secondary PAP.

Abnormal Surfactant Production

Murine models of PSMD develop lung diseases faithfully recapitulating their respective human diseases, which are clinically, histologically, and biochemically distinct from PAP in the GM-CSF–deficient mice, and have improved understanding of surfactant homeostasis. For example, SP-B–deficient mice develop respiratory failure at birth. Studies in these mice showed that SP-B is essential for the posttranslational processing of SP-C, organization of surfactant phospholipids in lamellar bodies, formation of tubular myelin in alveoli, generation of surfactant films capable of reducing surface tension, and lung function during the early postnatal period.[33–35] Expression of mutant SP-C in mice causes a severe interstitial lung disease phenotype.[36] ABCA3-deficient mice develop respiratory failure at birth.[37] Studies in these mice established ABCA3 as critical to lamellar body formation and pulmonary surfactant biogenesis.[38]

Murine models of abnormal surfactant production that develop a PAP-like phenotype provide insights to surfactant homeostasis, including severe combined immunodeficiency,[39] pulmonary overexpression of *interleukin* (IL)-4[40] or IL-13,[41] and SP-D deficiency.[42]

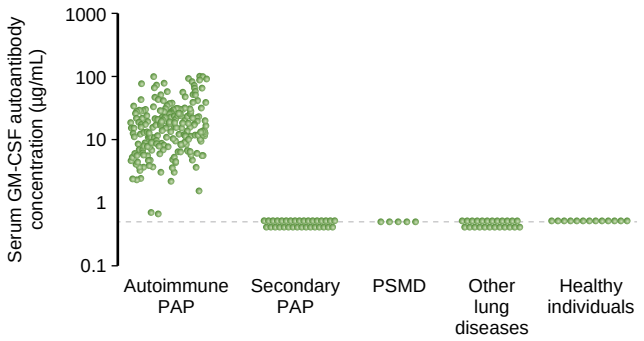

Figure 98.2 Serum antibodies to *granulocyte-macrophage colony-stimulating factor* (GM-CSF) are elevated in autoimmune *pulmonary alveolar proteinosis* (PAP). Serum GM-CSF autoantibody levels in individuals with autoimmune PAP ($n = 223$), secondary PAP ($n = 33$), *pulmonary surfactant metabolic dysfunction* (PSMD) ($n = 5$), other lung diseases ($n = 24$), and in healthy control subjects ($n = 13$). The detection limit of the assay was 0.5 μg/mL of serum. (Data from Inoue Y, Trapnell BC, Tazawa R, et al. Characteristics of a large cohort of autoimmune pulmonary alveolar proteinosis patients in Japan. *Am J Respir Crit Care Med.* 2008;177:752–762.)

ROLE OF GM-CSF AUTOANTIBODIES

In 1999, Nakata's group first identified neutralizing GM-CSF autoantibodies in the *bronchoalveolar lavage* (BAL) fluid and serum of idiopathic PAP patients.[43,44] Multiple subsequent studies confirmed that high levels of GM-CSF autoantibodies are associated with idiopathic PAP but not with secondary PAP, PSMD disorders, other lung diseases, or healthy individuals (Fig. 98.2).[1,2,4,45,46] In one study, the concentration of GM-CSF autoantibodies in 158 idiopathic PAP patients was 113 ± 7 μg/mL,[1,45] whereas levels were less than 1 μg/mL in patients with secondary PAP, PSMD disorders, or other lung diseases.[1] GM-CSF autoantibodies are composed of *immunoglobulin* (Ig) G, predominantly of the IgG1 and IgG2 subclasses; are highly specific for GM-CSF; have a very high binding affinity (20 ± 7.5 pM); and are capable of neutralizing GM-CSF at levels up to many thousands times higher than the physiologic concentrations of GM-CSF in vivo.[43,45,47] Notwithstanding these important observations suggesting a role of these antibodies in PAP, GM-CSF autoantibodies had been reported at low frequency in healthy people, in patients with autoimmune diseases without evidence of PAP, and to comprise the dominant anticytokine activity in pharmaceutical Ig prepared from healthy individuals.[48,49] In a more recent study using multiple detection methods, GM-CSF autoantibodies were demonstrated in all of 72 healthy individuals with no prior exposure to exogenous GM-CSF, albeit at a low level (median [interquartile range] = 1.0 [0.6–1.7] μg/mL serum).[47] Another confusing observation was that serum GM-CSF autoantibodies did not correlate with disease severity.[46]

To prove that GM-CSF autoantibodies were critical to the pathogenesis of idiopathic PAP and not a related but unimportant epiphenomenon, GM-CSF autoantibodies from these patients were isolated in pure form (i.e., a single band on sodium dodecyl sulfate gels) and used for passive immunization of healthy nonhuman primates. Results demonstrated unequivocally that GM-CSF autoantibodies reproduced the cardinal molecular and cellular features of PAP, including surfactant-filled alveoli with preserved wall architecture, foamy alveolar macrophages, cellular biomarkers of PAP (reduced PU.1, PPAR-γ, and ABCG1 messenger RNA), and BAL biomarkers (increased SP-D, turbidity).[50,51] GM-CSF autoantibodies isolated from the immunized primates or directly from patients had similar bioactivity.[50] Together with the clinical studies in humans, these data provided strong evidence that GM-CSF autoantibodies were in fact the pathogenic driver in idiopathic PAP, which is now recognized as autoimmune PAP.[50] Neutrophils from the immunized primates also had impaired phagocytosis similar to defects reported in these patients, GM-CSF–deficient mice, and normal human neutrophils incubated with purified GM-CSF autoantibodies in vitro.[52] Using the CD11b stimulation index assay (see later), GM-CSF signaling in immunized primates was found to decrease inversely with GM-CSF autoantibody concentration at values below 5 μg/mL and was zero at higher values, thus defining a critical threshold concentration needed to block GM-CSF signaling.[51] In a translational study using this assay, a similar relationship and threshold were observed in humans.[47] Thus seemingly discrepant observations (i.e., the critical role of GM-CSF autoantibodies in PAP pathogenesis and the lack of correlation between their concentration and disease severity) were reconciled by the hypothesis that a critical threshold level of GM-CSF autoantibodies was needed to reduce GM-CSF bioactivity sufficiently to impair surfactant clearance.[49]

GM-CSF autoantibodies are polyclonal and directed at epitopes throughout the GM-CSF molecule.[45] Evaluation of 19 monoclonal autoantibodies from six patients demonstrated that they use multiple V genes and targeted at least four nonoverlapping epitopes on GM-CSF, suggesting that GM-CSF drives the autoantibodies and not a B cell epitope on a pathogen cross reacting with GM-CSF.[53]

The observations that GM-CSF stimulation of neutrophil functions is impaired in autoimmune PAP and GM-CSF–deficient mice provides a further explanation for the increased infection risk in PAP caused by disruption of GM-CSF signaling. Further, the inverse correlation between GM-CSF autoantibody levels and neutrophil function (phagocytosis) in healthy people suggests that GM-CSF autoantibodies may have a physiologic role, such as in scavenging free GM-CSF, which can function as a proinflammatory cytokine. Supporting this concept, using methods capable of detecting GM-CSF whether it is bound by GM-CSF autoantibody or not, serum GM-CSF concentrations in healthy people are much higher than previously reported, and more than 99% is bound to GM-CSF autoantibodies in healthy individuals and in PAP patients.[47]

GENETIC FACTORS

Hereditary PAP

A series of reports established hereditary PAP as a recessive disease caused by genetic mutations in *CSF2RA* and *CSF2RB,* which encode GM-CSF receptor α or β chains, respectively (eFig. 98.1).[23–25,54,55] In some cases, the genes have been cloned and the defects reproduced in vitro, the signaling abnormalities studied in detail,[23–25] and results used to develop several novel biomarker-based diagnostic tests (see later). One particularly useful test, measurement of serum GM-CSF, was used to identify a number of patients

with hereditary PAP and is capable of identifying patients with defects in either chain.[23,24,25,56] Of importance to understanding the pathogenesis of PAP, in families with two siblings carrying the same function-impairing GM-CSF receptor gene mutation, the older sibling had minimal disease, whereas the younger sibling had severe disease, suggesting another factor besides loss of GM-CSF signaling is important in determining disease severity in hereditary PAP.[24]

Pulmonary Surfactant Metabolic Dysfunction Disorders

Mutations in three genes encoding surfactant proteins, *SFTPB, SFTPC,* and *ABCA3,* disrupt surfactant production and function and cause respiratory disease in neonates, children, and older individuals.[57–60] SP-B and SP-C are hydrophobic peptides that reside within the surfactant phospholipid layer, which functions to reduce surface tension at the alveolar wall–liquid-air interface,[35] whereas ABCA3 likely transports lipids, including phosphatidylcholine, cholesterol, sphingomyelin, and phosphatidylglycerol, into lamellar bodies in alveolar epithelial type 2 cells where the surfactant complex is assembled, processed, and stored.

SFTPB is a small gene (9.7 kb) encoding a 79–amino acid, hydrophobic protein. Infants homozygous for recessive loss-of-function mutations in *SFTPB* develop respiratory failure and die shortly after birth.[61,62] In contrast, individuals heterozygous for *SP-B*–deficiency alleles have normal lung function.[63] More than 30 mutations have been identified to date in fewer than 100 infants with SP-B deficiency.[60,64] Two-thirds have an insertional frameshift mutation caused by the replacement of a single nucleotide by three nucleotides at codon 121 (designated 121ins2). Among infants with SP-B deficiency, approximately 60% are homozygous for the 121ins2 mutation, 25% are heterozygous for this and another function-altering allele, and 15% have other mutations. SP-B deficiency is associated with the aberrant processing and secretion of an immature SP-C peptide, which may contribute to the respiratory failure associated with hereditary SP-B deficiency.[65]

SFTPC is a small gene (3 kb) encoding a 35–amino acid hydrophobic protein. Known mutations in *SFTPC* are expressed in a dominant fashion and are associated with interstitial lung disease in neonates, children, and adults.[60,66–69] Twenty-five percent of individuals with SP-C–associated lung disease have a point mutation in *SFTPC* causing the substitution of threonine for isoleucine at codon 73 (I73T).[67] Immunohistochemical analysis of lung tissue from an infant with the I73T mutation demonstrated normal staining patterns for pro–SP-B, SP-B, and pro–SP-C. Although infants with this mutation can present with respiratory distress syndrome, most children with the mutation become symptomatic with interstitial lung disease beyond the newborn period.[67,70]

ABCA3 is a large gene (80 kb) encoding a 1704–amino acid protein. Autosomal recessive mutations in *ABCA3* can result in fatal surfactant deficiency in neonates[71,72] and chronic respiratory insufficiency in older children.[69] Function-altering mutations in *ABCA3* result in surfactant that is deficient in phosphatidylcholine and has decreased function, suggesting that *ABCA3* has an important role in pulmonary surfactant phospholipid homeostasis.[73] A relatively common missense point mutation in *ABCA3,* causing the substitution of a valine for glutamic acid at codon 292 (E292V), is associated with chronic interstitial lung disease in older children who are heterozygous for this and a different function-altering mutation on the other *ABCA3* allele.[74]

NKX2.1 (also known as thyroid transcription factor 1 or TTF1) is a transcription factor essential for expression of SP-B, SP-C, and ABCA3. Haploinsufficiency of *NKX2.1* causes a complex phenotype in neonates that includes, albeit variably, hypothyroidism, brain abnormalities, and acute and chronic lung disease.[75,76]

Although the lung diseases associated with mutations in *SP-B, SP-C, ABCA3,* and *NKX2.1* disrupt surfactant homeostasis, cause varying degrees of surfactant accumulation (i.e., PAP), and are often cited as congenital forms of PAP in the medical literature, they are distinguished from disorders of surfactant clearance by their surfactant dysfunction (i.e., functionally abnormal surfactant), histopathologic abnormalities (gross parenchymal derangement and interstitial disease), and their clinical course. In consequence, the term *pulmonary surfactant metabolic dysfunction* (PSMD) disorders has been proposed for this group of genetic disorders.

DISEASE ASSOCIATIONS

PAP has been reported in association with various medical conditions believed to cause PAP, resulting in use of the term secondary PAP.[1,2,8] Systemic disorders associated with secondary PAP include malignant and other hematologic diseases, nonhematologic malignancies, immune deficiency syndromes, chronic inflammatory syndromes, and chronic infections (Table 98.1). In the past, chronic myelogenous

PAP, pulmonary alveolar proteinosis; tRNA, transfer ribonucleic acid.

leukemia and myelodysplastic syndrome were the most frequently reported hematologic disorders associated with PAP.[2,77–79] In one single-institution study, PAP developed in 5.3% of patients with hematologic malignancies and in 8.8% of those who were neutropenic.[78] Of pathogenic significance, 9 of 10 patients in one study were neutropenic when PAP developed and, in most, PAP resolved spontaneously after bone marrow engraftment. In another, PAP developed during a period of neutropenia that resolved after treatment with granulocyte colony-stimulating factor.[80] In a third report, PAP developed in three patients with acute myeloid leukemia with GM-CSF receptor abnormalities, including reduced levels of the β chain (3 of 3) and undetectable α chain (2 of 3).[81] PAP arises in about 10% of patients with lysinuric protein intolerance, an ultrarare inherited disorder caused by defective cationic amino acid transport.[82,83] Secondary PAP has been reported in association with various forms of immunodeficiency, including thymic alymphoplasia,[84] IgA deficiency,[85] solid-organ transplantation,[86] acquired immunodeficiency syndrome,[87] and mutations in methionyl-tRNA synthetase.[88]

Although the mechanism(s) responsible for secondary PAP are poorly studied, two common themes have emerged when considered in the context of the critical role of alveolar macrophages in surfactant homeostasis. Conditions reducing either the numbers or functions of alveolar macrophages would be expected to reduce the capacity of resident alveolar macrophages to clear surfactant from the lung surface.

ENVIRONMENTAL FACTORS

PAP has been associated with inhalation exposure to environmental agents, including cigarette smoke and a wide variety of organic and inorganic dusts, fumes, and gases (Table 98.2). Epidemiologic studies (see later) document that PAP is more common in smokers. Five of the 27 original patients reported by Rosen and colleagues[89] had been exposed to wood dust. Most reports implicating other environmental exposures are single cases or small retrospective series and, in general, have not established a causal relationship between the exposure and development of PAP. One early report of 138 PAP patients found that half had significant exposure to dust and fumes, of which the most common exposure was to inhaled silica.[90] With the advent of occupational protective equipment in the workplace, this form of "acute silicoproteinosis"[91,92] is rare. Other case reports document the association of PAP with exposure to aluminum dust,[93] cellulose fibers, cement dust, titanium dioxide,[94,95] indium-tin oxide,[96] and nitrogen dioxide. The link between silica and PAP is supported by studies in rats demonstrating that inhalation of silica particles disrupts surfactant homeostasis resulting in increased surfactant accumulation.[32,97] In an analysis of 1045 PAP patients from five separate large series,[2,4–7] a history of dust exposure, when data were available, was present in 26–54% of patients.[7] Further research is needed to determine what role environmental inhalation exposure plays in the pathogenesis of PAP, although one can speculate that the dust alters macrophage clearance functions.

Table 98.2 Pulmonary Exposures Reported to Be Associated With PAP Syndrome

INORGANIC DUSTS
Aluminum
Cement
Indium
Silica
Titanium
ORGANIC DUSTS
Agricultural
Bakery flour
Fertilizer
Sawdust
FUMES
Chlorine
Cleaning products
Gasoline/petroleum
Nitrogen dioxide
Paint
Synthetic plastic fumes
Varnish

PAP, pulmonary alveolar proteinosis.

MECHANISMS OF DISRUPTION OF SURFACTANT HOMEOSTASIS

Primary Pulmonary Alveolar Proteinosis

In mice, a series of observations has established GM-CSF as a critical regulator of pulmonary surfactant homeostasis, including the following: (1) surfactant homeostasis requires the presence of GM-CSF in the lung, and PAP develops in the absence of either pulmonary GM-CSF or its receptor; (2) surfactant accumulation in GM-CSF–deficient mice is caused by decreased clearance by alveolar macrophages, and not an increase in surfactant production; (3) pulmonary GM-CSF is required for normal expression of transcription factor PU.1 in alveolar macrophages, and enforced (i.e., retroviral mediated) expression of PU.1 restores surfactant catabolism in alveolar macrophages from *Csf2*KO mice; and (4) surfactant homeostasis can be restored in *Csf2rb*KO mice by transplantation of bone marrow from a wild-type mouse.

In humans, studies elucidating the pathogenesis of autoimmune and hereditary PAP show that GM-CSF effects on macrophages are also essential for surfactant homeostasis. Supportive data include (1) GM-CSF autoantibodies are present at high levels only in autoimmune PAP and, when isolated in pure form, cause PAP after injection into healthy primates[50,98]; (2) GM-CSF autoantibodies neutralize vastly higher amounts of GM-CSF than is present physiologically[45]; (3) in PAP patients, PU.1 expression is reduced in alveolar macrophages and increased by GM-CSF therapy[99]; (4) disruption of GM-CSF signaling by *CSF2RA or CSF2RB* mutations cause lung disease histopathology indistinguishable from that of GM-CSF knockout mice and autoimmune PAP in humans[23–25,54,55]; (5) reduced expression of GM-CSF receptor β on leukocytes is associated with PAP in children and with development of PAP in leukemia patients[81]; and (6) disorders that transiently reduce numbers and/or functions of alveolar macrophages are temporally related to the development and resolution of secondary PAP in humans.[80]

Available evidence suggests that GM-CSF regulates myeloid cell functions similarly in humans and mice. GM-CSF knockout mice and autoimmune PAP patients have remarkable

similarity in (1) pulmonary histopathologic appearance of the lung, (2) cytologic and ultrastructural appearance of alveolar macrophages, (3) elevation of certain cytokines (monocyte chemotactic protein-1, macrophage colony-stimulating factor), (4) the pattern of differential impairment of various neutrophil functions, and (5) the increased incidence of pulmonary and extrathoracic secondary infections.
