The pathogenic mechanism in primary PAP is disruption of GM-CSF signaling to alveolar macrophages, either by the absence of GM-CSF (observed in mice, but not yet in humans), disruption of GM-CSF signaling by mutations in the GM-CSF receptor proteins (in mice and humans), or an autoimmune attack targeted at GM-CSF that neutralizes GM-CSF, eliminating GM-CSF bioactivity and myeloid cell stimulation in vivo (in humans and nonhuman primates). GM-CSF, via PU.1, regulates catabolism of surfactant in alveolar macrophages (in mice and possibly humans). Surfactant accumulation in PAP is due to reduced clearance in alveolar macrophages, but the precise mechanism is unknown. Because pulmonary surfactant is internalized into macrophages by endocytosis and catabolized in phagolysosomes, it is possible that interruption of GM-CSF signaling blocks the translocation of endocytosed surfactant to lysosomes. Such a mechanism has been demonstrated for adenovirus internalized by macrophages from GM-CSF–deficient mice, in which PU.1 redirects adenovirus-containing endosomes to lysosomes for destruction. Alternatively, GM-CSF deficiency may result in a key enzyme deficiency. Potentially supporting this possibility are data related to PPAR-γ, a ligand-activated transcription factor regulating genes involved in lipid metabolism and other pathways.[100] PPAR-γ messenger RNA and protein are expressed in alveolar macrophages in healthy individuals, decreased in PAP patients, and increased by GM-CSF therapy of PAP patients.[99] CD36, a lipid scavenger receptor regulated by PPAR-γ, is regulated in a similar pattern. PPAR-γ deficiency has been noted in several other disorders, including sarcoidosis, acute respiratory distress syndrome, and asthma, where there have been reports of surfactant abnormalities.[101] Further studies are required to determine the mechanism by which interruption of GM-CSF signaling leads to reduced clearance of surfactant by alveolar macrophages.

Recent findings have revealed the importance of macrophage cholesterol clearance in maintaining surfactant homeostasis and alveolar macrophage function. In animal models of PAP and in PAP patient-derived macrophages, the capacity of alveolar macrophages to clear surfactant is impaired due to reduced cholesterol clearance, which is the rate-limiting step causing macrophage dysfunction in primary PAP.[102] Abnormal GM-CSF signaling results in reduced *PPAR-γ* gene expression in macrophages, resulting in lower expression of the cell surface cholesterol transporters ABCG1 and ABCA1. This, in turn, leads to reduced cholesterol clearance in alveolar macrophages, altering their ability to uptake and clear surfactant, resulting in alveolar surfactant accumulation. In patients with primary PAP, the foamy alveolar macrophages have elevated cholesterol content, and there is a corresponding increase in the ratio of cholesterol to phospholipid in BAL fluid.[103]

Secondary Pulmonary Alveolar Proteinosis

The mechanisms involved in secondary PAP, although less well supported by experimental data, likely involve reduced numbers or functions of alveolar macrophages. This would decrease the surfactant clearance capacity of resident alveolar macrophages and is supported by data demonstrating a temporal relationship of the onset and resolution of PAP with myeloid-cell suppression and its resolution in hematologic disorders. Other secondary mechanisms of PAP, for example, due to inhalation of toxic fumes and dusts, are less clear. Presumably, they would involve a reduction in the ability of alveolar macrophages to clear surfactant. However, because overexpression of certain cytokines (IL-4, IL-13) or decreased expression of some surfactant proteins (SP-D) also increases surfactant production in mice, other potential mechanisms appear possible.

Pulmonary Surfactant Metabolic Dysfunction

Mechanisms of PSMD involve mutations in genes of the surfactant synthetic pathway, including *SFTPB, SFTPC, ABCA3,* and likely others, and result in the production of biochemically and functionally abnormal surfactant. These disorders exhibit a lung histopathology and clinical course markedly different from PAP caused by interruption of GM-CSF signaling. Furthermore, the pathophysiology arises from surfactant deficiency and/or dysfunction rather than surfactant excess as in PAP. Thus, it seems appropriate to consider these disorders as distinct from PAP and not part of a spectrum of PAP.

NOMENCLATURE AND CLASSIFICATION

Since PAP was first described as a lung disease "of the filling of the alveoli by a periodic acid–Schiff–positive proteinaceous material, rich in lipid,"[89] it has become recognized as a syndrome caused by distinct diseases[1,8] and is reported in the medical literature using numerous terms, resulting in a nomenclature that is redundant, inconsistent, and confusing. Terms have been based on the biochemical characteristics of the accumulated material (e.g., alveolar proteinosis, phospholipidosis), pathogenesis (e.g., silicoproteinosis, idiopathic), disease category (e.g., primary vs. secondary), and timing of symptom onset (e.g., congenital, acquired) and are redundant (e.g., idiopathic PAP, acquired PAP, pulmonary alveolar lipoproteinosis, phospholipoproteinosis, alveolar lipoproteinosis, alveolar proteinosis, alveolar phospholipidosis, and alveolar lipophosphoproteinosis). Confusion arises from use of the same term for different diseases. For example, the term *congenital PAP* is used for the disease caused by mutations in *SFTPB* that is uniformly fatal at birth and caused by surfactant deficiency, and also for the disease caused by GM-CSF receptor deficiency that presents in children, is caused by surfactant accumulation, and can be treated successfully.

The foregoing discussion underscores the need for a classification and nomenclature that will facilitate clear communication about disorders of homeostasis necessary for clinical training, disease management, and research. Based on initial discussions of a global task force assembled by the Rare Lung Diseases Consortium, a simplified classified scheme is proposed (Table 98.3).

Disorders of surfactant homeostasis are separated into disorders of reduced clearance (PAP) or abnormal production (PSMD). PAP is further subdivided into primary and

secondary categories, depending whether it is due to a primary disturbance of GM-CSF signaling or secondary to another disease. Primary PAP is composed of several specific disease mechanisms: an autoimmune disease caused by GM-CSF autoantibodies (autoimmune PAP) or a genetic disease caused by mutations in the genes coding for the GM-CSF receptor, *CSF2RA* or *CSFR2B.* A third disease, caused by GM-CSF deficiency, has been described in mice and is predicted but not yet observed in humans. Secondary PAP arises in association with several disease categories, including hematologic disorders, malignancy, immunodeficiency syndromes, chronic inflammatory disorders, chronic infections (see Table 98.1), and in association with certain inhalation exposures, especially silica (sandblasters) (see Table 98.2). On the other hand, PSMD disorders are those arising from mutations in genes of the surfactant synthesis pathway, including *SFTPB, SFTPC, ABCA3, NKX2.1,* and likely others that have yet to be identified.[58] These disorders are included in a new classification of interstitial lung disease in young children.[104]

The plethora of terms used to report on the PAP syndrome are not recommended for continued use and should be replaced with the term *pulmonary alveolar proteinosis.* Terms referring to clinical presentation (i.e., acquired PAP, congenital PAP) should not be used when the underlying disease is known. For example, "SP-B deficiency" is far more informative than "congenital PAP" and more consistent with its pathogenesis as a disorder of surfactant deficiency (PSMD) rather than excessive surfactant accumulation (PAP). When the cause is unknown, the term "unclassified PAP" is preferred over "idiopathic PAP" because the latter is currently understood to be the disorder caused by a high level of GM-CSF autoantibodies and should be called autoimmune PAP.

EPIDEMIOLOGY

Disorders of surfactant homeostasis are found in worldwide distribution but are quite rare. Since the initial description of PAP, more than 1000 separate cases of PAP[2,4–6,23,89,105,106] and substantially fewer cases of PSMD* have been reported in the medical literature (eTable 98.1). A comprehensive meta-analysis of 410 separate cases of PAP representing all clinical subtypes and most or all cases of PAP reported in the medical literature through 1998 found that patients were more likely to be male (male/female ratio = 2.65:1.0) and that men predominated among smokers (male/female ratio = 2.78:1.0) but not among nonsmokers (male/female ratio = 0.69:1.0).[2] These results suggested that the high proportion of men among PAP patients may be explained by their higher frequency of tobacco use. More recent evaluations have refined these estimates for individual diseases. Consequently, the epidemiology of each is considered individually.

Autoimmune PAP has been studied worldwide. In a large national, multicenter, registry-based study of PAP conducted in Japan, 223 patients were identified with autoimmune PAP.[4] This study reported a male predominance (male/female ratio = 2.1:1.0) and that men predominated among smokers (male/female ratio = 9.3:1.0) but not among nonsmokers (male/female ratio = 0.6:1.0). The median age at the time of diagnosis was 53 years (52 years in men and 55 years in women). The prevalence was similar in nine nonoverlapping geographic regions encompassing the entirety of Japan, and the case rate correlated closely with the regional population size. An intensive screening within the Niigata prefecture in Japan (population 2.41 million) estimated the incidence and prevalence of autoimmune PAP to be 0.5 ± 0.1 and 6.2 per million, respectively.[4] This registry found that, among noncongenital cases of PAP, 89.9% of cases were autoimmune, 9.7% were secondary, and 0.4% were unclassified. In a meta-analysis of 1045 primarily adult PAP patients in five center-based series,[7] the mean age at diagnosis was similar in four of five series (range, 39–43 years) and slightly older in the Japanese series (mean age, 51 years). In all series, men prevailed over women, with a ratio ranging from 1.3:1 to 6:1. The interval between onset of symptoms and diagnosis was similar (range, 7–11 months). Of importance, 21–43% of PAP patients were never-smokers, indicating that PAP is not simply a smoking-related disease. A more recent study in the United States, using a medical insurance claims database to examine the records of 15 million patients, estimated the prevalence of PAP syndrome at 6.9 per million people.[110] It is likely these rates are all underestimated; indeed, a recent report from Japan using a Poisson distribution with the number of cases diagnosed annually estimated that the true incidence and prevalence of autoimmune PAP is roughly four times higher than previously estimated, at 1.7 and 26.6 per million, respectively.[111] In summary, PAP can present in men, women, and children of all ethnic backgrounds in all geographic locations and has an estimated overall prevalence of 7 to 20 per million in the general population.

Hereditary PAP is caused by various genetic mutations in *CSF2RA* or *CSF2RB* and usually presents in children between the ages of 1.5 and 11 years, although it has been reported to present in adults aged 29 to 35 years.[23–25,54,55]

Secondary PAP accounts for no more than 10% of all PAP cases in adults[2,4,8,112] and develops as a consequence of an underlying disease (see Table 98.1) or environmental exposure (see Table 98.2). The prevalence of secondary PAP is estimated to be approximately 0.3 per 100,000 individuals in the general population. Historically, hematologic malignancy was the most common cause of secondary PAP, accounting for up to 5.3% of cases.[78] However, in a recent study, myelodysplastic syndrome accounted for 65% of cases.[112] Secondary PAP arises as a function of the underlying clinical disorder and, in some cases, can resolve with successful treatment of the underlying disorder.

PSMD disorders are found in individuals with mutations in the genes involved in surfactant synthesis, such as *SFTPB, SFTPC, ABCA3,* and *NKX2.1,* as discussed earlier. The incidence of SP-B deficiency is estimated to be approximately 1 per 1.5 million births. Among infants with respiratory distress syndrome of unknown etiology, mutations appear more commonly in *ABCA3* than in *SFTPB*.[58] The prevalence of the common disease-associated mutations in the *SFTPB* (121ins2), *SFTPC* (I73T), and *ABCA3* (E292V) genes are not well established. However, a recent study in ethnically diverse cohorts from Missouri, Norway, South Korea, and South Africa (n = 420) found the population-based frequencies of these mutations to be rare (<0.4%). However, E292V was present in 3.8% of newborns with respiratory distress syndrome, suggesting it imparts an increased genetic risk for this syndrome.[57]

CLINICAL PRESENTATION

PULMONARY ALVEOLAR PROTEINOSIS

Autoimmune PAP presents as progressive dyspnea of insidious onset unless secondary infection is also present, in which case fever, cough, and, rarely, hemoptysis may also be present. The frequency of various symptoms was recently evaluated in a large contemporaneous cohort in Japan (Table 98.4). This nonspecific presentation may lead to months or years of misdiagnosis as "asthma" or "chronic bronchitis." The symptoms are frequently milder than expected from the radiographic findings, which should raise the suspicion of PAP. The physical examination is nonspecific and is frequently normal despite a grossly abnormal chest radiograph but may include basilar crackles. Cyanosis is seen in severe cases; hemoptysis and fever are rare. Clubbing is not a feature of autoimmune PAP or hereditary PAP caused by *CSF2RA* or *B* mutations. In the Japanese national PAP registry cohort, 31% of patients with marked radiologic manifestations were asymptomatic.[4]

Hereditary PAP caused by mutations in GM-CSF receptor genes (*CSF2RA* or *CSF2RB*) usually presents as progressive dyspnea of an insidious nature, as in autoimmune PAP, but more commonly in children than in adults.[23–25,54,55] Thus, although this disease is newly described, ultrarare, and less well studied, it appears quite similar to autoimmune PAP, except that it is mostly a disease of children.

Secondary PAP usually arises in an individual with an underlying systemic disorder, such as a hematologic malignancy or disease.[77,78,80,106,113,114] It can develop in the context of neutropenia or myeloid-cell dysfunction related to the underlying disorder and can resolve with successful treatment of the underlying disorder.

PULMONARY SURFACTANT METABOLIC DYSFUNCTION

PSMD disorders can present as a spectrum of lung disease, ranging from respiratory distress syndrome in neonates and infants to interstitial lung disease in children, adolescents, and adults, depending on the exact nature of the underlying genetic mutations. SP-B deficiency typically presents as respiratory distress immediately after birth.[61,70,115] *ABCA3* mutations can result in fatal respiratory distress syndrome in neonates and interstitial lung disease in infants, children, and adolescents.[71,74,108,116] SP-C mutations can present as interstitial lung disease in children and adults.[60,66,68,117]

EVALUATION AND DIFFERENTIAL DIAGNOSIS

This section describes the evaluation of PAP disorders, which are better defined and reported compared to the PSMD disorders.

RADIOGRAPHIC APPEARANCE

The chest radiograph in autoimmune PAP and secondary PAP of hematologic origin typically reveals patchy bilateral air space disease similar in appearance to that of pulmonary edema but without the other radiographic signs of left heart failure[89,118] (Fig. 98.3 and eFig. 98.2). Other patterns can include mixed alveolar, interstitial, or nodular opacities and asymmetrical or focal abnormalities (eFig. 98.3). Adenopathy, cardiomegaly, and effusions are not features of PAP. The chest radiography findings in hereditary PAP are similar but may be normal early in the clinical course or in mild cases.[23] The diagnostic value of the plain chest radiograph is limited by its lack of specificity.

Conventional 7- to 10-mm collimation chest *computed tomography* (CT) scans demonstrate bilateral areas of consolidation with poorly defined margins (Fig. 98.4).[119,120] High-resolution chest CT is superior to both conventional CT and chest radiography in the assessment of the pattern and distribution of abnormalities and may demonstrate lesions even when the radiograph is normal. The distribution of disease is variable and may reflect heterogeneity of underlying disease-causing PAP (Fig. 98.4). Several features are noteworthy.

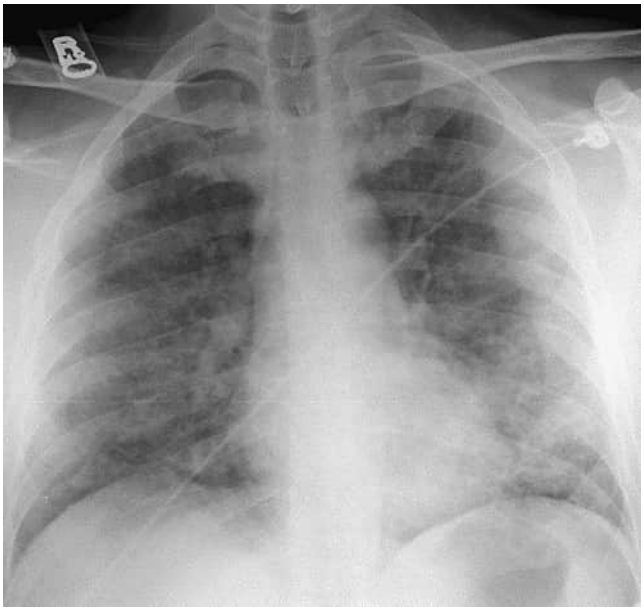

Figure 98.3 Pulmonary alveolar proteinosis: typical chest radiographic findings. Frontal chest radiograph shows multifocal, bilateral, poorly defined, somewhat linear-appearing opacities suggesting a diffuse interstitial lung process. (Courtesy Michael B. Gotway, MD.)

Areas of ground-glass opacification often have sharply defined straight and angulated margins, giving them a "geographic" appearance (Fig. 98.4 and eFig. 98.4). The sharp margination usually reflects lobular or lobar boundaries. A pattern of fine overlapping lines forming 3- to 10-mm polygonal shapes is seen in the majority of cases. Superimposition of these two patterns gives an appearance that has been described as "crazy paving," which is characteristic but not diagnostic of PAP (eFig 98.5).[121] Of note, crazy paving also happens in hypersensitivity pneumonitis, *Pneumocystis jirovecii* pneumonia, minimally invasive adenocarcinoma/lepidic invasive adenocarcinoma (formerly bronchioloalveolar carcinoma), lymphangitic carcinomatosis, cardiogenic pulmonary edema/acute lung injury, and lipoid pneumonia (eFig 98.6). One study reported that, among patients with PAP, a geographic appearance with crazy paving is more commonly seen in autoimmune than secondary PAP.[122]

Findings on the chest radiograph and high-resolution chest CT correlate with a restrictive ventilatory defect, reduced *diffusing capacity for carbon monoxide* (DL_{CO}), and hypoxemia.[120] An algorithm for quantitative assessment of longitudinal changes in ground-glass opacification, lung weight, and gas volume in patients with PAP has been reported.[123]

PULMONARY FUNCTION TESTING

The results of pulmonary function testing may be normal or, in more advanced disease, may show a restrictive ventilatory defect with mild impairment of the forced vital capacity and total lung capacity. There may be a disproportionate, severe reduction of the DL_{CO}.[2,4] Arterial blood gases show mild to severe hypoxemia; an increased *alveolar-arterial* Po_2 *difference* [(A–a)Po_2]; compensated respiratory alkalosis, depending on the degree of disease progression; and absence of hypercarbia. The shunt fraction is elevated compared to patients with other diffuse lung diseases.[124]

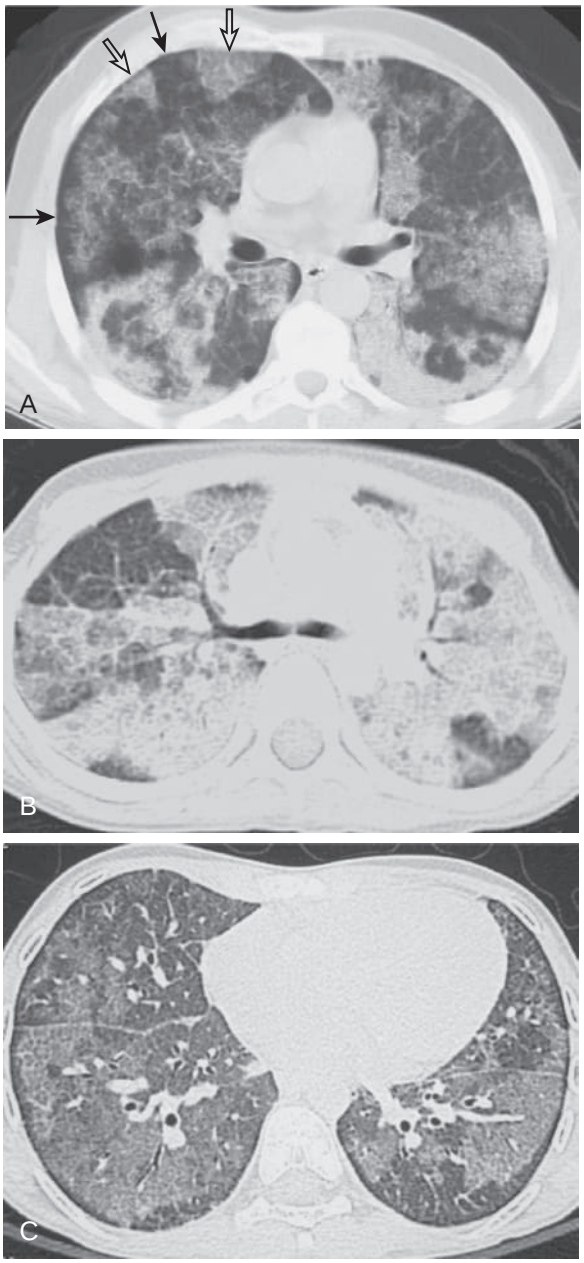

Figure 98.4 Computed tomography of the lungs in *pulmonary alveolar proteinosis* (PAP). Computed tomography of the chest illustrating differences in the radiographic appearance of the lungs in autoimmune PAP (A), hereditary PAP due to granulocyte-macrophage colony-stimulating factor receptor (α chain) dysfunction (B), and secondary PAP in a child with lysinuric protein intolerance (C). Note the juxtaposition of highly abnormal secondary lobules (*open arrows*), adjacent to more normal-appearing secondary lobules (*solid arrows*). This is referred to as a "geographic" pattern and is common in autoimmune PAP and is also present in hereditary PAP. More homogeneous and less geographic opacities are more common in secondary PAP (C).

Six-minute walk testing typically reveals early desaturation and, depending on disease severity, a reduction in the baseline saturation of peripheral oxygen (Spo_2).

BRONCHOSCOPY, BRONCHOALVEOLAR LAVAGE

Bronchoscopy is performed to obtain specimens to rule out infection and to identify the characteristic alveolar material

Figure 98.5 Whole-lung lavage. Gross appearance of the whole-lung lavage fluid from a patient with autoimmune pulmonary alveolar proteinosis demonstrating the milky appearance and dense sediment (*right*) compared to normal saline (*left*). The lavage fluid was allowed to settle overnight in a refrigerator.

of PAP. The BAL specimens reveal characteristic gross, cytopathologic, and biochemical findings highly suggestive or diagnostic of PAP. In autoimmune, hereditary, and secondary PAP (but not PSMD), the BAL fluid has a milky or waxy appearance, and sediment forms upon standing (Fig. 98.5). Cytologic examination of periodic acid–Schiff–Papanicolaou-stained specimens of BAL fluid and sediment reveals granular, acellular, lipoproteinaceous material,[125] cells, and fat globules. Strikingly, cytospin preparations reveal alveolar macrophages engorged with intracytoplasmic lipid droplets imparting a foamy appearance by light microscopy (Fig. 98.6). Electron microscopic examination of the sediment reveals the presence of tubular myelin, lamellar bodies, and fused membrane structures characteristic of pulmonary surfactant. The BAL cell differential in autoimmune PAP may be normal or reveal the presence of increased pulmonary lymphocytes composed of increased numbers of $CD4^+$ and $CD8^+$ cells.[126]

Biochemical analysis of BAL fluid reveals increased amounts of phospholipids and proteins, similar in composition to that of surfactant from healthy individuals,[127] except for an increase in the relative proportion of cholesterol.[127a] Surfactant proteins are variably increased in the BAL fluid in PAP.

LUNG BIOPSY

Macroscopically, the cut surface of lung biopsy specimens in autoimmune and hereditary PAP reveals a geographic pattern of 2 to 3 cm grayish-yellow regions of firm consolidation that exudes fatty material (eFig. 98.7). Microscopically, alveoli and terminal airways are filled with a fine eosinophilic material that stains strongly for surfactant proteins with periodic acid–Schiff reagent (see Fig. 98.6). The alveolar wall and interstitial architecture are relatively well preserved, but lymphocyte infiltration and, occasionally, fibrosis can be seen. The vasculature appears normal. Electron microscopy, which is seldom necessary, reveals characteristic, concentrically laminated surfactant structures (lamellar body inclusions) within the granular material and in alveolar macrophages.[128] Of importance, although a lung biopsy can establish the presence of PAP syndrome, it cannot identify the disease responsible, such as autoimmune or hereditary PAP (see Fig. 98.6E–F, respectively), which has important implications for newer therapies. However, it should be noted that biopsy can have a significant false-negative rate due to the patchy distribution of disease and can fail to identify the histopathologic changes of PAP syndrome.[129]

LABORATORY STUDIES

Routine laboratory studies are usually normal in PAP. Serum lactate dehydrogenase is typically elevated in proportion to lung disease severity, although this finding is nonspecific.[2,124] Serum levels of SP-A, SP-B, SP-D, C-reactive protein, and *Krebs von den Lungen protein-6* (KL-6), a mucin-like protein secreted by alveolar epithelium, are increased in PAP and correlate with lung disease severity.[4,46,130] However, these biomarkers can be elevated in other lung diseases.[131,132] Thus, although not useful in diagnosis, these biomarkers may be useful in monitoring disease activity in patients with PAP. For example, KL-6 has been reported to outperform *arterial partial pressure of oxygen* (Pa_{O_2}) and lactate dehydrogenase in predicting disease progression and need for therapy in autoimmune PAP.[133]

Several biomarker-based tests are effective for disease-specific PAP diagnosis. The most well established is the serum-based GM-CSF autoantibody *enzyme-linked immunosorbent assay* (ELISA) test.[1,45,52,134–136] Although serum GM-CSF autoantibodies are present at low levels in healthy people,[47] a high serum level is diagnostic of autoimmune PAP. In a validation study (MICEPAP) conducted in the United States, Germany, Italy, and Japan, both the sensitivity and specificity of an improved assay were found to be 100%.[136,137] Furthermore, an international monoclonal GM-CSF autoantibody reference standard was developed to help standardize test results from the few laboratories that currently perform the test. Measurement of GM-CSF signaling in whole blood is useful for confirming the functionality of GM-CSF autoantibodies for levels close to the diagnostic threshold and can be done by measuring the ability of exogenous GM-CSF to bind GM-CSF receptors on leukocytes and stimulate an increase in cell surface CD11b (the *CD11b stimulation index test* [CD11b-SI])[52] or an increase in STAT5 phosphorylation (the *STAT5-phosphorylation index* [STAT5-PI] test).[51] Both assays give similar results—a robust increase in healthy people and no change in autoimmune PAP. Measurement of the concentration of GM-CSF (not of the autoantibodies) in serum by ELISA is a useful screening test to identify patients with hereditary PAP because, in these patients, GM-CSF signaling is disrupted not by GM-CSF autoantibodies but by GM-CSF receptor dysfunction.[23,138] Receptor dysfunction results in the accumulation of GM-CSF due to reduced clearance. Various molecular and genetic tests are available to determine the specific abnormality in hereditary PAP and PSMD.[24,25]

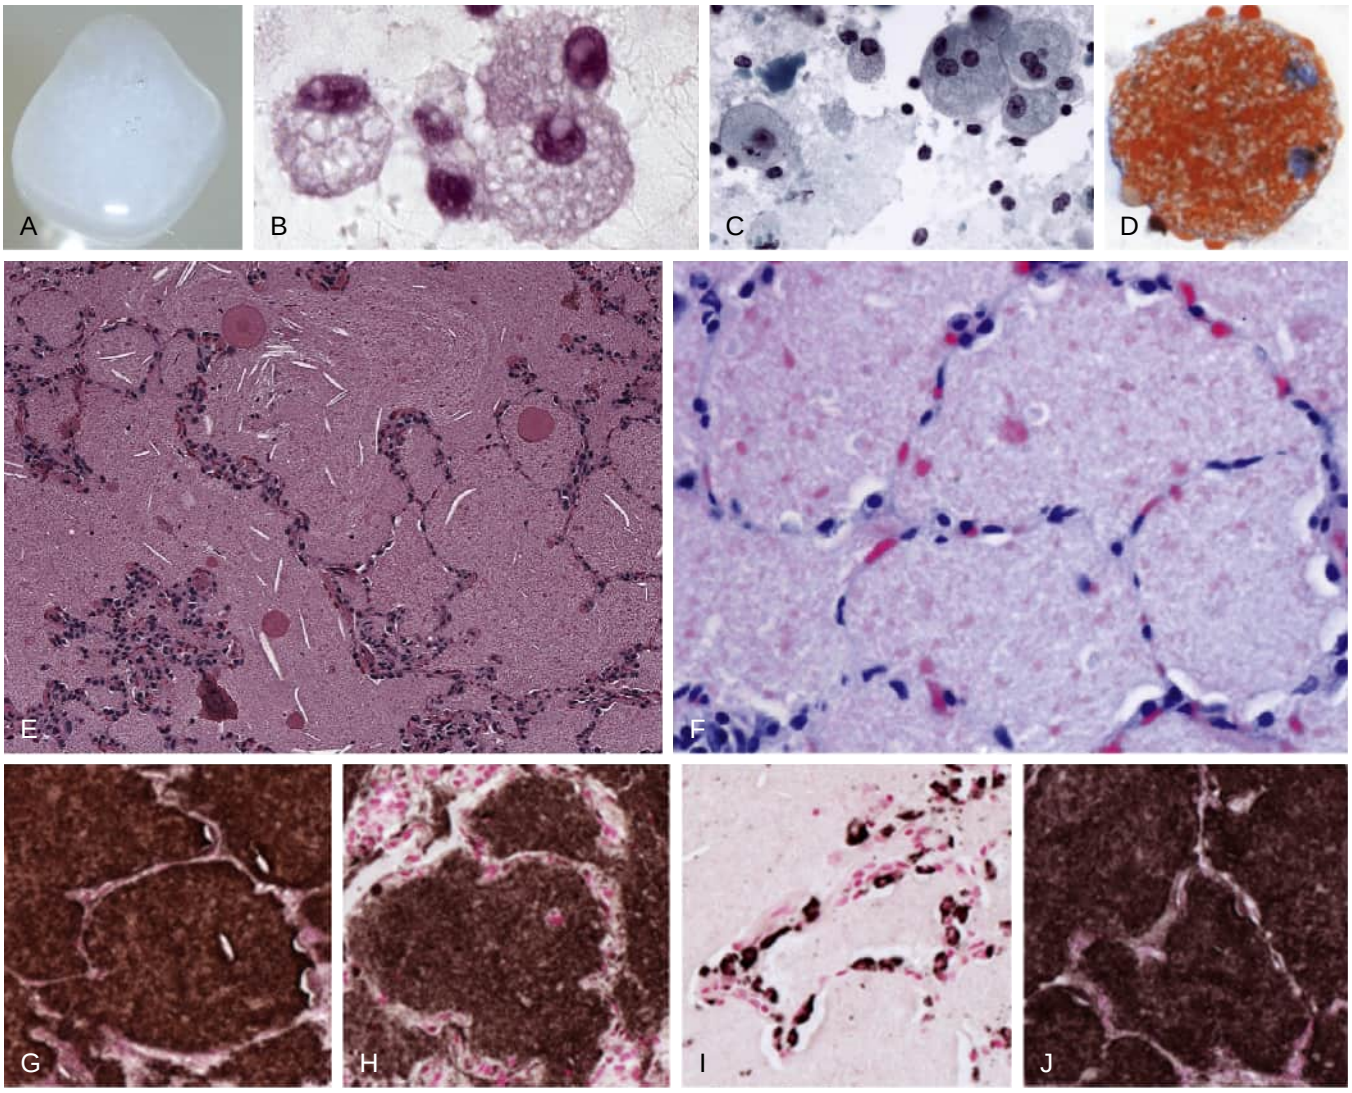

Figure 98.6 Appearance of the sputum, sputum cytology, and lung histopathology in *pulmonary alveolar proteinosis* (PAP) due to disruption of granulocyte-macrophage colony-stimulating factor signaling. (A) Gross appearance of freshly expectorated sputum from a patient with uncomplicated autoimmune PAP. (B) Sputum smear after staining with periodic acid–Schiff reagent. (C) Sputum smear after staining with Papanicolaou reagent. Note the appearance of large, foamy-appearing alveolar macrophages (B–C). (D) Alveolar macrophage stained with oil red-O. (E) Histopathologic appearance of an open-lung biopsy in autoimmune PAP after periodic acid–Schiff staining. Alveoli are filled with amorphous, acellular eosinophilic material as well as cholesterol clefts and eosinophilic bodies. Alveolar wall architecture is well preserved. (F–J) Histopathologic appearance of an open-lung biopsy in hereditary PAP caused by *CSF2RA* gene mutations after staining with hematoxylin and eosin (F), or immunostaining for SP-A (G), mature SP-B (H), pro–SP-C (I), or SP-D (J). (F–I, From Suzuki T, Sakagami T, Rubin BK, et al. Familial pulmonary alveolar proteinosis caused by mutations in *CSF2RA*. *J Exp Med.* 2008;205:2703–2710.)

APPROACH TO DIAGNOSIS

Timely diagnosis of PAP requires a high degree of clinical suspicion and should be suspected in patients with dyspnea of insidious onset and typical chest CT findings. In previously healthy adults with these findings, an abnormal serum GM-CSF autoantibody test is usually sufficient to establish the diagnosis of autoimmune PAP.[137] An abnormal STAT5-PI (or CD11b-SI) test confirms the diagnosis. Pulmonary function testing may be helpful if the disease is moderate or severe but is normal (except for D_{LCO}) in many patients.[4] Although surgical or transbronchial lung biopsy or BAL cytology can establish the presence of a PAP syndrome, none can identify the underlying disease.[106,139] An open-lung biopsy is usually not necessary. However, if the diagnosis is still unclear or if secondary PAP is suspected, a lung biopsy may help rule out disorders that have radiologic, cytologic, or pathologic features similar to PAP.

In younger patients in whom PAP is suspected, the presentation can be helpful. Autoimmune PAP has presented in children as young as 3 years and can readily be diagnosed by blood test without the need for a lung biopsy. Hereditary PAP can often present in children between the ages of 1.5 and 11 years but can present as late as 35 years. In hereditary PAP, the serum GM-CSF autoantibody test is normal, and the STAT5-PI (CD11b-SI) and serum GM-CSF test results are abnormal.[23–25] These blood-based tests are useful in evaluating young patients and should be used to minimize the use of more invasive procedures. PSMD disorders more commonly present in young patients: SP-B deficiency presents as respiratory failure at birth; ABCA3

dysfunction can present similarly or as interstitial lung disease in infants, children, and adolescents; and SP-C dysfunction presents as interstitial lung disease in children and adults.

The diagnostic workup of individuals with disorders of surfactant homeostasis, including PAP and PSMD disorders, consists of routine clinical evaluations, a series of biomarker evaluations, and genetic tests capable of distinguishing among autoimmune PAP, secondary PAP, hereditary PAP caused by receptor dysfunction, and PSMD disorders (Fig. 98.7).

NATURAL HISTORY

No longitudinal studies of the clinical course of PAP have been reported. However, cross-sectional evaluations of PAP cohorts in Japan, China, Germany, and Italy have been reported (see eTable 98.1).[4–7] In Seymour and Presneill's comprehensive meta-analysis of PAP, the actuarial survival rates for 343 patients with "acquired," probably autoimmune, PAP were 78% ± 8% at 2 years, 75% ± 8% at 5 years, and 68% ± 9% at 10 years. More than 80% of the deaths attributable to PAP during a 5-year observation period took place during the first 12 months after diagnosis. This study reported that, of the 69 deaths, death was caused by respiratory failure from PAP in 47 patients (72%), uncontrolled infection in 13 (20%), and unrelated causes in 5 cases (8%). In a contemporaneous cross-sectional cohort study of 223 autoimmune PAP patients in Japan, no deaths were recorded over the 5-year period of the study.[4] Autoimmune PAP follows one of three patterns: progressive deterioration, stable disease, or spontaneous resolution.[2] A recent study of 40 individuals with secondary PAP diagnosed premortem reported a median survival of less than 20 months from diagnosis, a prognosis far worse than for those with autoimmune PAP.[112]

SECONDARY INFECTIONS

Multiple reports document increased infections in PAP by microbial pathogens ranging from community- and hospital-acquired organisms to *Nocardia* spp. (eFig 98.8), mycobacteria (eFig 98.9), or opportunistic organisms.[2,52] GM-CSF–deficient mice also have increased mortality from infection and increased susceptibility to a wide variety of microbial pathogens, including bacteria, fungi, and mycobacteria. Further, myeloid cells from both patients with autoimmune PAP and GM-CSF–deficient mice have defects in innate immune functions, including phagocytosis, generation of reactive oxygen species, inflammatory signaling, and bacterial killing.[20,47,52,134,140] The finding of infections at extrathoracic locations in PAP patients and GM-CSF–deficient mice is consistent with a

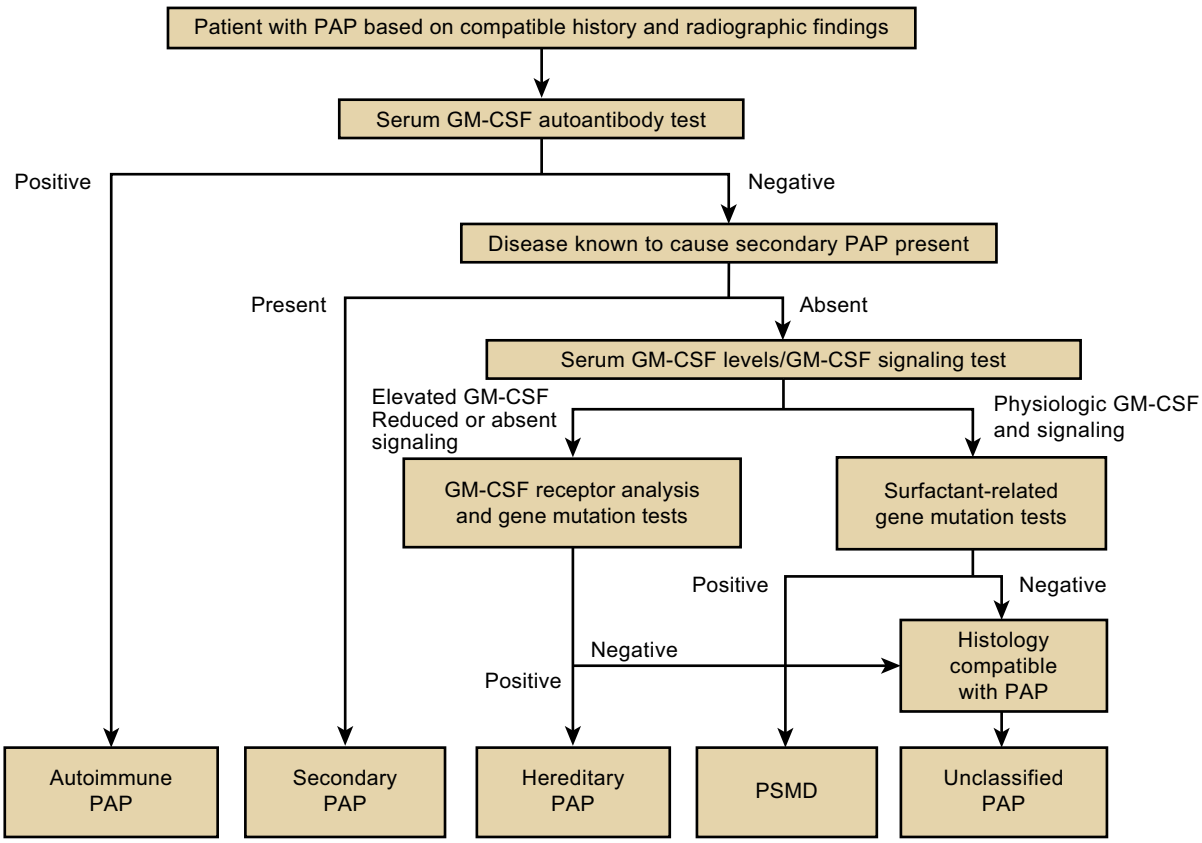

Figure 98.7 Diagnostic algorithm for evaluation for individuals with *pulmonary alveolar proteinosis* (PAP) syndrome. In hereditary PAP caused by mutations in *granulocyte-macrophage colony-stimulating factor* (GM-CSF) receptor genes *CSF2RA* or *CSF2RB,* further GM-CSF receptor function tests are needed to confirm and identify the specific nature of the defect. See text for details. PSMD, pulmonary surfactant metabolic dysfunction. (Modified from Trapnell BC, Nakata K, Bonella F, et al. Pulmonary alveolar proteinosis. *Nat Rev Dis Primers*. 2019;5:16.)

systemic immune defect caused by disruption of GM-CSF signaling.

PULMONARY FIBROSIS

Pulmonary fibrosis has been reported in association with PAP and has been reproduced in animal models of exposure to inhaled silica.[32,128] Further, exposure to oxygen or repeated *whole-lung lavage* (WLL) have been suggested as potentially contributing to fibrosis. However, although not adequately studied, "end-stage lung disease" or irreversible scarring of the lung is not commonly associated with PAP.

SPONTANEOUS RESOLUTION

Spontaneous improvement of PAP was noted in Rosen's initial report,[89] in subsequent case series, and in Seymour's comprehensive meta-analysis of 303 patients, where it was observed in 7.9% of patients (eFig 98.10). Recent cohorts in Japan, China, Germany, and Italy confirmed this value with estimates for spontaneous resolution ranging from 5–7% among 735 additional PAP patients (see eTable 98.1).[4–7]

TREATMENT

AUTOIMMUNE PULMONARY ALVEOLAR PROTEINOSIS

Whole-Lung Lavage

Originally developed by Ramirez in the early 1960s, WLL is a procedure performed under general anesthesia in which large volumes (up to 50 L) of saline are infused into each lung to "wash out" the accumulated surfactant lipids and proteins, while the other lung is mechanically ventilated.[141–143] A number of procedural variations have been tested (although none systematically), including the use of mechanical chest percussion, prone positioning, variation in the volume of infusate, and use of a hyperbaric chamber. Despite changes, WLL has not been standardized with respect to the method (i.e., volume infused, use of mechanical percussion, or the endpoint of an individual lavage procedure), indications for its use, methods for evaluating the treatment effectiveness, or timing of repeated procedures. The endpoint used clinically for terminating lung lavage in the operating room is an improvement in visual clearing of the lavage effluent. No studies have systematically evaluated the procedure, its use in clinical practice, or the efficacy or durability of clinical responses. Notwithstanding, WLL is widely held among practitioners to improve symptoms, radiographic findings, and gas exchange in PAP patients.[144,145]

Although WLL is safe in the vast majority of individuals, complications can include hypoxemia, pneumonia, sepsis, hydropneumothorax, acute respiratory distress syndrome, and pneumomediastinum (eFig. 98.11). The procedure should not be performed in a patient with an active bacterial lung infection because this can result in sepsis and shock. Bronchoscopic segmental or lobar lavage has been proposed as a safe alternative in patients in whom WLL under general anesthesia is considered risky due to severe hypoxemia.[146] Other alternatives include performance in a hyperbaric chamber[147] and use of complete cardiopulmonary bypass.[148]

A comprehensive literature review identified 231 individuals for whom sufficient WLL data were available and reported that lavage was associated with increased overall 5-year survival (94 ± 2% with lavage [n = 146] vs. 85 ± 5% without lavage [n = 85]; P = 0.04).[2] This study also reported that the median number of WLL procedures performed was two and that 70% of patients underwent the procedure within 5 years of diagnosis. Among 55 individuals undergoing the procedure, the median duration of benefit was 15 months, and only 20% of patients remained stable at 3 years. Among 41 patients with adequate available data, arterial Pao_2 improved by 20.1 mm Hg after WLL (see eTable 98.2). The improvement in other pulmonary function test parameters was less impressive. More than 95% of patients respond to WLL; however, a small fraction of patients did not respond despite aggressive lavage. Treatment-related improvement results from the physical removal of the accumulated surfactant can happen within hours of completion of therapy.

In practice, the indications for WLL therapy include dyspnea, exercise intolerance, and a desire to reduce the requirement for supplemental oxygen therapy. Reasonable indications for performing the procedure may include dyspnea-limiting activities of daily living, arterial Pao_2 less than 60 mm Hg while breathing room air, significant desaturation (>5%) on exercise,[7] and a shunt fraction greater than 10–12%.

Granulocyte-Macrophage Colony-Stimulating Factor

Subcutaneous recombinant GM-CSF therapy of PAP was first attempted in a single patient in 1995.[149] A follow-up open-label study of subcutaneous GM-CSF administered in escalating doses (5–20 μg/kg/day) to 14 autoimmune PAP patients over a 3-month period reported a therapeutic response rate of 43%.[150] In another open-label study, subcutaneous GM-CSF administered in escalating doses (5–18 μg/kg/day) to 21 autoimmune PAP patients over a 6- to 12-month period reported an overall response rate of 48%.[151] In these studies, a positive response was defined by a 10 mm Hg improvement in $(A–a)Po_2$ measured on room air. Several other case studies and small series reported similar findings. Together, results of these studies indicate that (1) daily subcutaneous GM-CSF therapy of autoimmune PAP improves the lung disease in approximately 50% of patients, (2) the therapeutic benefit varies among patients and is dependent on the dose and duration of administration, and (3) there may be a delay of at least 8 weeks before a therapeutic response is observed.

Inhaled aerosolized GM-CSF therapy of autoimmune PAP was first demonstrated in three patients in 2005.[152] In a retrospective unblinded evaluation in 12 patients receiving doses of inhaled GM-CSF, ranging from 125 to 500 μg per patient per day, all patients were found to have a positive response.[153] In a subsequent open-label study involving 50 patients, 39 patients with unremitting or progressive lung disease during a 3-month observation period received inhaled GM-CSF at a relatively higher dose during an induction period, and subsequently 35 of these patients received a relatively lower dose during a subsequent maintenance period.[154] The overall response rate was 62% based on intention-to-treat analysis, and no treatment emergent or drug-related adverse events were noted. A randomized, double-blinded study of inhaled GM-CSF therapy was conducted in 64 patients with mild to moderate autoimmune PAP (Pao_2 < 75 mm Hg but > 50

eTable 98.2 Therapeutic Response to Whole-Lung Lavage Therapy of Adults With PAP

Parameter	*N*	Mean Change ± SD	95% CI of the Mean	*P* Value*
Arterial Po_2 (mm Hg)	41	20.1 ± 14.3	15.6 to 24.6	<0.0001
(A–a)Po_2 (mm Hg)	21	−30.6 ± 18.0	−38.8 to −22.4	<0.0001
FEV_1 (L)	33	0.26 ± 0.47	0.09 to 0.42	<0.0034
VC (L)	40	0.50 ± 0.54	0.33 to 0.67	<0.0001
DL_{co} (mL/mm Hg/min)	25	4.4 ± 4.5	2.6 to 6.3	<0.0001

*Value is for the comparison of paired postlavage to prelavage data for individual patients for each parameter for only those patients with available data, using a two-sample *t*-test.

(A–a)Po_2, alveolar-arterial Po_2 difference; CI, confidence interval; DL_{CO}, diffusing capacity of carbon monoxide; FEV_1, forced expiratory volume in 1 second; PAP, pulmonary alveolar proteinosis; Po_2, partial pressure of oxygen; SD, standard deviation; VC, vital capacity.

From Seymour JF, Presneill JJ. Pulmonary alveolar proteinosis: progress in the first 44 years. *Am J Respir Crit Care Med*. 2002;166:215–235.

mm Hg), who received either sargramostim (recombinant human GM-CSF produced in yeast; 125 μg twice daily for 7 days on alternating weeks) or placebo for a total of 24 weeks. Compared to placebo, inhaled GM-CSF therapy had a significantly greater reduction in $(A–a)Po_2$ (0.2 ± 10.5 vs. −4.5 ± 9.0 mm Hg; $P = 0.02$) and a reduction in lung densitometry in the chest CT, which reflects the degree of abnormal surfactant accumulation, but clinical benefit was not demonstrated.[155] A global phase III randomized, double-blind, placebo-controlled study of inhaled GM-CSF therapy in autoimmune PAP (IMPALA trial) was recently conducted in 138 patients, who received either molgramostim (recombinant human GM-CSF produced in *Escherichia coli*) 300 μg daily (continuous group) or daily on alternating weeks (intermittent group) or placebo for 24 weeks.[156] Daily administration of inhaled molgramostim resulted in greater improvements in pulmonary gas transfer and functional health status than placebo and was more beneficial when given daily than when administered on alternating weeks.[157]

Combined WLL and inhaled GM-CSF therapy of autoimmune PAP has been evaluated in an 18-patient, open-label study in Italy. A preliminary report indicated patients receiving WLL, followed by inhaled GM-CSF (sargramostim, 250 μg daily every other week), had a greater improvement in D_{LCO} percent predicted, forced vital capacity, total lung capacity, and $(A–a)Po_2$ compared to patients receiving WLL alone.[158] In this study, GM-CSF also resulted in a reduction in the requirement for further WLL therapy.

Together, results from a number of open-labeled and randomized, blinded, controlled trials indicate that GM-CSF is effective as therapy of autoimmune PAP, inhaled delivery is more effective than subcutaneous delivery, and no important safety concerns have been identified. Notwithstanding, neither the optimal dose nor time required to achieve a maximal treatment benefit has yet been identified.

Targeting GM-CSF Autoantibodies

Other therapeutic strategies aimed at reducing the level of GM-CSF autoantibodies have been tried, including plasmapheresis and B lymphocyte depletion. One small study of a single cycle of rituximab therapy in 10 patients gave promising results,[159] with seven of nine patients demonstrating a slight improvement in $(A–a)Po_2$. However, this improvement was minimal after 6 months of follow-up. A retrospective report of 13 patients showed no improvement 6 months after treatment.[160] Although these strategies are theoretically attractive, their lack of definitive efficacy may reflect the lack of correlation between circulating GM-CSF autoantibody levels and disease severity.[46]

Targeting Cholesterol Homeostasis

The revelation of the pathogenic role of cholesterol clearance in determining surfactant clearance by alveolar macrophage has unlocked several therapeutic possibilities and the consideration of small molecules to target this pathway. In mouse models of PAP, the use of a PPAR-γ agonist (pioglitazone) was demonstrated to improve PAP lung disease,[102] resulting in a phase I/II trial of pioglitazone in autoimmune PAP (ClinicalTrials.gov identifier: NCT03231033). Furthermore, statins (3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors) have been shown to increase alveolar macrophage cholesterol homeostasis, resulting in improved lung disease in mouse models of PAP.[103] Although not established, statin-induced reduction in intracellular cholesterol accumulation leads to improved surfactant uptake and clearance by alveolar macrophages. Indeed, a case series of autoimmune PAP patients treated with statins demonstrated resolution of PAP lung disease with improvements in lung function, oxygenation, and radiologic findings.[103] These studies support the possibility of targeting cholesterol homeostasis as a novel pathogenesis-based therapeutic approach for autoimmune PAP and possibly other types of PAP syndrome. Carefully designed trials are required to investigate these potential strategies.

HEREDITARY PULMONARY ALVEOLAR PROTEINOSIS

WLL is the standard therapy for hereditary PAP caused by *CSF2RA* or *CSF2RB* mutations.[23,24] Bone marrow transplantation has been tried without success in one child.[55] Gene correction and pulmonary macrophage transplantation have shown promising results in mouse models of hereditary PAP.[21,161] Studies in mice have demonstrated that a single administration of wild-type or *Csf2ra*- or *Csf2rb*-gene–corrected macrophages results in nearly complete resolution of the lung disease, normalizes disease-specific biomarkers for more than 1 year, and increases the life span of the treated mice. Results also show that transplanted macrophages have a marked survival advantage over endogenous alveolar macrophages and replace them over the course of several months after transplantation, reaching wild-type levels at 1 year. Of interest, after pulmonary macrophage transplantation, transplanted macrophages remain in the lungs permanently. Furthermore, it is possible to correct the relevant genes in macrophages from patient-derived induced pluripotent stem cells,[161,162] allowing the possibility of translating this approach into human clinical trials in hereditary PAP.

SECONDARY PAP

Secondary PAP, in most cases caused by hematologic disorders, can resolve with resolution of the underlying disorder. There have been several case reports of effective resolution after stem-cell, cord-blood, and bone marrow transplantation.[163] Secondary PAP caused by a reduction in the number or functional capacity of alveolar macrophages can be treated with WLL; however, those associated with fibrosis (i.e., silicoproteinosis) are less responsive to this therapy.

SURFACTANT METABOLIC DYSFUNCTION DISORDERS

Therapy of these disorders depends on the disease and presentation; care is generally supportive and includes assessment of need for supplemental oxygen and nutritional support. In very young children, WLL is extremely challenging and of uncertain efficacy, and an adapted technical approach to airway management is required during lavage.[164] Neonates may show transient improvement with exogenous surfactant administration. Lung transplantation is particularly considered in cases of SP-B deficiency and in severe and progressive disease from *ABCA3* mutations.

Key Points

- *Pulmonary alveolar proteinosis* (PAP) syndrome presents in a group of clinically and mechanistically heterogeneous diseases and is characterized by surfactant accumulation in alveolar macrophages and alveoli due either to impaired surfactant clearance by alveolar macrophages or to abnormal surfactant production.
- The molecular pathogenesis is now known in most cases: Mechanisms include disruption of *granulocyte-macrophage colony-stimulating factor* (GM-CSF) signaling by GM-CSF autoantibodies (autoimmune PAP, ≈85% of cases) or GM-CSF receptor mutations (hereditary PAP, ≈5% of cases), a disease reducing alveolar macrophage numbers or functions (secondary PAP, ≈5% of cases), and mutations resulting in abnormal surfactant production (pulmonary surfactant metabolism dysfunction, ≈5% of cases).
- PAP can present in men, women, and children; of all ethnic backgrounds; in all geographic locations; and has an estimated overall prevalence of 7 to 20 per million in the general population.
- The clinical presentation is typically progressive dyspnea of insidious onset with or without cough. If infection is also present, depending on its nature, location, and severity, there may also be symptoms of fever, diaphoresis, or hemoptysis.
- The presence of relatively mild symptoms in the setting of abnormal chest imaging should raise the suspicion of a PAP syndrome.
- The natural history depends on which PAP-causing disease is present. In autoimmune PAP, the clinical course varies and includes respiratory failure and death in a small fraction, slowly progressive/stable disease in most and spontaneous improvement in 6–8% of patients.
- Characteristic (but nondiagnostic) chest computed tomography findings and transbronchial or surgical lung biopsy results can be used to diagnose PAP syndrome but cannot identify the underlying disease causing it. However, new blood tests (GM-CSF autoantibody levels, STAT5-phosphorylation index test, GM-CSF serum levels, and others) currently available as clinical research tests can identify the underlying disease in greater than 95% of cases, reducing the need for lung biopsy.
- Whole-lung lavage is the current standard therapy for autoimmune PAP, hereditary PAP, some (myelodysplasia) but not all (silica-induced) forms of secondary PAP and is usually not useful in pulmonary surfactant metabolic disorders.
- Inhaled GM-CSF and cholesterol-targeted therapy are promising experimental approaches under active study. Other potential therapies include pulmonary macrophage transplantation, bone marrow transplantation, and stem-cell transplantation (for hereditary PAP). Lung transplantation is a therapeutic option for multiple PAP-causing diseases when clinically indicated (usually by extensive fibrosis).

KEY POINTS

INTRODUCTION

Adverse drug reactions have been the object of intense scrutiny since the early 1990s and have been recognized as a top safety priority by health care quality improvement organizations.[1] Medical errors, including medication errors, may be responsible for 250,000 patient deaths per year in the United States.[2] Specifically, medication errors and preventable adverse drug events may injure 1.5 million people and cost billions of dollars annually. Up to 2–5% of hospitalized patients may have nonpreventable adverse drug reactions.[3] The classification of drug reactions includes allergic or hypersensitivity reactions, overdosage, intolerance, idiosyncratic reaction, and secondary side effects such as bronchospasm or cardiovascular suppression.

We know relatively little about the pharmacokinetic properties of drugs in individual patients. Indeed, only a small percentage of the population develops pulmonary toxicities to otherwise successful medications. Nevertheless, drug-induced pulmonary diseases represent a significant problem and are likely underrecognized.[1] The number of drugs associated with pulmonary toxicity is steadily increasing.[4] By 2019, more than 450 drugs had been identified as causes of adverse pulmonary reactions. These reports are of various types and quality, ranging from clear toxicities established in large series to isolated case reports. Some of these medications are listed in Table 99.1. To minimize mortality and significant morbidity, it is incumbent on the clinician to keep in mind at least the more common drugs that may induce pulmonary disease.[5-8]

Four mechanisms of drug injury to the lungs are recognized: (1) oxidant injury, such as during long-term nitrofurantoin ingestion; (2) direct cytotoxic effects (and these effects may be aggravated by oxidant injuries); (3) deposition of phospholipids within cells, such as those produced by cationic amphophilic drugs (e.g., amiodarone); and (4) immune-mediated injury through drug-induced *systemic lupus erythematosus* (SLE) reactions and immune checkpoint inhibitor toxicities.[6,9-13]

ONCOLOGY AGENTS

Chemotherapeutic agents are used extensively in solid and hematologic malignant diseases but are also increasingly used for their immunosuppressive properties in various inflammatory disorders. It remains a diagnostic challenge to determine the responsibility of the chemotherapeutic agent for a given toxicity. Diagnosis is usually made on the basis of exclusion of competing diagnoses, especially infection and recurrent malignant disease.

Oncology patients are prone to numerous pulmonary complications irrespective of their chemotherapy regimen, including opportunistic infections, atypical presentations of common lung infections, radiation-induced lung injury, cardiogenic or noncardiogenic pulmonary edema, and, of course, metastatic lung involvement. The various presentations of drug-induced pulmonary disease must be rapidly differentiated from these other causes whose clinical presentations, including fever and diffuse radiographic

Table 99.1 Classification of Drug-Induced and Related Pulmonary Diseases by Type of Medication

ONCOLOGY AGENTS

Cytotoxic
- Azathioprine
- Bleomycin
- Busulfan
- Chlorambucil
- Cyclophosphamide
- Etoposide
- Interleukin-2
- Melphalan
- Mitomycin C*
- Nitrosoureas
- Procarbazine
- Vinblastine
- Zinostatin

Noncytotoxic
- Bleomycin*
- Cytosine arabinoside*
- Gemcitabine*
- Methotrexate*
- Procarbazine*

Immunomodulatory
- Pembrolizumab*
- Nivolumab*
- Ipilimumab*

Molecularly Targeted
- Bevacizumab*†
- Cetuximab*
- Trastuzumab*
- Rituximab*
- Gefitinib,* erlotinimb,* imatinib*
- Ceritinib*

ANTIBIOTIC AGENTS
- Amphotericin B*
- Nitrofurantoin (short term,* long term)
- Sulfasalazine

ANALGESIC AGENTS
- Ethchlorvynol (Placidyl)*
- Propoxyphene*
- Salicylates*

CARDIOVASCULAR AGENTS
- Amiodarone*
- Angiotensin-converting enzyme inhibitors
- Anticoagulant agents
- β-Blockers*
- Dipyridamole
- Flecainide
- Protamine*
- Tocainide

ILLICIT AGENTS
- Heroin*
- Methadone*
- Methylphenidate
- Cocaine
- Talc granulomatosis

INHALANT AGENTS
- Aspirated oil
- Oxygen*

INTRAVENOUS AGENTS
- Blood products*
- Sodium morrhuate*
- Ethiodized oil (lymphangiogram)

MISCELLANEOUS AGENTS AND CONDITIONS
- Appetite suppressants
- Bromocriptine
- Complement-mediated leukostasis*
- Dantrolene
- Hydrochlorothiazide*
- Methysergide
- Radiation
- Systemic lupus erythematosus (drug-induced)
- Tocolytic agents*
- Tricyclic antidepressants*
- L-Tryptophan

*Typically manifesting as acute or subacute respiratory insufficiency.
†Can induce severe hemorrhage in patients with lung cancer.

Table 99.2 Selected Chemotherapeutic Agents With Associated Pulmonary Toxicities

ANTIBIOTIC-DERIVED AGENTS
- Bleomycin
- Mitomycin C

ALKYLATING AGENTS
- Busulfan
- Cyclophosphamide
- Chlorambucil
- Melphalan

ANTIMETABOLITES
- Methotrexate
- 6-Mercaptopurine
- Azathioprine
- Cytosine arabinoside
- Gemcitabine
- Fludarabine

NITROSOUREAS
- Bischloroethyl nitrosourea
- Chloroethyl cyclohexyl nitrosourea
- Methyl–chloroethyl cyclohexyl nitrosourea

PODOPHYLLOTOXINS
- Etoposide
- Paclitaxel
- Docetaxel

NOVEL ANTITUMOR AGENTS
- All-*trans* retinoic acid (ATRA)
- Gefitinib (Iressa)
- Erlotinib (Tarceva)
- Imatinib (Gleevec)
- Dasatinib

IMMUNOMODULATORY AGENTS USED IN MALIGNANT DISEASE
- Immune checkpoint inhibitors
- Interferons
- Interleukin-2
- Tumor necrosis factor-α

OTHER MISCELLANEOUS CHEMOTHERAPY AGENTS
- Procarbazine
- Zinostatin
- Vinblastine

abnormalities, may be extremely similar to drug-induced pulmonary reactions. Chemotherapy-associated pulmonary reactions have become a major problem, particularly in relation to therapeutic regimens containing bleomycin, methotrexate, cyclophosphamide, and a host of newer agents (Table 99.2).

Consistent criteria for drug-induced lung disease have not been officially established. Confirmation with rechallenge is generally avoided because it is often neither practical nor generally ethical. Hence the diagnosis of cytotoxic lung damage rests on an appropriate history of drug exposure, histologic evidence of lung injury, and the exclusion of other causes of the lung damage. No single diagnostic test or tissue biopsy can definitively confirm the diagnosis of chemotherapy-associated lung disease. A careful and thorough evaluation to eliminate the possibility that other conditions, particularly infections, may be producing these effects is warranted.[8,14] Thus the clinician should maintain a high index of suspicion and carefully screen for other competing causes of pulmonary injury that may affect these immunocompromised patients.

The clinical presentation of many chemotherapy drug effects is quite similar, with the exception that some effects manifest more acutely, whereas others tend to be more insidious in their onset. In general, nonproductive cough, dyspnea, and often fever begin weeks to years after the agent is first administered. Occasionally, symptoms may manifest acutely, as in the case of hypersensitivity reactions or infusion reactions. Symptoms may also manifest years after discontinuation of the drug, perhaps reactivated by radiotherapy. Fever is common with most chemotherapeutic drug-induced pulmonary injury, but it may not be consistently present, and chills are usually absent. Weight loss may be present. The chest radiograph in patients with chemotherapy-induced lung disease may be unremarkable for days or weeks before it shows typical changes of a diffuse interstitial infiltrative pattern. Alternatively, there may be a diffuse mixed alveolar-interstitial pattern, which may occasionally be useful in recognizing early drug effects (Fig. 99.1). Auscultation of the lungs frequently reveals crackles, which are also nonspecific. In some instances, pleural effusions may be present during adverse drug reactions, but not consistently.

Results of pulmonary function studies are abnormal in almost all patients compared with pretreatment testing. The *diffusing capacity for carbon monoxide* (D_{LCO}) may decrease before reduced volumes are detected. In addition, this decrease in D_{LCO} may precede the onset of symptoms and radiographic changes by days or weeks.[14,15]

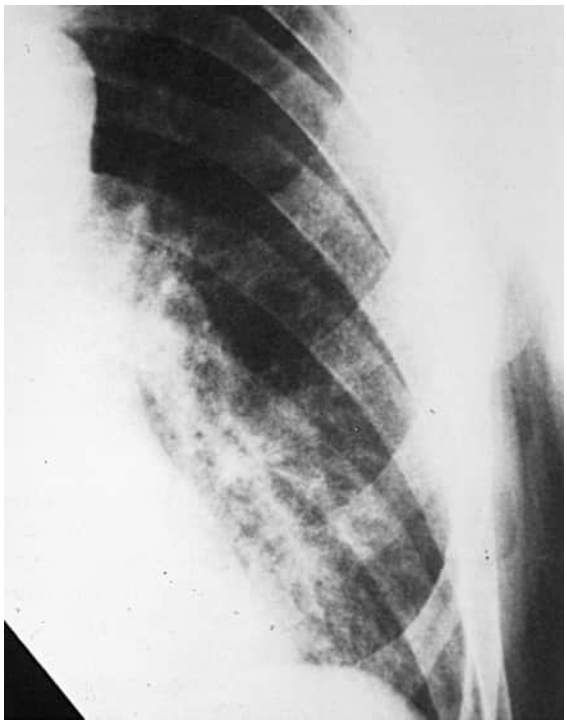

Fig. 99.1 Cytotoxic pattern of drug-induced lung disease. A close-up chest radiograph showing an alveolar interstitial pattern that is characteristic but not diagnostic of cytotoxic lung disease.

Bronchoalveolar lavage (BAL) may be another means of assessing early lung damage from these drugs; however, the results are often variable. In general, the greatest utility of BAL is to exclude infection.

ANTIBIOTIC-DERIVED AGENTS

Bleomycin

Bleomycin is an antibiotic chemotherapeutic agent whose pulmonary toxicity was recognized early, and this toxicity has since been one of the main factors limiting the use of this drug in the clinical setting. The incidence of bleomycin lung toxicity ranges anywhere from 0–46%; pulmonary function testing and chest radiographs reveal that 20% of patients treated with bleomycin develop overt pulmonary disease, and up to 3% die of pulmonary consequences of bleomycin therapy.[14,16]

Bleomycin exerts direct cytotoxic effects, prevents neoangiogenesis by the tumor, stimulates production of various cytokines, and generates free radicals by formation of a complex between ferrous iron and oxygen.[17-20] This last effect may explain increased bleomycin toxicity with high fractions of inspired oxygen, often during anesthesia and postoperative recovery.[21,22] This sensitivity to supplemental oxygen may persist for months and even years after discontinuation of the drug.

Perhaps one of the most consistent features of bleomycin-induced lung disease is cumulative toxicity. The incidence of pulmonary toxicity is significantly greater in patients who have received a cumulative bleomycin dose greater than 450 units, and a 10% death rate has been noted in patients who received a total dose greater than 550 units. However, doses as low as 50 units may occasionally be enough to cause pulmonary toxicity, especially when other synergic factors are present. Rapid rates of delivery by the intravenous route may also play a role, and slower infusion rates, as well as intramuscular injections, have been recommended.

Bleomycin is metabolized primarily by the kidneys. Hence renal failure predisposes patients to impaired metabolism of the drug and increased toxicity. The drug is also inactivated by an enzyme, bleomycin hydrolase, present in most tissues except for the lungs and skin. Radiotherapy is itself a common cause of pulmonary complications and is also thought to promote the generation of free radicals, toxic to both the tumor cells and the surrounding tissues. The concomitant use of bleomycin and radiotherapy may be synergistic. Treatment with bleomycin may reactivate prior radiation-induced lung disease *(radiation recall)*, as an example of a delayed drug reaction. Pulmonary toxicity is also increased in patients older than 70 years of age and in patients with preexisting lung disease. Good evidence indicates that pediatric patients may also be at increased risk; in one study, 70% of children treated with bleomycin for rhabdomyosarcoma developed pulmonary toxicity.[23] Impaired or immature ability to process free radicals and inadequate kidney function may explain these differences.

Although of uncertain value, determination of pretreatment D_{LCO} and its frequent monitoring have been suggested in an attempt to predict subsequent clinical deterioration.[24] Vital capacity and pulmonary capillary blood volume (Vc) may be better predictors of lung toxicity.[25] In addition, the enhanced sensitivity of *computed tomography* (CT) scanning may also be useful in establishing an early diagnosis of bleomycin pneumonitis.[26]

Other forms of bleomycin-induced lung disease have been described less commonly. Hypersensitivity reactions (eFig. 99.1) are possible with an association of fever and peripheral blood or BAL eosinophilia.[14,15] Discontinuation of bleomycin and initiation of corticosteroids usually bring about rapid reversal of this hypersensitivity variant of bleomycin pneumonitis.

An additional rare, but clinically important, presentation of bleomycin pneumonitis is that of nodular pulmonary lesions mimicking tumor metastasis (Fig. 99.2).[27] These reactions to bleomycin may require surgical biopsy to differentiate bleomycin-associated lung injury from recurrence of the primary malignant disease. Although bleomycin pulmonary toxicity may reflect diffuse alveolar damage (eFig. 99.2A), these nodular lesions from bleomycin often exhibit the histologic pattern of organizing pneumonia (eFig. 99.2B).[6]

In suspected cases of bleomycin lung toxicity, discontinuation of the drug is warranted. Administration of corticosteroids is often recommended. It would seem prudent to pay particular attention to avoid high fractions of inspired oxygen and concomitant radiotherapy and to monitor kidney function carefully during the duration of treatment. One study demonstrated that if the patient survives the acute injury from bleomycin,

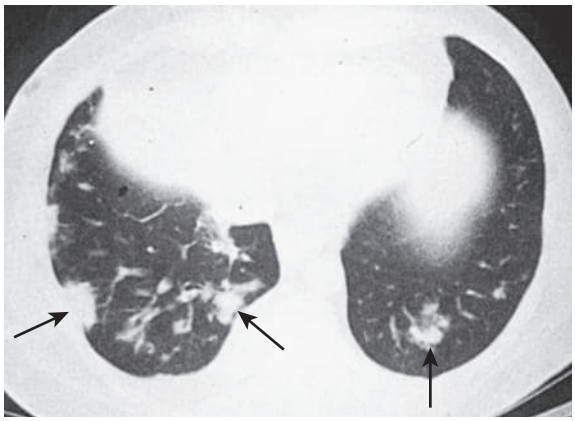

Fig. 99.2 Bleomycin-induced lung disease. A chest computed tomography scan of bleomycin pneumonitis showing a nodular pattern *(arrows)*. The histologic features of this form of bleomycin-induced lung injury are typical of organizing pneumonia.

pulmonary findings may improve substantially over time (see eFig. 99.1).[28] However, if significant fibrosis is present, the process may progress insidiously despite the administration of corticosteroids.

Mitomycin C

Mitomycin C is another antibiotic chemotherapeutic agent associated with pulmonary toxicity, which shares features similar to the toxic effects induced by bleomycin. The incidence of mitomycin-induced pneumonitis may range from 8% to as high as 39%.[29,30] Similar to bleomycin-induced lung toxicity, the cumulative dose appears to be associated with the incidence of pulmonary manifestations, with pulmonary fibrosis unlikely at doses less than 30 mg/m^2. Again, a high fraction of inspired oxygen and radiotherapy may exacerbate this phenomenon. Concomitant administration of other chemotherapeutic agents such as bleomycin, doxorubicin, or cyclophosphamide may also enhance pulmonary toxicity. The symptoms, imaging abnormalities, and histologic findings of mitomycin-induced pneumonitis are similar to those of other alkylating drug toxicities.[30] A favorable response to corticosteroid therapy has also been quite dramatic in many patients, possibly greater than in other forms of chemotherapy-associated lung injury.

In addition, there are reports of an unusual reaction to mitomycin C consisting of microangiopathic hemolytic anemia with associated noncardiogenic pulmonary edema and renal failure, taking the form of a hemolytic uremic syndrome. This develops in particular when mitomycin C is administered with 5-fluorouracil.[31] Most of these patients developed this hemolytic uremic syndrome between 6 and 12 months after beginning mitomycin C. Up to one-half of these patients also develop the *acute respiratory distress syndrome* (ARDS), with mortality as high as 95%. The mortality in patients with mitomycin C–associated hemolytic uremic syndrome who do not develop ARDS is still in the range of 50%. In some instances, this unusual drug reaction appears to be precipitated by blood transfusions. Microangiopathic changes are present in the lungs and kidneys. Treatment is essentially supportive, with initiation of plasma exchange with or without dialysis and corticosteroids when deemed appropriate.

ALKYLATING AGENTS

Busulfan

Busulfan can be responsible for significant pulmonary toxicity. The average duration from the initiation of therapy to the onset of respiratory symptoms is roughly 3.5 years, ranging between 8 months and as late as 10 years. However, busulfan pulmonary toxicity can develop as soon as 6 weeks following initiation of therapy. The incidence of busulfan pulmonary toxicity is estimated to be 6%, with a reported range of 3–43%.[32]

Dyspnea, fever, and cough begin in a more insidious fashion in busulfan toxicity than in many other chemotherapy-related lung toxicities. Such symptoms have even been reported to begin months after busulfan therapy has been discontinued. The chest radiograph in busulfan toxicity reveals a combined alveolar and interstitial process to a greater degree than in other chemotherapy reactions. This is likely the result of a high degree of desquamation of injured epithelial cells into the alveolar spaces. This alveolar debris may be so extensive as to suggest pulmonary alveolar proteinosis. Busulfan-induced pulmonary toxicity is also characterized by the presence of acute lung injury, with associated atypical alveolar epithelial type 2 cells with markedly enlarged pleomorphic nuclei and prominent nucleoli (eFig. 99.3).

The mortality rate is extremely high, in the range of 80%.[23] No effective therapy has been identified, but discontinuation of the drug with or without initiation of corticosteroid therapy is recommended.

Cyclophosphamide

Cyclophosphamide is widely included in combination chemotherapy for hematologic malignant diseases and solid tumors. It is also used in the treatment of granulomatous polyangiitis. The incidence of pulmonary toxicity is estimated at approximately 1%, although accumulating evidence suggests that the disorder may be much more common. A case series from a large tertiary referral center identified only 6 patients older than 20 years of age in whom cyclophosphamide was the only factor contributing to pulmonary injury.[33]

Clinical features of cyclophosphamide-associated pulmonary toxicity include fever, dyspnea, cough, gas-exchange abnormalities, parenchymal opacities, and pleural thickening. Two patterns of cyclophosphamide-induced lung toxicity have been described. First, there can be early-onset pneumonitis within the first 1 to 6 months after institution of therapy. This form generally responds to withdrawal of cyclophosphamide. In contrast, there may also be late-onset pneumonitis that develops after months or even years of therapy and results in progressive lung fibrosis and bilateral pleural thickening. This late-onset variety unfortunately has minimal response to withdrawal of cyclophosphamide or to corticosteroid therapy.[33] The dose of cyclophosphamide and the development of lung disease are not clearly related. Supplemental oxygen and radiotherapy may increase the likelihood of lung manifestations.

Chlorambucil

The clinical presentation, chest radiographic abnormalities, and histologic features of chlorambucil-associated pneumonitis are remarkably similar to those described in other alkylating agent–induced pulmonary toxicities.[8] Cumulative doses in excess of 2 g seem to increase the risk significantly. The presentation is usually insidious, beginning 6 months to a year or more after the start of therapy. Surveillance of lung function, particularly D_{LCO}, may be of benefit in anticipating which patients will have a deteriorating condition and will require discontinuation of the agent. Few data are available on the efficacy of corticosteroid therapy in chlorambucil-related lung toxicity.

Melphalan

Melphalan also has resulted in well-documented cases of pulmonary toxicity.[34] The course of melphalan-associated pulmonary injury varies from acute to subacute in tempo. Patients present with insidious to abrupt onset of dyspnea, cough, and frequently fever. There are no particular clues for predicting which patients will develop side effects. The incidence of pulmonary side effects from melphalan must be generally low because this agent has been widely used in the long-term management of myeloma.

Other Alkylating Agents

Procarbazine is rarely associated with interstitial pneumonias, which are sometimes characterized by significant eosinophilia suggesting a hypersensitivity reaction. Progression to widespread and irreversible fibrosis seems rare.[35]

Oxaliplatin has been associated with laryngeal dysesthesia and was thought to be responsible for the development of diffuse alveolar damage, often in association with 5-fluorouracil. More typically, there can be severe anaphylactic reactions during infusion of the drug in approximately 1.3% of the cases. Eosinophilic pneumonia has also been rarely reported.[36,37]

Temozolomide is a second-generation alkylating agent. Few respiratory side effects have been described, mainly pharyngitis, sinusitis, cough, upper respiratory tract infection, and dyspnea. Pneumonitis was found in up to 4.8% of patients in Phase II trials. One case of organizing pneumonia that resolved after discontinuation of treatment was described.[38]

ANTIMETABOLITES

Methotrexate

Methotrexate is present in many combination regimens for malignant diseases and is also used extensively for nonmalignant conditions, including psoriasis and rheumatoid arthritis. It interferes with the metabolism of folic acid, hence specifically targeting replicating cells and leading to a variety of well-described adverse effects, including bone marrow suppression, mucositis, alopecia, and gastrointestinal manifestations. Pulmonary toxicity is thought to develop in approximately 10% of all patients treated but is fortunately rarely fatal. Dyspnea, nonproductive cough, and fever usually commence a few days to several weeks after initiation of therapy. However, in rare cases, symptoms may be observed a few months or years after the onset of therapy.[39]

Methotrexate-associated pneumonitis (eFig. 99.4) is generally reversible with or without the addition of corticosteroids. Eosinophilia is seen in at least one-half of cases, and the disease is therefore believed to represent a hypersensitivity reaction.[14] The intriguing feature of this reaction is that the drug may be reinstituted following resolution of methotrexate pneumonitis without necessarily triggering a subsequent recurrence of symptoms or findings.[40] In about one third of patients, poorly formed granulomas are identified in lung biopsy; this finding is unusual in other forms of chemotherapy-associated lung disease (eFig. 99.5).[6] Hilar lymphadenopathy is occasionally present, and this may mimic sarcoidosis. There is no cellular atypia, such as is seen in many other cytotoxic drug toxicities.

The chest radiograph tends to reveal a homogeneous opacity throughout all lung fields. Hilar adenopathy or pleural effusion is seen in at least 10–15% of patients with methotrexate lung toxicity. In distinct contrast to most of the other chemotherapy-induced pulmonary toxicities, prospective investigations of patients receiving methotrexate have not demonstrated a diminished D_{LCO} that could predate subclinical toxicity. In addition, pulmonary toxicity in response to methotrexate does not appear to be dose related. Two other important manifestations associated with methotrexate should be mentioned. Opportunistic infections related to T cell deficiency need to be excluded, in particular *Pneumocystis* pneumonia.[41] Peculiar Epstein-Barr virus–related lymphomas that typically resolve after discontinuation of treatment have also been reported and may be directly related to an alteration in immune surveillance induced by methotrexate.[41]

Azathioprine and 6-Mercaptopurine

More than two dozen case reports of azathioprine-associated pneumonitis have been reported. However, the net overall incidence must be low, considering the widespread use of this agent for neoplastic and nonneoplastic conditions.[34] Nevertheless, the possibility of azathioprine pneumonitis must be considered in any individual receiving this agent. Azathioprine is metabolized to 6-mercaptopurine, and a handful of reports detailed cytotoxic interstitial pneumonitis in association with this metabolite.[5] However, most of these patients also received other agents that potentially could be implicated in the lung injury described.

Cytosine Arabinoside

Cytosine arabinoside (ara-C) is a cytotoxic agent used to induce remission in acute leukemia and other hematologic malignant diseases before bone marrow transplantation. Intensive ara-C treatment regimens have been associated with rapidly fatal noncardiogenic pulmonary edema (Fig. 99.3).[5] Histologic examination of lung tissue during ara-C pulmonary toxicity reveals substantial accumulation of intra-alveolar proteinaceous material without the cellular atypia and mononuclear infiltration described with other cytotoxic drugs. In two large series, 13–28% of the patients with toxicity developed respiratory distress

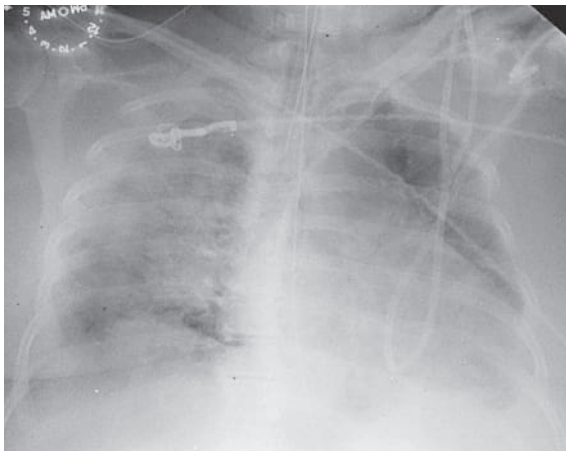

Fig. 99.3 Cytosine arabinoside–induced lung disease. A chest radiograph of a 44-year-old woman showing acute noncardiogenic pulmonary edema that resulted from cytosine arabinoside–induced lung disease. Histologic examination typically demonstrates intense intraalveolar proteinaceous material forming hyaline membranes, but little other reaction.

with administration of the drug. The mechanism underlying this reaction is unknown, and the associated mortality is high. Treatment for ara-C pulmonary toxicity is largely supportive.

Gemcitabine

Gemcitabine is a pyrimidine analogue, with structure and activities similar to ara-C. The incidence of respiratory complications has probably been underestimated. Dyspnea has been reported in 10% of treated patients, with severe dyspnea reported in up to 5%.[42-44] Noncardiogenic pulmonary edema is thought to develop in 0.1–7% of all patients treated.[45] There are three major patterns of respiratory involvement in gemcitabine-related pulmonary toxicity. The first pattern is a nonspecific, self-limiting dyspnea reported within hours to days of treatment. A second, relatively uncommon, pattern is that of an acute hypersensitivity reaction with bronchospasm. A third pattern of severe respiratory involvement is occasionally seen. This is a severe idiosyncratic reaction with profound dyspnea and pulmonary opacities that may progress to life-threatening respiratory insufficiency within hours of infusion (Fig. 99.4). Most cases of gemcitabine-related pulmonary toxicity resolve with discontinuation of this drug. In cases of severe symptoms, discontinuation of the agent along with institution of corticosteroids, careful fluid management, and diuretic therapy may be warranted.[42] Cases of diffuse alveolar hemorrhage, pulmonary veno-occlusive diseases, and thrombotic microangiopathy have also been described.

Fludarabine

The incidence of pulmonary toxicity related to fludarabine, another nucleoside analogue, was estimated to be approximately 8.6% in a series of 105 patients.[46-48] Affected individuals experience dyspnea as early as 3 days after the first round of chemotherapy, although later onset of pulmonary symptoms has also been reported. The chest radiograph reveals either interstitial

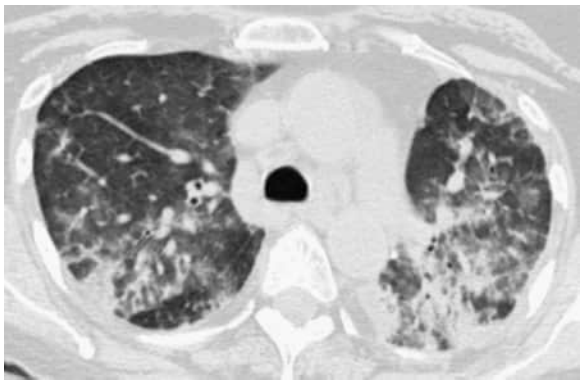

Fig. 99.4 Gemcitabine-induced lung disease. A chest computed tomography image of an individual with gemcitabine-induced lung disease. The pattern is a mixed alveolar and interstitial infiltration.

or mixed alveolar-interstitial opacities. Nodular opacities have also been described. Most patients respond to discontinuation of the drug and receive symptomatic and objective benefits from additional corticosteroid therapy.

Nitrosoureas

Pulmonary toxicity related to nitrosoureas is well recognized.[49] In particular, *bischloroethyl nitrosourea* (BCNU, carmustine) has been described to induce both acute-onset pulmonary injury (see eFig. 125.12) and delayed-onset pulmonary fibrosis, with a predilection for the upper lobes.[49] The incidence of pulmonary toxicity associated with the administration of BCNU varies from 2–20% and is dose related, with an incidence of lung disease of up to 50% in patients receiving a total dose of greater than 1500 mg/m^2. However, there have also been reports of pulmonary effects with much lower doses. The duration of therapy before the onset of pulmonary toxicity for the acute variant of nitrosourea lung injury has generally ranged from 6 months to 3 years. The outcome may be unpredictable and sometimes fatal. There have been fewer case reports of pulmonary toxicity with *methyl-chloroethyl cyclohexyl nitrosourea* (methyl-CCNU) and *chloroethyl cyclohexyl nitrosourea* (CCNU). Apparently, fever is less commonly associated with this form of pulmonary toxicity than with many other chemotherapeutic drugs. Therapy usually consists of withholding the offending agent and starting corticosteroids, which has variable and often only transient beneficial effects.[50]

A long-term complication of BCNU toxicity is upper lobe fibrosis that may appear many years after the completion of chemotherapy. O'Driscoll and colleagues[51] followed 17 patients for up to 17 years, and 12 (71%) developed delayed upper lobe fibrosis. The fibrosis is insidious in onset and, once discovered, appears to be intractably progressive. Corticosteroid therapy has not proven to be effective.

Cases of pulmonary fibrosis have been reported with several nitrosourea agents, including lomustine (CCNU), semustine (methyl-CCNU), fotemustine (CENU), bendamustine, and chlorozotocin (DCNU). Pneumothoraces have rarely been described with these agents.

PODOPHYLLOTOXINS

Etoposide and Teniposide

Etoposide (VP-16), a topoisomerase II inhibitor, has been widely used in combination chemotherapy for non–small cell and small cell lung carcinoma. Despite its extensive use, only a few cases of etoposide-associated pulmonary toxicity have been reported.[52] Toxicity may become apparent shortly after the first round of chemotherapy, although most patients present after prolonged treatment. Therapy consists of withdrawal of the agent and administration of corticosteroids, which provide variable improvement. Teniposide, another podophyllotoxin agent, is also associated with hypersensitivity reactions in 3.6–6.5% of cases. This toxicity may manifest with dyspnea, bronchospasm, and hypertension.[53]

Paclitaxel

Well-documented cases of pulmonary toxicity induced by paclitaxel can be found in the literature, but the frequency is unclear. Patients may report respiratory symptoms including cough, dyspnea, wheezing, and chest tightness within minutes of administration of the drug, thus suggesting a type I hypersensitivity reaction.[54] This reaction may be seen in up to 30% of patients, and premedication with corticosteroids is sometimes considered. Reticular and nodular opacities have been reported on chest radiographs.[55] Cases of transient pulmonary opacities and suspected interstitial pneumonitis have also been described (eFig. 99.6). The true incidence of lung toxicity directly related to paclitaxel is not well understood. A prospective study of lung function in 33 patients receiving paclitaxel with carboplatin (an agent with little lung toxicity) in the setting of nonthoracic malignant disease revealed an isolated decrease in D_{LCO} without other clinical or radiographic evidence of pulmonary toxicity.[56] In other studies, conducted in patients with lung carcinoma, significant early and late pulmonary toxicity has been noted in 10% and 68% of patients, respectively.[57,58] Therefore, clinicians should be aware of the potential of paclitaxel to impair pulmonary function.

Docetaxel

Docetaxel (Taxotere), another taxane, infrequently causes pulmonary toxicity based on a hypersensitivity reaction.[59] These patients have responded rapidly to corticosteroid therapy. The combination of docetaxel and gemcitabine may have particular propensity to induce severe pulmonary toxicity.[60] Some patients may develop capillary leak syndrome with peripheral edema, noncardiogenic pulmonary edema, and/or pleural effusions.[61,62] The severity of fluid retention can be reduced by prophylactic treatment with corticosteroids.[63]

ALL-*TRANS* RETINOIC ACID AND DIFFERENTIATION SYNDROME

All-trans retinoic acid (ATRA) has been used in acute promyelocytic leukemia, in which it promotes differentiation of myeloid precursors and stimulates the maturation of leukemic cells, thereby promoting remission. It has also been reported to reduce disseminated intravascular coagulation and hemorrhagic complications during promyelocytic leukemia. The main complication limiting its use is the development of the differentiation syndrome (previously called retinoic acid syndrome) in up to 25% of patients treated. This syndrome consists of diffuse edema, pleuropericardial effusions, and noncardiogenic pulmonary edema that may evolve into a generalized capillary leak syndrome (eFigs. 99.7 and 99.8). Hypotension and acute renal failure are commonly present. Toxicity may manifest suddenly between days 2 and 21 of treatment. Its pathogenesis remains elusive, but it is thought to result from a massive release of cytokines from newly mature myeloid cells and adhesion of granulocytes to the pulmonary endothelium. Indeed, high leukocyte counts have been associated with an increased incidence of the syndrome in some, but not all, studies. In addition, multiple hemorrhagic complications have also been described. One study reported that 9 of 35 patients with promyelocytic leukemia receiving ATRA developed respiratory distress.[64] Intravenous corticosteroid therapy seemed to be of benefit to these patients. The mortality associated with ATRA-induced pulmonary toxicity is estimated at approximately 9%.[65] Differentiation syndrome in acute promyelocytic leukemia has also been observed in patients receiving arsenic trioxide.

MOLECULARLY TARGETED THERAPY

Monoclonal Antibodies

Bevacizumab. Bevacizumab, a monoclonal antibody targeting vascular endothelial growth factor, is designed to inhibit tumoral neoangiogenesis. It is associated with hemorrhagic complications, including fatal pulmonary hemorrhage thought to result from extensive tumor necrosis. These complications have been predominantly seen in patients with squamous cell lung cancer. Although it may seem counterintuitive, bevacizumab is thought to increase the incidence of thromboembolic disease. This may be secondary to vascular injury with secondary exposure of the underlying endothelium and activation of the coagulation cascade. Cases of thrombotic microangiopathy with hypertension and acute renal failure have also been described. Tracheoesophageal and bronchoesophageal fistulas have been reported in patients treated with bevacizumab for lung cancer.[66-69]

Cetuximab and Panitumumab. Cetuximab and panitumumab are two monoclonal antibodies directed against the *epidermal growth factor receptor* (EGFR). Both have been associated with rare pulmonary toxicity. Interstitial lung disease has been reported in 0.4% of patients with cetuximab, and there may be infusion reactions with bronchospasm and hoarseness in 23% of the cases. With panitumumab, patients may have similar infusion reactions, which may be severe in 1% of the cases. Panitumumab has now been associated with interstitial lung disease and pulmonary fibrosis. The interstitial lung disease has been found to be fatal in some cases, so if toxicity develops, panitumumab should be stopped and steroids considered.[70,71]

Trastuzumab and Ado-trastuzumab Emtansine. Trastuzumab selectively binds the *human epidermal growth factor receptor-2* (HER-2) protein and is an

adjuvant treatment for metastatic HER-2–positive breast cancer. As with other monoclonal antibodies, infusion reactions may present in 15% of the cases and are potentially associated with angioedema, fever, and bronchospasm. Trastuzumab reactions may also manifest as acute or subacute interstitial pneumonia in approximately 0.5% of patients, with a mortality rate estimated at 0.1%.[72] Interstitial pneumonia is a rare toxicity of trastuzumab.

Ado-trastuzumab emtansine is an antibody-drug conjugate that contains trastuzumab and a cytotoxic microtubule inhibitor, emtansine. It is also used in breast cancer and has been associated with acute pneumonitis. The incidence is low, at 0.8–1.2%, but the toxicity may be life-threatening, so if pneumonitis develops, ado-trastuzumab should be discontinued.[73]

Rituximab. Rituximab is an anti-CD20 chimeric monoclonal. The most common side effect of rituximab is an infusion reaction in more than 50% of patients. Symptoms include fever, chills, dyspnea, hypotension, rhinitis, urticaria, pruritus, and a sensation of throat and tongue swelling. Slowing or stopping the rituximab infusion may help resolve the symptoms. Corticosteroids are occasionally required. Other pulmonary complications of rituximab appear fairly rare overall. Rituximab can also cause interstitial lung disease.[74]

Tyrosine Kinase Inhibitors

Gefitinib. Gefitinib is a selective EGFR tyrosine kinase inhibitor. Acute interstitial pneumonia has been associated with this drug, and the overall incidence of gefitinib-associated interstitial lung disease may be in the range of 1%, with a mortality rate approaching 30%.[75,76] The most common presentation is acute dyspnea with or without cough or fever.[75] The median onset of symptoms is 24 to 42 days.[75] Diffuse ground-glass opacities and multifocal airspace consolidation have been reported on CT scan.[77] Tissue examination demonstrates diffuse alveolar damage, interstitial inflammation with or without fibrosis, and organizing pneumonia.[76,78-80] Although some patients respond to withdrawal of the agent and institution of corticosteroid therapy, others progress to fulminant respiratory insufficiency. Hence the clinician should discontinue the agent if symptoms and radiographic abnormalities develop.

Erlotinib. Erlotinib is another EGFR antagonist. Erlotinib has also been rarely associated with pulmonary toxicity, including fatalities.[81-83] Patients who have undergone lung biopsy have shown organizing pneumonia or diffuse alveolar damage.[83] The presentation is similar to that of most drug-induced lung injury, with dyspnea, cough, and low-grade fever. The median time to toxicity is 47 days.[81] Treatment is supportive with removal of the drug. The benefit of corticosteroids is unclear.

Imatinib. Imatinib is an inhibitor of the BCR-ABL, KIT, and *platelet-derived growth factor receptor* (PDGFR) tyrosine kinases.[84] Fluid retention causing peripheral, periorbital, and pulmonary edema is a common complication.[85-87] There have been cases reported of pulmonary infiltration with eosinophilia or acute interstitial pneumonia.[84,88-91] Symptoms of dyspnea, cough, and low-grade fever develop at a median time of 49 days.[92] Radiographic studies have shown ground-glass opacities, consolidation, or nodular opacities. BAL findings demonstrate lymphocytes, foamy macrophages, and, in some cases, eosinophilia.[91,93,94] Peripheral eosinophilia has also been demonstrated.[93] Lung biopsies have demonstrated interstitial inflammation and fibrosis, alveolitis, and pulmonary alveolar proteinosis.[93-95] Treatment consists of removal of the drug and administration of corticosteroids. Rechallenge of the drug does not always cause recurrence of the lung injury, so physicians must carefully consider alternative agents and the risk and benefit of rechallenge.[93,96]

Dasatinib. Dasatinib is another BCR-ABL tyrosine kinase inhibitor. Dasatinib is associated with pleural effusions, pulmonary hypertension, and pulmonary parenchymal abnormalities. Pleural effusions have been reported in 10–35% of patients treated.[97-100] Effusions are mostly lymphocytic and exudative. Concomitant lung disease and higher initial daily dose are reported risk factors for development of pleural effusions.[99] Treatment of the pleural effusions is unclear but has included glucocorticoids, diuretics, thoracentesis, and discontinuation of dasatinib.[97,99,101,102] Pulmonary arterial hypertension is a rare complication of dasatinib use with symptom onset after 8 to 48 months of therapy.[103-107] Presenting symptoms include tachypnea, exertional dyspnea, fatigue, and peripheral edema.[103-107] Dasatinib therapy should be discontinued if pulmonary hypertension develops, and there should not be a rechallenge.[103-107] Pneumonitis is another rare complication of dasatinib. In a study of patients treated with dasatinib, 40 (23%) developed a lung abnormalitiy.[108] The lung changes resolved or partially resolved in all nine patients with parenchymal abnormalities.[108] Discontinuation of dasatinib resulted in resolution in five patients, and glucocorticoids were used in one patient with complete resolution.[108]

Sunitinib and Sorafenib. Sunitinib and sorafenib are small molecule tyrosine kinase inhibitors that block the intracellular domain of the vascular endothelial growth factor receptor. Sunitinib has been reported to cause dyspnea and cough.[109] Pulmonary embolism has also rarely been reported. Sorafenib is used to inhibit angiogenesis. Pulmonary toxicity has been reported during sorafenib use, with diffuse pulmonary opacities, dyspnea, cough, and fever.[110] Although a rare toxicity, it was fatal in some patients, so the drug should be stopped immediately if pulmonary toxicity is suspected.[110]

Anaplastic Lymphoma Kinase Inhibitors. Ceritinib, alectinib, crizotinib, and brigatinib are inhibitors of *anaplastic lymphoma kinase* (ALK) and are used for treatment of advanced non–small cell lung cancer. These agents have been reported to induce interstitial opacities and organizing pneumonia. These reactions can be severe, and treatment cessation is recommended. [111,112]

IMMUNOMODULATORY AGENTS

INTERFERONS

Interferons (α, β,and γ) have been used in a wide variety of malignant, infectious, and inflammatory disorders. Administration of interferons has been associated with a variety of pulmonary reactions. For instance, interferon-α has been linked to severe exacerbation of bronchospasm in patients with preexisting asthma.[113] In addition, a granulomatous reaction indistinguishable from sarcoidosis (eFig. 99.9) has been described in relation to interferon therapy.[114] These toxicities usually respond to either reduction or withdrawal of the interferon treatment with or without the addition of corticosteroids. Noncaseating granulomas have been documented in the lung, lymph nodes, liver, and skin of affected patients.

Interferon-associated interstitial lung disease has also been reported.[115] Dyspnea and cough are observed, and bilateral opacities are present on chest radiography. In some cases, interferon therapy has also been associated with an organizing pneumonia pattern.[116] Most affected patients respond to discontinuation of the interferon and administration of corticosteroids. Interferon-γ has been used in idiopathic pulmonary fibrosis. In one series, four patients with advanced idiopathic pulmonary fibrosis developed acute hypoxemic respiratory failure during interferon-γ treatment.[117] This respiratory failure was not responsive to corticosteroids and was fatal in three cases. Interferon-γ is also associated with a high incidence of severe radiation pneumonitis when it is used in multimodality therapy for non–small cell lung carcinoma.

RAPAMYCIN ANALOGUES

Sirolimus is an inhibitor of the *mammalian target of rapamycin* (mTOR), with antiproliferative and immunosuppressive properties, which has become an important treatment for lymphangioleiomyomatosis[118] (see Chapter 97). Several patterns of drug toxicity have been described with sirolimus, including the subacute onset of interstitial pneumonitis (eFig. 99.10) (which usually resolves after discontinuation of therapy), an organizing pneumonia pattern, and diffuse alveolar hemorrhage. Rare cases of alveolar proteinosis and granulomatosis have also been reported. Typically, these pulmonary complications are reversible after discontinuation of therapy.[119]

Everolimus is a similar inhibitor of the mTOR pathway. Several types of pulmonary toxicity have been described, including organizing pneumonia and the subacute onset of interstitial pneumonitis.[120] The interstitial pneumonitis has been reported in varying severity. In one report of interstitial lung disease in patients receiving everolimus, four patients underwent BAL, which demonstrated lymphocytosis; two patients also had increased eosinophil counts.[121] Transbronchial biopsy samples from three of the patients demonstrated interstitial lymphocytic inflammation and septal thickening.[121] Treatment may involve observation in mild cases but can require discontinuation of the drug and initiation of glucocorticoids in severe cases.[122,123] The use of glucocorticoids is of unclear benefit. Temsirolimus is yet another mTOR inhibitor with similar patterns of lung toxicity.[124-126]

IMMUNE CHECKPOINT INHIBITORS

Immune checkpoint inhibitors are potent immunomodulatory antibodies that enhance host T cell responses to help eliminate tumor cells and have become first-line therapies for many cancers, either as monotherapy or combined with chemotherapy.[127] The primary targets are the cytotoxic T lymphocyte–associated antigen 4 (e.g., ipilimumab), the programmed cell death-1 receptor (e.g., nivolumab and pembrolizumab), and the programmed cell death ligand-1 (e.g., atezolizumab). These agents are approved for metastatic melanoma and advanced non–small cell lung cancer, but they are increasingly used in other malignant diseases. Despite potent and often durable antineoplastic activities of these drugs, the release of normal immune checkpoint controls is associated with immune-related adverse events in a wide variety of organ systems. Accordingly, these agents are associated with immune-related toxicities in the skin, gastrointestinal tract, liver, thyroid, and lung.[128-130] Immune-related adverse events in total have been reported in up to 12% of treated patients.[131,132]

A spectrum of lung toxicities has been reported, including focal or diffuse pneumonitis and diffuse interstitial lung disease, seen in approximately 5% of treated patients.[131,132] In addition, immune checkpoint inhibitors have also been associated with the development of organizing pneumonia[133-135] (Fig. 99.5). These lung toxicities range from asymptomatic (grade 1), mildly symptomatic (grade 2), and severely symptomatic (grade 3) to life-threatening (grade 4). In most cases, lung infection should also be excluded. These

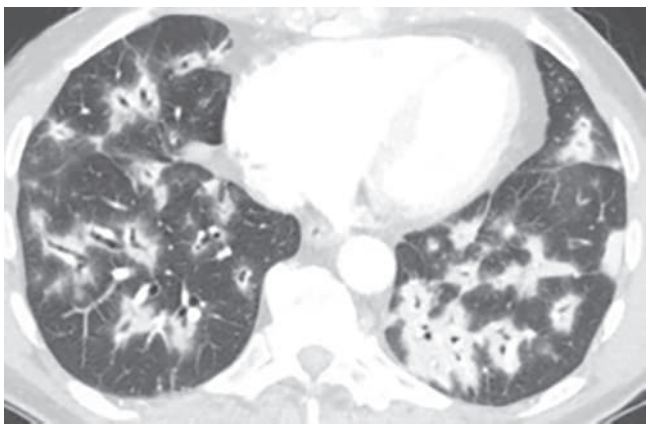

Fig. 99.5 Pembrolizumab-induced-pneumonitis with an organizing pneumonia pattern. Chest computed tomography through the lung bases in a patient with non–small cell lung carcinoma treated with pembrolizumab shows multifocal, bilateral extensive consolidation with a striking peribronchovascular distribution. Note the opacities are primarily distributed along the airways. Following discontinuation of the drug and use of corticosteroid therapy, the areas of consolidation regressed leaving some areas of architectural distortion suggesting scarring. (From Gotway MB. Medical image of the week: pembrolizumab-induced pneumonitis. *Southwest J Pulm Crit Care.* 2017;15:118-119.)

toxicities often respond to withholding the agents and instituting corticosteroids. Grade 1 lung toxicities involve 25% of the lung fields and usually respond well to withholding the immune checkpoint inhibitor. Grade 2 lung toxicities involve 25–50% of the lung fields and require withholding the immune checkpoint inhibitor, often with the addition of prednisone. Antibiotics are also frequently provided empirically to cover for potential infection. In grade 1 or mild grade 2 toxicities, consideration is sometimes given to reinstituting the immune checkpoint inhibitor, thus balancing the risk of recurrent malignancy against the potential risk for recurrent lung toxicity. In contrast, grade 3 toxicities involve more than 50% of lung fields or require hospitalization for oxygen and supportive care, and grade 4 toxicities involve urgent intervention for severe respiratory compromise. Grade 3 and 4 toxicities require permanent withdrawal of immune checkpoint inhibitors with hospitalization, bronchoscopy to exclude infection, empirical antibiotics, and high-dose corticosteroids (of at least 100 mg of prednisone equivalent per day). [136] Refractory cases are challenging to manage; some investigators have suggested the use of intravenous immunoglobin in such cases, although definitive data are lacking.[136] Overall, the checkpoint inhibitor–associated pneumonitis may have an adverse effect on survival in patients receiving immune therapy for non–small cell lung carcinoma.[137]

ANTIMICROBIAL AGENTS

NITROFURANTOIN

Acute Reaction

Nitrofurantoin pneumonitis is one of the most common drug-induced pulmonary diseases.[138-140] Acute pulmonary reactions are underestimated. The incidence has been estimated to be anywhere from 1 in 550 to 1 in 5400 individuals.[140] The mechanism of the acute nitrofurantoin reaction is unknown. The typical reaction begins a few hours to several days after initiation of therapy. It appears to be more common in women, perhaps because of the increased use of this drug in women. Fever, dyspnea, and cough are present in most cases. Other incidental findings include leukocytosis and eosinophilia in one third and an elevation in sedimentation rate in nearly one-half of cases. Imaging shows either an alveolar or an interstitial process or both. The reaction is generally most prominent at the bases. Pleural effusion has been found in one third of patients, most commonly unilaterally. Bronchospasm has been reported in some cases, but its incidence is unknown; it may happen in the absence of pulmonary parenchymal or pleural disease.[140]

The treatment consists of discontinuing the medication and providing supportive care. It is not known whether corticosteroids accelerate the resolution. Nitrofurantoin-induced SLE with pleuropulmonary disease and a positive antinuclear antibody test result has also been reported.

Chronic Reaction

There is no clinical overlap between the acute and chronic pulmonary reaction to nitrofurantoin. Chronic reactions are far less common than acute pulmonary reactions. In chronic reactions, fever and eosinophilia are much less common.[139-141] The onset of dyspnea and cough is usually insidious, beginning after 6 months to many years of continuous or intermittent use of nitrofurantoin. Chest imaging shows a diffuse interstitial process. There is no associated bronchospasm or obstructive airway disease. Pulmonary function testing demonstrates a restrictive pattern. BAL usually shows a lymphocytic reaction. Histologic analysis of lung tissue shows inflammatory cells and fibrosis. Clinically, radiologically, and histologically, this condition often mimics other forms of interstitial lung disease, including usual interstitial pneumonia or nonspecific interstitial pneumonia patterns (eFig. 99.11).

The literature on the utility of corticosteroids varies. Our experience is that these drugs are almost always required for significant resolution. Other investigators imply that the opacities resolve spontaneously on discontinuation of the medication.[141] Our policy is to observe the patient for 2 to 4 months after discontinuing nitrofurantoin and then repeat the imaging and pulmonary function studies. If there is no improvement, a trial of corticosteroids is given.[142]

SULFASALAZINE

Sulfasalazine is an antimicrobial drug used for its anti-inflammatory activity.[143] There appear to be two separate types of adverse pulmonary reactions: one is a pulmonary opacity with eosinophilia, and the other is an organizing pneumonia pattern of pulmonary injury. After 1 to 8 months of continuous therapy, patients experience the onset of cough, dyspnea and, in about one-half of cases, fever. The chest radiograph shows a variable pattern of lung opacities, ranging from upper lobe alveolar opacities to a diffuse interstitial process (eFig. 99.12). More than one-half of the patients have significant blood eosinophilia. Resolution is seen within 1 week to 6 months after discontinuing the drug and, if necessary, adding corticosteroids. Sulfasalazine is metabolized to 5-aminosalicylic acid and sulfapyridine, both of which have been implicated in eosinophilic pneumonitis. In cases of suspected sulfasalazine-associated pulmonary disorders, it is important to keep in mind that inflammatory bowel disease has been associated with a variety of pulmonary abnormalities independent of sulfasalazine use. Inflammatory bowel disease has been independently linked to airway inflammation, interstitial lung disease including an organizing pneumonia pattern of pulmonary injury, neutrophilic necrotic pulmonary nodules, and serositis. Most of these disorders respond to corticosteroid therapy.

ILLICIT DRUGS

HEROIN AND METHADONE

Heroin-induced pulmonary edema may be the most common drug-induced pulmonary disease worldwide. There are several postulated mechanisms to explain heroin-induced noncardiogenic pulmonary edema. These include the following: a direct toxic effect on the alveolar-capillary

membrane, leading to an increased permeability and extravasation of fluid into the alveolar spaces; a neurogenic response to central nervous system injury; an allergic or hypersensitivity reaction; and an acute hypoxic effect on the alveolar-capillary membrane in association with secondary increased permeability.

Up to 40% of addicts hospitalized for acute drug overdose have acute pulmonary edema with severe hypoxemia and hypercapnia. The noncardiogenic pulmonary edema is indistinguishable from other forms of ARDS. The pulmonary capillary wedge pressure is usually normal. Typically, symptoms of dyspnea and somnolence begin within minutes of the intravenous "push," but reports of delayed onset of hours and even a few days have been published. The patient hypoventilates and becomes hypoxemic and hypercapnic. The pupils are small. Imaging (see Fig. 133.6) typically shows changes of noncardiogenic pulmonary edema.

Up to one-half of these patients vomit and aspirate, which may complicate interpretation of the chest radiograph and later lead to bacterial infection. Infection should be suspected if the pulmonary opacities do not clear within 24 to 48 hours of treatment. Other pulmonary abnormalities may include septic emboli from infected thrombophlebitis or tricuspid endocarditis. Treatment consists of assisted ventilation using positive end-expiratory pressure, oxygen, and intravenous naloxone to reverse the respiratory depression. This is usually sufficient treatment for the noncardiogenic pulmonary edema, which will reverse with time. Corticosteroids are unnecessary. Appropriate use of antimicrobial drugs is indicated.

Bronchiectasis and necrotizing bronchitis in chronic heroin users have been reported. These may be more likely to be sequelae of recurrent gastric aspiration than of the heroin itself. In long-term users of heroin and other illicit intravenous drugs, pulmonary function abnormalities are more likely to be related to talc granulomatosis (see later) than to sequelae of a single acute injury.

Methadone has been reported to have similar pulmonary effects as heroin. Treatment is the same as for heroin-induced sequelae. Noncardiogenic pulmonary edema has been reported in cases of both oral and intravenous overdose of methadone.

METHYLPHENIDATE

Methylphenidate can be taken either intravenously or orally. In a series of patients who injected methylphenidate, all 22 patients had chest pain and wheezing, and most had abnormal pulmonary function test results and hemoptysis.[144] In another series, severe panlobular emphysema (eFig. 99.13) was found in 7 patients at autopsy.[145]

COCAINE

Cocaine use is associated with increasing reports of adverse pulmonary effects from both intravenous and inhalational use of the drug. These are over and above the known cardiac effects of cocaine, which produces left ventricular failure with pulmonary congestion and edema. The principal effects of cocaine are infection and aspiration, noncardiogenic pulmonary edema (eFig. 99.14), particulate embolization, talcosis, diffuse alveolar damage, diffuse alveolar hemorrhage (eFig. 99.15), intra-alveolar eosinophilic infiltration, lung mass with or without cavitation, and an organizing pneumonia pattern of lung injury (Table 99.3).[146,147]

Table 99.3 Principal Effects of Cocaine on the Lung

Infection and aspiration leading to noncardiogenic pulmonary edema
Particulate embolization
Talcosis
Diffuse alveolar damage
Alveolar hemorrhage*
Intra-alveolar eosinophilic infiltration
Lung mass with or without cavitation
Organizing pneumonia
Vasculitis*

*Also can be caused by the adulterant levamisole.

Illicit drugs such as cocaine are very frequently altered by the addition of other agents. These adulterants are commonly added to cocaine and have also been associated with causing lung disease. Levamisole, a white powder used in veterinary medicine, can add to the bulk of cocaine and may also add to its effects.[148] It has been detected in up to 70–80% of cocaine sources tested. Levamisole can induce an antineutrophil cytoplasmic antibody vasculitis, with pulmonary vasculitis and rarely diffuse alveolar hemorrhage.[149]

TALC GRANULOMATOSIS

Talc (magnesium silicate) and other agents, such as cellulose, are used as fillers in many medications intended for oral use. Addicts who inject oral medications such as meperidine, methadone, methylphenidate, and amphetamines often crush tablets and mix them with various solutions before injecting them intravenously. This results in the insidious onset of granulomatous interstitial fibrosis, granulomatous pulmonary arterial occlusion, or both.[150] In a large series of consecutive autopsies performed on addicts, depending on the type of addiction, the incidence of talc granulomatosis ranged from 15–80%.

Dyspnea is the major symptom, with cough in some patients; in more advanced stages, pulmonary hypertension may manifest with exercise-induced syncope, right-sided heart failure, and even sudden death. Chest radiography may be normal in up to one-half of patients with proven talc granulomatosis. Pulmonary function studies characteristically show a low D_{LCO}. Imaging in patients with injection granulomatosis may show diffuse micronodular densities varying in size between 1 and 3 mm (eFig. 99.16), which may mimic alveolar microlithiasis or hypersensitivity pneumonitis. Pulmonary opacities resulting from injection talcosis may show hyperattenuation on chest CT (eFig. 99.17). Therapy with corticosteroids provides little consistent improvement.

Histologically, the pulmonary tissue demonstrates granulomatous changes, with multinucleated giant cells, mononuclear inflammatory cells, lymphocytes, and fibrosis. Talc is detected by the presence of strongly birefringent crystals

(using polarized light) within the granulomas (eFig. 99.18). BAL fluid shows increased lymphocytosis and sometimes contains intracellular and free talc.

CARDIOVASCULAR DRUGS

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme (ACE) inhibitors are widely used for control of hypertension and congestive heart failure. Dry cough develops in 5–20% of patients on ACE inhibitors and is reported with virtually all ACE inhibitors. The mechanism of ACE inhibitor–induced cough likely involves accumulation of kinins and substance P, which are normally degraded by ACE and other endopeptidases. The cough generally is reported in the first few weeks after beginning therapy but may not be appreciated for several months. ACE-induced cough is usually benign but can be quite annoying, and it causes the discontinuation of these agents in one-half of the patients affected. Exacerbation of bronchospasm has been rarely associated with ACE inhibitors. Cough generally abates within 4 days of discontinuation of the agent, thus providing confirmation of the diagnosis. Rechallenge with a different ACE antagonist is not recommended because cough usually returns. Of note, selective angiotensin receptor antagonists have much lower incidence of dry cough compared with ACE inhibitors and may represent a therapeutic option for many patients.

Compared with cough, angioedema from ACE inhibitors is much less common, arising in 0.1–0.2% of patients. This complication usually arises within hours to, at most, 1 week after initiating therapy, and it can be life-threatening. Treatment is supportive and consists of airway protection. Although frequently used, epinephrine, antihistamines, and corticosteroids are of unclear value. The ACE inhibitor must be discontinued and future use avoided.

AMIODARONE

Amiodarone has significant benefit for ventricular and supraventricular dysrhythmias in patients who do not respond to other antiarrhythmic agents. This drug is associated with certain side effects, which include the following: corneal microdeposits; peripheral neuropathy; liver dysfunction; thyroid dysfunction, including hypothyroidism and hyperthyroidism; and bluish pigmentation of the skin. The most serious side effect is interstitial pneumonitis, which develops in up to 6% of patients and may be fatal.

The toxicity is dose related and has distinctive histologic features. The histologic findings generally include foamy alveolar macrophages and alveolar epithelial type 2 cells containing lamellar inclusions. The incidence of pulmonary toxicity from amiodarone varies widely but probably averages 4–6% of those patients.[11,151] Symptoms consist of insidious dyspnea, nonproductive cough, and occasionally a low-grade fever without chills, followed by subtle chest radiographic findings, which initially may be asymmetrical or even limited to the upper lobes. If the drug is continued, the process may diffusely involve the lungs with an interstitial or alveolar process. Pleural effusion is uncommon. Pleuritic chest pain exists in approximately 10% of patients. Crackles may be heard, but it is difficult to be certain whether these are caused by pulmonary edema during congestive heart failure. In approximately 20% of patients with amiodarone pneumonitis, the presentation is acute, mimicking pneumonia (eFig. 99.19).

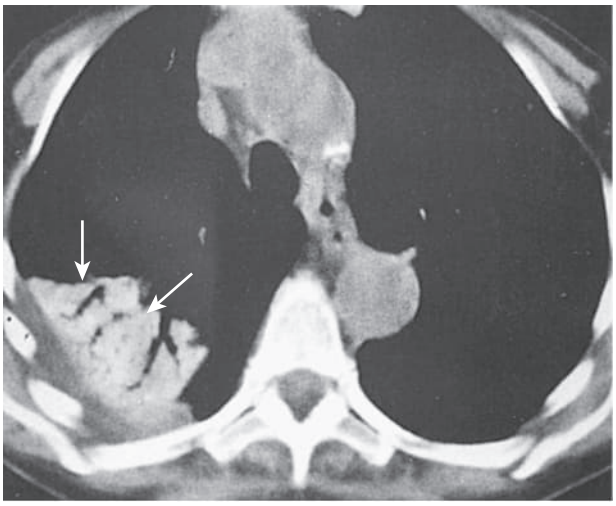

Fig. 99.6 Amiodarone-induced lung disease. A chest computed tomography scan showing confluent pulmonary masses *(arrows)* from amiodarone pneumonitis. Note that the masses are appreciably denser than the surrounding soft tissue in the chest wall in this scan without contrast; the reason for the increased density is that amiodarone is iodinated and thus is radiopaque.

On laboratory studies, there is a normal to mildly elevated leukocyte count, generally no eosinophilia, and an elevated sedimentation rate, with little or no reactivity to antinuclear antibody. Pulmonary function studies disclose a decrease in the total lung capacity and $D_{L_{CO}}$, as well as hypoxemia. There may be an increased predisposition to amiodarone pneumonitis if either pulmonary function test results or imaging studies are abnormal before administration of the drug.

Most patients who develop amiodarone pneumonitis have been taking the drug for at least a month, and some for a few years. Most are receiving at least 400 mg/day. However, there have been some reports of amiodarone pneumonitis in patients taking as little as 200 mg/day. There are also reports of patients receiving 200 mg/day for months or years and not developing amiodarone pneumonitis until the dose is boosted for better control of the arrhythmia. Generally, the systemic side effects of amiodarone, such as peripheral neuropathy and liver dysfunction, correlate with the serum levels, but this is not necessarily the case with pulmonary toxicity. The diagnosis of amiodarone pneumonitis is one of exclusion.

Normally, amiodarone pneumonitis is thought to be primarily an interstitial or alveolar process (or both) sometimes mimicking eosinophilic pneumonitis with peripheral opacities (eFig. 99.20), but some reports have noted confluent lesions and other patterns. Many of these lesions represent an organizing pneumonia injury pattern (eFig. 99.21A–B; see also eFig. 99.23D).[152,153] Chest CT imaging can further define these processes because amiodarone, being an iodinated compound, is radiopaque and, on a CT scan, the amiodarone pneumonitis lesions are denser than the surrounding soft tissue in the chest wall (Fig. 99.6, eFig. 99.22). This finding may help support the diagnosis.

Table 99.4 Drugs or Treatment Associated With the Induction of Organizing Pneumonitis

Amiodarone	Mitomycin C
Bleomycin	Nivolumab
Cocaine	Pembrolizumab
Cyclophosphamide	Penicillamine
Gold	Radiation
Interferons	Sulfasalazine
Methotrexate	

Treatment consists of drug withdrawal and leads to a variety of responses. Some patients who were not treated with corticosteroids have died of pulmonary fibrosis and respiratory failure. Others have died in spite of corticosteroids. The majority respond to discontinuation of the drug and addition of corticosteroids (see eFigs. 99.19 and 99.21), which are usually required for a period of at least 2 months and perhaps 6 months or longer. There are many case reports of patients who continued on amiodarone because it was the only drug that controlled their arrhythmia and who were given corticosteroids to suppress their pneumonic reaction.[154]

Tissue confirmation is occasionally needed to establish a diagnosis, although stopping the drug and adding corticosteroids may offer a presumptive diagnosis if the process clears. BAL produces variable results.[11] The presence of foamy macrophages in lavage fluid or on biopsy confirms exposure to the drug, whereas their presence alone does not necessarily indicate amiodarone toxicity. However, their absence does exclude the diagnosis. Although not used frequently in recent years, a positive gallium scan can be highly suggestive of an inflammatory pneumonitis rather than heart failure. If the diagnosis has not been established, the clinician must decide whether to proceed with a lung biopsy to rule out other disease processes or to consider diminishing the dose or discontinuing the drug, or adding corticosteroids, or both. A lung biopsy usually reveals the foamy macrophages and epithelial cells, as well as variable inflammatory cell infiltration (eFig. 99.23). The histopathologic patterns of amiodarone-induced pulmonary injury vary, and the most common pattern of injury is cellular interstitial pneumonia (see eFig. 99.23). However, some patients may exhibit an organizing pneumonia injury pattern (Table 99.4, see eFig. 99.23D). Reductions in the erythrocyte sedimentation rate following discontinuation of amiodarone or reduction of the dosage may help support the diagnosis.

There are reports that patients receiving amiodarone can develop postoperative ARDS, an injury that begins 18 to 72 hours after surgery.[155,156] In a population-based study, amiodarone was responsible for approximately 2.7% of cases of acute lung injury. It has been postulated that the high fraction of inspired oxygen given during the operation and postoperative period contributes to this complication.

β-ADRENERGIC ANTAGONISTS

β-Adrenergic antagonists are among the most commonly prescribed drugs. β-Adrenergic receptors can be divided into excitatory β_1-receptors, located in the heart, and inhibitory β_2-receptors, located in the bronchi. The β-adrenergic blockers, or β-blockers, are competitive antagonists.

Propranolol was the first β-adrenergic antagonist introduced. It was quickly recognized to have adverse effects on individuals with known obstructive lung disease, and was shown to increase airway resistance in patients with nonasthmatic COPD.[157] Thus, this agent should be avoided in patients with known obstructive lung disease when possible. The following β-adrenergic antagonists, presented in decreasing order of bronchoprovocation potential, are available for clinical use in the United States: propranolol, timolol, nadolol, metoprolol, atenolol, and labetalol.[158]

Two features of β-adrenergic antagonists predict their potential for bronchoprovocation: their cardioselectivity and their intrinsic sympathomimetic activity. Generally, cardioselectivity is the more important of the two in avoiding bronchoconstriction; if the drug is cardioselective, it has little effect on the inhibitory β-receptors located in the bronchial walls. Propranolol, timolol, and nadolol have essentially no cardioselectivity and thus a higher bronchoprovocation potential. Metoprolol has some cardioselectivity, and atenolol and labetalol have considerable cardioselectivity, making them the drugs of choice in an individual with obstructive airway disease who needs a β-adrenergic antagonist. Thus, among the drugs listed, atenolol and then metoprolol or labetalol are the three that can be used with relative safety in persons with obstructive lung disease, if absolutely necessary. However, these drugs should always be given in conjunction with an aerosolized β_2-adrenergic agent.

The same findings have been described in asthmatic patients receiving timolol eye drops for glaucoma.[159] Topically applied timolol is absorbed through the conjunctiva and bypasses the liver, thus resulting in a higher serum concentration than when given orally. A novel ocular β-adrenergic antagonist, betaxolol, has been shown to be safer in patients with known airway disease. There are scattered reports of β-blocker–associated interstitial pneumonitis.[160] Propafenone is an additional membrane-stabilizing antiarrhythmic agent that is structurally similar to propranolol and has the potential to aggravate bronchospasm.[161]

TOCAINIDE AND FLECAINIDE

Tocainide is used in the treatment of refractory ventricular arrhythmias. There are more than 100 known cases of acute interstitial pneumonitis beginning 3 weeks to several months after initiation of therapy.[162] The response to discontinuing the drug is good; corticosteroids may be necessary in some cases.

Flecainide, another antiarrhythmic agent, has been reported to be associated with ARDS and interstitial lymphocytic pneumonitis.[35,163]

ANTI-INFLAMMATORY AGENTS

ASPIRIN

Anti-inflammatory agents are among the most commonly used drugs, and many have pulmonary side effects. Aspirin is the most commonly used drug in the world. It is estimated that up to 5% of asthmatic patients are sensitive to

aspirin; ingestion may cause fatal aggravation of bronchospasm.[164] The exact cause of aspirin-sensitive asthma is unknown. One theory is that, by inhibiting cyclooxygenase, aspirin and similar compounds prevent the generation of cyclooxygenase products such as the prostaglandins. If certain individuals are reliant on the bronchodilator activity of prostaglandins such as prostaglandin E_2, then prostaglandin inhibition could cause bronchospasm. The aspirin-asthma triad consists of asthma, rhinitis, and nasal polyposis. Almost always there are other associated side effects, such as cutaneous rashes and gastrointestinal symptoms. These adverse reactions are not dose related and can develop with very small doses. Salicylates can induce noncardiogenic pulmonary edema in cases of overdose when the serum salicylate level is greater than 40 mg/dL.

OTHER NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Most of the nonsteroidal anti-inflammatory agents can produce the same side effects as aspirin, including aggravation of asthma, noncardiogenic pulmonary edema, drug-induced SLE, and pulmonary opacities with eosinophilia.[165] A few agents can cause hypervolemia and, in turn, pulmonary edema through the mechanism of increased sodium retention through the kidneys.

PENICILLAMINE

Penicillamine is used to treat Wilson disease, rheumatoid arthritis, and cystinuria and has been associated with pulmonary toxicity. There are three possible pulmonary complications with the use of penicillamine, with no apparent overlap: penicillamine-induced SLE, bronchiolitis obliterans, and *anti–glomerular basement membrane disease* (anti-GBM disease; formerly Goodpasture syndrome). Penicillamine-induced SLE may induce pneumonitis, alveolitis, and sometimes pleural effusion. Penicillamine-associated bronchiolitis obliterans is probably underestimated in its incidence and severity. Corticosteroids have little benefit in treating this condition, which usually manifests in an advanced state. There have also been several reports of penicillamine-associated anti-GBM disease with diffuse alveolar hemorrhage.[166] If this disorder is recognized early enough, appropriate therapy with hemodialysis, plasmapheresis, and immunosuppression may prevent a serious outcome.

LEFLUNOMIDE

Leflunomide is currently used to treat rheumatoid arthritis and psoriatic arthritis. It is a pyrimidine synthesis inhibitor, which exerts mainly an immunomodulating effect, although it was also found to exert significant anti-inflammatory effects. Its main described adverse effect is liver toxicity, and it may act synergistically with methotrexate. Several patterns of lung injury have been observed with leflunomide, mostly consisting of hypersensitivity reactions. In postmarketing surveillance, significant lung toxicity was identified in 61 of 5053 patients, with 24 patient deaths directly related to pulmonary complications.[166a] Preexisting lung disease and, to a lesser degree, loading dose, a smoking history, and low body weight were identified as independent risk factors for lung toxicity. A case-control study also showed a higher incidence of lung toxicity in patients with prior lung disease but suggested that the reason was that higher-risk patients were more likely to receive leflunomide.[167] True hypersensitivity pneumonias have also been reported in case series, as defined by interstitial opacities associated with ill-defined granulomas.[168] Nonspecific opacities with or without eosinophilia have also been reported. Diffuse alveolar hemorrhage and pulmonary alveolar proteinosis are rarely encountered. Cholestyramine washout therapy has been shown to treat leflunomide-induced pneumonitis; oral cholestyramine binds the drug and its metabolites, removes them from the body, and greatly shortens their otherwise long half-life.[169]

BIOLOGIC AGENTS

These agents have revolutionized the management of chronic inflammatory conditions such as rheumatoid arthritis, inflammatory bowel disease, and psoriasis. *Anti–tumor necrosis factor-α* (anti–TNF-α) medications such as infliximab (a chimeric monoclonal antibody targeting TNF-α), etanercept (a soluble TNF-α receptor), or adalimumab (recombinant monoclonal antibody targeting TNF-α) have been used in these conditions.

Not unexpectedly, infections are a major complication of these treatments. Tuberculosis, in particular, may easily reactivate in a context of impaired immunity. Tuberculosis skin tests or interferon-γ release assays for *Mycobacterium tuberculosis* are mandatory before treatment begins. Other opportunistic infections, including fungal lung infections, are also described with these agents.

Multiple patterns of lung injury have been described with infliximab, including acute hypersensitivity reactions with or without eosinophilia, nonspecific interstitial pneumonitis, lung fibrosis, or exacerbation of rheumatoid arthritis–associated usual interstitial pneumonia and vasculitis.[170]

Etanercept and adalimumab (eFig. 99.24) have also been described in association with pulmonary fibrosis, but these associations are relatively weak.[171,172] Etanercept has also been associated with pulmonary granulomatous inflammation.[173]

LEUKOTRIENE ANTAGONISTS

The leukotriene antagonists, zafirlukast, montelukast, and pranlukast, have been associated with *eosinophilic granulomatosis with polyangiitis* (EGPA).[174-176] A systematic review of the cases reported in the literature identified 62 cases of EGPA after initiation of leukotriene antagonists.[176] Although some of the patients may have had preexisting EGPA, many demonstrated a temporal relationship with the leukotriene antagonist.[176] Because these agents are added to a treatment regimen for asthma, corticosteroids are frequently tapered, thus suggesting that some of the effects are actually the result of tapering the corticosteroids. However, a few of these reported patients were not receiving oral or inhaled corticosteroids at the time the medication was added. EGPA has developed 6 to 18 months after initiation of these drugs. Remission of the signs and symptoms have been noted on removal of the leukotriene antagonist with or without escalation of corticosteroids.[176] The pulmonary reaction usually responds to discontinuation of the leukotriene antagonist and reinstitution of corticosteroids.

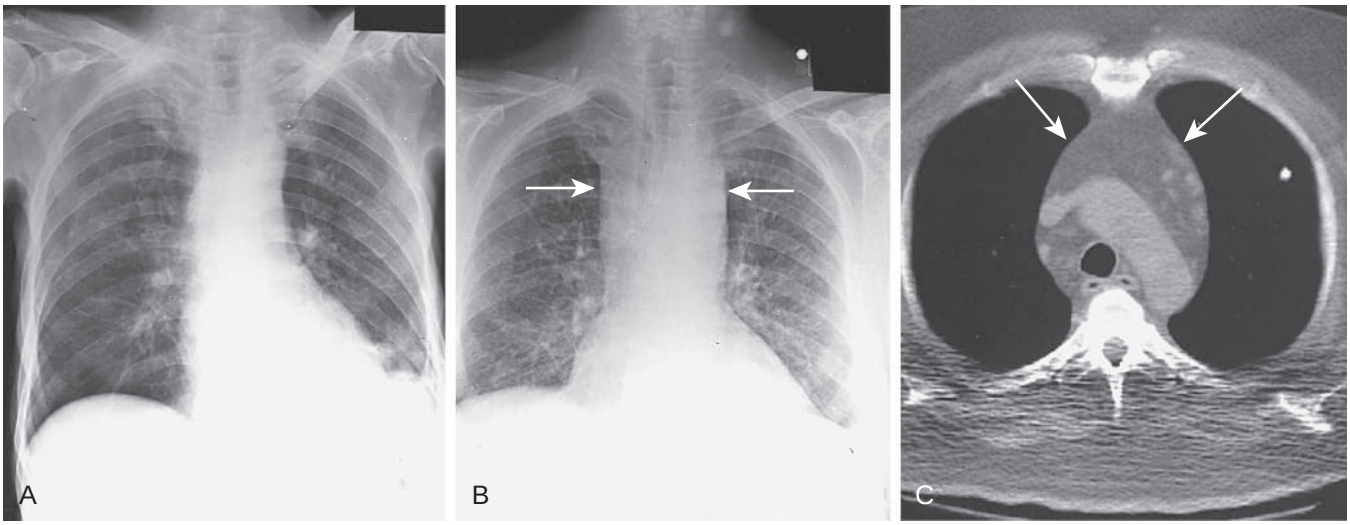

Fig. 99.7 Mediastinal lipomatosis in response to corticosteroids. (A) Chest radiograph before systemic corticosteroid administration. (B) Chest radiograph after corticosteroid administration shows a widened mediastinum *(arrows)*. (C) Chest computed tomography scan shows mediastinal lipomatosis, with radiographic fat density *(arrows)* surrounding the great vessels and tracheal shadows.

CORTICOSTEROIDS

Corticosteroids are well known for predisposing to opportunistic infections. A most unusual adverse effect of corticosteroids is mediastinal lipomatosis, the deposition of mediastinal fat, which produces a widening of the mediastinum that mimics lymphadenopathy or other neoplasms (Fig. 99.7). The chest radiograph does not show the lumpiness usually expected with adenopathy. Chest CT can usually make this diagnosis by establishing fat density throughout the mediastinal mass. Mediastinal lipomatosis does not necessitate tapering corticosteroids because the fat does not compromise vital structures.

DRUG-INDUCED SYSTEMIC LUPUS ERYTHEMATOSUS

Of more than 75 drugs associated with SLE, only five regularly induce antinuclear antibodies (hydralazine, procainamide, isoniazid, phenytoin, and penicillamine), and only a few patients taking these drugs develop the clinical lupus-like syndrome.[176a] It is thought that patients who develop antinuclear antibodies to these drugs are *slow acetylators,* with a slower rate of metabolism of the offending drug. Symptoms almost always begin insidiously after the patient has been taking the drug for many months or years. Systemic signs and symptoms of polyarthralgia, myalgia, fever, pleurisy, and cutaneous lesions are common. Renal disease is uncommon in the drug-induced form of SLE.

The antinuclear antibody assay is positive in all patients with drug-induced SLE. However, the test result for antinative (anti–double-stranded) DNA is negative. The complement level may or may not be abnormal. An elevated erythrocyte sedimentation rate and hypergammaglobulinemia are common nonspecific findings.

The chest radiographic findings of the drug-induced form of the disease are indistinguishable from spontaneous-onset SLE and include pleural effusions, basilar opacities, pneumonitis with atelectasis, and apparent cardiomegaly from pericardial effusion. Pleural fluid glucose is normal or at least correlates with the blood glucose levels. The symptoms usually resolve once the drug is discontinued. However, occasionally it is necessary to add corticosteroids.

OXYGEN

Exposure to high concentrations of oxygen may contribute to or aggravate ARDS. High fractions of inspired oxygen induce formation and release of free oxidant radicals. These short-lived molecules damage DNA, destroy lipid membranes, and inactivate intracellular enzymes.[177] Hyperoxia can also produce direct injury to endothelial cells and alveolar epithelial type 1 cells that results in alveolar-capillary leak.[178] Studies in volunteers breathing 100% oxygen for 24 hours produced variable effects, but some participants developed tracheobronchitis, with symptoms of substernal burning, chest tightness, nonproductive cough, and reduction in vital capacity and D_{LCO}.[179]

The sequelae of oxygen toxicity are separable into two phases, the acute exudative phase and the subacute proliferative phase. However, there is considerable overlap between the two phases. The exudative phase begins within 48 to 72 hours, depending on the fraction of inspired oxygen, and is associated with perivascular, interstitial, and alveolar edema with atelectasis, as well as alveolar hemorrhage. This phase appears to be reversible.

The proliferative phase begins after the fourth to seventh day and is characterized by progressive resorption of exudates and hyperplasia of alveolar epithelial type 2 cells. This is followed by the deposition of collagen and elastin in the interstitium and hyaline membrane deposition. This is usually an irreversible phase. Clinically, hypoxemia and diminished compliance progress, requiring a greater fraction of inspired oxygen with assisted ventilation, thus further aggravating the problem. Imaging shows an alveolar-interstitial pattern in an irregular distribution, with evidence of moderate loss of volume from patchy atelectasis.

There is no clinical way of diagnosing oxygen toxicity. A lung biopsy specimen may show changes consistent with

oxygen toxicity, but the primary value of the biopsy is to exclude other causes of lung injury. Keeping the arterial partial pressure of oxygen at less than 80 mm Hg or the inspired fraction of oxygen to less than 0.40 to 0.50 minimizes the likelihood of oxygen toxicity. Barotrauma and ventilator-induced injury may accompany and be indistinguishable from oxygen toxicity

MISCELLANEOUS DRUGS AND AGENTS

TOCOLYTIC-INDUCED PULMONARY EDEMA

Tocolytic drugs are agents that have been widely used in the treatment of premature labor. The most commonly used drugs are terbutaline, albuterol, ritodrine, and other β-mimetic drugs. There are many reports of these agents inducing pulmonary edema in otherwise healthy women. The incidence varies from 0.5–5%. Predisposing factors include the use of corticosteroids, twin gestation, fluid overload (particularly with saline), and anemia. The β-mimetic drugs typically stimulate β_2-adrenergic receptors, increase the maternal pulse rate and cardiac output, and produce peripheral vasodilation. Hemodilution can be detected by a drop in the hemoglobin, hematocrit, and albumin values. The blood pressure may drop as a result of the peripheral vasodilation.

A typical clinical scenario is as follows. In spite of the tocolytic agent, labor continues; the tocolytic agent is then stopped, and corticosteroids are added to accelerate fetal lung maturation. With the discontinuation of the tocolytic, the vasodilated vessels return to normal tone. During delivery, uterine contractions lead to autotransfusion. The increased venous tone and the increased blood volume can then lead to pulmonary edema, usually in the postpartum period.

The treatment consists of oxygen and diuresis. In certain cases, consideration has been given to resuming the tocolytic agent to recreate the previous peripheral vasodilation. Corticosteroids aggravate the situation by their mineralocorticoid effect, which promotes fluid retention. The differential diagnosis includes aspiration of gastric contents, left-sided heart failure, amniotic fluid embolism, and excessive transfusion.

HYDROCHLOROTHIAZIDE

Some cases of acute onset of diffuse pulmonary opacities are associated with hydrochlorothiazide.[180] It may begin with the first dose or days later; 90% of cases have been reported in women who take the drug intermittently rather than daily, presumably for fluid retention. Symptoms consist of fairly rapid onset of dyspnea that clears 48 to 72 hours after discontinuing the drug. A low-grade fever may be present. Eosinophilia and antinuclear antibodies are not present. The chest radiograph shows diffuse bilateral alveolar-interstitial opacities.

METHYSERGIDE, BROMOCRIPTINE, AND CABERGOLINE

Methysergide, bromocriptine, and cabergoline are structurally similar and produce similar pleuropulmonary reactions. Methysergide is now rarely used to treat vascular headaches because better alternative drugs are available. Bromocriptine and cabergoline have been used for Parkinson disease. The pleuropulmonary disease produced by both these agents has an insidious onset. The predominant features are pleural thickening and effusion, which are reversible by discontinuing the medication. Effusions are rarely large, are not commonly associated with pleuritic pain, and may show lymphocytosis.[181]

AMPHETAMINERGIC AGENTS

In the 1960s, excess cases of pulmonary hypertension were associated with the potent anorexigen, aminorex fumarate. More recently, pulmonary hypertension has been associated with dexfenfluramine, fenfluramine, and phenteramine.[182] Valvular heart disease has also been associated with these agents.[183] A careful drug history must be taken to exclude this possibility in patients presenting with dyspnea, cardiovascular symptoms, or heart murmurs because manifestations typically persist despite discontinuation of the drugs. A retrospective study of 340 patients with pulmonary hypertension identified a history of stimulant use in 29%; drugs included methamphetamine, amphetamine, and cocaine, thus emphasizing the importance of seeking a drug history that may not be easily volunteered by the patients.

Key Points

- The frequency of drug-induced pulmonary toxicity may be underestimated because the diagnosis is one of exclusion in most cases. Clinicians must maintain a high index of suspicion that unexplained pulmonary disease may be caused by medications.
- Most associations are based on anecdotal reports and circumstantial evidence.
- Potential mechanisms of lung injury include (1) oxidative injury, (2) direct cytotoxic effect, (3) accumulation of phospholipids, and (4) immune-mediated injury.
- Chemotherapy-induced lung toxicity should always be considered in the differential diagnosis of diffuse lung opacities because virtually all histopathologic presentations have been described.
- Even when cumulative toxicity is an issue, screening with serial imaging or physiologic studies is rarely helpful.
- Most drug-induced pulmonary reactions are reversible if the drug is stopped. If necessary, additional measures such as judicious use of corticosteroids may be helpful.
- Rechallenging the patient with the suspected drug is often dangerous and is generally not indicated.
- Many additional medications, more than space permits in this chapter, are associated with respiratory toxicities. If there is a question about whether a medication may be the cause of a particular pulmonary abnormality, one option is to call the medical director of the drug manufacturer, listed in the *Physicians' Desk Reference.* In addition, a useful online resource can be accessed at http://www.pneumotox.com.

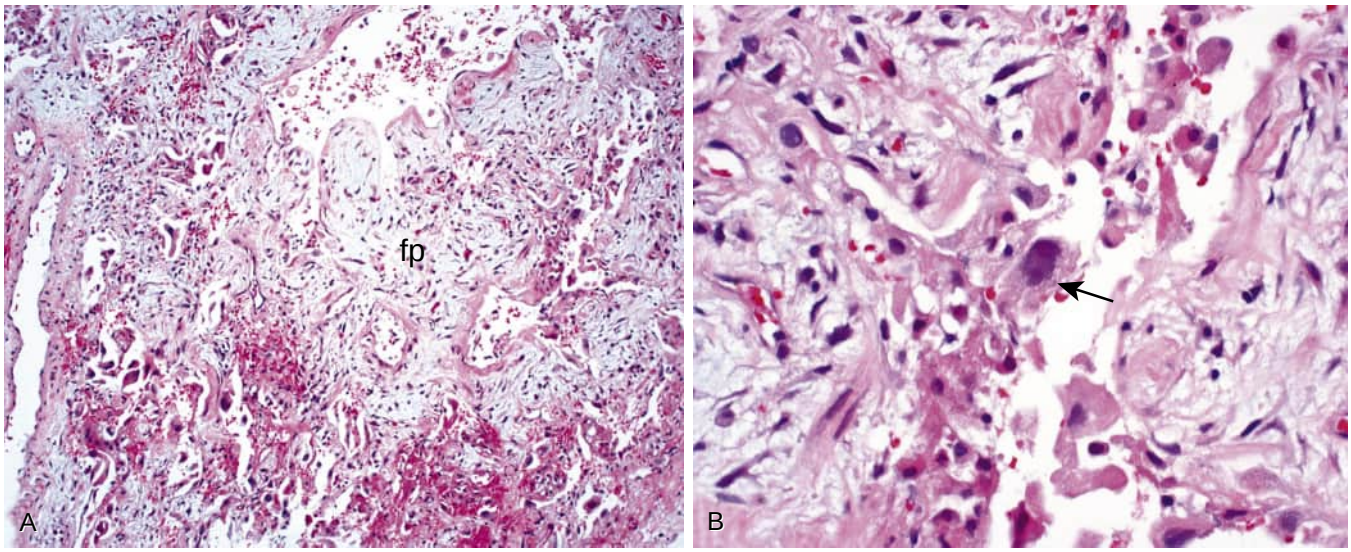
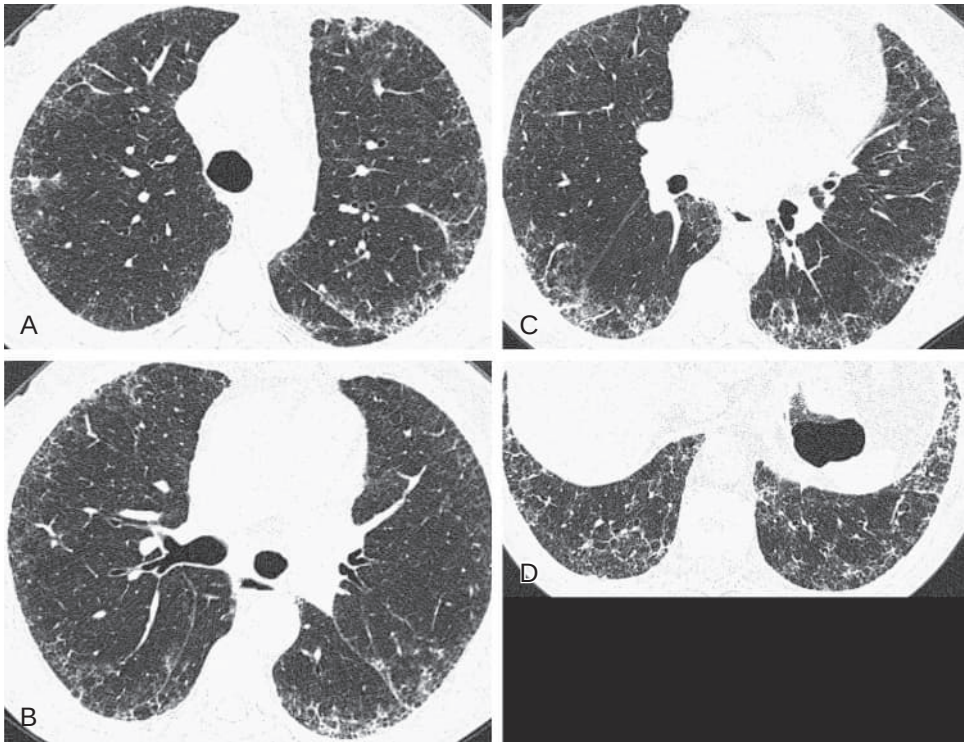
eFigure 99.1 Bleomycin-induced lung injury; hypersensitivity reaction. Anterior (A) and posterior (B) planar gallium-68 scintigraphic images in a patient with Hodgkin lymphoma treated with bleomycin shows increased uptake in the lungs *(arrows)* in a symmetrical, bilateral distribution. (C–F) Axial chest computed tomography obtained at the same time as the nuclear study (A–B) shows little evidence of an infiltrative abnormality on inspiratory images (C–D). On expiratory imaging, areas of decreased lung attenuation (E–F, *arrowheads*) are evident, representing air trapping and suggesting a small airway obstructive process. This pattern suggests bronchiolitis obliterans but can rarely be seen with hypersensitivity reactions. (G–H) Axial chest computed tomography obtained 2 weeks following (C–F) shows interval development of multifocal, bilateral areas of ground-glass opacity and reticulation; this pattern is consistent with an acute lung injury pattern, although the presence of the small airway obstruction, as shown on the initial computed tomography (C–F), suggests a combined infiltrative and obstructive disorder, which is typical of a hypersensitivity reaction. Evaluation for infection and pulmonary hemorrhage was unrevealing. (I–J) Axial chest computed tomography following withdrawal of bleomycin, obtained 4 months after (C–F), shows clearing of the infiltrative lung opacity with minimal anterior lung scarring remaining. (Courtesy Michael B. Gotway, MD.)

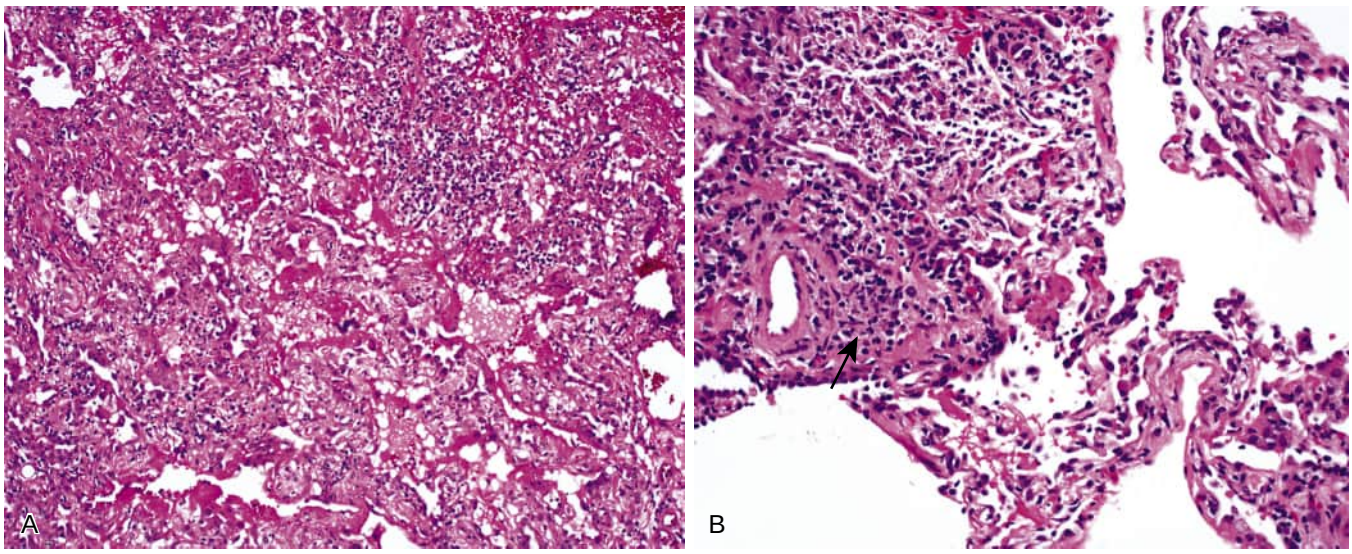
(B) Reactive alveolar epithelial type 2 cells and organizing pneumonia *(op)* are commonly found. (From Cheung Y, Graziano P, Leslie KO. Acute lung injury. In: Leslie KO, Wick MR, eds. *Practical Pulmonary Pathology: A Diagnostic Approach: A Volume in the Pattern Recognition Series.* 2nd ed. Philadelphia: Elsevier; 2011:117–137.)



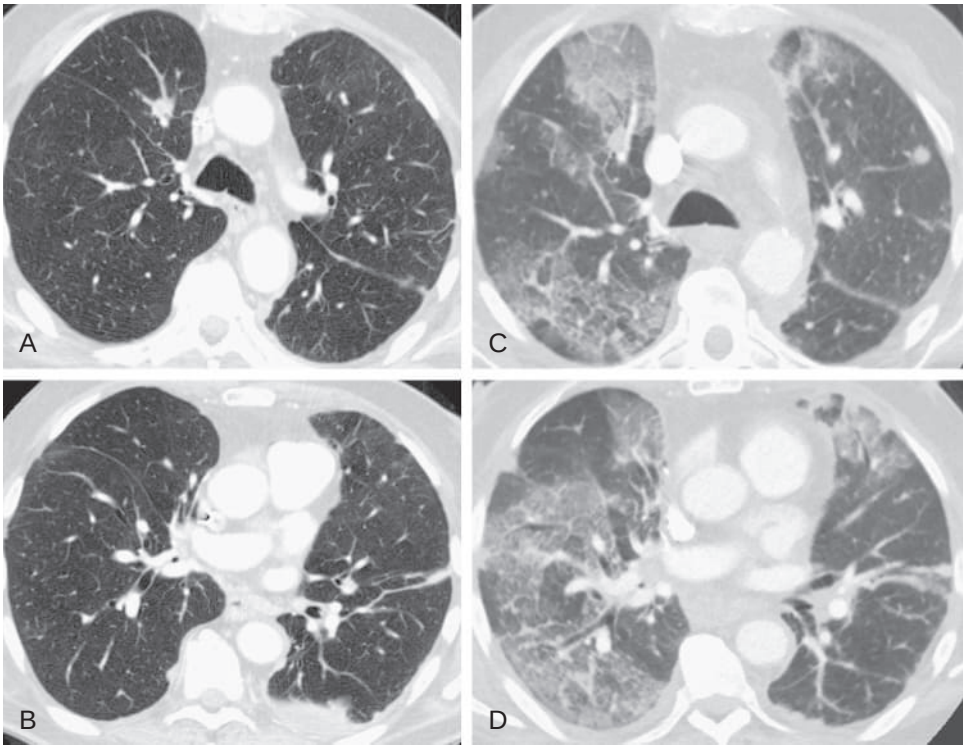
eFigure 99.3 Diffuse alveolar damage from busulfan toxicity. (A) Busulfan can produce diffuse injury characterized by the presence of prominently atypical alveolar epithelial type 2 cells. In this case, prominent interstitial organization with edematous fibroblastic proliferation *(fp)* is seen, and hyaline membranes are evident. (B) Reactive alveolar epithelial type 2 cells may appear alarmingly atypical *(arrow)*. (From Cheung Y, Graziano P, Leslie KO. Acute lung injury. In: Leslie KO, Wick MR, eds. *Practical Pulmonary Pathology: A Diagnostic Approach: A Volume in the Pattern Recognition Series.* 2nd ed. Philadelphia: Elsevier; 2011:117–137.)



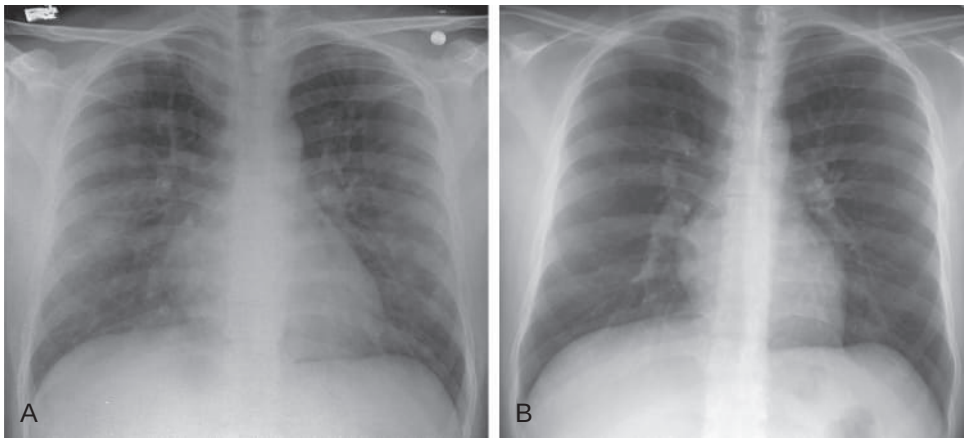
eFigure 99.4 Methotrexate-induced lung injury; non-specific interstitial pneumonia pattern. (A–D) Axial chest computed tomography in a patient receiving methotrexate shows bilateral basal and peripheral predominant linear and reticular abnormalities associated with architectural distortion and mild traction bronchiolectasis; the pattern resembles fibrotic nonspecific interstitial pneumonia. (Courtesy Michael B. Gotway, MD.)



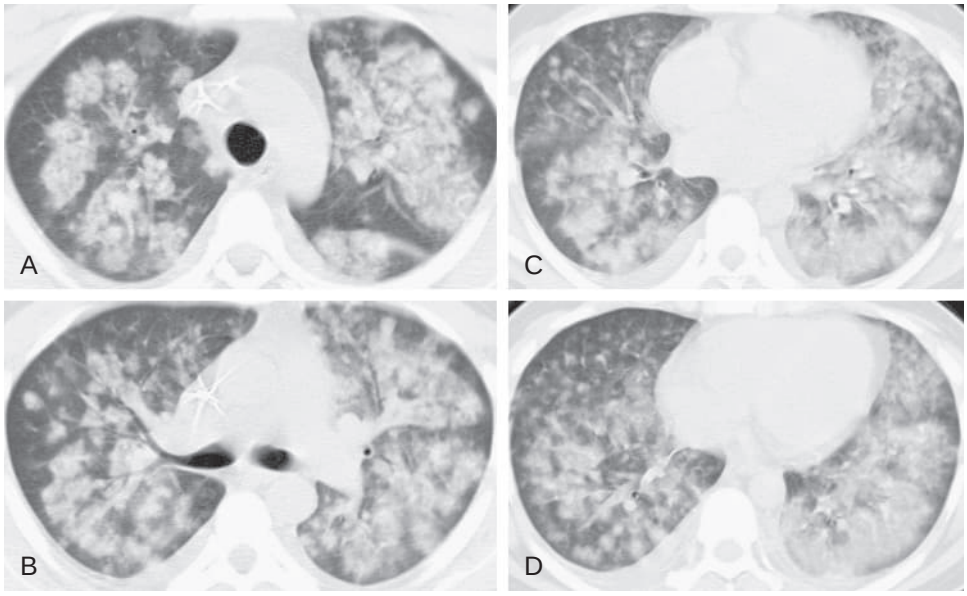
eFigure 99.5 Diffuse alveolar damage from methotrexate toxicity. (A) Methotrexate produces small, poorly formed granulomas in subacute and chronic manifestations of lung toxicity. (B) Early aggregations of macrophages may be seen resembling poorly formed granulomas in cases in which diffuse alveolar damage is the manifestation of injury, but these are not required for the diagnosis *(arrow).* (From Cheung Y, Graziano P, Leslie KO. Acute lung injury. In: Leslie KO, Wick MR, eds. *Practical Pulmonary Pathology: A Diagnostic Approach: A Volume in the Pattern Recognition Series.* 2nd ed. Philadelphia: Elsevier; 2011:117–137.)



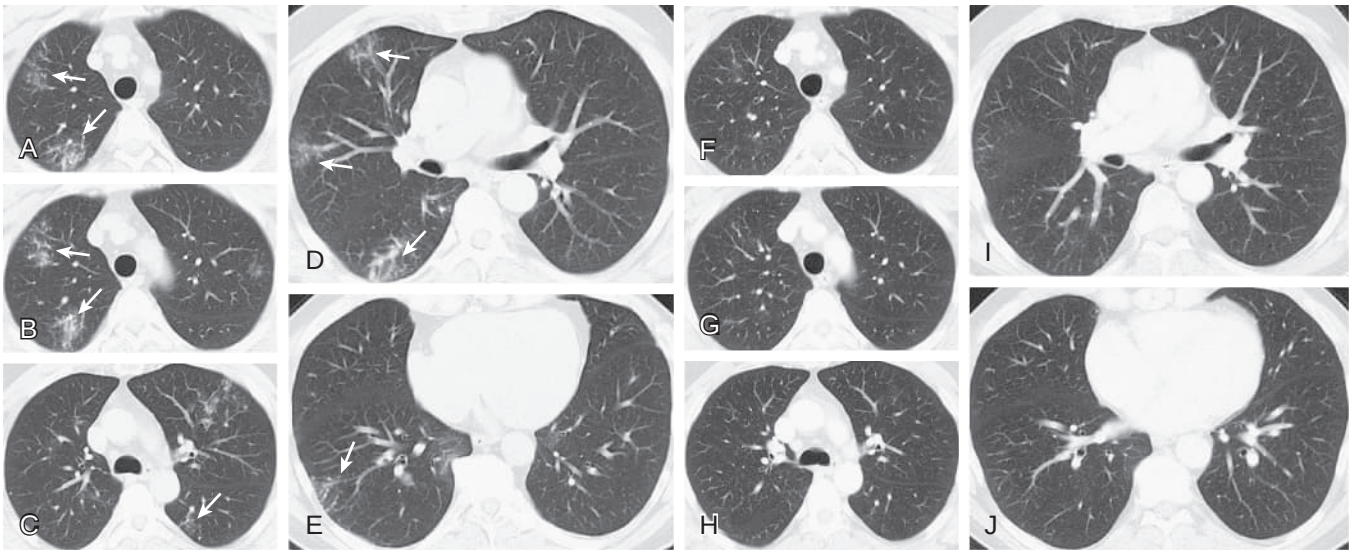
eFigure 99.6 Paclitaxel-induced pulmonary injury. (A–B) Axial chest computed tomography in a patient with non–small cell lung carcinoma at the onset of paclitaxel therapy. (C–D) Axial chest computed tomography performed 2 weeks following initiation of paclitaxel therapy shows interval development of multifocal ground-glass opacity associated with reticulation. No evidence of infection or pulmonary hemorrhage could be found. The computed tomography appearance is consistent with an acute lung injury pattern. (Courtesy Michael B. Gotway, MD.)



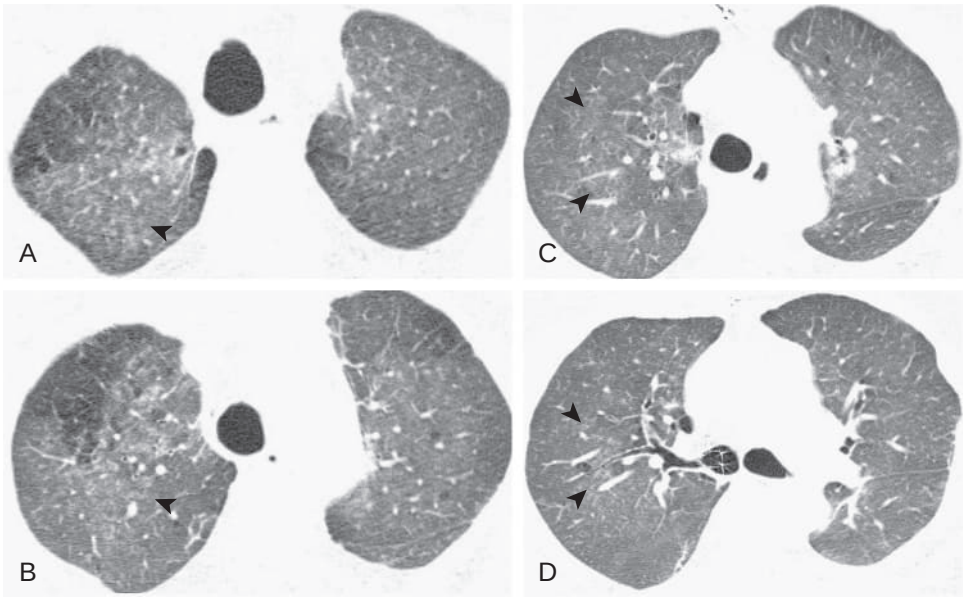
eFigure 99.7 All-*trans* retinoic acid syndrome in a patient treated for acute promyelocytic leukemia: chest radiographic findings. (A) Frontal chest radiograph performed shortly following initiation of therapy, when the patient developed renal insufficiency and peripheral edema, shows multifocal bilateral opacities consistent with an acute lung injury, or "capillary leak," pattern. (B) Frontal chest radiograph following withdrawal of therapy and corticosteroid treatment shows resolution of findings. (Courtesy Michael B. Gotway, MD.)



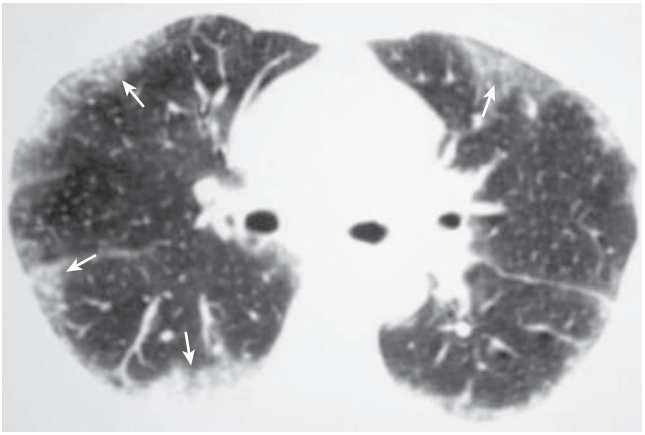
eFigure 99.8 All-*trans* retinoic acid syndrome in a patient treated for acute promyelocytic leukemia: chest computed tomography findings. (A–D) Axial chest computed tomography displayed in lung windows shows multifocal, bilateral areas of nodular ground-glass opacity resembling pulmonary hemorrhage, although no hemorrhage was found at bronchoscopy. The pattern is nonspecific but consistent with acute lung injury. The abnormalities resolved following cessation of all-*trans* retinoic acid therapy and corticosteroid treatment, and no infection was ever found. (Courtesy Michael B. Gotway, MD.)



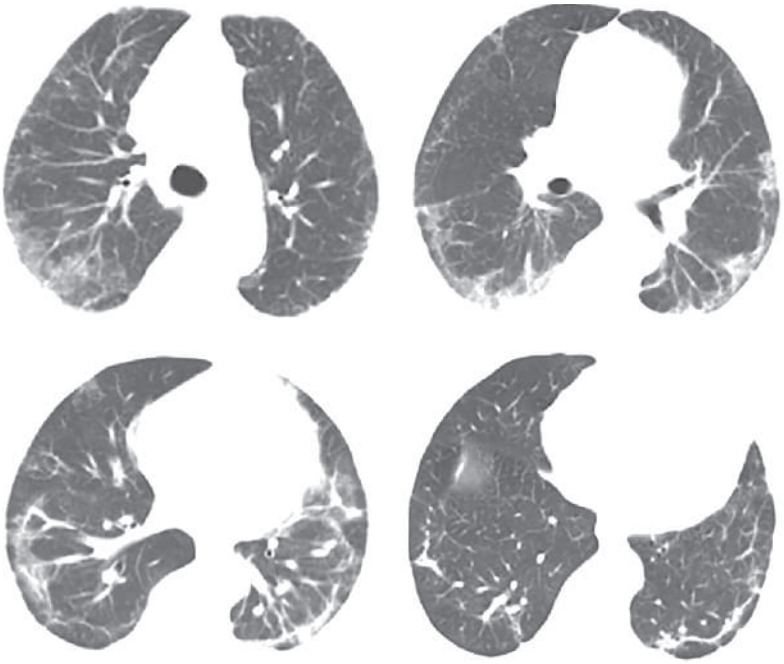
eFigure 99.9 Interferon-induced sarcoid-like reaction. (A–E) Axial chest computed tomography in a patient with renal cell carcinoma treated with interferon-alfa shows multifocal, bilateral, patchy nodules *(arrows)* distributed along the bronchovascular bundles and fissural surfaces, typical of the appearance of sarcoidosis. No infectious cause was found, and the findings worsened on repeat evaluation. (F–J) Axial chest computed tomography performed following withdrawal of interferon-alfa therapy shows resolution of the small nodules. (Courtesy Michael B. Gotway, MD.)



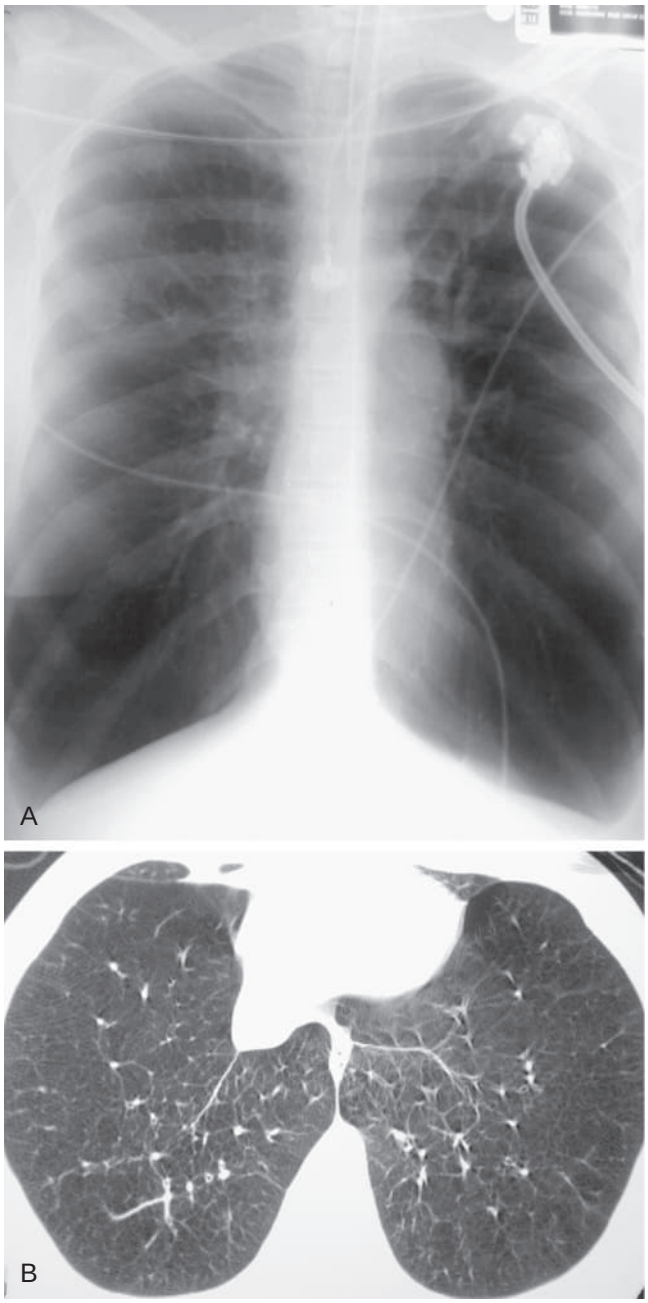
eFigure 99.10 Sirolimus-induced interstitial pneumonitis in a lung transplant recipient. (A–D) Axial chest computed tomography shows poorly defined, faintly nodular areas of ground-glass opacity *(arrowheads)* in the middle and upper lungs bilaterally. Extensive evaluation revealed no evidence of infection or hemorrhage, and the abnormalities resolved following withdrawal of sirolimus therapy. (Courtesy Michael B. Gotway, MD.)



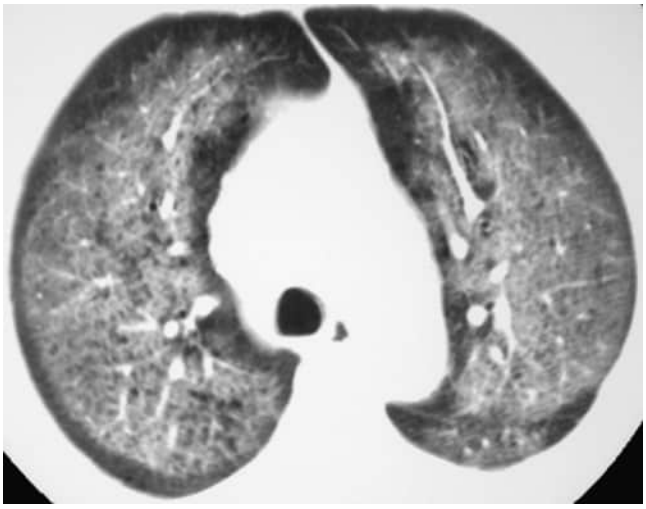
eFigure 99.11 Nitrofurantoin-induced interstitial pneumonitis. Axial chest computed tomography in a patient undergoing nitrofurantoin therapy shows bilateral, patchy, subpleural ground-glass opacity and reticulation *(arrows)* consistent with a nonspecific interstitial pneumonia lung injury pattern. (Courtesy Michael B. Gotway, MD.)



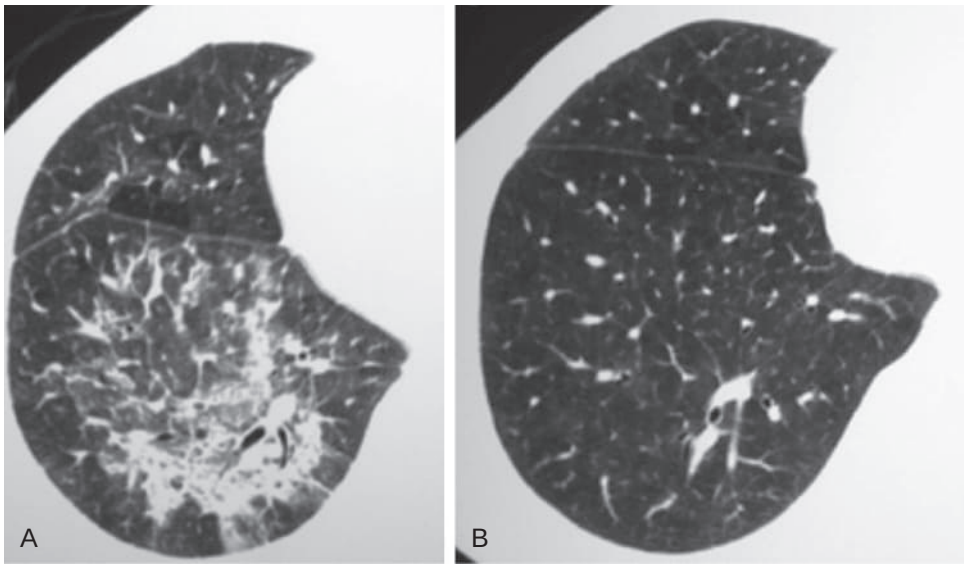
eFigure 99.12 Eosinophilic pneumonia pattern resulting from sulfasalazine. The patient was a 66-year-old woman who had taken sulfasalazine for inflammatory bowel disease. She developed cough and shortness of breath. The computed tomography images demonstrate patchy subpleural ground-glass opacity and consolidation bilaterally in a nonspecific pattern. Bronchoscopic biopsy confirmed eosinophilic pneumonia, which responded to withdrawal of sulfasalazine and corticosteroid therapy. (Courtesy Michael B. Gotway, MD.)



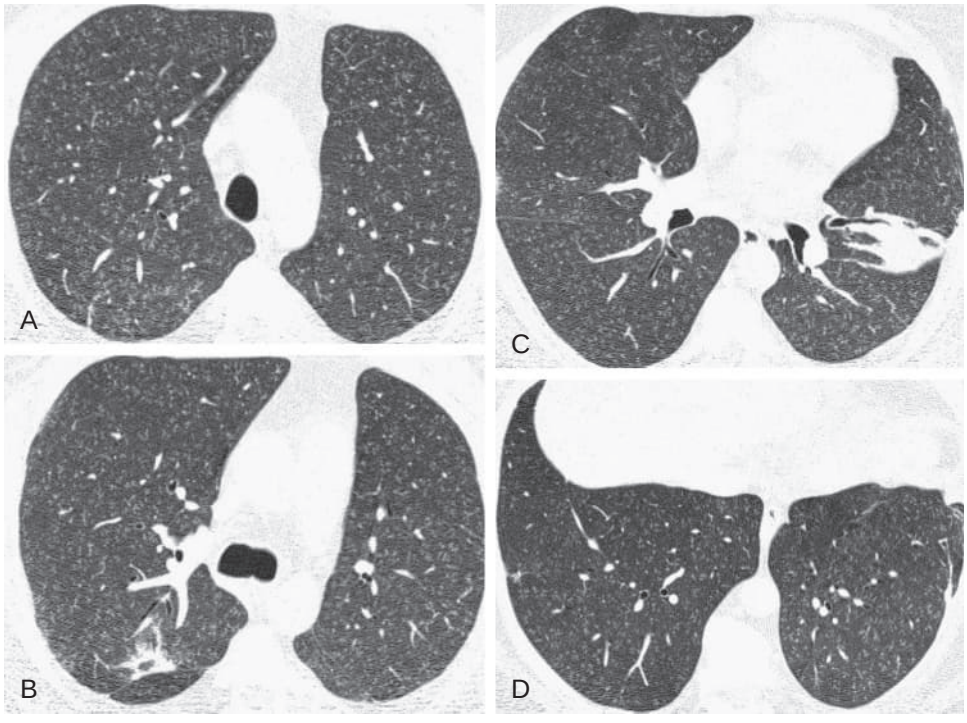
eFigure 99.13 Panlobular emphysema in a patient abusing methylphenidate. (A) Frontal chest radiograph in a 40-year-old woman with respiratory failure who was known to inject methylphenidate intravenously shows enormous lung volumes. Note diaphragmatic flattening. (B) Axial chest computed tomography through the lung bases shows diffuse low attenuation and simplification of pulmonary architecture, consistent with panlobular emphysema. (Courtesy Michael B. Gotway, MD.)



eFigure 99.14 Noncardiogenic edema following cocaine inhalation. Axial chest computed tomography performed in a patient who developed severe shortness of breath and cough following crack inhalation shows multifocal bilateral ground-glass opacity with peripheral sparing. No evidence of infection was noted. (Courtesy Michael B. Gotway, MD.)

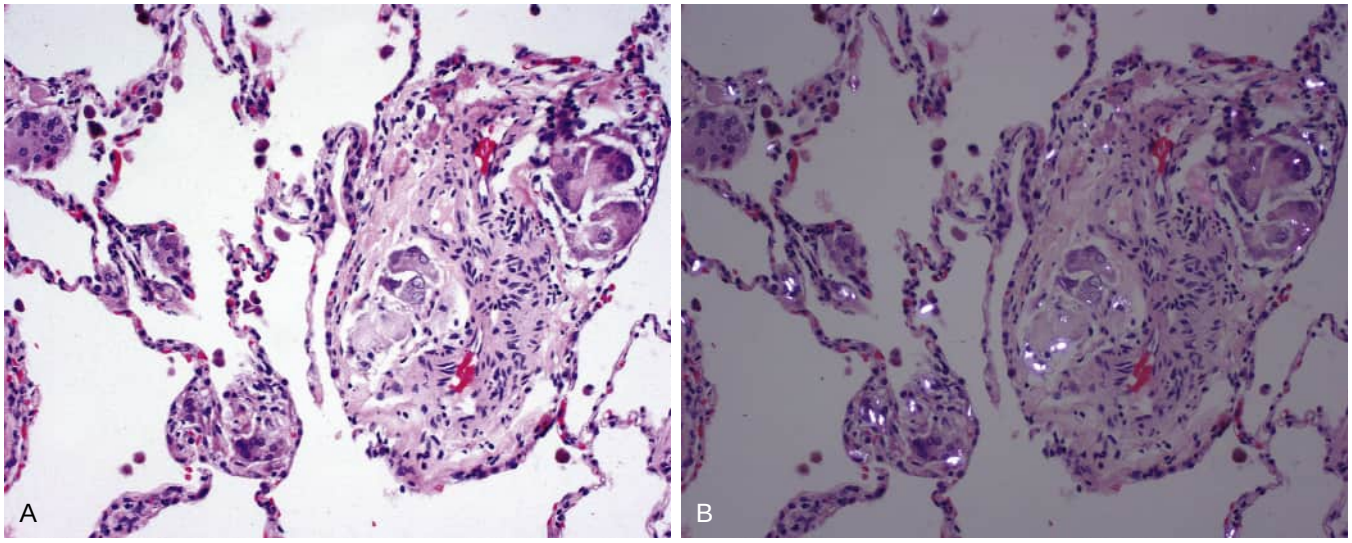


eFigure 99.15 Pulmonary hemorrhage following cocaine inhalation. (A) Axial chest computed tomography performed in a patient reporting shortness of breath and cough following crack inhalation shows patchy right lower lobe ground-glass opacity with interlobular septal thickening, consistent with hemorrhage; the latter was confirmed at bronchoscopy. (B) Repeat axial chest computed tomography 3 weeks later shows clearing of the right lower lobe pulmonary hemorrhage. (Courtesy Michael B. Gotway, MD.)

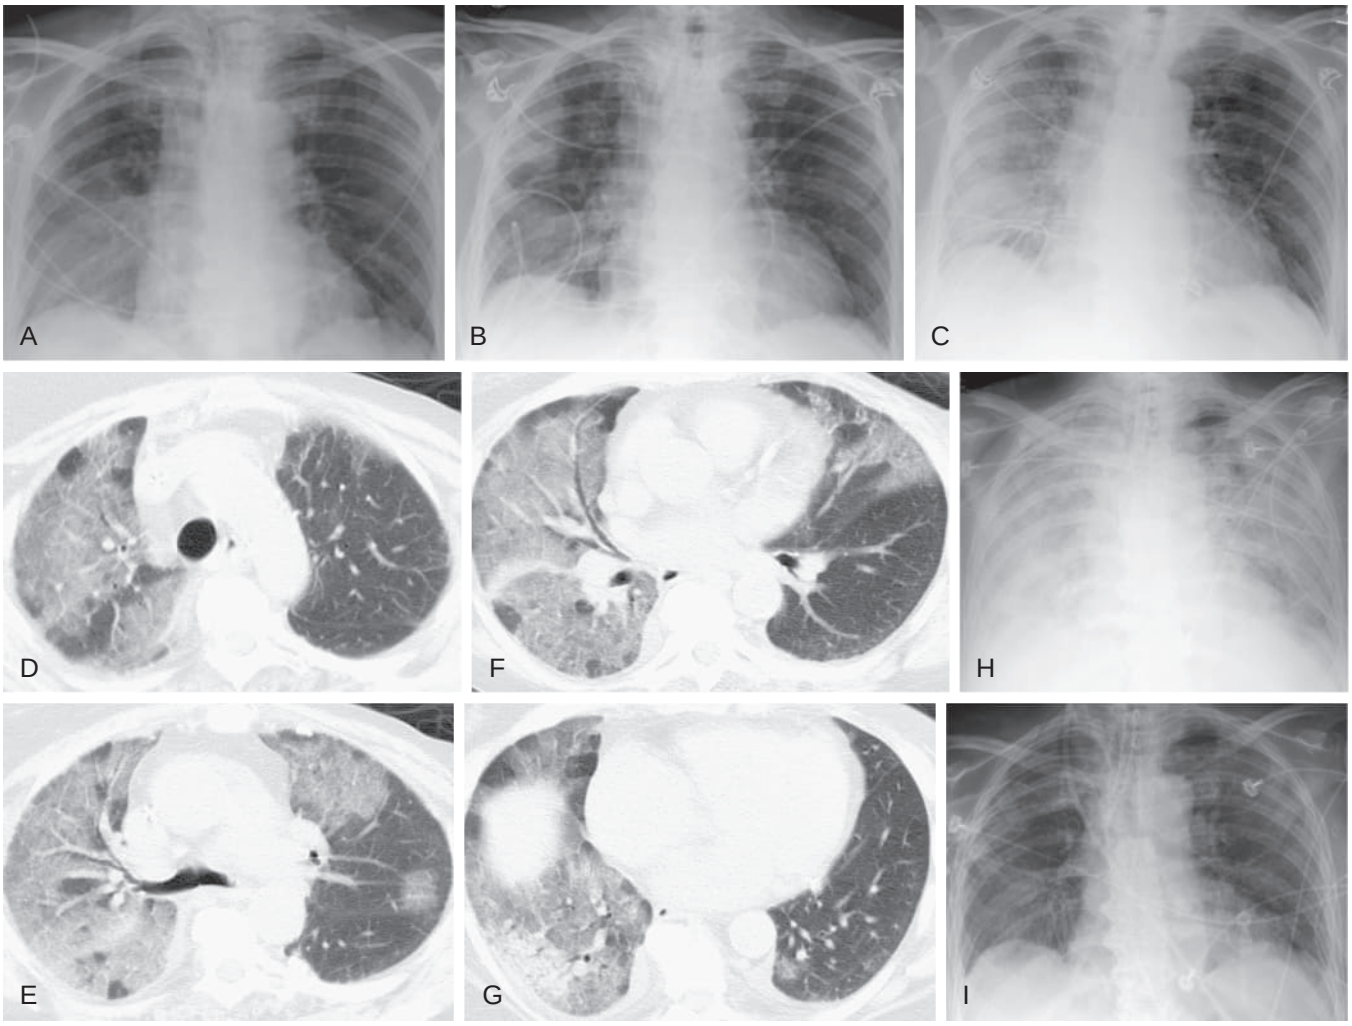


eFigure 99.16 Injection cellulose granulomatosis in a patient injecting Vicodin tablets intravenously. (A–D) Axial chest computed tomography in an injection drug user shows numerous, diffusely distributed, bilateral ground-glass opacity nodules; the appearance closely resembles subacute hypersensitivity pneumonitis. Surgical lung biopsy showed a perivascular foreign body giant cell reaction with granulomas and polarizable refractive crystals consistent with cellulose. (Courtesy Michael B. Gotway, MD.)

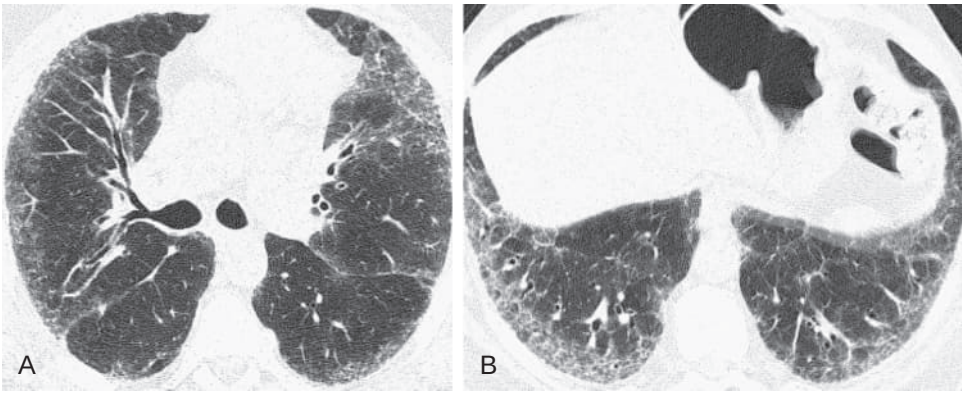
eFigure 99.17 Injection talcosis. Axial chest computed tomography displayed in soft tissue windows performed on an intravenous drug user shows bilateral masslike opacities consistent with injection talc granulomatosis. (Courtesy Michael B. Gotway, MD.)



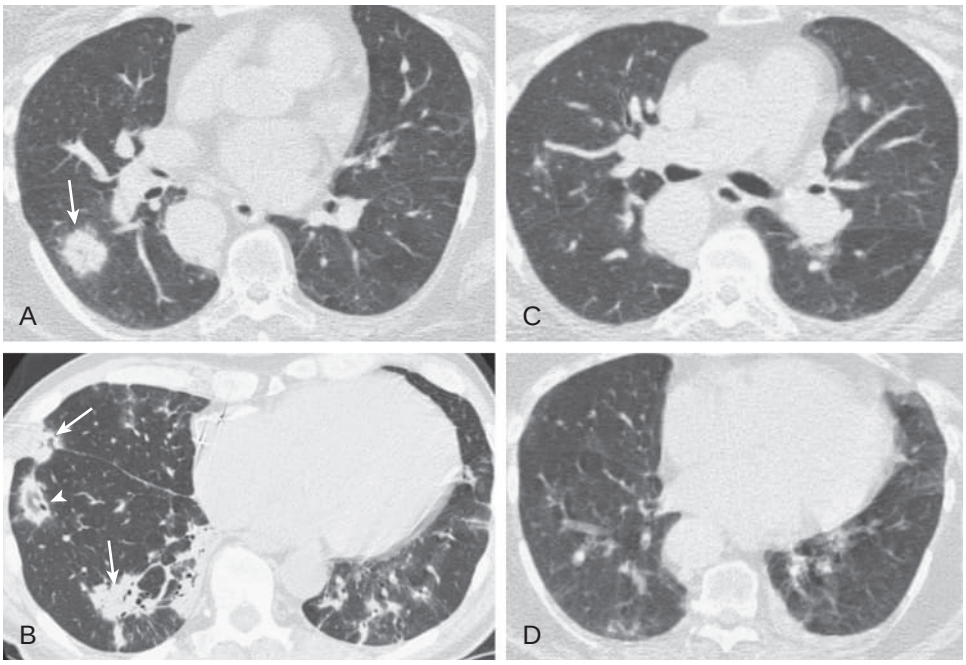
eFigure 99.18 Intravenous drug use-induced particulate foreign body reaction. (A) Normal light microscopy appearance. (B) Polarized light. A perivascular interstitial foreign body–type granulomatous reaction is associated with prominent vascular changes, as shown. (From Cheung Y, Graziano P, Leslie KO. Acute lung injury. Leslie KO, Wick MR, eds. *Practical Pulmonary Pathology: A Diagnostic Approach: A Volume in the Pattern Recognition Series.* 2nd ed. Philadelphia: Elsevier; 2011:117–137.)



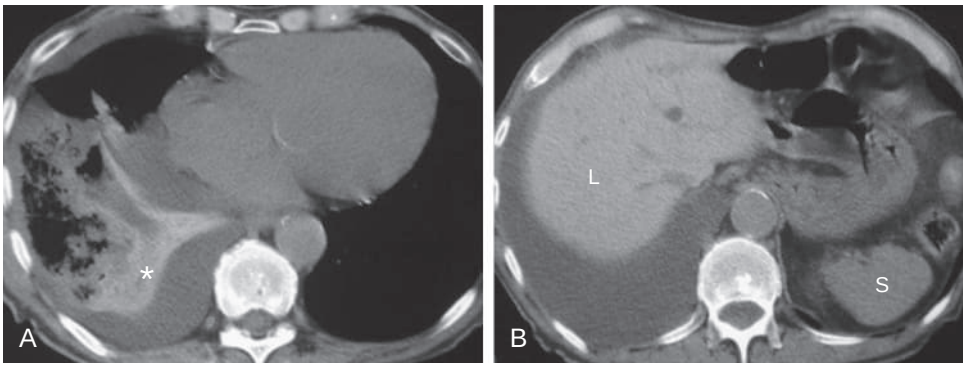
eFigure 99.19 Acute amiodarone pulmonary toxicity. (A) Frontal chest radiograph performed in a patient with supraventricular tachycardia recently loaded with amiodarone shows right lower lung opacity thought to reflect pneumonia. The patient was treated presumptively for pneumonia with broad-spectrum antibiotics. (B) Frontal chest radiograph performed several days following (A) shows slight improvement in right lower lung opacity, but new right upper lobe opacity is now present. (C) Follow-up frontal chest radiograph shows progression of the right lung abnormalities despite a normal intravascular volume and broad-spectrum antibiotic therapy. (D–G) Axial chest computed tomography displayed in lung windows shows multifocal, bilateral ground-glass opacities associated with fine reticulation and subpleural right lower lobe consolidation, but no features to suggest fibrosis. The findings are consistent with alveolitis or hemorrhage but are nonspecific. (H) Follow-up frontal chest radiograph shows continued worsening of bilateral lung opacities. (I) Frontal chest radiograph performed several days following discontinuation of amiodarone shows significant improvement in bilateral lung opacities. (Courtesy Michael B. Gotway, MD.)



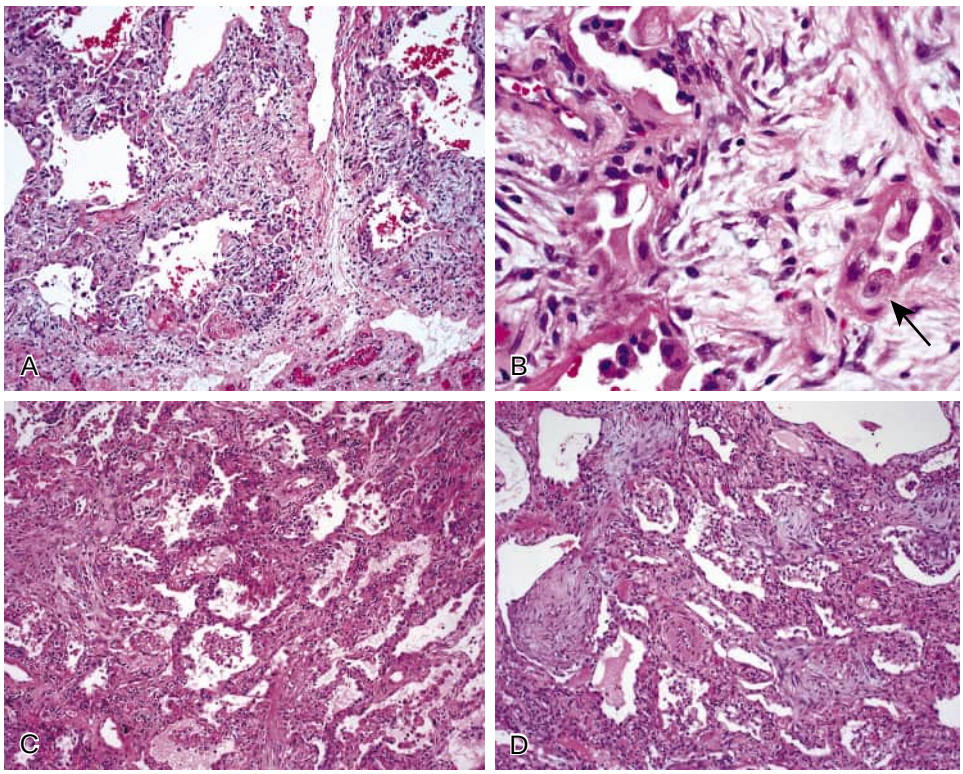
eFigure 99.20 Amiodarone pulmonary toxicity: nonspecific interstitial pneumonia pattern. (A–B) Axial chest computed tomography displayed in lung windows performed in a patient receiving long-term amiodarone therapy shows bilateral, subpleural fine intralobular interstitial thickening and ground-glass opacity; the appearance resembles a nonspecific interstitial pneumonia lung injury pattern. (Courtesy Michael B. Gotway, MD.)



eFigure 99.21 Amiodarone pulmonary toxicity: nodular organizing pneumonia pattern. (A–B) Axial chest computed tomography displayed in lung windows performed in a patient receiving long-term amiodarone therapy shows right lung nodules *(arrows)* associated with air bronchograms; one nodule shows ground-glass opacity surrounded by consolidation (B, *arrowhead*), consistent with the "reverse ground-glass halo" sign, or "atoll" sign, suggestive of organizing pneumonia. (C–D) Axial chest computed tomography performed following discontinuation of amiodarone therapy and implementation of corticosteroid treatment shows nearly complete resolution of the nodules. (Courtesy Michael B. Gotway, MD.)



eFigure 99.22 Amiodarone exposure: high-attenuation lung consolidation. (A) Axial chest computed tomography performed in a patient taking amiodarone for an atrial arrhythmia shows high-attenuation right lower lobe consolidation *(asterisk),* consistent with amiodarone exposure. (B) Axial chest computed tomography through the upper abdomen shows increased attenuation of the liver parenchyma (L) relative to the spleen (S), also consistent with amiodarone exposure. (Courtesy Michael B. Gotway, MD.)



eFigure 99.23 Amiodarone toxicity. (A) Scanning magnification of amiodarone-induced diffuse alveolar injury. (B) The finely vacuolated macrophages in alveolar epithelial type 2 cells are clearly evident *(arrow)*. (C) The most common pathologic change seen in amiodarone toxicity is cellular interstitial pneumonia associated with prominent intra-alveolar macrophages whose cytoplasm shows fine vacuolation. (D) In some patients with amiodarone toxicity, an organizing pneumonia pattern develops, resulting in a mass effect on thoracic imaging studies. (From Cheung Y, Graziano P, Leslie KO. Acute lung injury. Leslie KO, Wick MR, eds. *Practical Pulmonary Pathology: A Diagnostic Approach: A Volume in the Pattern Recognition Series.* 2nd ed. Philadelphia: Elsevier; 2011:117–137.)

eFigure 99.24 Adalimumab-induced lung injury. (A–C) Axial chest computed tomography in a patient with rheumatoid arthritis undergoing adalimumab therapy shows multifocal bilateral ground-glass opacity with reticulation, consistent with an acute lung injury pattern. (Courtesy Michael B. Gotway, MD.)

INTRODUCTION

DEFINITIONS OF ASTHMA IN THE WORKPLACE

Work-related asthma (WRA) is a major public health concern because of its high prevalence and societal burden. WRA is a broad term indicating that asthma is worsened by the workplace.[1] WRA encompasses *occupational asthma* (OA), which is asthma caused by a specific agent at the workplace, and *work-exacerbated asthma* (WEA), which corresponds to asthma exacerbated by, but not caused by, nonspecific stimuli in the workplace[2] (Fig. 100.1). WRA is prevalent; the Centers for Disease Control estimates that among the 9% of adults with asthma, 15.7% have work-related cases. This proportion of adults with WRA varies according to state from 9–23%.[3]

OA includes two main entities: sensitizer-induced OA and irritant-induced asthma. Several definitions of OA have been proposed. The American College of Chest Physicians defines OA as follows[4]:

…de novo asthma or the recurrence of previously quiescent asthma (i.e., asthma as a child or in the distant past that has been in remission) induced by either sensitization to a specific substance (e.g., an inhaled protein [high-molecular-weight protein of >10 kd] or a chemical [low-molecular-weight agent]), at work, which is termed sensitizer-induced OA, or by exposure to an inhaled irritant at work, which is termed irritant-induced OA.

Sensitizer-induced OA has also been defined as "asthma with a latency period," suggesting the presence of an underlying immunologic mechanism responsible for a latency period from the beginning of the occupational exposure to the onset of asthma symptoms.[5]

Irritant-induced (occupational) asthma (IIA), also called OA without a latency period or nonimmunologic OA, encompasses a wide spectrum of asthma phenotypes related to irritant mechanisms, as opposed to OA caused by immunologic mechanisms. The rapid onset of asthma within a few hours after a single exposure to very high levels of irritant substances (i.e., acute-onset IIA or *reactive airways dysfunction*

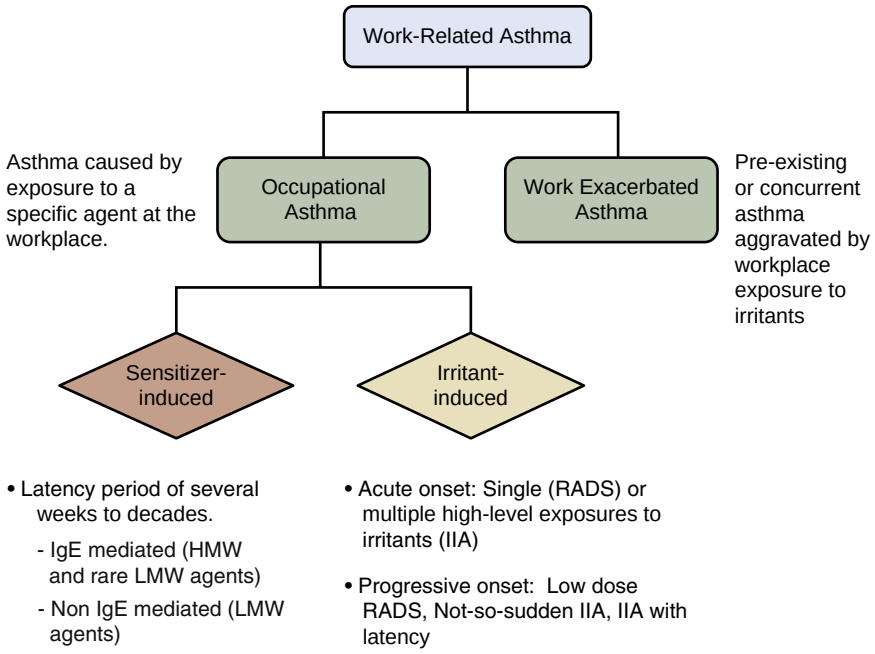

Figure 100.1 Categorization of work-related asthma into subsets based on the cause and timing of the asthma. HMW, high molecular weight; IgE, immunoglobulin E; IIA, irritant-induced (occupational) asthma; LMW, low molecular weight; RADS, reactive airway dysfunction syndrome.

syndrome (RADS) is the best characterized phenotype of IIA, whereas other clinical phenotypes (e.g., low-dose reactive airways dysfunction syndrome, not-so-sudden IIA, or IIA with latency)[6-11] are mainly described in epidemiologic studies because the causal relationship with workplace irritant exposures is difficult to establish at the individual level.

WEA has received growing attention. The latest definition of WEA was proposed by the American Thoracic Society Task Force on Work-Exacerbated Asthma[2] and consists of four criteria:

- There is preexisting or concurrent asthma. The asthma may have begun either before the current employment or while at the worksite of interest, but it was not caused by specific exposures within that workplace.
- An increased frequency of asthma symptoms, medication use, or health care use is temporally associated with work. Medical test results may document more frequent abnormalities.
- Workplace exposures or conditions exist that can exacerbate asthma.
- OA (asthma caused by a specific, identified workplace exposure) is unlikely.

In spite of these clear definitions, differentiating those conditions is often difficult in clinical practice. An accurate diagnosis is crucial because the diagnosis of this condition can result in a change of career and/or financial compensation. This chapter reviews the epidemiology, pathophysiology, diagnosis, management, prevention, and socioeconomic impacts of sensitizer-induced OA, IIA, and WEA.

SENSITIZER-INDUCED OCCUPATIONAL ASTHMA

EPIDEMIOLOGIC ASPECTS

Estimates of the frequency of OA have been derived from various sources, including cross-sectional and longitudinal studies of high-risk workforces, occupational disease registries, voluntary notification programs, and population-based surveys. A pooled analysis of data published up until 2007 indicated that 17.6% of all adult-onset asthma is attributable to workplace exposures.[12]

Cross-sectional surveys of workforces exposed to sensitizing agents reported highly variable prevalence rates of OA, but these estimates were largely affected by the criteria used to identify the disease and by selection biases. Prospective cohort studies reported incidence rates ranging from 1.8 to 4.1 cases of OA per 100 person-years among workers exposed to laboratory animals,[13] wheat flour,[14] and latex gloves.[15] Incidence rates derived from notification schemes and compensation statistics in various countries ranged from 24 to 174 new cases per million active workers per year.[16-22] Differences from one country to another may result from geographic differences in industrial activities, as well as from the heterogeneity in diagnostic criteria and in data collection procedures.

The European Community Respiratory Health Survey II provided higher estimates of 250 to 478 incident cases of work-attributable asthma per million people per year.[23,24] These data suggest that the disease remains largely unrecognized, although population surveys are affected by the lack of confirmation of OA through objective tests.

Assessing mortality related to WRA is challenging because WRA does not usually have a specific *International Classification of Diseases* (ICD) code.[25]

CAUSAL AGENTS

Many substances (more than 400) used at work can cause sensitizer-induced OA.[26] They are usually categorized as *high-molecular-weight* (HMW) or *low-molecular-weight* (LMW) agents (Table 100.1). HMW agents are (glyco)proteins originating from plants and animals, whereas LMW agents include chemicals, metals, and wood dusts. The intrinsic characteristics of occupational agents that determine their sensitizing potential remain largely uncertain. However, LMW agents causing OA are typically highly reactive electrophilic compounds capable of combining with hydroxyl, amino, and thiol

Table 100.1 Principal Agents Causing Occupational Asthma

Agent		Occupation or Industry
HIGH-MOLECULAR-WEIGHT AGENTS		
Cereals, flour	Wheat, rye, barley, buckwheat	Flour mills, bakers, pastry makers
Latex	Proteins from the *Hevea* tree	Health care workers, laboratory technicians
Animals	Mice, rats, cows, seafood	Laboratory workers, farmers, seafood processing
Enzymes	α-Amylase, maxatase, alcalase, papain, bromelain, pancreatin	Baking product production, bakers, detergent production, pharmaceutical industry, food industry
LOW-MOLECULAR-WEIGHT AGENTS		
Isocyanates	Toluene diisocyanate, methylene diphenyldiisocyanate, hexamethylene diisocyanate	Polyurethane production, plastic industry, insulation, molding, spray painting
Metals	Chromium, nickel, cobalt, platinum	Metal refinery, metal alloy production, electroplating, welding
Biocides	Formaldehyde, glutaraldehyde, quaternary ammonium compounds	Health care workers, cleaners
Persulfate salts	Hair bleach	Hairdressers
Acrylates	Cyanoacrylates, methacrylates, diacrylates, and triacrylates	Adhesives, dental and orthopedic materials, sculptured fingernails, printing inks, paints and coatings
Acid anhydrides	Phthalic, trimellitic, maleic, tetrachlorophthalic anhydrides	Epoxy resin workers
Reactive dyes	Reactive black 5, pyrazolone derivatives, vinyl sulfones, carmine	Textile workers, food industry workers
Woods	Red cedar, iroko, obeche, oak, and others	Sawmill workers, carpenters, cabinet and furniture makers

functionalities on airway proteins. Quantitative structure-activity relationship models have identified certain reactive groups associated with a high risk of respiratory sensitization (e.g., isocyanate [N=C=O], carbonyl [C=O], and amine [NH_2]), particularly when two or more groups are present within the same molecule.[27]

Actually, a handful of agents (i.e., flour, diisocyanates, latex, persulfate salts, aldehydes, animals, wood dusts, metals, and enzymes) usually account for the majority (50–90%) of reported cases of OA.[22,28] A large European multicenter study reported the frequency of OA attributed to those occupational agents in Europe (Table 100.2).[29] Nevertheless, the distribution of causal agents may vary widely across geographic areas, depending on the pattern of industrial activities.[16-22] The highest incidence of OA is seen in bakers and pastry makers, other food processors, spray painters, hairdressers, wood workers, health care workers, cleaners, farmers, laboratory technicians, and welders.

PATHOPHYSIOLOGY

The pathophysiology of sensitizer-induced OA often involves an *immunoglobulin E* (IgE)–dependent mechanism. This mechanism is encountered mainly with HMW agents. Although specific IgE has also been encountered in OA caused by some LMW agents (e.g., platinum salts, trimellitic anhydride, and other acid anhydrides), the production of specific IgE antibodies or the up-regulation of IgE receptors has not been identified in the majority of cases of OA induced by LMW agents.[30]

Immunologic, Immunoglobulin E–Mediated Occupational Asthma

The pathophysiology of OA induced by IgE-dependent agents is similar to allergic asthma unrelated to work. HMW agents are proteins; they act as complete antigens and induce the production of specific IgE antibodies. Subepithelial immature dendritic cells residing within the airway walls take up the antigen and migrate to the regional lymph nodes for maturation. They express antigenic peptide on their surface in conjunction with major histocompatibility complex type II molecules. Dendritic cells interact with $CD4^+$ T cells expressing high-affinity receptors for the antigen–major histocompatibility complex II complex. Type 2 T helper (Th2) cells, attracted by chemokines, eventually reach the airways. With future exposures in the airways, CD4 T cells may react to antigen presentation,[31] thereby releasing *interleukin* (IL)-4, IL-5, and IL-13. With help from Th2 cells, B cells switch isotype and produce IgE. IgE binds to a number of cells through both high- and low-affinity receptors. On subsequent exposure to an antigen, mast cells and basophils release mediators inducing bronchospasm and airway inflammation.

LMW occupational agents are less likely to induce specific IgE antibodies because they act as haptens and have to bind with proteins to form functional antigens. OA caused by platinum salts or anhydride acid is clearly IgE mediated. Demonstrating the presence of specific IgE to platinum salts or anhydride acid is useful in the diagnosis of OA related to those agents. In contrast, the role of specific IgE is still controversial in isocyanate-induced asthma.[32] The presence of specific IgE to isocyanates seems a good predictor of isocyanate-induced OA (specificity, 89–100%),[4] whereas specific *immunoglobulin G* (IgG) seem to be mostly associated with exposure to isocyanates.[33] However, whether isocyanate-induced asthma is an IgE-mediated disease is still a matter of debate.[32]

Immunologic, Non–Immunoglobulin E–Mediated Occupational Asthma

Cell-mediated reactions are probably important in OA caused by LMW agents. The predominant immune response to chemical respiratory allergens may be of the Th2 type, but other cells are also likely to play important supportive or regulatory roles. CD4 and $CD8^+$ T cells, as

Table 100.2 Frequency of Agents Causing Sensitizer-Induced Occupational Asthma According to a Large European Multicenter Study

HMW Agents	n (%)*	LMW Agents	n (%)*
Flour/grains	369 (31.3)	Isocyanates	206 (17.4)
Latex	36 (3.0)	Persulfate salts	78 (6.6)
Enzymes	26 (2.2)	Metals	42 (3.6)
Storage mites	12 (1.0)	Quaternary ammonium compounds	38 (3.2)
Rodents	11 (0.9)	Acrylate compounds	35 (3.0)
Cow dander	11 (0.9)	Wood dusts	35 (3.0)
Fish and seafood	8 (0.7)	Welding fumes	30 (2.5)
Insects and derived products	6 (0.5)	Cleaning products or disinfectants (NOS)	27 (2.3)
Ornamental plants	6 (0.5)	Epoxy resins	18 (1.5)
Molds	5 (0.4)	Aldehydes	17 (1.4)
Soybean flour	3 (0.2)	Drugs	16 (1.4)
Spices	3 (0.2)	Metalworking fluids	15 (1.3)
Vegetable gums	3 (0.2)	Resins, glues, or paints (NOS)	15 (1.3)
Various plant-derived products	26 (2.2)	Acid anhydrides	11 (0.9)
Various animals and derived products	18 (1.5)	Amines	10 (0.8)
		Colophony	4 (0.3)
Total:	543 (46.5)	Styrene	3 (0.2)
		Reactive dyes	2 (0.2)
		Triglycidyl isocyanurate	2 (0.2)
		Other low-molecular-weight agents (NOS)	21 (17.8)
		Total:	624 (52.9)

*Percentage of total identified agents ($n = 1167$); the causal agent was not precisely identified in 13 subjects.
HMW, high molecular weight; LMW, low molecular weight; NOS, not otherwise specified.
From Vandenplas O, Godet J, Hurdubaea L, et al. Are high- and low-molecular-weight sensitizing agents associated with different clinical phenotypes of occupational asthma? *Allergy*. 2019;74:261-272.

well as different cytokines such as IL-1, IL-4, IL-5, IL-6, and IL-15, have been found in biopsy specimens,[34] bronchoalveolar lavage samples, and the sputum of patients with isocyanate-induced asthma.[33] In murine models of toluene diisocyanate "asthma," the presence of both CD4 and CD8 cells seems necessary to produce airway hyperresponsiveness and Th2-type inflammation. IL-4 and IL-13 are major determinants of the pathobiology. Innate lymphoid cells and lineage negative cells contribute to type 2 cytokine production in the airways in response to nonallergenic stimuli. Although few in number, these type 2 innate lymphoid cells may produce significant quantities of IL-5 and IL-13.

IL-13 has the ability to affect epithelium, smooth muscle, and immune cells, and it may possibly drive allergic asthma or even irritant-induced asthma. Neutrophils are also likely to be involved in isocyanate-induced asthma, as shown by an increase in myeloperoxidase and IL-8 after exposure to toluene diisocyanate.[35] Mixed Th1-Th2 cytokine production has been observed in subjects with red cedar–induced asthma.[36] Furthermore, a specific inhalation challenge test induced a mixed Th2/Th1 response in which $CD8^+$ cells were the main producers of interferon-γ.[37]

Isocyanates may stimulate human innate immune responses by up-regulating immune pattern-recognition receptors of monocytes and increasing the chemokines that regulate monocyte and macrophage trafficking (macrophage migration inhibitory factor, monocyte chemoattractant protein-1).[38]

RISK FACTORS

OA results from the complex interaction between environmental and individual susceptibility factors (Table 100.3).[28]

Environmental Factors

The intensity of exposure to sensitizing agents is currently the best identified and the most important environmental risk factor for the development of OA. Strong evidence supports a dose-response relationship between the level of exposure to HMW agents and the development of IgE-mediated sensitization and OA. Such a dose-response relationship has also been documented for some LMW agents, such as platinum salts, acid anhydrides, and isocyanates. Exposure-response relationships may be affected by individual susceptibility factors and the timing of exposure. For instance, the role of genetic susceptibility markers, such as certain *human leukocyte antigen* (HLA) class II alleles, may become more apparent at low levels of exposure to occupational agents.[39] The incidence of WRA symptoms is consistently higher within the first 1 to 4 years of exposure to HMW agents, and exposure-response gradients are more clearly documented in this early period of exposure.[13]

Cigarette smoking can increase the risk of IgE-mediated sensitization to some HMW and LMW agents, but the evidence supporting an association between smoking and the development of clinical OA is still weak. The role of other environmental cofactors, such as nonrespiratory routes of exposure and concomitant exposure to endotoxin and pollutants at work, remains largely uncertain.

Host-Related Factors

Atopy has been consistently demonstrated to be an important host risk factor for the development of IgE sensitization and OA, but only for HMW agents. Preexposure sensitization to common allergens structurally related to workplace allergens, such as exposure to pets in laboratory animal workers, could be a stronger risk factor for OA than atopy.

Table 100.3 Potential Risk Factors for Occupational Asthma

Risk Factor	Evidence	Agents or Settings
ENVIRONMENTAL FACTORS		
High level of exposure	Strong	HMW agents
	Moderate	LMW agents: platinum salts, acid anhydrides, isocyanates
Cigarette smoking	Moderate	For IgE sensitization: laboratory animals, snow crab, prawn, salmon, psyllium, green coffee, enzymes, acid anhydrides, platinum, reactive dyes
	Weak	For clinical OA: laboratory animals, enzymes
Skin exposure	Weak	Isocyanates
HOST-RELATED FACTORS		
Atopy	Strong	HMW agents
	Weak	LMW agents: platinum, acid anhydrides
Genetic markers:		
HLA class II alleles	Moderate	LMW agents: isocyanates, red cedar, acid anhydrides, platinum salts HMW agents: laboratory animals, latex
Antioxidant enzymes*	Moderate	Isocyanates
SNPs of alpha-T catenin	Moderate	Isocyanates
TLR4 polymorphisms	Weak	Laboratory animals
IL-4 receptor alpha and IL-13 polymorphisms	Weak	Isocyanates
Preexisting nonspecific bronchial hyperresponsiveness	Moderate	HMW agents: laboratory animals, flour, latex
Work-related rhinitis	Strong	Laboratory animals
Sex (female)	Weak	Snow crab processors

*Glutathione-S-transferase and N-acetyltransferase.
HLA, human leukocyte antigen; HMW, high molecular weight; IgE, immunoglobulin E; IL, interleukin; LMW, low molecular weight; OA, occupational asthma; SNPs, single nucleotide polymorphisms, TLR4, toll-like receptor-4.

Prospective cohort studies suggest that the presence of nonspecific bronchial hyperresponsiveness[40,41] and rhinitis[41,42] before exposure to HMW occupational agents is an independent risk factor for subsequent IgE sensitization to these allergens. Conversely, strong evidence indicates that the development of occupational rhinitis during exposure is associated with an increased risk for the development of OA.[43,44] However, the proportion of persons with occupational rhinitis who will develop OA remains unknown. Among workers exposed to laboratory animals, the predictive value of work-related nasal symptoms on the subsequent development of probable OA was only 11.4% over a follow-up period of 30 to 42 months.[45]

Certain HLA class II molecules (i.e., HLA-DR, HLA-DQ, and HLA-DP alleles), which are involved in the presentation of processed antigens to T lymphocytes, were found to confer either susceptibility to or protection against OA caused by various LMW and HMW occupational allergens.[46] There is also some suggestion that genes associated with Th2-cell differentiation (i.e., polymorphism of the IL-4 receptor alpha-chain, IL-13, and CD14 [C159T] genes) could play a role in the development of OA. Genes involved in the protection against oxidative stress, such as *glutathione-S-transferase* (GST) and *N*-acetyltransferase, have been associated with an increased risk of isocyanate-induced OA (i.e., GSTM1 null genotype and slow *N*-acetylator phenotypes) or a protective effect (i.e., GSTP1*Val/Val allele).[47] Overall, the currently available information indicates that genetic markers have a low predictive value in identifying susceptible workers. In addition, there is convincing evidence that a wide variety of environmental factors can interact with genetic determinants to affect disease susceptibility.

DIAGNOSIS

The diagnosis of OA is difficult to establish. A comprehensive and integrated approach, including the assessment of occupational history, clinical symptoms, and functional and inflammatory characteristics at baseline and in response to exposure to occupational agents, is needed to achieve an accurate diagnosis. This approach is summarized in Figure 100.2. Each step of the investigation has substantial limitations that may be avoided by combining several tests.[48] The validity of the different diagnostic tests and their practical limitations and advantages are summarized in Table 100.4.

OA should be suspected in every adult with new-onset asthma. Although the respiratory symptoms (e.g., wheezing, dyspnea, chest tightness, cough, and sputum production) are similar to those encountered in *non–work-related asthma* (NWRA), in OA, their appearance and severity are usually modulated by the work exposure. The symptoms can start at the beginning of the work shift or toward its end or even after work, with remission or improvement during weekends and holidays. Rhinitis is associated with respiratory symptoms in the majority of cases of OA and often precedes the respiratory symptoms, especially with exposure to HMW agents. Although a thorough clinical and occupational history must be carefully recorded, the diagnosis of OA cannot be made only on the basis of a compatible history, which has a low positive predictive value.[49] Some clinical characteristics seem to be associated predominantly with exposure to HMW compared with exposure to LMW agents. For example, atopy, work-related rhinitis, conjunctivitis, and an immediate asthmatic reaction seem to be the hallmarks of OA caused by HMW agents, whereas chest tightness, sputum production, and a late asthmatic reaction are more common in patients with OA caused by LMW agents.[50]

A good occupational history must detail not only current employment and exposure, but also past employments and exposures. Work history (current and past employments), symptoms (nature and temporal relationship with work), and potential risk factors need to be recorded.[51] The substances to which the worker is potentially exposed at work can be checked against a comprehensive list of

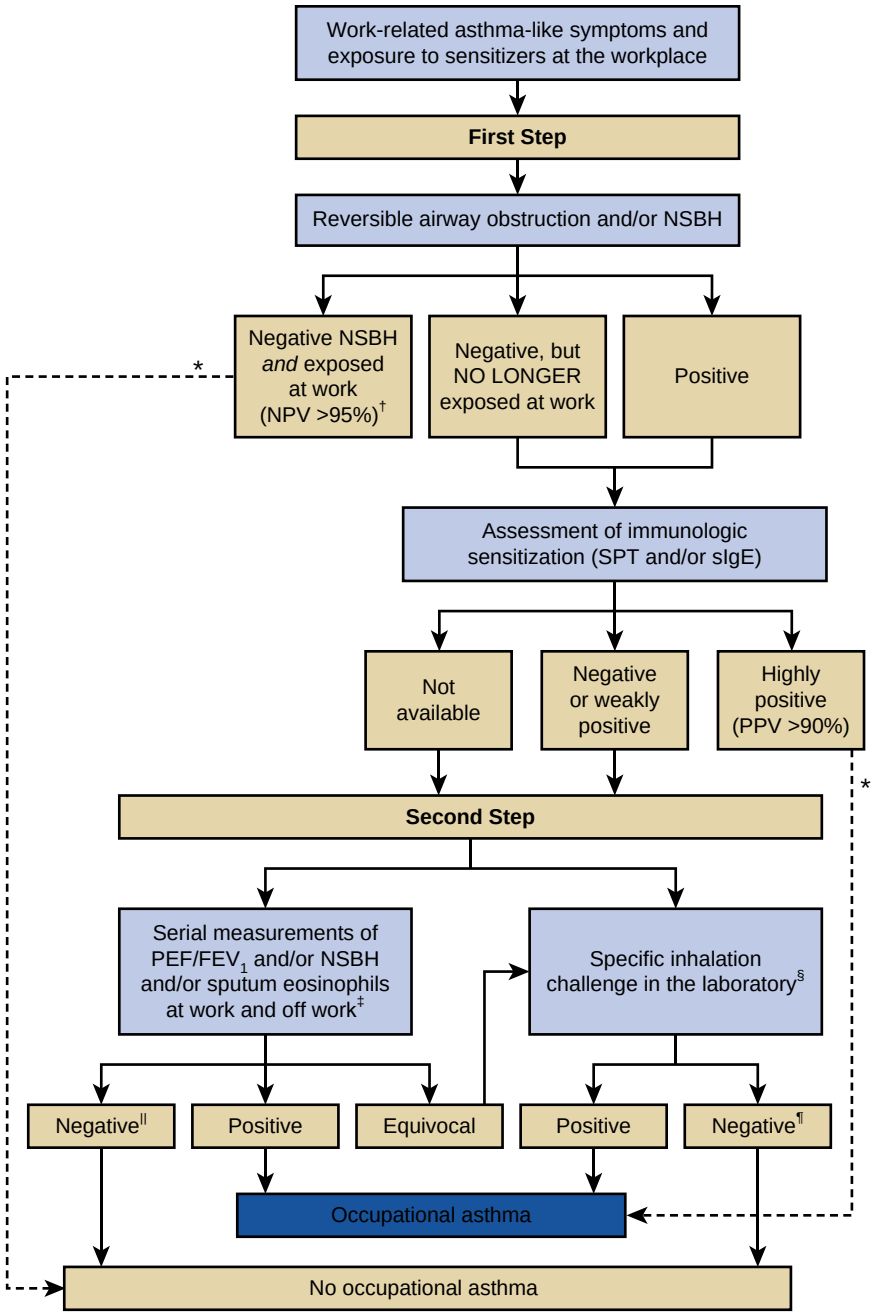

Figure. 100.2 Diagnostic approach to the investigation of sensitizer-induced occupational asthma. *High *negative predictive value* (NPV) and *positive predictive value* (PPV) have been established in selected populations with a high pretest probability of occupational asthma and may be applicable only in those populations. †Consider assessing sputum eosinophil counts to identify occupational asthma. ‡Especially useful when the patient is exposed to multiple potential sensitizers at work and no agent known to cause occupational asthma has been identified at work, specific inhalation challenge is not easily available, or the conditions of exposure at work cannot be reproduced in the laboratory. §Especially useful when specific inhalation challenge can be performed efficiently and safely, the patient is no longer exposed at work, the highest level of diagnostic accuracy is required, there is a need to identify a particular agent, and peak expiratory flow rate records are inconclusive. ‖Consider specific inhalation challenge if the clinical history is highly suggestive of occupational asthma. ¶Consider workplace inhalation challenge if the clinical history is highly suggestive of occupational asthma. FEV_1, forced expiratory volume in 1 second; NSBH, nonspecific bronchial hyperresponsiveness; PEF, peak expiratory flow; sIgE, serum-specific immunoglobulin E; SPT, skin prick test.

agents recognized as causing OA, and the person's employment can be searched on the list of at-risk occupations.[4] Material safety data sheets can be requested from the workplace and may be of help in clarifying the presence of a workplace sensitizer. However, if the content of the causal agent is less than 1%, it may not be listed. If available, the occupational health record and the industrial hygiene record from the company should also be reviewed. A list of agents responsible for OA can be found at https://www.csst.qc.ca/en/prevention/reptox/occupational-asthma/Pages/occupational-asthma.aspx. A list of occupations in which exposure to those agents is encountered can be found at https://www.csst.qc.ca/en/prevention/reptox/occupational-asthma/Documents/Occupational%20Asthma%20-%20Agents%20by%20occupation.pdf.

Once the history has been obtained, the diagnosis of asthma should be confirmed by documenting reversible airflow limitation and/or airway hyperresponsiveness. However, the lack of airway hyperresponsiveness does not exclude the diagnosis of OA in persons who have been removed from exposure.

Assessing airway responsiveness is an important step in the investigation of OA. Finding airway hyperresponsiveness can confirm the diagnosis of asthma; finding a reduction of airway hyperresponsiveness after a period away from work can support the diagnosis of OA. Normal airway responsiveness after a period at work at which time the workers experience their respiratory symptoms makes the diagnoses of OA and asthma improbable. The negative predictive value of normal airway responsiveness for OA while the worker is exposed to the offending agent at the workplace has been reported to be as high as 98%.[52] In this case, an alternative diagnosis should be investigated.[4]

Table 100.4 Advantages and Limitations of Diagnostic Tests for Occupational Asthma

Diagnostic Tests	Advantages and Limitations
Assessment of nonspecific bronchial hyperresponsiveness	■ Simple, low cost ■ Confirms the diagnosis of asthma ■ Low specificity for diagnosis of OA. The absence of airway hyperresponsiveness does not exclude the diagnosis of OA in patients who have been removed from the workplace
Immunologic tests	■ Easy to perform, low cost ■ Commercial extracts are available (skin prick tests or specific IgE for HMW agents) ■ Measurement of specific IgE available for some LMW agents (anhydrides, acids, isocyanates, aldehydes) but low sensitivity ■ Lack of standardization for most occupational allergens except for latex ■ Can identify the sensitization but not necessarily the disease
PEF monitoring	■ Low cost ■ Requires workers' collaboration ■ Low adherence (<60%) ■ Possible falsification of results ■ Requires 2 weeks at and away from work (not always possible) ■ Impossible to perform when the worker has been removed from work ■ No standardized method for interpreting the results ■ Interpretation of the results requires experience
Specific inhalation challenges in the laboratory	■ Confirmation of the diagnosis of OA when test result is positive ■ False-negative test results are possible ■ Costly ■ Available in only a few centers worldwide
Specific inhalation challenges at the workplace	■ Exclude diagnosis if negative when performed in the usual work conditions ■ Require usual work conditions ■ Costly
Noninvasive measures of airway inflammation	Sputum cell counts ■ Impossible to falsify ■ Bring additional evidence to the diagnosis of OA ■ Costly ■ Not widely available ■ Does not allow confirmation or exclusion of the diagnosis of OA by itself Exhaled NO ■ Easy to perform ■ Inconsistent results ■ Difficult to interpret ■ Affected by many different factors

HMW, high molecular weight; IgE, immunoglobulin E; LMW, low molecular weight; NO, nitric oxide; OA, occupational asthma; PEF, peak expiratory flow.

Immunologic testing is useful in demonstrating sensitization of the worker to the suspected agent. Although the negative predictive value of these tests is high in the case of HMW, these tests are limited by the lack of standardized commercially available reagents for skin and in vitro tests. Skin prick tests are seldom useful when LMW agents are suspected.[53]

The work relatedness of asthma should be assessed through two additional tests: serial measurements of *peak expiratory flow* (PEF) and/or nonspecific bronchial hyperresponsiveness at work and off work and/or specific inhalation challenges in the laboratory or at the workplace.

Serial measurement of PEF at work and away from work has been found to be useful in confirming OA.[51] The minimum period of PEF monitoring should be 2 weeks at work with a significant exposure to the suspected causative agent and a similar period away from work, unless significant changes are recorded earlier at work. However, a study using analytic software showed that reasonable sensitivity and specificity can be achieved within a shorter period of time.[54] Asthma treatment should be kept constant throughout the period of monitoring. However, as in common asthma, compliance with PEF monitoring has been shown to be poor, and the results may be falsified if an electronic PEF meter is not used.[55,56]

Specific inhalation challenge tests consist of exposing the subjects to the suspected occupational agent in the laboratory and/or at the workplace.[57,58] These tests are considered the reference tests, but they are time-consuming and require specialized facilities available in only a few centers. Specific inhalation challenge tests are useful when (1) the diagnosis of OA remains in doubt after serial monitoring of PEF or airway responsiveness, (2) a patient clearly has OA but the causal agent needs to be identified, (3) a new agent is suspected of causing OA, and (4) the patient cannot be returned to the incriminated workplace. A false-negative response may be obtained if the wrong agent is used or if the exposure conditions are not comparable to those in the workplace.

Noninvasive Measures of Airway Inflammation

Noninvasive measures of airway inflammation are increasingly used during the investigation of OA.

Although there is limited evidence in the literature, the eosinophil count in the peripheral blood does not seem to be an effective tool to aid the diagnosis of OA.[59] However, the percentage of eosinophils in *sputum* increases during periods at work and decreases after removal from exposure in subjects with OA.[60,61] In settings where this tool is available, sputum eosinophil counting complements the

investigation of OA during the investigation both at and away from the workplace in addition to serial PEF measurement, as well as during specific inhalation challenges before and after exposure to the offending agent.

Although the measurement of *fractional exhaled nitric oxide* (FeNO) is easier to obtain than sputum differential cell counts, the current evidence does not show a clear benefit of using FeNO in the investigation of OA.[62] The interpretation of increased FeNO is more difficult than that of sputum differential cell counts because of the lack of specificity, as well as the potential confounding factors that may influence the results (i.e., inhaled corticosteroid treatment, smoking). However, evidence shows a high specificity of FeNO in subjects exposed to HMW agents.[63] The use of FeNO may be more useful in patients exposed to HMW agents where an IgE-dependent reaction is involved.[64]

The predictive values of those tests at baseline, while the patient is not exposed to the offending agent, is modest at best. The combination of several biomarkers improves the accuracy of the diagnosis of OA. The combination of sputum eosinophil differential cell counts[59,65] or FeNO levels[65] with measurement of airway responsiveness improves the sensitivity of the methacholine or histamine challenge alone. The combination of the changes in sputum eosinophil differential cell counts and airway responsiveness after exposure to the offending agents improves the diagnostic accuracy for the diagnosis of OA.[59]

OUTCOME AND MANAGEMENT

According to systematic reviews of the existing data, complete avoidance of exposure to the causal agent remains the optimal treatment of sensitizer-induced OA.[66,67] Although a reduction of exposure to the agent can be considered an alternative option, the limited available evidence indicates that this option is less beneficial than complete cessation of exposure because it is associated with a lower likelihood of asthma improvement and a higher risk of asthma worsening.[68,69]

Immunotherapy has been tested only in workers with allergy and/or OA to HMW agents for which an IgE-dependent reaction has been demonstrated, mainly in health care workers allergic to latex.[70] Although immunotherapy can reduce cutaneous and respiratory symptoms in health care workers allergic to latex, this treatment can induce systemic reactions in a large number of treated subjects.[71] Small or uncontrolled studies have reported an improvement of allergic and respiratory symptoms after immunotherapy to some selected agents (cereal,[72] sea squirt,[73] laboratory animal,[74] and wood[75]). However, whether immunotherapy can alter the course of OA in the long term remains to be determined. Further studies need to be conducted before immunotherapy can be recommended for the treatment of OA to HMW agents.

A few case reports have suggested that treatment with the anti-IgE agent omalizumab could improve asthma control in subjects with flour-induced OA who remain exposed to the causal work environment, although further prospective investigations are required in persons who choose to continue exposure.[4]

Clinicians should be aware that OA is not always reversible after cessation of exposure to the sensitizing agent. Asthma symptoms and airway hyperresponsiveness persist in approximately 70% of the patients with OA even several years after removal from the offending environment.[76] Besides environmental interventions, the pharmacologic treatment of OA should follow the clinical practice guidelines for asthma.

PREVENTION

Primary prevention aims at preventing the development of immunologic sensitization to workplace agents and subsequent OA.[4,77] Primary preventive strategies should focus on the control of workplace exposures because strong evidence supports a dose-response relationship between the level of exposure to sensitizing agents and development of OA. The control of exposure can be achieved through a panel of measures that include the elimination of agents with a known sensitizing potential whenever feasible: (1) the modification of sensitizing materials (e.g., encapsulation of detergent enzymes), (2) the substitution of highly sensitizing agents by materials with lower asthmagenic potential (e.g., nonvolatile oligomers of diisocyanates, latex gloves with a lower content in powder and protein allergens), (3) engineering changes to the workplace (e.g., exhaust ventilation, enclosure of industrial processes), (4) information and education of workers and employers on safe work practices, and (5) the use of personal protective equipment for specific tasks.[78,79] Another approach is to identify susceptible individuals at the time of preemployment examination and exclude them from employment or from high-risk jobs. However, this strategy is inefficient and unduly discriminatory because the currently identified markers of individual susceptibility (see Table 100.3) offer only a low positive predictive value for the development of OA, especially when these markers, such as atopy, are highly prevalent in the general population.[4] Nevertheless, physicians caring for adolescents with asthma and allergic diseases may offer useful advice regarding careers in which their underlying atopic status increases the risks for work-related sensitization to HMW agents.[80]

Secondary prevention of sensitizer-induced OA involves the detection of the disease process at an early (preferably preclinical) stage to modify the disease process through appropriate interventions to eliminate exposure. The rationale underlying secondary prevention is the consistent finding that the outcome of OA is better with an early diagnosis and with milder disease at the time of removal from exposure.[75,81] Increasing awareness of the disease among workers and health professionals is a key step to enhance the recognition of OA because the condition still remains underdiagnosed and inappropriately investigated.[82] Evidence indicates that appropriately designed surveillance programs are effective in identifying OA in persons with less severe asthma, thereby leading to a more favorable outcome.[83]

A few observational studies and historical data indicate that prevention is effective in reducing the incidence of OA and occupational rhinitis caused by natural rubber latex in health care workers,[84] enzymes in the detergent industry,[85] flour,[86] laboratory animals,[87] and isocyanates.[83] However, available data do not distinguish among the relative effects of the diverse components of prevention strategies, given that they are usually implemented as multicomponent

programs targeting education, control of exposure, and medical surveillance.

SOCIOECONOMIC IMPACT

Studies worldwide have shown that OA is associated with substantial financial consequences for affected workers and society as a whole.[88,89] Growing evidence indicates that WRA is associated with more severe asthma,[90-92] and with higher health care resource use,[93] as compared with asthma unrelated to work. In addition, OA generates higher indirect costs than asthma that is not OA because OA most often requires job changes either to avoid or to reduce exposure to the causative agent.[94] Follow-up studies of workers with OA have consistently documented that the condition is associated with a high rate of prolonged unemployment, ranging from 18–69%, and a reduction in work-derived income in 44–74% of affected workers.[95] A poorer socioeconomic outcome is associated with the need for complete avoidance of exposure to the sensitizing agent, a lower level of education, older age, and lack of effective job retraining programs.[95]

Because the specific bronchial hyperreactivity to occupational agents hardly ever completely disappears, workers with OA should be considered permanently and completely disabled for jobs involving exposure to the sensitizing agent that caused their OA.[96] They should be thoroughly informed about the possibilities for compensation, and established cases should be reported to the appropriate public health authorities, according to national regulations. Evaluation of physiologic impairment should consider the characteristic features of asthma and should be based on the level of airway obstruction, the degree of nonspecific bronchial hyperresponsiveness, and the intensity of medication required for controlling asthma.[4]

IRRITANT-INDUCED ASTHMA

EPIDEMIOLOGIC ASPECTS

Surveillance programs conducted in various countries have indicated that RADS and IIA account for 5–18% of all reported cases of WRA.[97] However, few population-based surveys have addressed the impact of acute inhalation incidents on the global burden of asthma. The longitudinal part of the European Community Respiratory Health Survey found that reported acute inhalation incidents were associated with a higher risk of new-onset asthma.[24] Several cross-sectional studies revealed that asthmatic individuals more often report a history of a single high-level exposure to irritant cleaning products than do healthy control subjects.[98-100] A longitudinal study of rescue and recovery workers exposed to high levels of alkaline dust during and after the World Trade Center disaster showed an increased risk of new-onset asthma in the follow-up period of 5 to 6 years, particularly in the first months after exposure.[101]

Longitudinal workforce-based studies have documented an increased risk of asthma among workers with repeated exposures to high levels of chlorine, ozone, and sulfur dioxide in metal production and among pulp mill workers.[102-104] Exposures to high levels of irritants in the workplace are called "gassings" and are often recalled by workers in epidemiologic studies. Few epidemiologic studies have supported the role of repeated and/or long-term exposure to lower levels of irritant compounds at work in the development of asthma, except for workers exposed to cleaning agents.[105] In these workers, the frequent use of chlorine bleach and ammonia has been associated with an increased risk of asthma.[98] A spectrum of exposures to irritant agents is likely to induce different clinical presentations of asthma ranging from RADS, when workers are exposed to high concentrations of irritants, to "low-dose reactive airways dysfunction syndrome," "not-so-sudden IIA," or "IIA with latency" when workers are exposed to irritants at lower concentrations. However, "low-level" IIA cannot currently be reliably diagnosed in the individual worker.

Table 100.5 Examples of Exposures Causing Acute Irritant-Induced Asthma

Exposure	Examples
Gases	Chlorine (e.g., released by mixing sodium hypochlorite with acids), chloramines (released by mixing sodium hypochlorite with ammonia), sulfur dioxide, nitrogen oxides, dimethyl, sulfate
Acids	Acetic, hydrochloric, hydrofluoric, hydrobromic acids
Alkali	Ammonia, calcium oxide (lime), hydrazine
Biocides	Formalin, ethylene oxide, fumigating agents, insecticides (sodium methyldithiocarbamate, dichlorvos)
Halogenated derivatives	Bromochlorodifluoromethane (fire extinguisher), trifluoromethane, chlorofluorocarbons (CFC, thermal degradation products of freons), uranium hexafluoride, hydrogen, and carbonyl fluoride
Solvents	Perchloroethylene
Fumes	Diesel exhaust, paint fumes, urea fumes, fire smoke, iodine compounds (iodine and aluminum iodide, hydrogen iodide), diethylaminoethanol (corrosion inhibitor)
Sprays	Paints (not specified), floor sealant (aromatic hydrocarbons)
Dusts	World Trade Center alkaline dust, calcium oxide (lime)
Potential sensitizers	Isocyanates, phthalic anhydride

PATHOPHYSIOLOGY

Several factors may influence the pulmonary responses to irritants, such as intensity of exposure, physical properties (e.g., vapor pressure and solubility), and chemical reactivity.[106] Although many irritants are odorous and pungent, it is worth remarking that odor is not related to toxicity. The resulting biologic effect depends on the deposition of the irritant in the upper and/or lower airways. Water-soluble irritants and particles with an aerodynamic diameter larger than 5 μm are predominantly deposited in the upper respiratory tract and proximal airways. Water-insoluble agents and particles measuring 0.5 to 5 μm can reach the distal airways and alveoli, often without causing much sensory irritation (see Chapters 13 and 103).

The development of acute IIA has been associated with a wide variety of high-level exposures to irritant fumes, gases, sprays, or even dusts (Table 100.5).[107] Typically, the

exposure is caused by spills of volatile compounds, accidental releases of irritants under pressure, accidental fire with release of complex mixtures of thermal degradation products, or inadvertent reduction of the air ventilation rate in a confined space.[106] The nature and concentrations of inhaled irritants generated during workplace exposure incidents are most often unavailable.

Inhaled irritants provoke epithelial cell damage and persistent inflammatory response and airway remodeling, although the precise pathophysiologic mechanisms leading to persistent asthma remain largely speculative.[106] Bronchial biopsy samples obtained after a high-level exposure to irritants revealed marked epithelial desquamation, inflammatory changes with predominance of lymphocytes, airway remodeling, and collagen deposition in the bronchial wall.[107,108] Similar changes have been described in animal models.[109-112] Two studies provided information on the long-term outcome of airway inflammation and remodeling in a large series of subjects with acute IIA.[109,113] Both studies showed an inflammatory profile similar to what has been described in sensitizer-induced OA after removal from exposure, with an increase of eosinophils in some patients or neutrophils in others. However, in patients with IIA, subepithelial fibrosis was more prominent than in patients with sensitizer-induced OA. Altogether, in IIA, the pathologic changes observed during the acute phase are consistent with an acute toxic injury, whereas those observed during the long-term phase are consistent with sensitizer-induced OA.

RISK FACTORS

The environmental and host factors that determine the initiation and persistence of IIA remain largely unknown. A relationship between the level of exposure assessed qualitatively by industrial hygienists and the prevalence of nonspecific bronchial hyperresponsiveness has been documented in subjects who had been exposed to a spill of acetic acid.[114] In a follow-up survey of pulp mill workers exposed to high levels of chlorine, the severity of gassing incidents, as evidenced by hospital *emergency department* (ED) visits, was a more significant risk factor for the persistence of nonspecific bronchial hyperresponsiveness than was the number of incidents.[115] The development of IIA did not appear to be associated with smoking and atopy.[114,115] Among the World Trade Center rescue and cleaning workers, the main risk factors for the development of a respiratory disease were the presence on the site during the first 48 hours and the duration of exposure during rescue and cleaning.[116] Smoking was a predisposing or an additive risk factor, whereas atopy was identified as a risk factor for upper, but not lower, airway disease.

DIAGNOSIS

RADS (i.e., acute IIA) is characterized by the onset of asthma symptoms within 24 hours after a single, most often accidental, high-level exposure to a wide variety of irritant substances in subjects without preexisting asthma. Brooks and coworkers proposed stringent clinical and functional criteria for the diagnosis of this condition (Table 100.6).[4,117] The presence of asthma should be substantiated by spirometry demonstrating airflow limitation with a significant bronchodilator response or nonspecific bronchial hyperresponsiveness to methacholine or histamine. Conditions with similar clinical manifestations, such as irritant-induced vocal cord dysfunction, should be carefully considered.[4] The causal role of the workplace exposure can be documented with a reasonable level of confidence by the strong temporal association between an inhalation accident and the rapid onset of asthma symptoms. Such cases should be considered as "definite" IIA. Nevertheless, the World Trade Center tragedy brought new insights by suggesting that asthma can develop insidiously over a few months after a massive exposure to a complex mixture of alkaline dust and combustion products.[118,119] In persons who reported multiple high-level exposures to irritants, although less clearly massive than those that cause RADS, the causal relationship can be supported by the documentation of repeated symptomatic inhalation accidents requiring medical care or of reports to first aid units or occupational health services. These subjects should be regarded as having "probable" IIA.

Table 100.6 Diagnostic Criteria for the Reactive Airways Dysfunction Syndrome (i.e., Acute-Onset Irritant-Induced Asthma)

Absence of preexisting asthma symptoms or a history of asthma in remission
Onset of asthma symptoms after a single specific inhalational exposure or accident
Exposure to an irritant vapor, gas, fume, or smoke in very high concentration
Onset of asthma symptoms within minutes to hours and less than 24 hours after the exposure
Presence of airflow limitation with a significant bronchodilator response or nonspecific bronchial hyperresponsiveness to histamine or methacholine
Exclusion of other pulmonary disorders that can explain the symptoms or simulate asthma

Modified from references 4, 106, 117.

Some clinical features clearly distinguish acute IIA from sensitizer-induced OA. Unlike sensitizer-induced OA, acute IIA does not require a latency period of exposure before the appearance of asthma, but an apparent latency period can be present in IIA that develops after multiple high-level exposures. Persons with IIA do not develop WRA symptoms after reexposure to low concentrations of the irritant that initiated the symptoms because they are not "sensitized" to the offending agent. However, persons with acute IIA may experience WRA symptoms because their nonspecific bronchial hyperresponsiveness makes them more susceptible to irritant stimuli at work. The development of specific bronchial hypersensitivity has been documented after a single, intense exposure to some LMW chemicals.[120] Conversely, known sensitizers can induce IIA when inhaled at very high concentrations.[121,122] In such instances, it may be difficult to differentiate sensitizer-induced OA from IIA; specific inhalation challenges with the suspected agent may be useful in distinguishing between those two conditions.

In clinical reports that described the onset of asthma after repeated, often daily exposure to "moderate" levels of respiratory irritants at work, the evidence supporting the work

relatedness of asthma was very weak and relied on the following findings: (1) a history of adult-onset asthma (or even the reactivation of a previously quiescent asthma[7]), (2) a history of repeated exposure to irritants, and (3) the absence of an identified sensitizer in the patient's working environment. Distinguishing IIA attributed to repeated, moderate level exposures from coincidental asthma that is not work related is difficult in any individual case. The possibility of "chronic–delayed-onset IIA" can be inferred only from epidemiologic studies documenting an increased risk of adult-onset asthma in certain occupations associated with frequent moderate-to-excessive exposures to irritant compounds.

OUTCOME AND TREATMENT

The outcome of IIA is thought to be quite similar to what has been described in patients with sensitizer-induced OA after avoidance of exposure to the causal agent. Nonspecific bronchial hyperresponsiveness can improve over several years after an acute symptomatic inhalation accident.[115,123] Over the long term, however, about three quarters of subjects with acute IIA show persistent nonspecific bronchial hyperresponsiveness and require treatment with inhaled corticosteroids.[124]

Limited data exist on the management of IIA, mainly from case reports of acute IIA.[125] There is some evidence that subjects with IIA benefit rapidly from treatment with oral and/or inhaled corticosteroids, although the dose and duration of treatment remain unknown. Unlike workers with sensitizer-induced OA, workers with acute IIA may be able to continue in their usual jobs with appropriate asthma management, although they may subsequently experience worsening of their asthma symptoms on exposure to irritants at work that may substantially reduce their capacity to work in polluted or dusty environments. The management of IIA may be further complicated by associated disorders, such as chronic rhinitis, perceived intolerance to multiple chemicals, and posttraumatic stress syndrome, which can result from an accidental exposure to irritant substances at work.[101,124,126]

PREVENTION

Prevention of IIA should be primarily aimed at eliminating the risk of high-level exposures that can cause asthma. Such strategies should be directed toward the control of exposures to safe levels by occupational hygiene measures such as containment and adequate ventilation. Continuous monitoring of airborne concentrations of potential respiratory irritants and alarm systems to detect peak exposures may be appropriate in some settings. An important component of prevention is the implementation of workers' educational programs on safe handling of chemicals, effective use of personal protective equipment, and measures to take in the event of an accident at work.

WORK-EXACERBATED ASTHMA

EPIDEMIOLOGIC ASPECTS

The prevalence of WEA reported in the literature varies according to the definition and the type of setting (clinical vs. epidemiologic) in which the WEA was assessed. Twelve studies provided overall estimates of prevalence of WEA.[127] These studies were conducted in the general population or in general health care settings in seven countries. The definition of asthma was not consistent and included physician-diagnosed asthma, as determined from self-reports or medical records, or a diagnosis based on an objective measurement of pulmonary function.[128,129] Some of the studies reported prevalence as a percentage of all adults with asthma, and others reported prevalence as a percentage of all working adults with asthma. The prevalence of WEA from these 12 studies ranged from 13–58% of adults with asthma, with a median of 21.5%. In the study where WEA was diagnosed according to changes in PEF between periods at and away from work, the prevalence of WEA was 14% in asthmatic workers.[130] The most recent systematic review of the literature estimated that 21.5% of the cases of asthma were exacerbated by conditions at the workplace.[2] Data from Michigan, Oregon, and Minnesota showed that 53% of the asthmatic adults surveyed reported that their work worsened or caused their asthma.[131] WEA was suspected in 41% of an Italian cohort of 893 asthmatic patients and in 50% of asthmatic patients exposed to gas, fumes, and dust.[132] Therefore, although the prevalence varies quite widely from one study to another because of the definition and the population of interest, the prevalence of WEA can be estimated to be approximately 20% of adults with asthma.

PATHOPHYSIOLOGY

The pathophysiology of WEA is likely to be largely dependent on the type of triggers inducing asthma exacerbations. There is no reason to believe that the pathophysiology of WEA is different from the pathophysiology of asthma exacerbations observed in NWRA when the triggers are common allergens. When triggers consist of irritant agents, the pathophysiology probably resembles what is seen in IIA. An airway epithelial injury is likely to play a pivotal role, and the intensity of the injury to the epithelial layer may be correlated with the respiratory function impairment, as demonstrated in New York firefighters who responded to the September 11 terrorist attacks.[133] In murine models of chlorine exposure, oxidative stress plays a pivotal role in the pathogenesis of this condition, and the administration of antioxidants can mitigate the epithelial damage.[134] Furthermore, chlorine exposure induces Th2 airway inflammation in ovalbumin-sensitized mice.[135,136] As shown in animal models of chlorine exposure, the extent of damage is likely to depend on the dose of the irritant agent inhaled.

WORK EXPOSURES ASSOCIATED WITH WORK-EXACERBATED ASTHMA

The exposures associated with WEA have been identified either in studies that recorded the agents to which the subjects with WEA were exposed in clinical settings, in surveillance programs, or in worker compensation programs or by using a risk-set approach, in which associations between occupational exposures and WEA were tested while controlling for potential confounders. The

studies assessing individual cases of WEA were performed mainly in North America[137-145] or in Europe.[146] The most commonly described agents were chemicals, dust, smoke, paints, and cleaning products. Although less frequently encountered than these agents, physical factors, such as exercise,[145] temperature,[137] or emotional stress,[138] have also been reported to be associated with WEA. Exposures to gas, smoke, dust, dampness and mold, cold, LMW agents, or physically strenuous work seem to be associated with asthma exacerbations in asthmatic workers.[147]

DIAGNOSIS

WEA should be suspected in all patients whose asthma is difficult to control, in patients who report worsening of their symptoms, or in patients who require an increase in their asthma medication when at work.[4]

Before establishing a diagnosis of WEA, the diagnosis of asthma needs to be confirmed by objective measures. Most asthma guidelines recommend the performance of spirometry, both before and after bronchodilator use, to show an increase in forced expiratory volume in 1 second of 12% with an absolute increase of at least 200 mL.[148] In the absence of reversible airflow limitation, the measurement of airway hyperresponsiveness can confirm the diagnosis of asthma. The lack of objective confirmation of the diagnosis of asthma can lead to misdiagnosis in 30% of cases.[149] Furthermore, nonspecific respiratory symptoms are frequent and can mimic asthma in workers exposed to a dusty or irritant environment.[150]

The diagnosis of WEA relies on the demonstration of (1) a relationship between asthma exacerbations and occupational exposures or (2) poor asthma control during periods at work, along with (3) the determination that OA is unlikely. Asthma exacerbations or loss of asthma control can be documented by a change in the frequency and severity of asthma symptoms or by the need for an increase in asthma medications. Asthma exacerbations can also be documented by the need for ED visits or hospitalizations or by changes in respiratory function at work. Serial PEF monitoring can show increased variability during periods at work compared with periods away from work.[151] Identifying the factors that trigger asthma symptoms is important not only to confirm the diagnosis of WEA, but also to decrease or remove the adverse environmental conditions at the workplace. Identifying multiple triggers is common because the workers are frequently exposed to several agents concomitantly.

Although data on the management of WEA are limited, professional organizations have advised minimizing exposures at work and optimizing standard medical management for asthma (e.g., pharmacologic treatment and avoidance of symptom triggers).[4,152] Clear evidence indicates that persistent exposure to the occupational agent that caused their asthma is detrimental for workers with OA,[66] but the impact of continuing exposure to triggers for WEA has not been well studied and thus is unknown at this time. There is limited evidence that workers with OA may have a greater improvement in their lung function and better asthma control than workers with WEA when removed from exposure.[153-155]

DIFFERENTIATING WORK-EXACERBATED ASTHMA FROM NON–WORK-RELATED ASTHMA OR OCCUPATIONAL ASTHMA

A few studies have compared workers with WEA with adults with NWRA. The clinical characteristics of workers with WEA did not differ greatly from those of adults with NWRA. Some studies reported that workers with WEA tended to be older,[153,156] and they had a higher rate of smoking.[93] No specific risk factors have been clearly identified for WEA.

Workers with WEA are often very difficult to differentiate from asthmatic patients with OA, especially in workers who report a new onset of asthma while in the current workplace. The studies that compared persons with WEA and OA report discrepant findings that can be explained by the different populations studied (general population vs. tertiary clinics). Based on cases in the United States that fulfilled the surveillance case definitions set by the *Sentinel Event Notification System for Occupational Risks* (SENSOR), Goe and colleagues[157] found that patients with WEA were more likely to be female, young, nonwhite, and nonsmokers. These findings were not confirmed in the studies in which WEA cases came from a referral clinic and were defined by a worsening of asthma symptoms when at work and a negative result of a specific inhalation challenge to the suspected agent or agents.[61,158]

The occupational exposures encountered in patients with WEA tend to differ from those found in patients with OA. Whereas occupational exposures of patients with WEA are mainly composed of irritants, chemicals, fumes, mineral dust or particles, patients with OA tend to be exposed to sensitizers such as enzymes or animal-derived dust.[159]

Lemière and associates[155] found that, after adjusting for age, asthma control, and forced expiratory volume in 1 second, the diagnosis of WEA was associated with more frequent prescriptions of inhaled corticosteroids, a noneosinophilic phenotype, and a trend toward a higher proportion of smokers than the diagnosis of OA.

The timing of the onset of asthma with respect to the start of employment at the workplace does not necessarily differentiate WEA from OA; for example, Larbanois and colleagues[158] defined WEA by the presence of WRA symptoms and a negative specific inhalation challenge test result and showed that only 7% of the 71 patients with WEA had asthma before employment. In addition, the onset of asthma before employment in the workplace of interest does not preclude the diagnosis of OA. Workers with previously diagnosed asthma can become sensitized to a new agent at their workplace and develop OA. An increase in asthma symptoms or severity is usually noticed at this time.

In both WEA and OA, asthma symptoms worsen at work and improve when the patient is removed from exposure. Serial PEF monitoring can show a greater variability during periods at work compared with periods away from work in both types of cases, and the PEF variability is greater in persons with OA than with WEA.[151] However, in clinical practice, the difference in the magnitude of PEF variability does not differentiate WEA from OA.

Specific inhalation challenge testing can be performed to diagnose OA, with a positive result considered indicative of OA. Although there can be false-negative test results, a negative challenge test result favors the diagnosis of WEA. In

Table 100.7 Characteristics of Work-Exacerbated Asthma Compared With Non–Work-Related Asthma and Occupational Asthma

Characteristics	Compared With Adults With Non–Work-Related Asthma	Compared With Adults With Occupational Asthma
Sex	Similar,[153,156] or predominance of men in subjects with WEA[93]	Similar,[93] or greater number of women in subjects with WEA[157]
Age	Older[153,156]	Similar or younger[157]
Race	More nonwhite[153]	More nonwhite[157]
Education	Less[153]	N/A
Smoking habits	More likely to have smoked cigarettes[153]	More smokers[93]
Asthma severity	More asthma exacerbations requiring ED visits or hospitalizations in workers with WEA[93] More days with asthma symptoms, more severe asthma based on self-report[153]	Same number of asthma exacerbations requiring ED visits or hospitalizations[155] Greater need of ICS in subjects with WEA[155]
Functional characteristics	Similar FEV_1, PC_{20}[93]	Less PEF variability when at work in subjects with WEA compared with OA[151] PC_{20} may be lower in subjects with WEA[158]
Airway inflammation	Neutrophilic inflammation inconsistently found depending on the study[60,61]	Less likely to have eosinophilic airway inflammation[61,155]

ED, emergency department; FEV_1, forced expiratory volume in 1 second; ICS, inhaled glucocorticoids; N/A, not applicable; OA, occupational asthma; PC_{20}, provocative concentration of methacholine; PEF, peak expiratory flow; WEA, work-exacerbated asthma.

several clinical studies, the definition of WEA or OA relied on the negativity or positivity, respectively, of specific inhalation challenge test results.[61] However, those tests are not available in most settings.

An eosinophilic phenotype is more frequently found in subjects with OA compared with WEA. Workers with OA usually show an increase in eosinophilic inflammation when they are exposed to the agents to which they are sensitized. In contrast, one report found that workers with WEA had no increase in eosinophilic inflammation when at work compared with periods away from work or during exposure to the suspected agents in the laboratory.[61]

Table 100.7 summarizes demographic, clinical, functional, and inflammatory differences among patients with WEA, NWRA, and OA.

SOCIOECONOMIC IMPACT

WRA has a major impact on workers and society as a whole. The workers tend to experience asthma symptoms that interfere with their work productivity and cause absenteeism. Although there are no current data on absenteeism in persons with WEA, the cost related to reduced workforce participation, restrictions in job duties, loss of work days ("absenteeism"), or decreased effectiveness while at work ("presenteeism") is likely to be substantial. *Presenteeism* is the term used to describe employees who are physically present at their jobs but who have decreased productivity because of illness or other barriers to performance; such workers seem to represent even higher costs than workers who are absent. In addition to decreased work productivity, these workers must seek medical care, go to the ED, or be hospitalized.

When examining all cases of WRA, the 2001 and 2002 data from Breton and associates[160] showed that patients who reported having WRA in the United States were 4.8 times more likely to report having an asthma exacerbation, 4.8 times more likely to visit the ED at least once, and 2.5 times more likely to visit their physician for an asthma exacerbation in the previous 12 months compared with individuals with NWRA. Lemière and associates[93] confirmed these data and showed that 341 subjects with WRA who were followed in a tertiary Canadian clinic had more visits to the clinic for asthma (4.1 vs. 1.2; $P < 0.05$) and more hospitalizations for asthma (0.04 vs. 0.008; $P < 0.05$) during the year preceding their diagnosis than 381 subjects with NWRA. In a more recent cohort study of subjects with WRA followed in two Quebec tertiary clinics, Lemière and colleagues[155] showed that the health care–related costs were similar between WEA and OA but were 10-fold greater than the costs related to NWRA in the year preceding the assessment of those patients in tertiary clinics.

Although the cost of OA decreased significantly after the diagnosis was made and the patients were removed from exposure, the cost of WEA following the diagnosis did not decrease significantly because most workers with WEA remained at their workplace. In the few studies in which the work disruption of persons with WEA was evaluated, it was reported to be similar to that seen in OA.[154,158] There is a high rate of unemployment in workers with WEA (30–50%)[158,161] equivalent to patients with OA. Job changes are frequent in workers affected with WEA, but the reduction in earnings seems to be similar in WEA and OA.[158] WEA is likely to have a negative impact on the psychological state of the workers. A small Canadian study showed a trend toward higher depression and anxiety scores in subjects with WEA compared with subjects with OA.[162] Overall, WEA exerts a large socioeconomic impact on workers and society by using a large amount of health care resources and inducing substantial disruption of work.

Key Points

- The workplace environment can lead to the development of different types of work-related asthma, including occupational asthma (i.e., asthma caused by work through either immunologic [sensitizer-induced] or nonimmunologic [irritant-induced] mechanisms) and work-exacerbated asthma (i.e., preexisting or coincident asthma exacerbated by nonspecific stimuli at work).
- Work-related asthma represents a significant public health concern because of its high prevalence, long-term respiratory health consequences, and socioeconomic consequences for affected workers.
- Sensitizer-induced occupational asthma should be diagnosed with the highest level of accuracy by comprehensive investigations to avoid unwarranted removal from exposure and the associated socioeconomic consequences.
- For patients with sensitizer-induced occupational asthma, the recommended treatment is complete avoidance of the causal agent, although the rate of recovery is low, especially when the diagnosis is delayed.
- Irritant-induced asthma is characterized by early onset after exposure; however, irritant-induced asthma can also develop insidiously over a few months after massive exposure to a complex mixture of alkaline dust and combustion products, as shown in the World Trade Center disaster.
- Unlike patients with sensitizer-induced occupational asthma, those with irritant-induced occupational asthma do not develop work-related asthma symptoms after reexposure to low concentrations of the irritant that initiated the symptoms.
- Work-exacerbated asthma should be suspected in all patients whose asthma is difficult to control, in patients who report a worsening of their symptoms, or in those who require an increase in their asthma medication when at work.
- Workers with work-exacerbated asthma are often very difficult to differentiate from asthmatic patients with occupational asthma, especially in individuals who report a new onset of asthma while in the current workplace.

INTRODUCTION

The pneumoconioses are a class of entirely preventable diseases caused most commonly by workplace exposures to fibrogenic mineral dust. In 2005, the World Health Organization estimated that the most important of these diseases, silicosis, asbestosis, and coal workers' pneumoconiosis, respectively, caused 486,000, 376,000, and 366,000 disability-adjusted years of life lost globally.[1] Pneumoconiosis is caused by the inhalation of respirable dust, which accumulates in the lungs and results in pathologic tissue reactions. Although occupational exposures are the main cause (Figs. 101.1 and 101.2), environmental pneumoconioses may also be seen.

PATHOGENESIS AND EXPOSURE-RESPONSE RELATIONSHIPS

Dust deposition in the lungs depends on the size, geometry, and aerodynamic properties of the inhaled dust particles. Their clearance is determined by the mucociliary escalator and cellular mechanisms, particularly engulfment by macrophages. The balance of dust deposition and its clearance determines dust accumulation in the lungs. Tissue reactions to dust are generally determined by the quantity and duration of exposure to accumulated dust, the surface physicochemical properties of the dust particles, and host responses.

In epidemiologic studies, the cumulative exposure to dust is estimated using a job exposure matrix, which combines information taken from the worker's job and task history with industrial hygiene environmental measurements. These diseases generally follow clear exposure-response relationships. However, given the variability in host susceptibility, there may be heavily exposed individuals who remain unaffected and less severely exposed individuals with disease. Therefore, a clinician should not reject the diagnosis of pneumoconiosis solely because exposure is believed to be too remote, too brief, or of too low a level. Workplace data demonstrating compliance with regulatory limits may not reflect the totality of a worker's exposure and do not account for workers who are especially susceptible, had an unusual exposure profile, or retained more dust than other workers who were similarly exposed.

CHEST IMAGING

Chest radiographs have been the cornerstone of surveillance for pneumoconiosis in the workplace given wide international availability, portability, and low cost. The International Labour Office International Classification of Radiographs of Pneumoconioses[2] provides a widely accepted framework for evaluation of posteroanterior chest radiographs taken for medical surveillance of occupational lung disease. The system requires users to compare the images of the subject with standard calibration radiographs to classify the shape, size, and profusion (or abundance) of pneumoconiotic opacities. This system improves consistency in the reading of pulmonary parenchymal and pleural disease, and places an individual case in the context of available epidemiologic information.[2,3]

High-resolution computed tomography (HRCT) is more sensitive than chest radiographs and is used primarily in

Figure 101.1 Underground longwall coal miners in Ukraine. Note the miner in foreground with skin and clothing heavily soiled with coal mine dust, who, despite earlier respirator use, has significant dust deposition around his nose and mouth. Individuals performing work in dusty conditions are at significant risk of pneumoconioses despite engineering controls such as dust suppression technologies and personal protective equipment such as respirators. (Courtesy Robert Cohen, MD.)

Figure 101.2 Engineered stone fabricator. Worker cutting engineered stone, a composite material high in content of silica along with resins and pigments. Note highly dusty work conditions with lack of dust suppression measures. The primary control for respiratory disease prevention in this worker's case is use of a respirator, which is generally less effective than measures limiting overall respirable dust, such as wet cutting of the stone product. Similar workers are at considerable risk for silicosis. (Courtesy Ling Mao, MD, PhD.)

a diagnostic clinical setting to characterize lung, mediastinal, and pleural lesions. HRCT is not widely applied in disease surveillance, although reductions in cost and radiation exposure raise the possibility of future application in this setting. A classification system for HRCT similar to the International Labour Office system for chest radiographs has been proposed.[4]

Magnetic resonance imaging is of limited value, but it can be useful in differentiating benign pleural thickening from mesothelioma.[5] Positron emission tomography is also of limited utility because pneumoconiotic lesions and lymph nodes may demonstrate metabolic activity similar to that of neoplastic lesions.[6–8]

CLINICAL ISSUES, LUNG FUNCTION, AND PRINCIPLES OF DIAGNOSIS

The clinician is faced with two main tasks when evaluating a case of suspected pneumoconiosis. *First,* the clinician must assess the nature of the disease process, as well as determine whether it has decreased the worker's capacity to perform his or her job. Assessment of *impairment* is based on symptoms and measurements of pulmonary function at rest and during exercise where indicated (see Chapters 32, 33, and 35). Assessment of *disability* is made in the wider context of whether subjects' impairment makes them unfit for work and thus requires detailed knowledge of the job tasks and exertional requirements. Pneumoconiosis may be associated with normal lung function or with obstructive, restrictive, or mixed patterns of impairment. Lung function measurements in the normal reference range may be misleading given that persons who undertake heavy labor may have higher initial lung function measurements than the general population, on which most reference values are based.[9]

Second, the clinician needs to determine whether there has been environmental or occupational exposure of sufficient duration and intensity to be a significant contributing cause of the patient's condition. For this task, the key tool is the occupational exposure history, provided by the worker, who generally possesses extensive knowledge of the materials, processes, and exposure controls involved. Reliance on job titles for determining exposures is insufficient because individuals often perform job tasks not indicated by the job classification. A complete exposure history, including student summer jobs, military service, avocations, and short-term jobs, is of vital importance. On occasion, it may be necessary to establish occupational exposure through analysis of biologic material (e.g., sputum, *bronchoalveolar lavage* [BAL], or lung biopsy specimens) for the putative dust or its breakdown products, particularly in cases in which the exposure is remote or the exposure history is incomplete.

In the discussion that follows, the pneumoconioses caused by silica, coal mine dust, asbestos, and beryllium are considered separately with respect to occupations at risk, epidemiology, and pathophysiology, as well as the clinical issues of diagnosis, prognosis, and management. Lists of occupations and jobs at risk are never exhaustive for a given exposure but are a guide for use in general office practice. Less frequently encountered pneumoconioses, including those resulting from nonasbestos silicates such as talc and mica, hard metal dust exposure, and silicon carbide, are outside the scope of this chapter.

SILICOSIS

DEFINITION

Silicosis is a fibrotic lung disease caused by the inhalation of *respirable crystalline silica* (RCS) usually in the form of quartz and, less commonly, as cristobalite and tridymite.[10,11] Amorphous silica is relatively nontoxic.

INDUSTRIES AND OCCUPATIONS AT RISK

Silicosis is an ancient disease, with outbreaks and associated deaths that continue to be reported worldwide.[1]

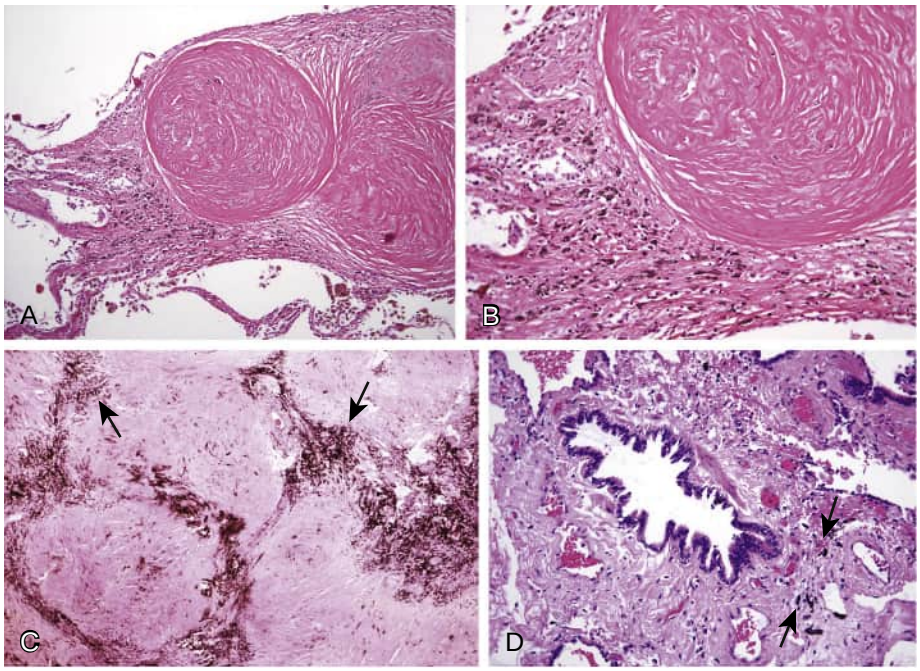

Figure 101.3 Pathologic lesions of chronic silicosis. (A) Silicotic nodule characterized by a central zone of a cellular hyalinized collagen with a whorled appearance and a peripheral zone of dust-laden macrophages. (B) Silicotic nodule at higher magnification to show these characteristics to better advantage. (C) Progressive massive fibrosis showing confluent silicotic nodules and aggregates of dust-laden macrophages *(arrows).* (D) Mineral dust small airways disease characterized by peribronchiolar fibrous tissue containing a moderate amount of pigment *(arrows).* (Courtesy National Institute for Occupational Health, South Africa.)

Despite significant improvements in dust control regulations, silicosis continues to be reported in workers from a variety of industries in the 21st century. Silicosis cases are likely to be underreported as is often the case in chronic occupational illnesses.[12] Construction, surface and underground mining, tunneling, and foundry work are major sources of silica dust exposure.[12a] Reports have shown a severe silicosis risk for workers fabricating artificial or engineered stone countertops[13–15,15a,15b] (see Fig. 101.2) and stonemasons. Workers who repair or demolish concrete structures,[16] including roads, have significant risk of disease.[17] Less common occupational groups associated with silicosis include workers producing stressed denim by sandblasting,[18] stone carvers,[19] dental technicians,[20] and jewelers using chalk molds.[21] Many of the current cases of silicosis come from industries using relatively new technology that, if unaccompanied by modern dust controls, results in exposures to finer dust particles than in traditional industries and jobs. Cases of silicosis have also been reported following environmental exposure to dust storms or volcanic particulate,[22,23] as well as in agricultural workers.[24,25]

PATHOLOGY

Three clinicopathologic types of silicosis have been described. *Chronic silicosis* is the most common form of the disease, and it typically follows exposure measured in decades rather than years. The pathologic hallmark of chronic silicosis is the silicotic nodule, a well-circumscribed lesion and one of the few agent-specific lesions in pathology (Fig. 101.3A–B; eFig. 101.1). Silicotic nodules are believed to develop first in the hilar lymph nodes,[26] and they may be confined to this area; they may become encased in calcification and impinge on or erode into airways. The disease process next involves the lung parenchyma. It is usually bilateral, predominantly involving the upper lung zones. The silicotic nodules may grow or become confluent with disease progression, leading to the development of *progressive massive fibrosis* (PMF) (Fig. 101.3C), also known as *complicated silicosis.* These lesions, which are larger than 1 cm in diameter (and often significantly larger), frequently involve the upper lobes. They may cause substantial scarring and volume loss. Rarely they cavitate, which may be an indication of tuberculosis (see later and eFig. 101.7).[27]

Accelerated silicosis differs from chronic silicosis in the earlier development of silicotic nodules, usually after 3 to 10 years of more intense RCS exposure. The nodules may be more widely distributed in the lung and are more cellular than fibrotic. PMF may develop in accelerated silicosis as well.

Acute silicosis follows intense exposure to RCS, such as that caused by sandblasting, for periods measured in months rather than years.[27] This form has many features of pulmonary alveolar proteinosis (see Chapter 98), and it is also known as silicoproteinosis. Silica particles and various biomarkers of tissue reaction can be identified in BAL material.[28]

Rheumatoid nodules may occasionally develop in the setting of silicosis and may be seen in patients with rheumatoid arthritis or high levels of circulating rheumatoid factor.[27] There may be silicotic nodules in the background. Silicotic nodules may also develop in the cervical and abdominal lymph nodes and, occasionally, in the liver, spleen, and bone marrow.

PATHOGENESIS

The toxicity of silica dust is dependent on the physical and chemical properties of the particles, as well as the cellular mechanisms that initiate and drive the process of inflammation and fibrosis. Animal studies have shown that the mechanisms likely involve activation of inflammasomes that induce the secretion of proinflammatory cytokines, including interleukin-1β, interleukin-18, tumor necrosis factor-α, and interferon-β from antigen-presenting

cells that lead to fibrosis.[29,30] Growth factors, including transforming growth factor-β, are important in fibrogenesis and also have been implicated in carcinogenesis in association with silica.[31,32] Reviews have described the immune response to silica in more detail, including the role of innate and adaptive immunity.[33,34] There is agreement that freshly fractured silica, such as that generated during drilling, cutting, and blasting, is more toxic to the alveolar macrophages than is "aged" silica, presumably because of its increased redox potential.[35,36] Other minerals, particularly clay components, may adhere to the surfaces of silica particles and produce "coated" silica that is less toxic than uncoated silica dust. Although the major determinant of silicosis is the level of exposure to silica-containing dust, individual susceptibility to the disease may play a role in its development and severity.[37–39]

AIRFLOW OBSTRUCTION, CHRONIC BRONCHITIS, AND EMPHYSEMA

COPD and chronic bronchitis are common manifestations of long-term occupational exposure to environments contaminated by silica dust and can develop in silica-exposed individuals with or without silicosis.[40–45] *Mineral dust airways disease* refers to disease of small airways, including fibrosis and pigmentation of respiratory bronchioles (see Fig. 101.3D), and it is seen in association with exposures to a variety of mineral dusts, including silica.[46] In a study of adolescents and young adults working in a stone-crushing plant, lung function changes were interpreted as evidence for impaired lung growth attributed to their high RCS exposure.[47] Additionally, smoking can potentiate the effect of silica dust on airflow obstruction.[40]

CONNECTIVE TISSUE DISEASES, RENAL DISEASE, AND CARDIOVASCULAR DISEASE

Silica exposure has been associated with connective tissue diseases. The relative risk of rheumatoid arthritis, systemic lupus erythematosus, and systemic sclerosis is substantially higher in silica-exposed populations.[41,48,49]

Renal disease has also been reported in silica-exposed workers. Some studies have implicated an immune complex–mediated glomerulonephritis or a direct toxic effect of silica.[41,50,51] Silicosis has been linked with antineutrophil cytoplasmic antibody positivity and possibly with vasculitis.[48,52] Cardiovascular disease may also be associated with silica exposure. A report of a cohort of 74,040 silica-exposed workers found an increased risk of mortality compared with nonexposed workers; cardiovascular disease was the major cause of death.[53]

LUNG CANCER

The association between silicosis and lung cancer is well established. Silica was classified as a known human carcinogen by the International Agency for Research on Cancer in 1997 and again in 2012.[54,55] A review of large epidemiologic studies and analysis of pooled data have established that silica, as well as silicosis, conferred increase risks for lung cancer in occupationally exposed cohorts.[56,57]

TUBERCULOSIS

The association between silicosis and tuberculosis has long been recognized. Rates of active tuberculosis in silicotic subjects range from 2- to 30-fold higher than rates in the same workforce without silicosis.[58] Workers with acute and accelerated silicosis are at even greater risk for tuberculosis.[10] Other risk factors include high prevalence of tuberculosis in the local population, older age, smoking, poor general health, and HIV-positive status.[58–62] Exposure to silica, without silicosis, may also predispose individuals to tuberculosis.[58,59]

In most areas, *Mycobacterium tuberculosis* is the more frequent mycobacterial pathogen in the setting of silicosis. However, in areas where tuberculosis is less prevalent, nontuberculous mycobacterial infections are more common.[50,63] Some evidence suggests that persons with silicosis are also at increased risk for fungal infections.[64]

CLINICAL FEATURES

Workers with silicosis commonly present with shortness of breath. Cough and sputum production are common symptoms and usually relate to chronic bronchitis, but they may reflect the development of tuberculosis or lung cancer. Patients with abnormal radiographs found during medical surveillance may be asymptomatic. Chest pain is not a feature of silicosis. Systemic symptoms such as fever and weight loss should be attributed to tuberculosis or lung cancer until proved otherwise. Clubbing is also not a common feature of silicosis and should raise concern for lung cancer. Accelerated silicosis and acute silicosis cause a more rapid onset of breathlessness developing over months or a few years rather than decades, and they often cause severe impairment in gas exchange.

RADIOGRAPHIC FEATURES

Chronic simple silicosis and accelerated silicosis are characterized by small rounded opacities on the chest radiograph. Silica exposure has been associated with rounded opacities that are between 3 and 10 mm in diameter,[65] although smaller or irregular opacities may be seen. In general, there is good correlation among cumulative dust exposure, the retained dust in the lungs, the presence and severity of lung disease, and the chest radiograph.[66] However, occasionally, even histologically confirmed advanced silicosis may not be apparent on a chest radiograph.[67]

Silicotic nodules are usually symmetrically distributed and tend to appear first in the upper zones and later, although not invariably, involving other zones (eFig. 101.2). Enlargement of the hilar nodes may precede the development of the parenchymal lesions. Eggshell calcification of lymph nodes, when present, is strongly suggestive, although not pathognomonic, of silicosis (eFig. 101.3).

PMF is characterized by the coalescence or growth of small rounded opacities to form larger lesions (eFig. 101.4, Videos 101.1 and 101.2). With time, the mass lesions tend to contract, usually to the upper lobes, and leave hyperlucent zones at their margins (eFigs. 101.5 and 101.6) and often at the lung bases. In this process, small rounded opacities, previously evident, may disappear, sometimes resulting in a picture that must be distinguished from sarcoidosis

or tuberculosis. The rapid development of several large lesions may indicate rheumatoid silicosis or concomitant tuberculosis.

In contrast to chronic and accelerated silicosis, acute silicosis is characterized by diffuse changes that usually display an air space and interstitial pattern. Findings include consolidation with or without calcification, centrilobular nodules, and ground-glass opacification.[68]

LUNG FUNCTION

The lung function profile is determined by the extent of silicosis, as well as by the associated airway and vascular changes. In chronic silicosis, spirometric tests usually reflect airflow limitation. Reduction in single-breath carbon monoxide uptake (*diffusing capacity for carbon monoxide* [D_{LCO}]) is generally apparent in more advanced chronic silicosis and may reflect dust-related fibrosis and/or associated emphysema.

In the accelerated and acute forms, functional changes are more marked, and progression is more rapid. In acute silicosis, lung function shows a restrictive defect and impairment of gas exchange, which can lead to respiratory failure.

DIAGNOSIS AND COMPLICATIONS

Silicosis is diagnosed on the basis of the history of exposure and characteristic radiographic changes. Problems arise when the history of exposure is remote, forgotten, or missed, or when the exposure took place outside a recognized occupation. The duration and intensity are important factors used to calculate cumulative dose. Short periods of intense exposure are also important. The physician should never dismiss the diagnosis of silicosis when that diagnosis is suggested by clinical and radiologic features but exposure appears to have been insignificant or in an occupation not known to be associated with silicosis.

HRCT scanning is superior to plain chest radiography in detecting the presence and profusion of silicotic opacities (Fig. 101.4), as well as early conglomeration (see eFig. 101.4B–E). Occasionally, the radiologic features are unusual; examples include diffuse irregular interstitial fibrosis, hilar lymphadenopathy, or large lung opacities in the absence of typical small nodules.

Detection of silica in BAL fluid may suggest the diagnosis. Lung biopsy may be necessary to distinguish PMF or other atypical features from lung cancer, tuberculosis, and other diagnoses. Biopsy material should be reviewed under polarizing light microscopy or submitted for mineralogic analysis.

Less common complications include right heart dysfunction, spontaneous pneumothorax, broncholithiasis, and tracheobronchial obstruction from enlarged calcified hilar nodes. The presence of cough, hemoptysis, weight loss, fever, or any new radiologic feature, such as cavitation, should be pursued with further evaluation, including culture and histologic examination of tissue, to exclude tuberculosis or malignancy (eFig. 101.7, Video 101.3).

MANAGEMENT AND CONTROL

Once established, the fibrotic process of chronic silicosis is thought to be irreversible. Management of the individual case is therefore focused on preventing disease progression or complications. Removal from exposure to silica or other respiratory hazards should be advised. Although the disease may progress without further exposure, the rate of deterioration may be reduced.

Interventions to interrupt the inflammatory process that leads to chronic silicosis have not been shown to be successful. There has been interest in the use of whole-lung lavage to remove silica from the lung, but a favorable impact on progression of acute or chronic silicosis has not been clearly demonstrated.[69,70]

Patients with silicosis should be monitored for mycobacterial disease and other infections, and they should be treated for latent tuberculosis infection (see Chapters 42 and 51). This is especially true for patients with acute or accelerated silicosis, as well as for those with silicosis who are infected with human immunodeficiency virus.

The interaction between silica exposure and smoking in the development of COPD, tuberculosis, and lung cancer makes it important to implement smoking-cessation programs in the workplace. Patients with severe disease may be considered for lung transplantation (see Chapter 140).

The most important aspect of the management of silicosis relates to its prevention. Each patient with silicosis represents not only a sick patient, but also potentially a sick workplace. Such cases should be considered sentinel events and reported to public health authorities. More recent deaths from silicosis in younger subjects in the United States have been reported after exposure in the construction and manufacturing sectors. Deaths of young persons who sandblasted denim or worked with engineered stone are reminders that there is often a lack of awareness of the hazards of silica outside the occupations traditionally associated with silicosis.

COAL MINE DUST LUNG DISEASE

DEFINITION

Coal mine dust lung disease (CMDLD) is a spectrum of chronic lung diseases caused by prolonged excessive exposure to coal mine dust.[71] Classic *coal workers' pneumoconiosis* (CWP) is one manifestation, with findings of small nodules or masslike lesions and obstructive lung disease. In addition, coal mine dust exposure may contribute to other phenotypes, including COPD, as well as pulmonary fibrosis, termed *dust-related diffuse fibrosis* (DDF). The diversity of these manifestations reflects variation in host responses as well as variation in coal mine dust composition.

COMPOSITION OF COAL MINE DUST

Coal is a heterogeneous material that is high in carbon content, but contains a number of other substances, including silica, silicates such as mica and kaolinite, metals, and volatile compounds such as hydrocarbons. Coal is extracted using underground or surface mining techniques.

Coal miners are exposed to mixed dusts during the mining process. *Respirable crystalline silica* (RCS) is an important component of coal mine dust. RCS is created as miners cut through siliceous layers above, below, and within the coal seams. Dust exposure may also vary within a mine as a result of differences in local ventilation and dust-control

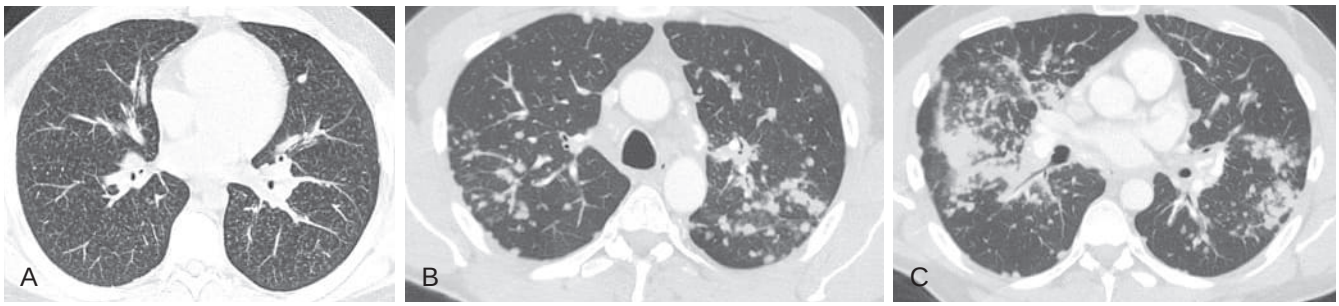

Figure 101.4 Imaging appearance of lesions in silicosis. (A) Axial chest computed tomography from an artificial stone countertop fabricator with heavy respirable crystalline silica exposure, with innumerable centrilobular ground-glass micronodules. (B) Axial chest computed tomography from a stonemason demonstrating somewhat larger, well-circumscribed nodules consistent with simple silicosis. (A, Courtesy David Deller, MD. B–C, Courtesy Robert Cohen, MD.)

techniques.[71a] Coal miners working close to the mining face, particularly when downwind of production, are often exposed to greater concentrations of respirable dust than other workers at the same mine.

The introduction of modern mining technology has likely changed coal mine dust composition. Unlike the older technology of drilling and blasting, newer, more powerful mining equipment pulverizes rock layers, thereby generating large quantities of RCS. Newer coal preparation plant technology permits large amounts of coal to be separated from waste rock. These innovations may increase worker exposure to noncoal dust, possibly increasing the risk of lung disease. Specific job tasks, such as roof bolting (in which workers drill bolts upward into the roof of the mine to stabilize it) and the operation of continuous mining machines, have been frequently associated with CMDLD.

PATHOLOGY

Histologically, simple CWP may initially manifest as a *coal macule*, a collection of dust-laden macrophages containing reticulin and collagen (Fig. 101.5A). These macules are located within the wall of respiratory bronchioles and may be surrounded by centrilobular or focal emphysema. Compared with coal macules, coal nodules contain a greater degree of collagen and are not confined to respiratory bronchioles (Fig. 101.5A). The nodules may grow or coalesce into lesions larger than 1 cm, indicating progression to PMF (Fig. 101.5B). PMF lesions may necrose and cavitate, raising the possibility of superimposed mycobacterial or fungal infection.[72] The lesions may be irregular in shape, in some cases mimicking usual interstitial pneumonia[73] (Fig. 101.5C). Silicotic nodules may also be identified when there has been significant RCS exposure.[74]

EPIDEMIOLOGY AND NATURAL HISTORY

Radiologic surveillance has been the primary tool used in public health programs to identify coal workers with CWP and to evaluate the prevalence and progression of disease. A meta-analysis of studies published from 2001 to 2011 concluded that the prevalence of radiologic CWP in Chinese miners was approximately 6%.[75] In the United States after the institution of modern dust-control regulations, the Coal Workers' X-Ray Surveillance Program operated by the National Institute for Occupational Safety and Health reported a decline in prevalence from nearly one-third of working miners with 25 years of tenure in the 1970s to a low of less than 5% in the 1990s. More recently however, simple CWP prevalence has increased to more than 10% of surveyed workers nationally and 20% of workers in the central Appalachian states of Kentucky, Virginia, and West Virginia. Disturbingly, the rate of PMF in central Appalachia has also increased to levels not seen since the institution of modern dust controls.[76–78]

DISEASE PHENOTYPES

Classic Coal Workers' Pneumoconiosis

CWP may be diagnosed in an individual with compatible radiographic findings and a history of coal mine dust exposure of at least 10 years, although shorter-duration exposures of high intensity may be associated with disease. Typical chest imaging findings of CWP may include nodular or masslike opacities, areas of hyperlucency consistent with emphysema, and, in more advanced disease, architectural distortion of neighboring anatomic structures resulting from loss of lung volume.

The likelihood of developing disease depends on multiple factors, the most important of which is cumulative coal mine dust exposure.[79,80] In addition, increasing coal rank—reflecting greater carbon content of the coal—is believed to be a factor.[80,81] Exposure to dust with a high component of RCS is also a significant contributor to disease. Although the chest radiograph is insensitive for detecting early lesions of CWP,[82] it remains a useful tool in the assessment of severity of CWP because the number of small opacities correlates well with the number of small lesions observed on pathologic examination.[83]

Like silicosis, CWP is divided into "simple" or "complicated" disease on the basis of the size of the radiographic or pathologic lesions. The abnormalities in simple CWP are often rounded and upper zone predominant (eFig. 101.8), although data from large studies of surveillance radiographs show that significant proportions of affected workers have irregular and lower zone–predominant lesions.[65] Increasing

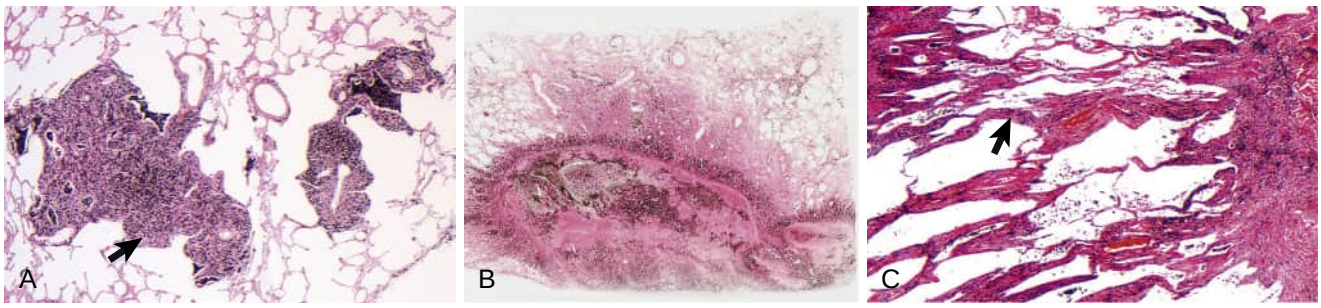

Figure 101.5 Pathologic lesions of coal mine dust lung disease. (A) Coal macule and micronodule *(arrow)* with associated emphysema. (B) Lesion of progressive massive fibrosis formed from enlargement and coalescence of two lesions, with pigmented dust deposition, central necrosis, and cholesterol clefts. (C) Dust-related diffuse fibrosis *(arrow)* bridging two coal nodules. (From Petsonk EL, Rose C, Cohen R. Coal mine dust lung disease. New lessons from an old exposure. *Am J Respir Crit Care Med.* 2013;187:1178–1185. Courtesy Dr. Francis Green.)

profusion of simple pneumoconiotic opacities is associated with reduced lung function, contrary to prior dogma.[84]

Complicated lesions or PMF lesions have a long-axis diameter exceeding 10 mm. These lesions are often located in the upper zones and frequently become bilaterally distributed with progressive disease. Lower lobe and asymmetrical distribution of these large opacities has been reported.[85] PMF is always associated with a background of smaller opacities, although their profusion may be low because many nodules are subsumed into these larger scars. Additionally, with severe disease, there may be emphysema, volume loss, and distortion of thoracic architecture. The risk of development of PMF increases with older age and greater cumulative dust exposure,[86] as well as with a higher baseline profusion of the small opacities of simple CWP in a miner.[86,87]

Rapidly Progressive Pneumoconiosis

In the United States, rapidly progressive pneumoconiosis, defined as radiographic progression of more than one International Labour Office profusion subcategory within 5 years or the development of PMF after 1985, has been observed with increasing frequency.[88] Histologic examination of lung tissue from miners with rapidly progressive disease demonstrated lesions of silicosis and mixed-dust pneumoconiosis.[74] The distribution of this disease entity appears concentrated in the central Appalachian region of the United States.

Dust-Related Diffuse Fibrosis

Although less common than CWP, interstitial pulmonary fibrosis is a recognized disease among workers exposed to coal, silica, and mixed mineral dusts.[73] This entity, DDF, typically manifests radiographically with lower lung zone–predominant reticular disease with or without honeycombing. There also may be a background of nodular interstitial opacities. Pathologically, the observed fibrosis may be pigmented or unpigmented,[89] with a lobular distribution similar to that of usual interstitial pneumonia. Examination of the histologic specimen with polarized light microscopy or scanning electron microscopy with energy dispersive x-ray spectroscopy may demonstrate silica and other minerals within the lung tissue.[90]

Overall, the clinical course of DDF is thought to be less aggressive than that of *idiopathic pulmonary fibrosis*.[91] Distinguishing DDF from idiopathic pulmonary fibrosis sometimes poses a diagnostic challenge. However, it is imperative to bear in mind that the diagnosis of idiopathic pulmonary fibrosis requires the exclusion of other known causes of interstitial lung disease, including occupational and environmental exposures.[45]

Chronic Bronchitis, Emphysema, and Lung Function Impairment

Chronic cough and sputum production resulting from chronic bronchitis are commonly encountered among coal miners.[92,93] The prevalence of chronic bronchitis increases with increased cumulative coal mine dust exposure. Symptoms of chronic bronchitis are also associated with significant declines in the *forced expiratory volume in 1 second* (FEV_1).[94]

Coal mine dust is also an important cause of emphysema (Fig. 101.6).[95–97] Emphysema severity scores are strongly associated with increased lung dust content.[98,99] Centrilobular emphysema is the most common type of emphysema associated with coal mine dust exposure and can develop in nonsmoking miners as well as smoking miners.[98] The effect of cigarette smoking on emphysema is additive to that of coal mine dust exposure.[95] All pathologic types of emphysema, including centriacinar, panacinar, and bullous emphysema, are associated with both dust exposure and cigarette smoking.[100]

Coal mine dust exposure is associated with impairment in lung function as measured by spirometry, even in the absence of radiographic evidence of CWP.[101] Examination of multiple cohorts of miners is notable for evidence of an excess lifetime risk of significant loss of lung function attributable to dust exposure.[102] After adjusting for age and smoking status, the magnitude of decline in lung function is proportional to estimated cumulative coal mine dust exposure.[103–106] The correlation between the rate of decline in FEV_1 and cumulative coal mine dust exposure is greater in nonsmokers,[106] and it is the same order of magnitude as that caused by exposure to tobacco smoke. In addition to being a marker for respiratory symptoms, the magnitude of FEV_1 decline is associated with increased risk of death from cardiovascular and nonmalignant respiratory disease.[107]

Asthma may be caused or exacerbated by exposure to the coal mine atmosphere. Mines contain contaminants that may contribute to asthma, including isocyanates[108,109] and diesel exhaust particulate.

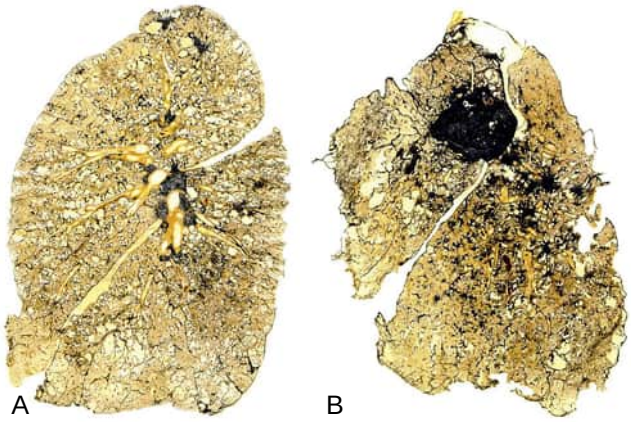

Figure 101.6 Coal mine dust lung disease. (A) Whole-lung section from a never smoker with 28 years of coal mining experience, showing macular and nodular coal workers' pneumoconiosis and a background of severe emphysema, predominantly centriacinar. (B) Whole-lung section from a never smoker with 36 years of coal mining experience, showing progressive massive fibrosis and moderately severe emphysema. (Modified from Kuempel ED, Wheeler MW, Smith RJ, et al. Contributions of dust exposure and cigarette smoking to emphysema severity in coal miners in the United States. *Am J Respir Crit Care Med.* 2009;180:257–264.)

Rheumatoid Pneumoconiosis

Eponymously known as Caplan syndrome, rheumatoid pneumoconiosis is the association of rheumatoid arthritis with CWP.[110] This is an uncommon manifestation of CMDLD, observed in less than 1% of autopsied cases.[111] The chest radiograph typically demonstrates large, well-defined nodules or masses, ranging from 5 to 50 mm in diameter, typically without a background of smaller opacities. Pulmonary tuberculosis and fungal infections may need to be considered in some cases, particularly when nodules cavitate.

LUNG CANCER

Historically, coal mine dust exposure was not believed to be associated with increased risk of bronchogenic lung cancer.[112] However, more recent studies with longer follow-up suggest that there may be an association between coal mine dust exposure and lung cancer.[113–115] This may reflect the heterogeneous composition of coal mine dust, with the presence of multiple other carcinogenic coal mine dust constituents, including silica and diesel exhaust particulate.

CLINICAL FEATURES

Respiratory symptoms of CMDLD include dyspnea, wheezing, and cough with or without chronic sputum production. Symptoms develop insidiously; they may often begin when the worker is still being exposed to coal mine dust or may instead begin or progress after the worker is no longer exposed. The degree of radiographic involvement may not always correlate with symptoms. The worker may be asymptomatic at the time of discovery, such as when radiographic abnormalities are identified during medical surveillance. There is no specific laboratory test for CMDLD, although levels of angiotensin-converting enzyme,[116] antinuclear antibodies,[117] or rheumatoid factor may be abnormal.

CHEST IMAGING

Plain chest radiography is discussed earlier, under the disease phenotype of CWP. HRCT scanning is a more sensitive means of identifying certain CMDLD manifestations, including emphysema[118,119] and early pulmonary fibrosis. HRCT is also useful in evaluating other radiographic features that may coexist with CMDLD, including lung neoplasms. HRCT may be most useful in the evaluation of symptomatic workers with normal or borderline chest radiographs,[120] or for the evaluation of radiographic lesions atypical for CWP.

Similar to PMF observed in the setting of silicosis, PMF in the setting of CMDLD may sometimes be difficult to distinguish from other lesions, particularly neoplastic disease and granulomatous infections. Malignant disease should be distinguished from PMF, particularly when there is a paucity of background small opacities, or when disease is unilateral. Prior imaging may be helpful in estimating the doubling time of growth of the lesion. Increased ^{18}F-fluorodeoxyglucose uptake at the time of positron emission tomography scanning may not be useful because PMF lesions may also exhibit increased uptake.[7]

The likelihood of developing tuberculosis has been observed to be variably increased in coal miners,[121,122] a finding that may reflect their silica exposure. Histoplasmosis and miliary tuberculosis may be alternative explanations for profuse small opacities and should be kept in mind.

LUNG FUNCTION

Given the heterogeneous nature of the manifestations of CMDLD, there is no characteristic pattern of physiologic abnormality in CMDLD.[98,123] Spirometry may demonstrate obstructive, restrictive, or mixed ventilatory defects. Diffusion impairment may be observed,[94,124] even in the absence of spirometric abnormalities. Abnormalities on spirometry and of D_{LCO} are associated with increased emphysema on chest HRCT and profusion of small nodules on chest radiography.[118,125] Cardiopulmonary exercise testing may be useful in the assessment of individuals with dyspnea whose resting pulmonary function test results do not explain the severity of their symptoms.

DIAGNOSIS

As in silicosis, the diagnosis is most commonly made on the basis of the exposure history and chest imaging findings. Lung biopsy should not be used routinely in the diagnosis of CMDLD in an exposed individual with typical radiographic findings. Surgical biopsy may be appropriate if there is diagnostic uncertainty, such as concern for neoplasm. The clinician must keep in mind the variety of manifestations of CMDLD and be careful to include this in the differential diagnosis in coal miners with COPD or diffuse fibrotic lung disease.

MANAGEMENT

There is currently no specific treatment for CMDLD. Therapy should be directed at specific manifestations of the disease spectrum, such as by prescribing bronchodilators

for patients with COPD. Secondary prevention by avoiding further exposure to respiratory hazards is recommended. Smoking cessation is imperative. Treatment is otherwise supportive, with some patients eventually requiring oxygen supplementation and potentially lung transplantation. Similar to silicosis, whole-lung lavage has been advocated as a potential treatment through removal of coal mine dust and possibly inflammatory mediators and cells, but there is insufficient evidence to support routine treatment.[69]

As discussed earlier, CMDLD may progress after cessation of exposure. CWP may become more profuse or even initially develop after an individual has stopped working as a coal miner. Physiologic abnormalities also may develop or worsen after cessation of exposure. This likely reflects incomplete clearance and retention of coal mine dust within the lungs. Therefore, former coal mine workers with and without disease should be monitored with regular physiologic and radiographic evaluation.

ASBESTOS-RELATED FIBROSIS OF THE LUNGS (ASBESTOSIS) AND PLEURA

Asbestosis and asbestos-related pleural disease are fibrotic lung and pleural reactions caused by the inhalation of respirable asbestos fibers. *Asbestos* refers to naturally present mineral silicates of the serpentine and amphibole group. These silicates are characterized by their natural formation in bundles from which fibers can be easily separated. Humans have utilized asbestos from prehistoric times because of its durability, heat resistance, and fibrous nature, which enabled it to be spun. Asbestos is currently banned in 55 countries, although 2 million tons are still consumed globally each year, with the result that significant human exposure will continue into the foreseeable future.[126,126a] Although asbestos mining is banned in the United States, its use is not[127]: more than 1000 metric tons per year are imported for domestic manufacturing, and an estimated 1.3 million American workers continue to be exposed.[128]

INDUSTRIES AND OCCUPATIONS AT RISK

Workers involved in the mining, milling, transporting, or manufacturing of asbestos products, as well as those who perform maintenance or demolition of structures containing asbestos materials, are at risk of exposure. More recently, workers involved in asbestos abatement operations or disposal of industrial waste have been exposed.

Domestic exposure is less common in recent years than previously, and it happened when workers brought home fiber-laden work clothes. This exposure mainly resulted in pleural disease. Environmental and residential exposure may take place as a consequence of living within proximity of asbestos mines, mills, or plants or from living in homes with asbestos tile roofing.[129,130] Mining of nonasbestos products has also led to significant environmental asbestos exposure. Vermiculite mined near Libby, Montana was found to be contaminated by amphibole asbestos. In addition to asbestos exposure among vermiculite miners, use of contaminated material in landscaping and other applications led to widespread environmental asbestos exposures in Libby.[131] Beyond Libby, exposure to waste piles of Libby vermiculite in Minneapolis[132] and other US locations led to significant environmental asbestos exposure.

PATHOGENESIS

The toxicity of asbestos fibers depends on the cumulative dose, fiber dimensions, and fiber durability in lung tissue.[133–135] Clearance of fibers from the lung is greater for short and chrysotile fibers than for long and amphibole fibers.[136] Fibers equal to or less than 3 μm are phagocytosed by activated macrophages and then are translocated to lymphatic channels. Longer fibers are incompletely phagocytosed, often by more than one macrophage, and become the core of what were originally called *asbestos bodies* because of their association with asbestos exposure. Although most coated fibers in human lungs have been shown to contain asbestos (usually amphibole), the term *ferruginous bodies* has been suggested to underline the fact that other mineral fibers may undergo coating in human lungs. Far more uncoated fibers, which are visible only on electron microscopy, are present in an exposed individual than ferruginous bodies, which are visible by light microscopy.[137]

For many years, the asbestos body has been considered the hallmark of exposure, no doubt because of its distinctive structure and because it is readily visible under the light microscope. The presence of more than one coated fiber has been cited (and challenged) as a necessary criterion for the pathologic diagnosis of asbestosis, even in a person with an appropriate exposure history.[137]

Epidemiologic studies have consistently demonstrated exposure-response relationships for asbestos-related parenchymal lung fibrosis.[138] Mineralogic analysis has also shown that the degree of fibrosis correlates with fiber concentration. Additional relevant factors in fibrogenesis and probably in carcinogenesis are the solubility of the fibers, their surface properties and electrical charge, and their length-to-width aspect ratio.[27,139] For asbestos-related pleural disease, exposure-response relationships can also usually be demonstrated, but the residence time of the dust in the lungs is more important than the cumulative exposure,[134,140] possibly reflecting the time required for fibers to move to and accumulate in the pleura.

ASBESTOSIS (PULMONARY PARENCHYMAL FIBROSIS)

Pathology

Asbestosis tends to be most prominent in the lower lobes and subpleural areas. The lesions of mild asbestosis are found at scattered sites and usually consist of foci of peribronchiolar fibrosis with local chronic interstitial inflammation, accumulation of macrophages in the air spaces, and proliferation of alveolar epithelial type 2 cells. Second- and third-order bronchioles and alveolar ducts tend to be involved as the disease progresses and the fibrosis spreads to involve the alveolar interstitium (Fig. 101.7A). When disease is advanced, the lungs are small, with streaks of fibrosis outlining lobar and interlobar septa, and the visceral pleura is thickened. Honeycombing may be prominent subpleurally and in the lower lobes. Advanced asbestos-related fibrosis

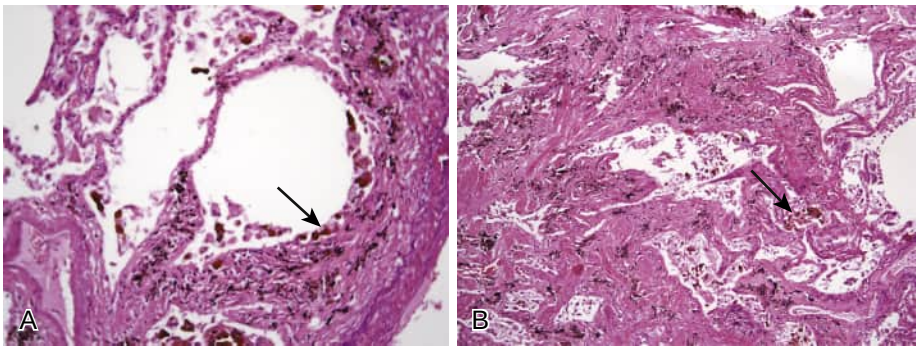

Figure 101.7 Pathologic features of asbestosis: examples from South African asbestos workers. (A) Asbestos *bodies (arrow)* with commencing fibrosis. The architecture of the surrounding lung parenchyma is preserved. (B) Diffuse interstitial fibrosis with destruction of the lung architecture and honeycombing; asbestos bodies are seen in the air spaces and interstitial tissue *(arrow).* (Courtesy National Institute for Occupational Health, South Africa.)

is distinguishable from advanced fibrosis from any other cause only by the presence of asbestos bodies or uncoated asbestos fibers seen on light microscopy or mineralogic analyses (Fig. 101.7B).[27]

In general, the degree of pulmonary fibrosis relates to the fiber burden carried by the lungs.[27] On the basis of animal and human data,[27,141,142] asbestosis is thought to commence with alveolitis that may resolve if the fiber burden is low and the fibers are cleared. If the fiber load is low but retained, mineral dust–induced peripheral airway disease, a nonprogressive distal airway lesion, may develop.[136,139,141–143] If the retained dust load is high and phagocytosis of fibers by macrophages is incomplete, fibroblasts are recruited to the site of the injury, where they proliferate and lay down collagen. If sustained, this leads to irreversible damage, loss of alveolar spaces, and the development of chronic interstitial lung fibrosis, asbestosis.[136]

Epidemiology and Natural History

Clinical asbestosis is becoming less frequent and less severe as exposure levels in workplaces around the world are increasingly meeting currently recommended control levels.[134,144] It is estimated that there are up to 255,000 deaths each year from asbestos-related diseases.[126,145] In the United States, the rate of asbestosis increased possibly by as much as 10-fold between 1968 and 1999 and plateaued, remaining relatively constant through 2010.[128,146] A similar trend was apparent in Australia.[147] With low-level exposure to asbestos, the interval between exposure and disease increases.[134] Exposure at a young age is an independent determinant of both attack and progression rates of parenchymal and pleural radiologic abnormalities, a finding suggesting that residence time of dust in the lung is important in their pathogenesis.[134,148,149] Other determinants of progression are intensity and duration of exposure, cumulative exposure, and fiber type; asbestosis is more frequent after exposure to the amphiboles, or mixtures of amphibole and chrysotile, than exposure to chrysotile alone.[134] This may reflect the comparatively low biopersistence of chrysotile compared with the amphiboles.[150]

Asbestosis may initially appear after exposure ceases, and it may progress without further exposure. In a study of chrysotile miners and millers in Quebec, appearance and progression rates of 31% and 9%, respectively, were observed for pleuroparenchymal disease over an average follow-up period of 17 years after exposure.[134,148] Genetic features appear to play a role in determining the development and extent of asbestos-induced lung fibrosis.[134,151,152] Pathologic studies do not show evidence of an association between asbestosis grade and smoking,[153] although evidence suggests that smoking enhances the retention of fibers in the lungs.[27,153]

Clinical Features

Workers with asbestosis commonly report shortness of breath and dry cough. Acute asbestos-associated pleural reactions may cause chest tightness or pain. Basal crackles, which are early and distinctive features of asbestosis, are fine, crisp, persistent sounds, often heard first over axillary and basal regions and then more generally as the disease advances.[154] Other sounds, including coarse crackles and rhonchi, reflect airway disease that may be related to cigarette smoking or to dust in the occupational environment.[155] Digital clubbing develops in some subjects. Late manifestations include respiratory and circulatory failure, and these conditions, along with cancer, are common causes of death attributable to asbestos.

Radiographic Features

As for coal workers, the posteroanterior chest radiograph remains a key tool in the health surveillance of asbestos-exposed workers and in the initial identification of asbestosis. The irregular, reticular parenchymal opacities associated with this disease are usually seen first in the lower lateral zones (eFig. 101.9). The coarse linear opacities at the bases can blur the heart border, thus giving a "shaggy heart" sign (eFig. 101.10). Small rounded opacities are unusual when the exposure has been primarily to fibers, and they may rather suggest mixed-dust exposures (e.g., silica).[17]

Early fibrotic changes are better visualized by HRCT (eFig. 101.11).[156] Visceral pleural thickening of the interlobar fissures is common.[140] Changes in the parietal pleura are also common, and the presence of pleural plaques or thickening provides additional evidence that the parenchymal disease is asbestos related. HRCT can also identify coexisting lung disease such as emphysema, identify the pattern of rounded atelectasis (see later), and distinguish subpleural fat from pleural thickening and plaques (eFigs. 101.12 to 101.14, Video 101.4).

Lung Function

Patients with asbestosis may demonstrate restrictive, obstructive, or mixed patterns of impairment, often associated with diffusion impairment.[148,157]

Diagnosis

As with disorders related to coal and silica, the clinical diagnosis of asbestosis depends on establishing the appropriate exposure history, typically 20 to 30 years between

initial asbestos exposure and detection of disease, although this period may be shorter or longer. Given an appropriate exposure history with compatible chest imaging findings, histopathologic evaluation is generally unnecessary.[158] In the absence of a clear history of exposure, it may be reasonable to perform a biopsy of the lung to establish the nature of the disease and the presence of asbestos fibers in the lung.

PLEURAL PLAQUES, PLEURAL FIBROSIS, AND VISCEROPARIETAL REACTIONS

Pathology and Pathogenesis

Pleural plaques are smooth, white, raised lesions with irregular borders usually found on the parietal pleura and rarely on the visceral pleura (eFig. 101.15). Common sites are the posterolateral midzones, where they may follow the rib contour, and on the diaphragm. They are less commonly found on the pleura adjacent to the mediastinum and pericardium and are only rarely located in the apices and costophrenic sulci.[140]

Pleural plaques are thought to develop after asbestos fibers move into the pleural space. Once the fibers are within the pleural space, macrophage and cellular interactions may determine plaque formation. On microscopic section, pleural plaques consist of avascular, acellular, laminated collagen fibers arranged parallel to the surface or in whorls, with hyaline changes and occasional fibroblasts. Calcifications are common. Fine asbestos fibers can be seen on electron microscopy.[140]

Like pleural plaques, pleural fibrosis and visceroparietal pleural reactions may be localized or diffuse and may vary in thickness from a milky discoloration of the lung surface to a thick, white peel encasing much of one or both lungs. The interlobar fissures are commonly involved. Visceral pleural disease may be severe even in the presence of minimal parenchymal reaction.[137,140] Occasionally, a localized pleural reaction may fold on itself and the surfaces adhere, trapping the underlying lung and leading to a well-defined pleuroparenchymal lesion or pseudotumor, also called *rounded atelectasis*[140] (eFig. 101.13). Asbestos bodies and fibers are usually found in the visceral pleura, the underlying parenchyma, or both,[140] and the lung dust burden usually reflects the occupational exposure, although fiber counts are considerably less than those seen in asbestosis.

Epidemiology

Pleural plaques continue to be the most frequent and often the only manifestations of asbestos exposure in individual cases,[140,159,160] and asbestos exposure is the most common cause of pleural plaques. Bilateral pleural plaques are more likely to be associated with asbestos exposure than unilateral plaques, for which other causes, such as trauma or prior infection, should be considered.[154] Age and residence time of dust in the lungs are determinants of these distinctive pleural lesions.[140] Domestic, residential, and environmental exposures have been implicated in the development of pleural plaques.

Of greater concern to the patient and the clinician is the prognostic significance of plaques. In one study, they were associated with alveolitis, as reflected in BAL cell counts,[161] and, by implication, with an increased likelihood of developing parenchymal disease. The results of a Swedish cohort mortality study involving 1596 men were interpreted as showing that pleural plaques on the chest radiograph indicated significant exposure to asbestos, as well as an increased risk of mesothelioma and possibly also lung cancer.[162] This risk raises the question of radiographic screening for malignancy in patients with pleural plaques, a topic that remains controversial in the absence of clear evidence of benefit.[154,162,163]

Pleural fibrosis and visceroparietal reactions may also be found in the absence of radiologic parenchymal fibrosis, and they have increased in frequency.[140] Latency is usually long, 34 years in one report,[164] reflected in the finding that these reactions relate to time since first exposure and not to cumulative exposure dose.[140] Pleural fibrosis, like other manifestations of asbestos-related pleural disease, has been reported in association with environmental asbestos exposures.[165,166]

Clinical Features and Diagnosis

Pleural plaques, in the absence of parenchymal disease, typically do not cause abnormal signs and symptoms and are usually detected as an incidental finding on a routine chest radiograph (eFigs. 101.9, 101.10, 101.12A). Only modest proportions of pleural plaques seen at autopsy are detected on posteroanterior chest radiographs. CT scans can identify pleural plaques (Fig. 101.8, eFigs. 101.12B and 101.13) at an earlier, less well-developed stage and can differentiate plaques from extrapleural fat pads. The lung volumes of patients with pleural plaques are on average modestly reduced,[167,168] whereas the D_{LCO} is generally normal.[137,148,169] Increasingly, it is recognized that, in some individuals, pleural plaques may be associated with respiratory disability.[170] The underlying mechanism may be inhibition of inspiratory capacity during exercise that results in an increase in the work of breathing.

Pleural fibrosis (eFig. 101.14) is less specific for asbestos exposure than are pleural plaques, and other causes need to be considered in the differential diagnosis. Clinical presentation, like that of pleural plaques, is often as an incidental abnormality detected on a routine chest radiograph (see Fig. 101.8). After careful inquiry, a remote history of exposure, often quite brief but usually heavy, can be obtained from the patient. In the absence of associated parenchymal disease, clinical signs may be minimal, even though functional impairment is detectable. Impairment may be modest even in the presence of severe pleural disease.[140,148,171] In one study, the presence of pleural plaque or pleural thickening was associated with an average FEV_1 deficit of 0.22 L and a forced vital capacity deficit of 0.40 L,[170] but pleural fibrosis occasionally becomes severe enough to precipitate respiratory and cardiac failure and to require pleurectomy.[140,172] (See Chapter 112.)

Given a history of exposure, obliteration of the costophrenic angle is likely to represent the residuum of asbestos pleural effusion.[140] Some subjects present with breathlessness, chest pain, or both, with or without a history of acute episodes, attributable to benign pleural effusions. In rounded atelectasis, the CT scan is particularly useful in delineating the relationship of the rounded lesion to other pleural changes (see Fig. 101.8).[173] Nevertheless, the

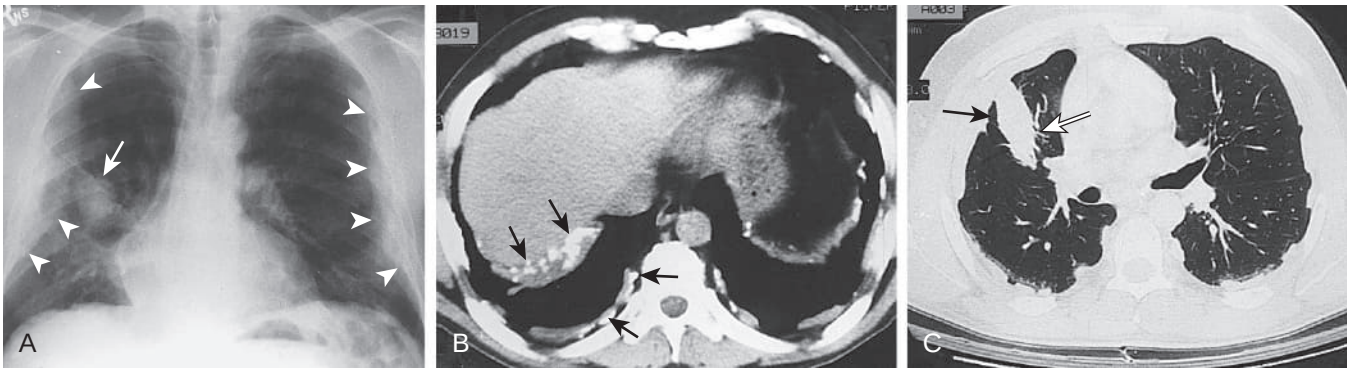

Figure 101.8 Asbestos-related pulmonary parenchymal and pleural disease (bilateral pleural fibrosis and atypical rounded atelectasis) in a 50-year-old man. The patient had worked as an electrician from the age of 17 years, first in construction for 10 years (with known exposure to asbestos), then briefly on naval ships during World War II, and in a chemical plant (with known exposure to talc) for the past 20 years. His only complaint was a dry cough. Chest radiographic abnormalities had been noted 4 years previously. (A) Posteroanterior chest radiograph shows bilateral diaphragmatic plaques, extensive bilateral pleural thickening *(arrowheads),* and a circumscribed lesion in the right midlung zone *(arrow).* (B) On computed tomography, the pleural plaques were shown to be much more extensive than appeared from the chest radiograph. Many plaques *(arrows)* were calcified. In addition, high-resolution computed tomography revealed bands of subpleural fibrosis related to the pleural plaques or thickening, or both. Lung volumes and carbon monoxide diffusing capacity were normal. (C) Axial computed tomography shows the circumscribed lesion also shown in (A) *(arrows).* Because the lesion had enlarged over the past year, it was removed surgically. The lesion consisted of pleural, subpleural, and interstitial fibrosis. Analysis of lung digest revealed 36 asbestos bodies/mg of dry lung tissue and 7570 fibers/mg of dry lung tissue, more than one-half of which were asbestos fibers and less than 1% of which consisted of talc. These findings implicated his earlier, rather than his more recent, occupational exposures as the cause of his pleural disease. (Courtesy Dr. J. Kosiuk, Department of Radiology, Royal Victoria Hospital, Montreal, Canada, who carried out the radiographic studies; and Dr. A. Dufresne, School of Occupational Health, McGill University, Montreal, Canada, who performed the lung dust analyses.)

differential diagnosis of rounded atelectasis includes lung cancer and, in some cases, the diagnosis can be established only by tissue biopsy.

BENIGN ASBESTOS-RELATED PLEURAL EFFUSIONS

Benign asbestos-related pleural effusions may arise without evidence of prior pleural involvement from asbestos exposure or may mark an increase in the extent or severity of an already present pleural reaction. The term "benign" does not imply a lack of clinical significance but rather that the effusion is not associated with mesothelioma.[140]

Benign asbestos-related pleural effusions usually appear within 15 years of the first exposure, often after exposure has ceased.[140] The episodes are usually transient and may be silent, or they may be associated with chest tightness and, occasionally, pleural pain, fever, and dyspnea.[140] Frequently, other benign asbestos-related pleural disease, including pleural plaques and diffuse pleural thickening, are encountered.[174,175]

The effusion is usually small, exudative, and blood tinged.[27] Asbestos bodies are rarely found in the fluid.[176] The sedimentation rate is often raised.[176] Diagnosis is by exclusion, and suggested criteria include (1) an exposure history, (2) the absence of other causes, and (3) absence of tumor on a 3-year follow-up.[136] Because cytologic examination of the pleural fluid is rarely conclusive, a thoracoscopic biopsy is usually required for the following reasons: to exclude other causes; to establish the presence of fibers in the pleural fluid (rarely demonstrable), pleura (sometimes demonstrable), or the underlying lung parenchyma (more frequently demonstrable); and to rule out malignancy, in particular malignant pleural mesothelioma. The usual pathologic findings in benign asbestos-related pleural effusions are those of chronic fibrous pleurisy with minimal cellularity.

The prognosis of benign asbestos-related pleural effusions is generally good because most effusions clear spontaneously. They may recur on the opposite side. Although pleural effusion is a common form of presentation for mesothelioma, there is no evidence that a benign effusion signals a future pleural malignancy. It appears rather to represent a stage in the evolution of asbestos-related pleural fibrosis and carries an associated risk of development of parenchymal fibrosis (asbestosis).[134]

MANAGEMENT, PREVENTION, AND HEALTH MONITORING

No active treatment measures have been shown to influence the course of asbestosis. Patients with end-stage asbestosis have been the recipients of lung and heart-lung transplants, but technical difficulties may arise because of associated pleural disease. The presence of asbestosis is associated with an increased risk for lung cancer.[177,178]

For the nonmalignant asbestos-related pleural disorders, the evidence is reasonably clear that patients with pleural fibrosis are at greater risk for parenchymal fibrosis in the future.[134] The presence of pleural fibrosis or pleural plaques indicates significant asbestos exposure and, consequently, indicates that the patient is at increased risk for malignant pleural mesothelioma and lung cancer.[162] Workers with a history of occupational exposure to asbestos and smoking should be considered for low-dose CT scanning even with lower smoking histories than used for non–asbestos-exposed workers.[179,180] A document from the American College of Chest Physicians highlights areas in which there is and is not consensus regarding the health effects of asbestos exposure.[181]

Smoking cessation is an important preventive measure. The possible role of smoking in the initiation and progression of fibrotic parenchymal disease and its established role

in multiplying the risk of lung cancer in asbestos-exposed individuals are strong indications for smoking cessation.

It is important to make the appropriate notification of a case of asbestos-related disease. Employment advice should be guided by knowledge of the impact of further exposure on the natural history of the disease,[137,140,148] as well as by the risks for developing additional asbestos-related disease. It is important to emphasize that, even in the absence of any further exposure, all nonmalignant asbestos-related diseases may progress because of the dust load already in the lungs. Working in a dusty occupation also puts the worker at risk for developing COPD.[157]

BERYLLIUM LUNG DISEASE

BERYLLIUM: USES, HUMAN TOXICITY, AND EXPOSURES

Beryllium is a rare metal that has many applications in modern industry because of its light weight, tensile strength, high melting point (1500°C), excellent alloying properties (beryllium-copper alloys are the most widely used), good thermal and electrical conductivity, resistance to corrosion, and ability to reduce the speed of nuclear fission.

Workers can be exposed to beryllium in a wide variety of industries, including the manufacture of alloys, ceramics, radiographic equipment, and vacuum tubes and in the extraction and smelting of beryllium. At least 134,000 current US workers are estimated to be exposed to beryllium, and more are at risk when former, contract, and construction workers are added to the list.[182] Industries that actively use beryllium alloys and salts include foundries, aerospace, automotive parts, electronics, ceramics, metal smelting and recycling, nuclear (reactors, weapons), telecommunications, tool and die, and welding.[183,184] Environmental exposure to beryllium has been reported in residents living near a beryllium manufacturing facility.[185] Individuals with trivial exposures, including security guards, secretaries, and bystanders, have been reported to develop disease, thus indicating that there may not be a clear dose-response relationship.

PATHOLOGY AND IMMUNE PATHOGENESIS

Chronic beryllium disease (CBD) is a multisystem disorder characterized by the formation of noncaseating granulomas throughout the body, although their primary manifestation is in the lung.[183] On pathologic examination, CBD is characterized by the presence of a lymphocytic (helper/inducer T cells) alveolitis, as well as of noncaseating epithelioid granulomas indistinguishable from those of sarcoidosis (eFig. 101.16). There is a variable amount of fibroblastic activity that progresses to interstitial fibrosis as the lesions mature. Granulomatous lesions may occasionally be found in other sites, including thoracic and abdominal lymph nodes, spleen, liver, kidneys, and adrenal glands.

Beryllium enters the body by inhalation and, occasionally, through the skin, where it acts as a specific antigen, alone or as a hapten. Subsequently, beryllium-specific $CD4^+$ lymphocytes proliferate and release lymphokines. There is a wide range in the reported prevalence of beryllium sensitization, from less than 1% to as high as 20% of exposed individuals,[186] and this range appears to be related to the level of beryllium exposure. Progression to CBD develops in a smaller number of sensitized individuals, 6–8% in some studies, with the highest risk in the first few years after exposure.[187,188] Because the agent persists in the lung, its slow release over time explains the appearance and progression of disease, even without further exposure.[27] There is evidence for an underlying genetic basis for susceptibility to beryllium disease, linked to a major histocompatibility complex class II marker (human leukocyte antigen $DP\beta\text{-}1^{Glu69}$) carrier status. A review of the immunology and genetic susceptibility summarizes current understanding of these complex gene-environment interactions.[189]

CLINICAL FEATURES

Acute beryllium disease is now uncommon. The disorder is associated with high, and usually accidental, exposure, and it may manifest with an acute syndrome with features of the acute respiratory distress syndrome or in a subacute form with features of pneumonitis.[190]

CBD may follow acute beryllium pneumonitis but more usually develops in individuals with low-level long-term exposure. The clinical features of CBD are similar to those of pulmonary sarcoidosis, although extrapulmonary manifestations, including hilar and mediastinal lymphadenopathy and splenomegaly, are less common.[190,191] There may be no associated symptoms,[192] but symptoms when present often include dyspnea, cough, chest pain, weight loss, fatigue, and arthralgias. Physical signs may include crackles, but signs of lung disease are often absent.

The usual radiographic findings are ill-defined nodular or irregular opacities (eFig. 101.17A–B, Video 101.5). Hilar lymphadenopathy (eFigs. 101.17C–D) is seen in approximately 40% of cases but is usually mild.[183] In the later stages of the disease, patchy fibrosis is seen, with adjacent hyperinflation or distortion and extensive honeycombing.

Obstruction is the most commonly encountered pulmonary function abnormality, but restriction, a mixed process, or an isolated reduction in D_{LCO} may also be observed.[193] The clinical course of CBD is variable; some cases remain stable, some relapse and remit, and some relentlessly progress.[183]

DIAGNOSIS AND MANAGEMENT

Suspicion for possible beryllium exposure, sarcoidosis, or interstitial lung disease should prompt a thorough occupational history, one that spans the worker's lifetime as a result of the latency between exposure and disease. Seemingly minimal exposure to beryllium has been reported in cases of CBD.[194,195]

Evidence for delayed hypersensitivity to beryllium may be assessed by the in vitro *beryllium lymphocyte proliferation test* (BeLPT) on lymphocytes from blood or BAL fluid.[196,197] Diagnosis of beryllium sensitization or beryllium-related lung disease requires demonstration of a beryllium-specific immune response, which is confirmed by one of the following: two abnormal peripheral blood BeLPT results, one abnormal and one borderline peripheral blood BeLPT result, one abnormal BAL BeLPT result, or a positive skin patch

test result.[193] The BeLPT has allowed for the introduction of three categories of beryllium-associated disorders: beryllium sensitization (positive BeLPT result with negative biopsy or absence of clinical or radiologic features of beryllium-related lung disease), subclinical beryllium disease (positive BeLPT result and biopsy without clinical or radiologic features of the disease), and CBD (positive BeLPT result and biopsy with clinical and radiologic features of disease).[198]

Despite the generally lower beryllium exposures since the 1950s and its decreasing frequency, CBD should remain in the differential diagnosis of sarcoidosis because of the long latency time of disease. Clusters of suspected sarcoidosis in a workplace should alert the clinician to the possibility that these represent examples of CBD. In this context, note should be made of the wide range of occupations associated with potential exposure to beryllium. Additionally, beryllium is considered a human carcinogen, especially in the presence of beryllium lung disease; in 1993, the International Agency for Research on Cancer classified beryllium as a class 1 human carcinogen.[199]

The most important step in case management in the setting of beryllium sensitization is to consider complete cessation of further exposure to beryllium because of the risk of progression to CBD. Regular medical surveillance is indicated in these individuals. There is limited evidence that CBD will improve with removal of the worker from additional beryllium exposure.[193] Although there is no randomized clinical trial to evaluate this treatment, corticosteroid therapy has been recommended in CBD,[200] initiated on the basis of symptoms, imaging, and pulmonary function test results. Long-term steroid therapy is believed to alter the course of the disease favorably.[193] A small trial with infliximab showed improvement in immune response, quality of life, and a trend toward improved D_{LCO} in the subgroup of patients with low D_{LCO} at baseline.[201]

Acknowledgments

We thank Robert Cowie, MD, and Margaret Becklake, MBBCh, MD, for their contributions to earlier versions of this chapter.

Key Points

- Workplace and environmental exposure to disease-causing dust is a common cause of lung disease. Therefore, a detailed history that includes current and prior occupations should be part of every respiratory assessment.
- Chest imaging and physiologic evaluation are the cornerstones of evaluation for pneumoconiosis. Lung biopsy may be necessary in selected cases.
- In addition to classic pneumoconioses caused by silica, coal mine dust, and asbestos, exposed workers may develop a spectrum of disease that includes obstructive lung diseases, lung cancer, connective tissue diseases, and infections such as tuberculosis.
- Silicosis has long been associated with exposure to toxic respirable crystalline silica in construction, mining, tunneling, and foundry work. Silicosis has more recently been described in newer industries and tasks, such as sandblasting of denim, fabrication of engineered stone products, and jewelry production.
- Coal mine dust lung disease is a spectrum of lung diseases caused by a mixture of dust constituents including coal, silica, silicates, and diesel exhaust particulate. The condition may manifest not only as classic coal workers' pneumoconiosis, but also as obstructive lung disease and pulmonary fibrosis, known as dust-related diffuse fibrosis.
- Despite well-known health risks, asbestos remains a widely used mineral resource, including in the United States. As a result, workers remain at risk for asbestos-related diseases, including asbestosis, pleural plaques, pleural mesothelioma, and lung cancer. Given the long latency times for these disease manifestations, asbestos-related disease will remain clinically relevant in the decades to come.
- Pneumoconioses are untreatable and cause significant long-term impairment, disability, and death. Therefore, prevention of pneumoconioses should be a primary public health concern.

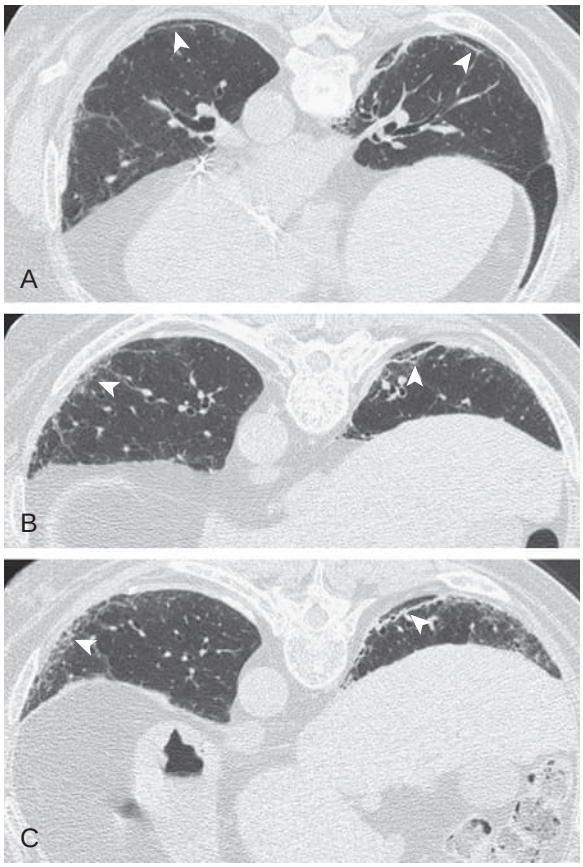
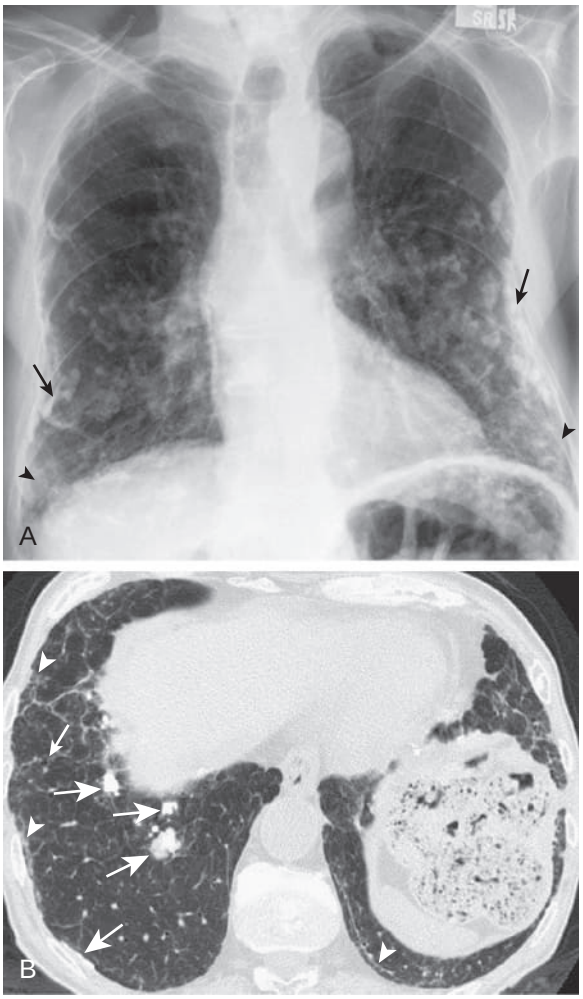
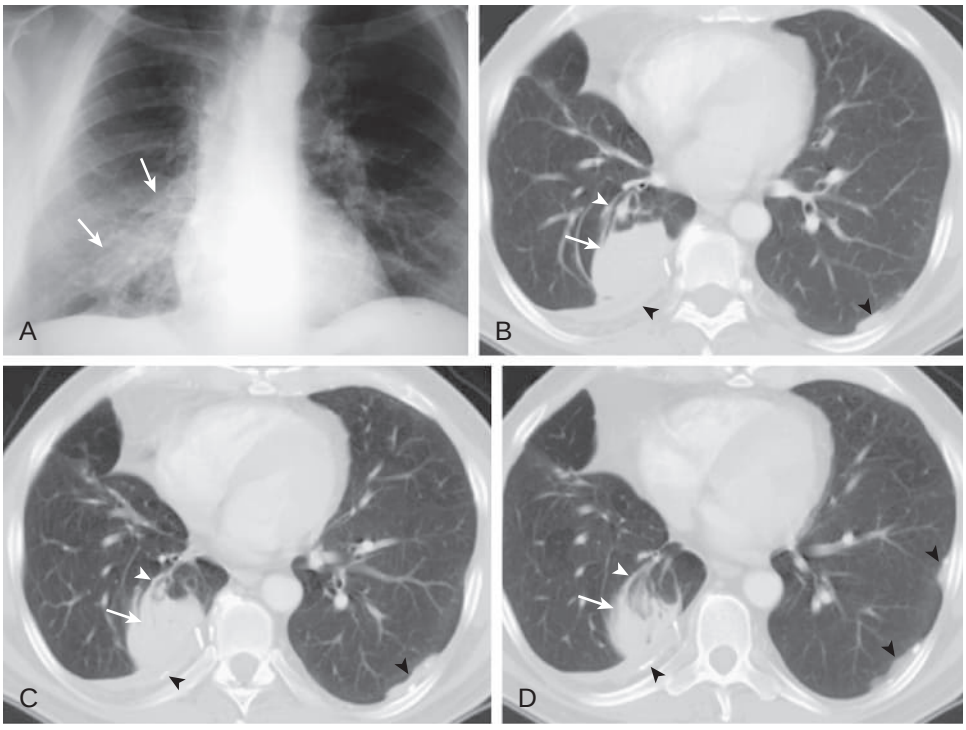
Frontal chest radiograph in a patient with asbestos exposure shows bilateral calcified pleural plaques *(arrows)* and obscuration of the left cardiac border *(arrowheads),* representing the "shaggy heart" border sign in asbestosis. (Courtesy Michael B. Gotway, MD.)



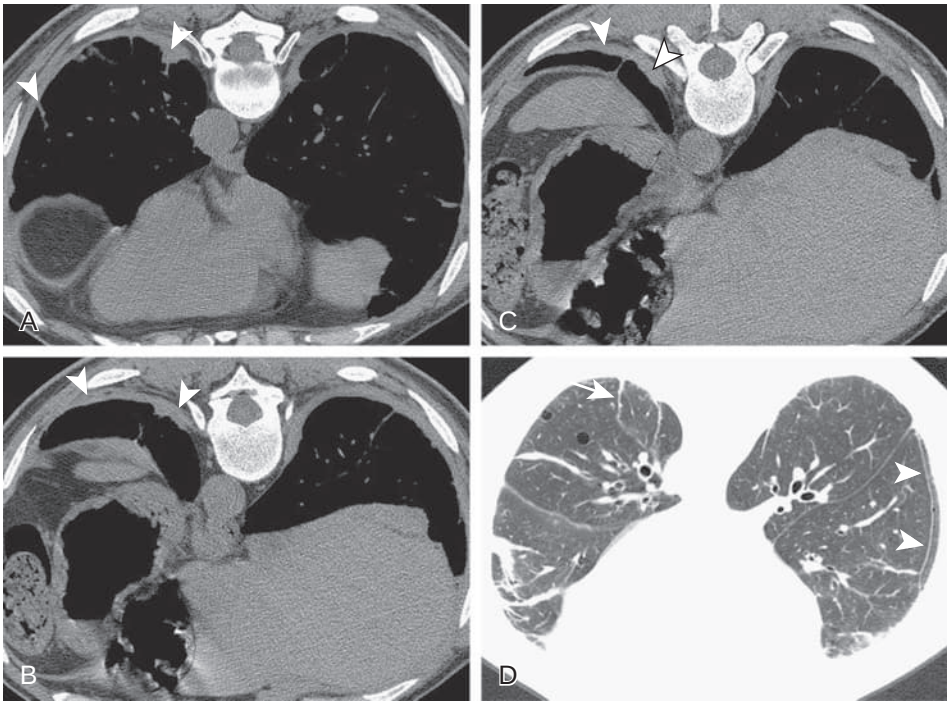
eFigure 101.11 Asbestosis: axial chest computed tomography. (A–C) Axial prone high-resolution computed tomography of the lung through the bases in a patient with asbestos exposure shows bilateral, subpleural linear, and reticular opacities *(arrowheads)* consistent with asbestosis. (Courtesy Michael B. Gotway, MD.)



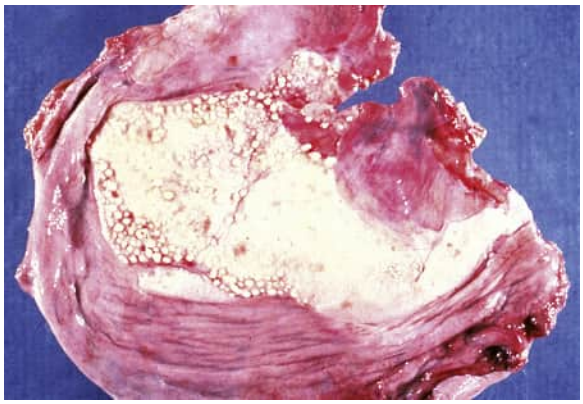
eFigure 101.12 Asbestosis with calcified pleural plaques: chest radiograph and axial chest computed tomography. (A) Frontal chest radiograph in a patient with asbestos exposure shows bilateral calcified pleural plaques *(arrows)* and faint basal linear and reticular abnormalities *(arrowheads)* suggesting possible fibrotic lung disease. The heavy pleural calcification limits assessment. (B) Axial chest computed tomography through the lung bases shows pleural calcifications *(large arrows)* and peripheral linear and reticular opacities *(arrowheads)* with mild traction bronchiectasis *(small arrow),* confirming fibrotic lung disease. (Courtesy Michael B. Gotway, MD.)



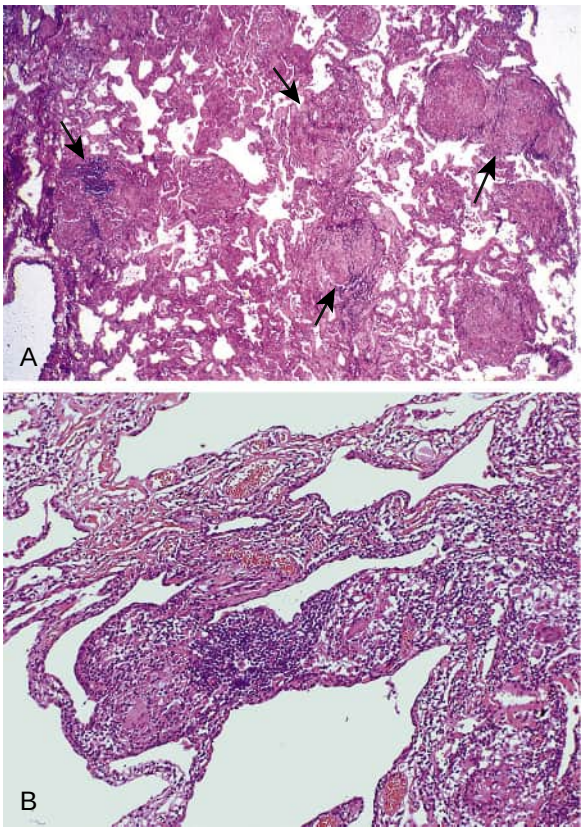
eFigure 101.13 Asbestos-induced pleural plaques and rounded atelectasis: chest radiograph and axial chest computed tomography. (A) Frontal chest radiograph in a patient with asbestos exposure shows a poorly defined right lower lobe opacity *(arrows).* (B–D) Axial chest computed tomography through the lung bases shows calcified and noncalcified pleural plaques *(black arrowheads)* and confirms the right lower lobe subpleural mass *(arrows).* The mass is in contact with abnormal pleura and is associated with a spiraling configuration of the bronchovascular bundles *(white arrowheads)* leading to the mass, as well as right lower lobe volume loss—these features are consistent with rounded atelectasis (see Video 101.4). (Courtesy Michael B. Gotway, MD.)



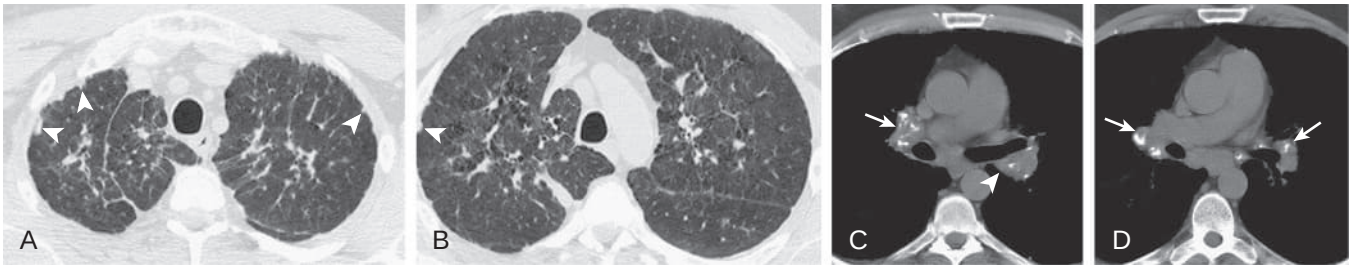
eFigure 101.14 Diffuse pleural thickening related to asbestos exposure: axial chest computed tomography. Axial prone chest computed tomography in soft tissue (A–C) and lung windows (D) shows extensive contiguous pleural thickening (*arrowheads*, A–C) extending continuously from the posteromedial thorax along the right lateral thorax. (D) Image displayed in lung windows shows other pulmonary parenchymal findings associated with asbestos exposure, such as parenchymal bands *(arrow)* and a subpleural line *(arrowheads).* (Courtesy Michael B. Gotway, MD.)



eFigure 101.15 Pleural plaque: gross appearance. The whitish plaque has been resected along with surrounding tissue and is viewed en face. Its gross appearance has been likened to that of candle wax drippings. (From Butnor KJ, Roggli VL. Pneumoconioses. In: Leslie KO, Wick MR, eds. *Practical Pulmonary Pathology: A Diagnostic Approach: A Volume in the Pattern Recognition Series.* 2nd ed. Philadelphia: Elsevier; 2011:311–338.)



eFigure 101.16 Chronic beryllium disease: pathology. (A) The presence of numerous granulomas is characteristic of chronic beryllium disease *(arrows)*. (B) In addition to granulomatous inflammation, there is a chronic interstitial inflammatory infiltrate. (From Butnor KJ, Roggli VL. Pneumoconioses. In: Leslie KO, Wick MR, eds. *Practical Pulmonary Pathology: A Diagnostic Approach: A Volume in the Pattern Recognition Series.* 2nd ed. Philadelphia: Elsevier; 2011:311–338.)



eFigure 101.17 Chronic beryllium disease: axial chest computed tomography. (A–B) Axial chest computed tomography shown in lung windows shows subpleural nodules (*arrowheads*) associated with central bronchovascular thickening and architectural distortion. The appearance resembles sarcoidosis. (C–D) Axial chest computed tomography shown in soft tissue windows shows mild, symmetrical, bilateral calcified lymph node enlargement *(arrows)*. An uncalcified, mildly enlarged left retrobronchial lymph node (*arrowhead*, C) is present. The appearance is identical to that of sarcoidosis. Video 101.5 shows the upper lobe distribution of the pulmonary parenchymal abnormalities to advantage. (Courtesy Michael B. Gotway, MD.)

KEY POINTS

INTRODUCTION

Catastrophic air pollution events in the Meuse Valley of Belgium (1930)[1]; Donora, Pennsylvania (1948)[2]; and London (1952)[3] arose when air stagnation caused high levels of ambient pollutants, especially sulfur dioxide and particles. In each case there was a marked increase in respiratory symptoms and mortality. These "fog disasters" provided incontrovertible evidence that air pollution can have immediate lethal consequences. Since that time, scientific investigations have uncovered myriad adverse respiratory health effects of air pollution, ranging from asthma exacerbation to respiratory mortality.

Because it is the portal of entry for air pollutants, the respiratory system suffers the major consequences of air pollution. This chapter reviews the key air pollutants, which are termed *criteria pollutants* by the *U.S. Environmental Protection Agency* (EPA), and how they affect the airways and lungs (Table 102.1). Both indoor and outdoor air pollution are considered. Respiratory health conditions most strongly linked with air pollution are reviewed. Although evidence is accumulating that links air pollution to noncardiopulmonary outcomes (e.g., adverse birth outcomes, metabolic dysfunction, cognitive development, and dementia), these topics are not considered.

AIR POLLUTANTS

POLLUTANTS: WHAT THEY ARE AND WHY THEY MATTER

Air pollution involves the contamination of the atmosphere by chemicals, particles, or biologic materials that cause human morbidity and mortality; damage other living organisms, such as plants; or adversely affect the natural environment, such as by reducing visibility. Pollutants can be emitted from mobile sources (e.g., vehicles), stationary sources (e.g., factories, power plants, refineries), and indoor sources (e.g., building materials, gas stoves, passive smoking, cleaning products).[4,5]

The major types of air pollutants affecting the respiratory system are *particulate matter* (PM), *sulfur dioxide* (SO_2), *nitrogen dioxide* (NO_2), and *ozone* (O_3) (Table 102.2).[4,5] These pollutants arise directly from mobile and stationary sources. O_3 is a secondary pollutant that arises from the action of sunlight on nitrogen oxides and hydrocarbons present in motor vehicle exhaust. It is a major component of photochemical pollution, or smog. The respiratory health effects of these pollutants are considered later in this chapter. Two other air pollutants, *carbon monoxide* (CO) and lead, which also enter via the respiratory tract, have primarily nonpulmonary toxicity and are not discussed in this chapter. Toxic air pollutants (*air toxics*) are a subset of air pollutants that may cause cancer or other serious health effects, such as birth defects. These substances, such as benzene and cadmium, also produce primarily nonrespiratory effects despite entering the body via the respiratory tract; as a result, they are also not discussed in this chapter.

Carcinogens are also found in outdoor air, including the known lung carcinogens *polycyclic aromatic hydrocarbons* (PAHs), *n*-nitroso compounds, and asbestos. Their concentrations in ambient air, however, are quite low. Diesel exhaust, in particular, contains particles with PAHs as constituents. Epidemiologic studies have provided consistent evidence of an excess risk of lung cancer in workers exposed to diesel exhaust; it is listed by the International Agency

on Cancer Research as a known human carcinogen.[6–9] Several large population-based epidemiologic studies have also linked lung cancer to long-term exposure to PM and traffic-related air pollution.[10,11]

As levels of outdoor ambient air pollution have decreased in many areas throughout the United States, the relative impact of indoor air pollution has increased. Moreover, North American residents spend the majority of their time indoors, increasing their exposure to indoor air pollutants.[12,13] At the same time, changes in home and office building construction have resulted in lower air exchange rates, increasing the levels of pollutants emitted indoors. In the developing world, indoor air pollution due to biomass smoke from domestic cooking and heating is a major source of morbidity and mortality.[14] Biomass smoke is a mixture of gases and PM similar to tobacco smoke, with the exception that it does not contain nicotine. In the developed world, emissions from cooking may also be an underappreciated source of morbidity. Both indoor and outdoor pollution must be considered when assessing the total health effects of air pollution.

Table 102.1 National Primary Air Quality Standards in the United States (Criteria Pollutants)

Pollutant	Standard*	Averaging Period
Particulate matter < 10 μm (PM_{10})	150 μg/m³	24 hr
Particulate matter < 2.5 μm ($PM_{2.5}$)	12 μg/m³ 35 μg/m³	1 yr 24 hr
Sulfur dioxide	75 ppb (214 μg/m³) 500 ppb (1430 μg/m³)	1 hr 3 hr
Nitrogen dioxide	100 ppb (188 μg/m³) 53 ppb (100 μg/m³)	1 hr 1 yr
Ozone	70 ppb (100 μg/m³)	8 hr
Lead	0.15 μg/m³	Rolling 3-mo average
Carbon monoxide	9 ppm (10 mg/m³) 35 ppm (40 mg/m³)	8 hr 1 hr

*Where two standards are listed, the first is the primary air quality standard set by the U.S. Environmental Protection Agency to protect health. The second standard listed is the so-called secondary standard, which is set to protect the public welfare (i.e., to protect against decreased visibility and damage to animals, crops, vegetation, and buildings).
ppb, parts per billion; ppm, parts per million.

GENERAL PROPERTIES, SOURCES, AND DISTRIBUTION OF POLLUTANTS

Particulate matter (PM) is an important pollutant. In the western United States and many other areas of the world, particulate pollution is not driven by the combustion of sulfur-containing fuels. Atmospheric particulate air pollution arises from a variety of sources, including both natural (e.g., sea spray, windblown dust) and synthetic (e.g., power plants, motor vehicles) sources. Moreover, PM that enters the atmosphere can be primary (particles emitted directly) or secondary (particles formed by complicated chemical reactions happening in the atmosphere and involving gas-phase precursors, such as SO_2 and nitrogen oxides). In North America, secondary particles comprise most of the fine-particle pollution.

In epidemiologic studies, researchers have defined the size of particles in terms of aerodynamic diameter because most particles have irregular shapes with geometric diameters not easily measured. The aerodynamic diameter is the diameter of a perfect sphere of unit density (1 g/mL) with the same aerodynamic properties (e.g., settling velocity) as the particle in question. Larger particles are filtered in the nose and throat, but particles less than 10 μm in diameter (PM_{10}) can be deposited in the respiratory tract. Fine particles, which are less than 2.5 μm in diameter ($PM_{2.5}$), penetrate to the alveoli, and ultrafine particles ($PM_{0.1}$) can pass through the alveoli and spread to other organs.

Size also determines how far particles travel and persist in the environment. Coarse particles (>2.5 to 10 μm) travel for rather short distances and have atmospheric half-lives of minutes to hours. Fine particles can travel for long distances and remain in the atmosphere for days to weeks.

Table 102.2 Major Pollutants Associated With Adverse Pulmonary Effects

Pollutant	Outdoor Sources	Indoor Sources	Adverse Effects
Particulate matter	Motor vehicle exhaust, power plants	Tobacco and wood smoke	Exacerbations of asthma and COPD, increased cardiopulmonary mortality
Sulfur oxides	Power plants, oil refineries, smelters	Kerosene space heaters	Bronchoconstriction
Nitrogen oxides	Motor vehicle exhaust, power plants, oil refineries	Gas stoves and furnaces, kerosene space heaters	Airway injury (respiratory bronchiolitis), impaired lung defenses, enhanced response to allergens
Ozone	Motor vehicle exhaust	Aircraft cabins, welding, copiers, ozone generators	Airway injury (respiratory bronchiolitis), decreased lung function, exacerbations of asthma, enhanced response to allergen
Radon	None	Residential basements	Lung cancer
Polycyclic aromatic hydrocarbons	Diesel exhaust	Tobacco smoke	Lung cancer

Ultrafine particles are typically generated from combustion processes and, due to their high reactivity, have short atmospheric half-lives due to physical agglomeration and chemical growth. For example, the concentration of ultrafine particles emitted from motor vehicles on a major roadway rapidly decreases with distance from the roadway; the concentration returns to the background level at or beyond 300 m.[15]

Fine particles ($PM_{2.5}$) are composed mainly of varying amounts of water and several major components (sulfates, acids, nitrates, elemental carbon, organic carbon, and trace metals) depending on their sources.[16] They are directly emitted during combustion but are also formed from gases by nucleation, condensation, or liquid-phase reactions. Coarse particles ($PM_{10-2.5}$) are composed primarily of crustal (rock, soil), biologic (pollen, spores), and industrial components; they are formed primarily by mechanical processes that produce small particles from larger particles.

Sulfur dioxide (SO_2) is produced by the combustion of sulfur contained in fossil fuels, such as coal and crude oil. The major sources of SO_2 pollution are power plants, oil refineries, smelters, and paper pulp mills. A newly recognized source of exposure to SO_2 associated with acute health effects is volcanic emissions.[17] For example, the major source of SO_2 exposure on the island of Hawai'i is the Kilauea Volcano, which has been erupting for nearly 40 years, sometimes emitting up to 12 kilotons in a day.[17] Although eruption events are impressive, global satellite data suggest that passive degassing of SO_2 from nonerupting volcanoes is the major global source, with 63 kilotons emitted daily worldwide.[18] In the United States, SO_2 levels are generally higher in the Northeast and Midwest because sulfur-containing coal is used in power plants. SO_2 itself is a clear, highly water-soluble gas, so it is effectively absorbed by the mucosal surfaces of the upper airways. Only a small proportion of inhaled SO_2 reaches the distal regions of the lungs, but susceptible persons, such as those with asthma, may still suffer adverse respiratory health effects.[19] The SO_2 released into the atmosphere does not, however, remain uniquely in the form of a gas; rather, it undergoes chemical reactions with water, trace metals, and other pollutants to form particulate aerosols. The nature of particles generated from sulfur-containing fuels varies geographically, but sulfuric acid and various metallic, acidic, and ammonium sulfates are commonly present. The mixture of sulfur oxides and small particles may be blown great distances from its source, undergoing continuous transformation from a gas to a particle phase and ultimately becoming acid rain.

Nitrogen dioxide (NO_2) is rapidly generated from nitrogen oxides, which are produced whenever there is combustion. Motor vehicles and power plants are the major sources of this pollutant. The areas with the highest concentrations of NO_2 tend to be the downtown cores of large cities, where there are major roadways and traffic congestion. Because NO_2 tracks well with traffic emissions, it is often considered a marker of traffic-related air pollution in epidemiologic studies. NO_2 reacts with oxygen to generate O_3 and nitric oxide, but this is a bidirectional reaction so that O_3 levels tend to be lower in areas where NO_2 is concentrated. Thus, O_3 levels tend to be lower in neighborhoods adjacent to major roadways. High concentrations sometimes found in silos are well known to cause the acute and sometimes lethal pulmonary edema of silo filler's disease.[20] However, the much lower levels of NO_2 in outdoor air were not linked to adverse health effects in epidemiologic studies until the late 20th century.

Ozone (O_3) arises primarily from the action of sunlight on emissions from internal combustion engines of motor vehicles.[21] The most important of these emissions are unburned hydrocarbons (so-called *volatile organic compounds* [VOCs]) and nitrogen oxides. In the atmosphere farther away from traffic sources, ultraviolet irradiation of the mixture of VOCs and NO_2 results in a complex series of chemical reactions, producing O_3, alkyl nitrates, peroxyacyl nitrates, alcohols, ethers, acids, peroxyacids, and other organic and inorganic compounds that exist in both gas and particulate aerosol phases.[21] This mixture of pollutants typifies the smog found in areas with large numbers of automobiles and abundant sunlight, such as the Los Angeles basin.

Because O_3 and NO_2 are the gases present in the highest concentration in smog and cause toxic effects in animals and humans, they have been the oxidant pollutants most extensively studied. Both gases are relatively insoluble and poorly absorbed by the upper airways. A high proportion of the inhaled dose therefore reaches the peripheral portion of the lungs and can cause injury at any site from the upper airways to the alveoli.

MECHANISMS OF DEFENSE AGAINST AIR POLLUTION–RELATED RESPIRATORY EFFECTS

The respiratory system, which encounters myriad particles and gases daily, has evolved an effective defense system for removing impurities from inhaled air. The various mechanisms of defense are interrelated and work in a coordinated manner. A perturbation of any defense mechanism, whether because of congenital deficiency, disease, or the effect of an inhaled pollutant itself, may result in the breakdown of the coordinated defense system and the development of disease.

DEPOSITION OF AND CLEARANCE OF PARTICLES (see Chapter 13)

The size of particles determines their site of deposition in the respiratory tract.[23] Large particles (diameter > 10 μm) are efficiently removed in the nose by simple filtration via the cilia. Those particles not removed by filtration will largely be deposited by a process termed impaction. The pathway through the nose, mouth, and branching airways is tortuous. Because inhaled particles cannot easily change direction to follow the abrupt changes in the pathway of airflow, they impact on the mucosa of the upper and lower respiratory tract. Airway bifurcations are especially prone to particle impaction. The complementary mechanisms of filtration and impaction are efficient; therefore, few particles more than 10 μm in diameter reach the lower respiratory tract.

Smaller particles are less affected by filtration and impaction; the sites of their deposition are more determined by the processes of sedimentation and diffusion.[23] Sedimentation is the tendency for particles to fall at a constant rate under the influence of gravity. It is strongly influenced by particle density, particle diameter, and the viscosity of the surrounding gas. As air moves deeper into the lung, the airflow rate decreases, and particles fall out of the air stream under the influence of gravity. Sedimentation is the predominant mechanism for deposition of particles of intermediate size (0.5 to 3.0 μm) in the smaller bronchi, bronchioles, and alveoli.

The smallest particles (<0.5 μm), however, are deposited by the mechanism of diffusion. These particles have random (Brownian) motion and will impact the airway mucosa in the terminal bronchioles and alveoli, removing them from the stream of inspired air.

The pattern of breathing can influence the deposition of particles. A higher respiratory rate increases the velocity of airflow, promoting impaction of particles in the more proximal airways. Conversely, increased tidal volume results in deeper lung penetration by particles; when the respiratory rate is slow, there is more time for diffusion and sedimentation to deposit particles in the distal airways and alveoli. In exercise, the increase in tidal volume will have a larger effect than the effect of increased velocity, resulting in higher overall deposition into the deep lung despite some increased airway impaction.

In the larger, more central airways, cough is the most effective mechanism for clearing particles. It is provoked by stimulation of afferent nerves located most densely in the mucosa of the larynx and branching points of the tracheobronchial tree, sites at which particles are most likely to be deposited.[24]

In the proximal trachea down to the terminal bronchioles, the "mucociliary escalator" is the critical system for clearing particles. The mucus blanket is the product of secretion by goblet cells and serous cells of the epithelium and by the mucus cells and serous cells of the submucosal glands. The mucus blanket is propelled toward the mouth by the coordinated beating of epithelial cell cilia. The effective removal of particles by the mucociliary system thus requires secretion of glycoproteins by specialized secretory cells, maintenance of liquefaction by the transport of water and solute by airway epithelial cells, and coordinated function of airway cilia. Impairment of any of these functions, whether by congenital or acquired conditions affecting mucus or water secretion (e.g., cystic fibrosis, chronic bronchitis) or ciliary function (e.g., dysmotile cilia syndrome, tobacco smoking), leads to longer residence of particles in the airway and a greater likelihood of adverse health effects.

In the distal airway and alveoli, particles are beyond the reach of the mucociliary escalator. The central mechanism for clearing these particles involves the alveolar macrophage, which phagocytoses particles deposited in the gas-exchanging parts of the lung and either digests them or removes them as it migrates to the respiratory bronchiole and ascends the mucociliary escalator. A smaller number of particle-laden macrophages migrate to peribronchial or perivascular connective tissue, a slow method of clearance that takes many weeks. Because macrophages are the primary phagocyte for inhaled PM, the carbon content of macrophages has been used as a biomarker of exposure to particulate pollution in epidemiologic studies.[25]

GASES: DEPOSITION AND DAMAGE ARE FUNCTIONS OF SOLUBILITY

For gaseous pollutants such as SO_2, NO_2, and O_3, the site of deposition in the respiratory tract is largely a function of water solubility. For highly soluble gases, the nose serves an important defensive function because the air inhaled transnasally is passed over the large, irregular surface of the turbinates. The promotion of turbulent flow prolongs contact with the mucosal surface, increasing adsorption. Under conditions of quiet breathing, when most air is inspired transnasally, the concentration of SO_2 that reaches the glottis is less than 2% of the concentration inspired at the nose.[26] As the inspiratory flow rate increases, the proportion of SO_2 reaching the glottis increases. Compared to the nose, the mouth is substantially less efficient at adsorbing gases, and the proportion of air inhaled through the mouth increases as the ventilatory demands of exercise rise. Therefore, the dose of a soluble pollutant delivered to the lower airways is increased by exercise for three reasons: the inspiratory flow is higher, the proportion inhaled through the mouth is increased, and the total quantity inhaled over time is greater. The importance of the level of ventilation, which depends on the level of exercise, and of the oral-nasal distribution of breathing has perhaps best been shown in studies of the bronchoconstrictor response to SO_2, in which the responses are greatest during oral breathing and smallest during nasal breathing.[27] In addition, people with obstructive nasal disease also appear to be at greater risk for adverse respiratory effects of soluble pollutant gases.

OXIDATIVE STRESS

Air pollution, especially involving particles and O_3, can increase the oxidative burden to the lung. To minimize oxidant damage to biologic molecules, the human lung has an integrated antioxidant system of enzymatic and expendable soluble antioxidants. This system includes several antioxidant defense mechanisms that detoxify reactive products or convert them to products quenched by other antioxidants. If the oxidant burden is sufficiently great, the reactive species may overwhelm or inactivate the antioxidant system. An imbalance between the production of reactive oxygen species and reactive nitrogen species and antioxidant capacity leads to a state of oxidative stress that contributes to the pathogenesis of respiratory and cardiovascular diseases.[28–30]

When imbalance exists, the excess oxygen species induce a cellular stress response that activates a number of the redox-sensitive signaling cascades. This initial response is mediated in large part through the transcription factor nuclear factor erythroid 2–related factor 2, which leads to transcriptional activation of antioxidant and detoxification

enzymes collectively known as the phase 2 response.[30] Examples of phase 2 enzymes include heme oxygenase 1, glutathione-*S*-transferase isoenzymes, reduced nicotinamide adenine dinucleotide phosphate–quinone oxidoreductase, catalase, superoxide dismutase, and glutathione peroxidase. If phase 2 responses fail to prevent a further increase in reactive oxygen species production, major cellular components, including membrane lipids, protein, carbohydrates, and DNA, will be damaged and inflammation and tissue damage may ensue.

Oxidative stress–induced proinflammatory effects are mediated by the redox-sensitive cascades responsible for the expression of cytokines, chemokines, and adhesion molecules.[30] Cytotoxic effects are associated with mitochondrial membrane damage, which leads to a release of factors that induce apoptosis of lung cells. Pathophysiologic consequences of pollutant-induced oxidant injury include airway inflammation, leading to clinical exacerbation of asthma, increased susceptibility to infection, enhanced allergic responses and, if repetitive or chronic, airway remodeling and systemic effects.[29,30]

METHODS OF STUDYING THE HEALTH EFFECTS OF AIR POLLUTION

To develop sound public policy aimed at protecting the public from the adverse health effects of pollutants, scientific studies are necessary both to elucidate the health effects of various pollutants and to define the threshold level at which the risk substantively increases. The scientific basis of public policy is based on several lines of evidence: epidemiologic studies of the association between air pollution and disease in the population, controlled human exposure studies conducted in the laboratory, studies of the effects of pollutants on lung structure and function in animals, and in vitro studies of toxicity. Each of these study designs has advantages and disadvantages, and none alone can provide irrefutable proof of harmful effects from a particular pollutant under realistic conditions of exposure (Table 102.3).

According to the 1970 Clean Air Act, air quality standards are set to provide a margin of safety to protect susceptible subgroups of the general population. For each putative pollution-related health effect, evidence must be compiled from published literature, synthesized, and evaluated for the likelihood of a causal association. Traditionally, the EPA uses a weight-of-the-evidence approach to assess the strength, consistency, and specificity of the association; coherence with related health effects; biologic plausibility; and exposure-response relationship. Epidemiologic studies are required because they evaluate the impact of real-world air pollution on respiratory health outcomes among the general population. However, epidemiologic studies have limitations (see later).[31]

EPIDEMIOLOGIC STUDIES

The strengths of epidemiologic studies include the ability to evaluate a wide array of health effects, longer durations of exposure, and representative sampling of the larger population. Epidemiologic studies, crucially, allow the study of questions that could not ethically or feasibly be addressed via a randomized controlled trial. Although their weaknesses must also be understood, they remain a valuable source of scientific information. Because epidemiologic studies do not provide mechanistic data, other studies providing human, animal, and cellular toxicologic data are required to understand mechanistic pathways.

One challenge of epidemiologic studies is the risk of confounding or other sources of bias. To make causal inferences regarding air pollutant exposures, the issue of confounding must be addressed in epidemiologic studies of air pollution–related health effects. It is often difficult to be sure that all confounders (e.g., cigarette smoking, occupational exposures, socioeconomic status) have been identified and controlled.

Another challenge of epidemiologic studies is that most environments include a complex mixture of pollutants.

Table 102.3 Methods for Studying Air Pollution

Method	Strengths	Weaknesses
Epidemiologic study	▪ Representative sample of general population ▪ Naturalistic exposure ▪ Broad range of pollutants ▪ Wide range of health outcomes ▪ Study of susceptible subgroups	▪ Chance, bias, confounding are threats to study validity ▪ Difficulty separating effects of individual pollutants when present as multipollutant mixtures ▪ Usually no information on biologic mechanisms
Controlled human exposure study	▪ Rigorous experimental design ▪ Elimination of bias and confounding ▪ Systematic control of exposure levels ▪ Study of susceptible subgroups	▪ Acute effects do not necessarily predict chronic effects ▪ Limited range of exposures and outcomes evaluated
Animal study	▪ Best method for evaluating impact of pollutants on structure and function of lung ▪ Dose-response relationship (from minimal level producing health effects to death)	▪ Large interspecies response to pollutants ▪ Applicability to humans often uncertain
In vitro study	▪ Elucidate cellular mechanisms ▪ Rigorous experimental control	▪ Limited to available cell lines ▪ Applicability to intact human organism often uncertain

Assessing the effects of individual pollutants, one by one, might miss the effects of the mixture. A related issue is multicollinearity, which arises because air pollutant concentrations are correlated with one another, making it difficult to parse out the individual health effects of each pollutant. Sophisticated statistical modeling attempts are used to address these potentially confounding issues, but they remain challenges to valid inferences.[22]

Another major challenge to air pollution epidemiologic studies is exposure assessment. Many studies estimate individual exposure by mapping each individual subject's home (and sometimes schools or workplaces) relative to stationary pollution monitors. Recent advances have also allowed investigators to conduct land-use regression modeling, personal monitoring of exposure to specific pollutants, and the use of remote-sensing satellite data.[32] Choosing the metric of exposure most relevant to disease causation requires careful consideration. With O_3, for example, the 8-hour average from 10 AM to 6 PM may be most appropriate because the EPA air quality standard uses an 8-hour averaging time, and these hours reflect the impact of photochemistry on O_3 precursors emitted from motor vehicles during the morning commute. In contrast, with SO_2, shorter peak exposures would be more appropriate for assessing its effect on exacerbations of asthma. Whether a time lag between onset of exposure to the pollutant and onset of the health outcome (e.g., one or several days) should be considered is also an important question.

CONTROLLED HUMAN EXPOSURE RESEARCH

Experimental studies expose human subjects to pollutants under carefully controlled conditions. Such studies can rigorously evaluate the impact of a single pollutant or a mixture such as diesel exhaust on acute responses, such as lung function or airway inflammation. In addition to documenting the acute health effects of pollution, controlled human exposure studies can evaluate the minimal concentration of a pollutant that causes reduction in lung function or other acute responses. These studies can also evaluate the effects of pollutants on susceptible subgroups of the population, such as on adults with asthma. Moreover, measurement of biomarkers of inflammation, oxidative stress, and other pathophysiologic processes can provide mechanistic insights.

A major advantage of controlled human exposure studies is the (near) elimination of confounding and bias because exposures are experimentally induced and carefully controlled. Because these studies evaluate acute effects, however, they cannot, by themselves, be easily extrapolated to the effects of more chronic or recurrent exposure. The finding that a brief exposure to O_3 causes acute decrements in lung function does not, for example, necessarily indicate that prolonged or repeated exposure will lead to the development of COPD. However, controlled human exposure studies, when combined with epidemiologic and animal toxicologic studies, can provide important data for establishing the causal effect of pollution on a respiratory health outcome.

ANIMAL RESEARCH

Animal studies offer the most effective way to investigate the impact of air pollution on lung structure. In addition, animal studies permit assessment of the effects of a range of concentrations so that a dose-response curve can be constructed for outcomes ranging from the first measurable change in lung function or structure until death. Animal studies also afford a unique opportunity to dissect the pathogenetic mechanisms of pollution-related health effects.

The major limitation of animal studies is the large interspecies variations in response to pollutants. As such, applicability of animal studies to humans, especially for dose-response relationships, may not always be clear. Rodents, for example, can tolerate relatively high levels of O_3 without developing structural injury to the lungs, whereas rhesus monkeys develop injury at levels approaching ambient concentrations.[33] Moreover, common human lung diseases, such as asthma and cystic fibrosis, have not been fully reproduced in animals, precluding study of these susceptible subgroups for pollution-related effects.

IN VITRO RESEARCH

Exposure of cell and model tissue cultures to specific air pollutants has helped to elucidate the mechanisms of lung injury, inflammation, and other adverse respiratory health effects. Specifically, cell culture systems have been used to study the impact of particulate and other air pollutants on inflammatory cytokines, oxidative stress, DNA damage, and cytotoxicity.[34–37,39] Cultures of bronchial and alveolar epithelial cells, monocytes, dendritic cells, and other cell lines have been useful for studying the mechanisms of air pollution on the respiratory system.[37] Models of respiratory epithelium using air-liquid interface exposures can be used to mimic in vivo air pollutant exposures.[37,39]

OUTDOOR AIR POLLUTION: STANDARDS AND ADVERSE RESPIRATORY EFFECTS OF SPECIFIC POLLUTANTS

In the United States, the EPA has established regulatory standards for the criteria air pollutants (PM, O_3, NO_2, SO_2, CO, and lead) (see Table 102.1). Each standard provides a concentration that should not be exceeded, which is intended to be health protective, as well as an averaging time, which ranges from 1 hour to 1 year. Brief, high spikes in air pollutant levels can be obscured in longer-term data; if a pollutant level was near zero most days of the year, a few days of very high levels may not increase the annual average much, even though those days could provoke acute health effects. Thus, for some pollutants, shorter-term standards have been introduced. Because high spikes can be obscured in long-term data, even though these shorter-term standards are often at higher concentrations, they are *more* health protective than the lower concentration standards with longer averaging times. Globally, the World

Health Organization guidance levels are used as a target for protecting human health; these are lower than EPA levels, although there is no regulatory enforcement associated with these.

PARTICULATE MATTER

Since the catastrophic air pollution events of the Meuse Valley, Donora, and the London Fog, hundreds of epidemiologic studies have examined the health impacts of particulate air pollution. There is strong and consistent evidence that particulate pollution causes premature death, principally from cardiovascular and respiratory causes.[38,40–43] Both short-term exposure, measured as daily fluctuation of particulate pollutant levels, and longer-term chronic exposures have been linked with mortality.[44] In particular, the Harvard Six Cities Study[38] and the American Cancer Society study[41] have provided key insights into the long-term health impacts of particulate air pollution. Evidence linking PM_{10} and $PM_{2.5}$ to mortality is robust but is particularly strong for $PM_{2.5}$.

PM increases respiratory symptoms. For example, exposure to PM has been associated with lower respiratory tract symptoms in children, such as cough, wheezing, or shortness of breath.[45,46] Children with asthma are especially vulnerable.[47,48] Adults with asthma who are exposed to higher levels of PM have an increased risk of exacerbations.[49]

PM is also associated with poorer lung function, both in children and in adults. The Children's Health Study conducted in Southern California, which has followed thousands of children over many years, found that fine-particulate pollution was linked to a reduced rate of lung function growth but, with improved air quality over time, growth of lung function improved.[50,51] In adults, particulate pollution has also been linked to poorer lung function and increased risk of COPD, which may reflect decreased growth of lung function in childhood or accelerated decline subsequently.[52] In support of a link between particulate pollution and COPD, other studies have linked ambient particle exposure to a greater risk of hospitalization and death from COPD.[53,54]

Of importance, a reduction in particulate air pollution translates to improved pulmonary function and a longer life span for the population. A Swiss study (SAPALDIA) examined the association between the change in air quality over 11 years and the decline in lung function among a large sample of adults.[55] A reduction in PM_{10} of 10 $\mu g/m^3$ was associated with a decreased rate of annual decline of *forced expiratory volume in 1 second* (FEV_1). To address the impact of declining $PM_{2.5}$ levels on mortality, another study examined 211 metropolitan counties throughout the United States from approximately 1980 to 2000.[42] A decrease in $PM_{2.5}$ of 10 $\mu g/m^3$ was associated with a mean increase in life expectancy of 0.61 years, after taking into account measures of sociodemographic and smoking factors. During the 2 decades of the study, the average life expectancy increased 2.72 years. The authors estimated that up to 15% of this improvement in life span could be attributed to declining particulate pollution levels. In the Harvard Six Cities Study, declining fine particle levels were also shown to be associated with reduced mortality in the United States.[40]

Diesel exhaust is another important component of particulate pollution. Diesel exhaust from heavy-duty trucks and diesel-engine cars is a major contributor to particulate air pollution in many parts of the world. Diesel exhaust particles have a central carbon core and adsorbed organic compounds, including PAHs and other known carcinogens. Occupational exposure to diesel exhaust among truck drivers, railroad workers, and miners has been associated with an elevated risk of lung cancer.[6–8] Toxicologic studies have confirmed the carcinogenic properties of diesel exhaust.[9]

Diesel exhaust exposure can cause acute deterioration of lung function among persons with asthma. A randomized crossover study randomly assigned adult subjects with mild to moderate asthma to walk for 2 hours at lunchtime along Oxford Street in London (the busiest shopping street, in which only diesel-powered buses and taxis are allowed) or in Hyde Park.[56] Fine and ultrafine particle levels were approximately three times higher on Oxford Street than in Hyde Park. The maximal decline in FEV_1 was much greater for subjects during and after a single 2-hour walk on Oxford Street than in Hyde Park, and sputum biomarkers of neutrophilic inflammation were also increased. A second study, including older subjects with COPD, also showed a lung function response while walking for 2 hours on Oxford Street.[57] Other studies indicate that diesel exhaust may favor a type 2 T helper cell (lymphocyte) immune response, further connecting this form of particulate pollution with allergic disease and asthma.[58] Diesel exhaust contains PAHs that have been shown to worsen asthma outcomes, potentially through an epigenetic mechanism decreasing T regulatory cell function.[59]

SULFUR DIOXIDE

Bronchoconstriction is the primary acute effect of SO_2 and is likely mediated by chemosensitive receptors in the tracheobronchial tree. In particular, persons with asthma are most sensitive to the effects of SO_2, which may result from preexisting airway inflammation that leads to enhanced release of mediators, alterations in the autonomic nervous system, and exaggerated response of the chemosensitive receptors. Multiple controlled human exposure studies have observed symptomatic bronchoconstriction in exercising asthmatics after 5- to 10-minute exposures to SO_2 at concentrations similar to those found in ambient air.[60,61] In the published studies, 5–30% of relatively healthy asthmatic subjects experienced moderate or greater decrements in lung function (>100% increase in specific airway resistance or >15% decrease in FEV_1) with exposures to SO_2 concentrations of 200 to 300 *parts per billion* (ppb) during exercise.[60] A clear concentration-response relationship has been demonstrated after exposures to SO_2 at concentrations between 200 and 1000 ppb, with increases in both the severity of effect and the proportion of asthmatic individuals affected. Individuals without asthma do not typically experience bronchoconstriction at these levels.[61]

The results of multiple epidemiologic studies show associations between short-term exposures (generally 24-hour averages) to ambient SO_2 and respiratory morbidity. Several multicity studies and single-city studies have found an association between 24-hour average SO_2 concentrations

and respiratory symptoms in children, particularly those with asthma.[62,63] Generally consistent associations have also been observed between ambient SO_2 concentrations and lung function decrements and health care utilization for all respiratory causes, particularly among children and older adults (≥65 years), and for asthma.[19,63] Because SO_2 and $PM_{2.5}$ are both emitted from the combustion of sulfur-containing fuels, such as coal and heating oil, studies of SO_2 need to address potential confounding by coexposure to PM. This is often statistically difficult because these exposures are related to each other, so many studies use only single-pollutant models. The use of complex statistical methods to consider mixtures is expected to provide further insights in the future.

The observed associations of asthma symptoms and lung function changes with 24-hour average SO_2 exposures in epidemiologic studies may be due to short-term peak exposures similar to the 5- to 10-minute exposures that have produced symptomatic bronchoconstriction in controlled human exposure studies. In other words, the effects of SO_2 on respiratory symptoms and lung function observed in human experimental studies using peak exposures are coherent with the increased emergency department visits and hospital admissions observed in epidemiologic studies. In the initial EPA standards, SO_2 exposures were regulated only in 24-hour and annual averages. This meant that very high short-term exposures, which could trigger acute bronchoconstriction, could be allowed as long as the overall average was low. In 2010, to protect asthmatic individuals from acute episodes of bronchoconstriction, the EPA added a 1-hour ambient air quality standard for SO_2 of 75 ppb.

Several studies have assessed the effects of decreases in SO_2 concentrations on respiratory symptoms due to air quality regulations. In eastern Germany, a marked decline in ambient SO_2 concentrations (90% across the decade of the 1990s) was associated with a decrease in the prevalence of respiratory symptoms.[64] During the study period, however, concentrations of other ambient air pollutants also decreased, including that of PM, which was approximately 60% lower. In a similar study of the effect of a 1990 regulation requiring use of low-sulfur fuel for power generation and on-road vehicles in Hong Kong, large reductions in ambient SO_2 concentrations of up to 80% were associated with reduced respiratory symptoms; in this study, reductions in ambient PM were less than 20%.[65] Although the improved respiratory symptoms observed in both of these intervention studies may be partially attributable to declining concentrations of air pollutants other than SO_2, the results nevertheless provide support for a causal relationship between SO_2 and respiratory health.

NITROGEN DIOXIDE

Controlled human exposure studies provide evidence for increased airway responsiveness to both nonspecific and specific challenges in asthmatic subjects after short-term exposure to NO_2. The results of several older studies suggested that short-term (30- to 60-minute) exposures to NO_2 at concentrations in the range of 100 to 300 ppb may cause increased airway responsiveness to nonspecific bronchoconstrictor agents, such as methacholine and histamine.[66] Other studies involving allergen challenge in asthmatics suggest that NO_2 may enhance both allergen-induced bronchoconstriction and inflammatory responses after exposures as low as 260 ppb NO_2 for 30 minutes during rest.[67,68]

Evidence from a number of epidemiologic studies supports an association between ambient NO_2 and respiratory morbidity, especially among persons with asthma. Multiple epidemiologic studies have shown positive associations between short-term ambient NO_2 concentrations and emergency department visits and hospital admissions for respiratory causes, especially asthma.[19,69] These associations are particularly consistent for children and older adults (age 65+ years) when considering all respiratory diseases and, for children and adults of all ages, when considering asthma.

In addition to the epidemiologic evidence that short-term exposure to ambient NO_2 can cause respiratory morbidity, long-term exposure to NO_2 has been associated with decreased rate of growth of lung function. Results from the longitudinal Children's Health Study indicated that decrements in lung function growth were substantial for boys and girls who lived in southern California communities with higher annual average ambient NO_2,[50] even though the mean annual NO_2 concentrations in these communities ranged from approximately 5 to 40 ppb, well below the current EPA national ambient air quality standard of 53 ppb as an annual average. Similar associations have also been found for PM, inorganic (mostly nitric) acid vapor, and proximity to traffic (<500 m) in this cohort; the high correlation among traffic-related pollutants makes it difficult to determine the independent effect of NO_2 on lung function growth.[70] As noted previously for PM, Children's Health Study investigators have demonstrated improved lung function growth with improved air quality in their study communities.[51]

Of interest, the results of several studies, including two from the Children's Health Study, suggest that long-term residential exposure to NO_2 is associated with increased risk of developing asthma in children.[71–73] However, it may be that NO_2 itself is not the causal agent, but rather that NO_2 concentrations are a good marker of exposure to the traffic pollution mixture.[72] A recent follow-up analysis from the Children's Health Study showed decreased risk of incident asthma with improved air quality in southern California.[74]

Because short-term exposures to NO_2 can induce greater airway responsiveness among asthmatic subjects in human experimental studies and are associated with respiratory outcomes, especially asthma, in epidemiologic studies, there is coherent evidence to support a short-term averaging time for air quality standards to control this pollutant. To protect individuals with asthma from acute exacerbations, the EPA promulgated a new 1-hour ambient air quality standard for NO_2 of 100 ppb in 2010.

OZONE

Although O_3 has long been associated with southern California smog, many other areas of North America also experience high concentrations of this pollutant, especially Houston, Mexico City, and cities in the eastern United States and Canada during the summer months. In these areas,

there are many days each year when the current EPA national ambient air quality standard for O_3 is exceeded.

O_3 is a potent oxidant and is capable of reacting with a variety of extracellular and intracellular molecules. When O_3 reacts with unsaturated lipids, free radicals and toxic intermediate products are generated that can lead to cellular damage or cell death.[75] Direct cytotoxicity is a major mechanism of O_3-induced tissue injury; secondary damage from the inflammatory response likely also plays a role.

Dosimetric studies indicate that much of the inhaled O_3 is deposited in the upper and proximal lower airways.[76] However, because of its relative water insolubility, a considerable fraction will penetrate to the distal airways and alveoli. At these sites, there is a clear relationship between cumulative dose and epithelial injury.[77] Increased inspiratory flow, as would be seen with exercise, may overwhelm the upper airway "scrubbing mechanisms" and cause greater deposition of O_3 in the distal lung.[78]

Most of the research on the health effects of O_3 has focused on short-term exposure. In controlled human exposure studies, O_3 inhalation by healthy subjects causes decrements in FEV_1 and forced vital capacity that correlate with concentration, exposure duration, and minute ventilation.[79,80] These decrements in lung function are primarily a result of decreased inspiratory capacity rather than airway obstruction. The mechanism of the decreased inspiratory capacity appears to be a neurally mediated involuntary inhibition of inspiratory effort involving stimulation of C fibers in the lungs.[75] Somewhat surprisingly, older subjects demonstrate lower O_3-induced decrements in pulmonary function than younger, healthy subjects.[81] The acute decrements in pulmonary function induced by O_3 usually resolve within 24 hours. Statistically significant decrements in FEV_1 have been demonstrated in healthy subjects with exposures during exercise to concentrations below the current U.S. air quality standard.[82]

Respiratory symptoms (e.g., substernal chest discomfort, cough, wheeze, dyspnea) are correlated with these decrements in pulmonary function. Another adverse effect of short-term exposure to O_3 is enhanced airway responsiveness to nonspecific stimuli, such as methacholine and histamine. This effect may persist longer than the acute decrements in lung function and may be seen even in individuals who do not experience a decline in their FEV_1.

O_3 exposure may induce adverse respiratory consequences through a variety of mechanisms. These include nasal inflammatory changes, injury to alveolar epithelial type 1 cells, ciliated airway epithelial cell injury, infiltration of the airway mucosa by neutrophils, and increased bronchoalveolar lavage fluid neutrophils and inflammatory mediators.[75] Airway inflammation has been demonstrated after exposure to ambient concentrations with exercise, including levels below the current U.S. air quality standard.[81,82]

The effects of *chronic* O_3 exposure in humans have not been adequately defined. It has been hypothesized that chronic exposure would lead to structural changes; however, to date, most toxicologic studies involving rodents have failed to demonstrate structural damage after long-term exposure to ambient concentrations. However, studies with rhesus monkeys have shown that O_3 exposure of neonatal rhesus monkeys led to abnormal development of conducting airways, especially with coexposure to house dust mites.[33] In addition, some epidemiologic studies, but not all, suggest that long-term residence of children in a high ambient O_3 environment can lead to remodeling of the small airways.[50,83,84]

Multiple epidemiologic studies show that high ambient O_3 concentrations are associated with an increased rate of asthma attacks and increased respiratory-related hospital admissions/emergency department visits for respiratory disease.[19,66] The biologic plausibility of these findings is supported by the results of controlled human exposure studies showing that O_3 increases nonspecific airway responsiveness, asthmatic subjects have a greater inflammatory response to exposure, and specifically sensitized asthmatic subjects have enhanced bronchoconstrictor responses to inhaled allergen.[85] In addition to the exacerbation of preexisting asthma, some evidence exists that exposure to O_3 could induce new cases of asthma. For example, children playing outdoor sports in polluted areas of the Los Angeles basin have a threefold to fourfold increased risk of asthma compared to children not playing outdoor sports, but this association was not present in areas with lower O_3 levels.[86]

Both short-term and long-term exposures to O_3 have been associated with increased risk of mortality, as reported in Europe and the United States.[87–92]Although this effect was first reported for respirable PM, both O_3 and fine PM are capable of generating oxidative stress and inflammation deep in the lung. Similar to what has been observed in PM mortality studies, it appears that elderly people with preexisting heart and lung disease represent the group at greatest risk for O_3-related death. If excess oxidative stress is a critical step in a pathway that leads to early mortality in individuals with heart and lung disease, it is not surprising that exposure to both ambient O_3 and PM is associated with increased risk. Of additional concern, several studies have suggested that young adults living in southern California have increased oxidative stress and cytogenetic damage compared with those living in northern California, perhaps related to differential exposure to O_3.[93,94]

In summary, tens of millions of persons in the United States are exposed to levels of O_3 above the current U.S. national ambient air quality standard. This exposure is capable of inducing both acute decrements in lung function and respiratory symptoms. Although these effects are transient, acute respiratory tract injury and inflammation can also be induced by short-term exposure to ambient concentrations of O_3. Exacerbations of asthma and increased risk of death of the elderly appear to be the most important health effects of short-term exposure. The long-term consequences of O_3-induced acute injury and inflammation are not well understood, but there is epidemiologic evidence that O_3 can lead to airway remodeling.

INDOOR AIR POLLUTION

Indoor air quality has been increasingly recognized as an important determinant of human health. Because levels of outdoor ambient air pollution have decreased throughout the developed world and because residents of these countries spend the majority of their time indoors, the relative

impact of indoor air pollution has increased.[12] In low- and middle-income countries, cooking and heating with solid fuels and lighting with kerosene cause household air pollution. To characterize personal exposure to air pollution, indoor air quality must be taken into account (Table 102.4).

SOURCES OF INDOOR POLLUTION

The concentrations of indoor air pollutants depend on both indoor and outdoor emission sources (Fig. 102.1).[12] Outdoor emission sources determine outdoor pollution concentrations, which, in turn, affect indoor air quality. The degree of penetration of outdoor pollution into the indoor environment depends largely on the rate of air infiltration from outdoors to indoors.[95] The rate of air infiltration is a complex function of the "tightness" of building construction and insulation, building location and orientation, number of exterior walls and windows, surrounding terrain and barriers, wind speed and direction, indoor-outdoor temperature gradient, and type and efficiency of ventilation system (e.g., heating, ventilation, air-conditioning).[95]

Time-activity patterns influence personal exposure. The relative time spent indoors versus outdoors affects the contribution of indoor pollutants to total personal exposure. Time spent in specific locations within the home affects exposure to particular pollutants because the distribution of indoor pollutant concentrations varies among different zones of a building, especially for pollutants generated indoors.[95] In addition, activity level affects metabolic rate and ventilatory rate, which also influence personal exposure to indoor pollutants.

Table 102.4 Indoor Air Pollutants

Category of Pollutant	Indoor Pollution Source
Combustion (e.g., NO_2, CO, $PM_{2.5}$, PAHs)	Secondhand smoke Gas stoves, ovens, heaters, and fireplaces Wood smoke (stoves, fireplaces) Kerosene heaters Candles and incense
Building materials (e.g., formaldehyde, volatile organic compounds)	Plywood Particle board Carpeting Paints
Cleaning materials (e.g., ammonia gas, chlorine gas, choramine)	Bleach, ammonia, detergents

CO, carbon monoxide; NO_2, nitrogen dioxide; PAHs, polycyclic aromatic hydrocarbons; $PM_{2.5}$, particulate matter less than 2.5 μm in diameter.

INDOOR COMBUSTION: MAJOR SOURCE OF INDOOR AIR POLLUTION

The major source of indoor pollution is from combustion, particularly *secondhand tobacco smoke* (SHS) exposure, gas stove use, and solid fuel (dung, crop waste, wood, charcoal, coal) burning in stoves and fireplaces. Kerosene space heaters and wick lamps are also an important source of indoor air pollution. Table 102.4 shows the major indoor

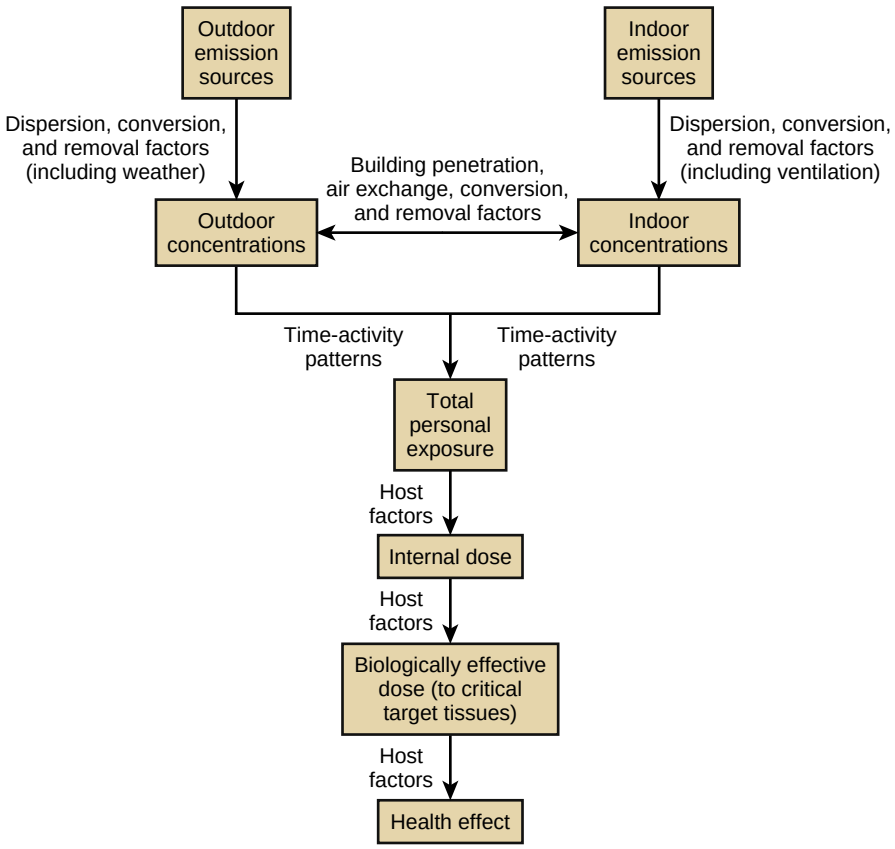

Figure 102.1 Relationships among outdoor pollution, indoor pollution, and health effects.

pollutants released from these sources and are associated with adverse pulmonary effects.

SECONDHAND SMOKE AND OBSTRUCTIVE LUNG DISEASE

SHS is perhaps the best known and studied indoor pollutant. Strong evidence implicates it as a cause of lung cancer, coronary heart disease, and decreased life span.[96,97] In addition to these adverse health effects, SHS contains respiratory irritants, such as SO_2, ammonia, acrolein, and formaldehyde. SHS is a complex mixture containing thousands of gas-phase and particulate substances. In homes where smoking is allowed, $PM_{2.5}$ levels are found up to 10 times higher than in nonsmoking homes.[98] Workplace exposures can be even higher, especially in bars and casinos.

Passive smoking has also been linked with allergic phenomena, such as elevated serum immunoglobulin E levels.[99,100] As a consequence, SHS has the potential to induce new cases of asthma through irritant or sensitizing mechanisms. The results of multiple studies provide evidence that SHS exposure is causally associated with new-onset asthma among children.[101]

Exposure to SHS also appears to be associated with new-onset asthma in adulthood. Cross-sectional, case-control, and cohort studies have suggested a link between SHS exposure and adult-onset asthma.[102] SHS exposure in the workplace, in particular, appears to be related to adult asthma induction.[103]

Beyond asthma induction, SHS exposure is a likely cause of asthma exacerbation in both children and adults.[104] Parental smoking causes increased symptoms, poorer pulmonary function, and other indicators of worsened asthma control among children with established asthma.[105] Similarly, SHS exposure, both at home and at work, appears to cause asthma exacerbation among adults.[106] Moreover, the negative impact of SHS exposure on pulmonary function appears to be greater among adults with asthma than in the general population.[107]

Exposure to SHS may also cause respiratory symptoms and impaired lung function among nonasthmatic individuals.[106] In a cohort of older adults, lifetime home and workplace exposure to SHS was associated with a more rapid decline of lung function during a decade of follow-up.[108] Studies of bartenders and restaurant workers with high occupational exposures to SHS have revealed a strong link between SHS and poorer respiratory health; smoke-free workplace laws have led to a reduction of respiratory symptoms and improved lung function in such workers.[109]

Emerging evidence now suggests that SHS exposure may also be a cause of COPD independent of personal cigarette smoking.[110,111] Population-based studies from multiple countries have found that both cumulative home and work SHS exposures were associated with a greater risk of COPD, controlling for potential confounders.[112] Among patients with established COPD, SHS exposure may increase the risk of respiratory symptoms, poor health status, and disease exacerbations.[113]

GAS STOVE EXPOSURE: CAUSE OF ASTHMA EXACERBATION?

When it became apparent that indoor concentrations of NO_2 often exceeded outdoor concentrations, particularly in homes equipped with gas stoves, research interest focused on the possibility that exposure to NO_2 in indoor air might increase the frequency of respiratory infections, in part because of animal studies showing that exposure increased risk of infection.[114]

In fact, the 2015 Institute of Medicine report concluded that short-term high NO_2 levels are associated with airway responsiveness, and that there is suggestive evidence for an association with asthma exacerbations.[115] In childhood, there appear to be consistent deleterious respiratory effects of living in a home with gas appliances. A recent meta-analysis demonstrated a summary odds ratio of 1.32 for asthma among children living in households with gas stoves.[116] When considering interventions, a study that evaluated the effect of reduced indoor exposure to NO_2 from gas heaters provided evidence of improvement in respiratory symptoms in asthmatic children,[117] and a nationally representative study in which parents were queried about cooking ventilation use showed higher rates of asthma, wheezing, and cough in households that did not use the stove hood.[118,118a]

In adults, the findings have been less consistent.[119–121] Overall, the evidence has not been sufficient to implicate gas stove use as an exacerbating factor in preexisting adult asthma. Among children with asthma, however, there is stronger evidence of a deleterious effect of indoor NO_2 exposure and poorer asthma control.[122,123]

WOOD SMOKE EXPOSURE: RESPIRATORY HEALTH EFFECTS

Wood smoke, which is produced from domestic fireplace or wood stove use, contains potent respiratory irritants, such as formaldehyde, acrolein, nitrogen oxides, and SO_2. It is also a major source of particulate air pollution.[124] Exposure to extremely high wood smoke levels has been linked with respiratory problems. After a work shift, forest firefighters experience an acute decrement in pulmonary function.[125] Similarly, wildland fires have been associated with increased respiratory symptoms and health care utilization for respiratory problems.[126] In developing countries, wood smoke from domestic cooking and heating in poorly ventilated homes has been associated with chronic bronchitis and COPD.[14,127] The exposure levels in such settings are extremely high and are likely the major cause of COPD in women in the developing world because women in these regions tend not to smoke cigarettes.[128] Cooking with other biomass fuels, such as crop residues or dung, and with coal can also lead to chronic respiratory symptoms and airflow obstruction.[129] Cooking with wood and/or charcoal has been associated with risk of COPD in developed countries as well.[124]

As opposed to COPD, asthma is not as clearly associated with biomass smoke exposure. Previous studies have reported conflicting results.[14,130] However, an analysis from the International Study of Asthma and Allergy in Children, which included more than 250,000 children from more than 31 countries, did find an association between use of an open fire for cooking and prevalence of asthma symptoms and reported asthma.[131] Exposures to wood smoke in developed countries are usually at much lower levels than in countries where a large proportion of the population cooks on open fires, so it is less clear how such exposures contribute to asthma burden. That said, wood smoke in communities that rely on burning wood for home heating or in which

fireplaces are frequently used during winter months can contribute to asthma exacerbations.[124]

RESPIRATORY EFFECTS OF KEROSENE HEATER USE

Kerosene heaters can substantially increase indoor levels of fine particles ($PM_{2.5}$), sulfate aerosol (SO_4^{2-}), and acidic aerosol (H^+), as well as CO.[132] Kerosene is similar to diesel fuel in chemical composition. The existing evidence, however, is inconclusive about whether kerosene heater use is a cause of respiratory and asthma symptoms in developed countries. In developing countries, where kerosene may also be used for lighting, using inefficient wick lamps, this fuel has been associated with increased risk of respiratory infections, especially tuberculosis.[133,134]

OTHER INDOOR POLLUTANTS: "TOXIC" INDOOR ENVIRONMENT

Besides indoor combustion, there are many other sources of indoor pollutants. Building materials, such as plywood or particle board, and carpeting can emit formaldehyde; furniture may release formaldehyde and VOCs; paints, cleaning compounds, and photocopiers may release VOCs; and radon can arise from soil sources.[135] Cleaning with disinfectants, such as bleach or quaternary ammonia compounds, can release airway irritants. A combination of bleach and ammonia or other nitrogen sources can also produce chloramine, which may induce upper and lower respiratory tract symptoms.[136,137] Indoor radon exposure has been associated with lung cancer[138] (see also Chapters 74 and 103).

Key Points

- Epidemiologic studies, taken together with controlled human exposure studies, animal studies, and in vitro studies, have delineated many of the serious respiratory and cardiovascular health effects of air pollution.
- The major types of air pollutants affecting the respiratory system are particulate matter, sulfur dioxide, nitrogen dioxide, and ozone.
- In developing countries, a major source of air pollution is biomass smoke from domestic heating and cooking, which may be the world's leading cause of obstructive lung disease among women.
- Exposure to air pollutants can decrease the normative growth of lung tissue and lung function during childhood and adolescence, with the potential for life-long effects.
- Great progress has been made in clearing the air in the United States and other developed countries, but levels of indoor and outdoor pollutants remain higher than is desirable for human health.
- Despite progress, significant questions remain about the impact of multiple pollutants acting together, the effect of pollution on susceptible populations, and the minimum ambient levels at which the risk of health effects increases. Further research is needed to answer these important questions.

Key Readings

KEY POINTS

INTRODUCTION

This chapter focuses on the acute effects on the lung after exposure to toxic substances. For most acute toxicant exposures, inhalation is the route of delivery leading to the lung injury. Importantly, *target organ* does not equate with *route of exposure.* In some instances, inhalation may be the route of exposure for the toxicant, and yet the primary target organ is not the lung (e.g., solvent inhalation that causes central nervous system depression). Inhalation exposures leading to nonpulmonary illnesses are not addressed here.

As used in this chapter, *acute* indicates short-term exposures (minutes to hours), with the initial onset of pulmonary responses within a similarly rapid time period. Generally, the relevant toxicant exposures are of high intensity, far in excess of recommended safety limits for population-wide environmental levels.

Because ingestion may also lead to lung injury, paraquat and hydrocarbon, examples of ingested toxins with severe acute target organ effects on the lung, are included in this chapter.

Moreover, this chapter does not address brief exposures, inducing acute responses mediated by anamnestic (i.e., allergic or other immune-mediated) mechanisms. These responses require prior exposures that already have led to sensitization, such as *hypersensitivity pneumonitis* (HP) (see Chapter 91) or occupational asthma (see Chapter 100). Although there is overlap with certain specific exposures that at far lower levels are also relevant to ambient air pollution (such as oxides of nitrogen, ozone, and sulfur dioxide), these are addressed at the population level in the chapter on air pollution (see Chapter 102).

Finally, some toxicants cause unusual pulmonary syndromes after subacute (days to months) exposure. Some of these syndromes have emerged in recent years associated with new technologies or novel toxicants, such as diacetyl-caused popcorn worker's lung and other flavor industry workers' diseases linked to this chemical,[1–3] "flock worker's lung" caused by short synthetic textile fibers,[4–6] and "Ardystil lung," a dye chemical–induced organizing pneumonia.[7,8] Some of these syndromes are discussed elsewhere in this text.

PATHOGENESIS OF LUNG INJURY FROM INHALED TOXICANTS

PATTERNS OF RESPONSE TO IRRITANT INHALATION

Acute lung toxicity results from a variety of exposures but nonetheless is manifest by a narrow repertoire of injury (Table 103.1). Irritant toxicants can be encountered in various physical states relevant to their inhalational properties. Such states include *gases, vapors* (i.e., the gaseous form of a substance that is a liquid or a solid at normal temperatures and pressures), and *fumes* (i.e., solid material, often metals, of small particle size suspended in a gaseous medium [most <1.0 μm and many <0.1 μm in diameter]). *Aerosols* encompass a mix of potential states (i.e., liquid droplets or fine particulates dispersed in a gaseous medium; *smoke* is a subset of aerosols from incomplete combustion).

These various classes of exposures include heterogeneous toxicants capable of causing extensive cell injury throughout the upper and lower respiratory tract. The primary location of respiratory tract injury and the onset of clinical symptoms partly depend on the solubility of the gas, vapor, fume, or aerosol involved and, in the case of fumes or aerosols, on the physical characteristics of the particle or droplet. Other factors that determine the injury pattern following exposure include (1) the amount of the toxicant inhaled, (2) the duration of exposure to the inhalant, (3) the concentration of the inhalant in the ambient air, (4) other physical properties (such as pH or chemical reactivity), and

Table 103.1 Major Clinical Scenarios of Pulmonary Responses Shortly After Acute Toxicant Exposure

Clinical Scenario	Exemplar Exposures	Additional Comments
Mucous membrane and airway irritation (burning eyes, nose, and throat; laryngospasm and bronchospasm) with or without lower lung injury (pulmonary edema, diffuse alveolar damage)	Chlorine, chlorine dioxide, chloramine; bromine; sulfur dioxide; acid aerosols (sulfuric, hydrochloric, hydrofluoric); ammonia; zinc chloride (smoke bombs)	At low exposures, mucous membrane irritation may be the sole effect; with heavy exposure, lower lung injury may be seen
Lower lung injury (pulmonary edema, diffuse alveolar damage) with little or no mucous membrane irritation or airway effects	Nitrogen dioxide, phosgene, ozone, cadmium fume, mercury vapor, nickel carbonyl, fluorocarbon (waterproofing)	Exposure can be inadvertent or occult with presentation delayed 24–48 hr
Self-limited flulike illness with fever and leukocytosis beginning 6–12 hr after a clear exposure history	Zinc oxide fume, heavy organic dust inhalation, polymer fume, endotoxin	The presence of hypoxemia or lung injury indicates another diagnosis
Foreign substance ingestion followed by pneumonitis	Hydrocarbon aspiration, exogenous lipoid pneumonia, paraquat fibrosis	Heavy aerosol inhalation can cause lipoid pneumonia; paraquat can also be absorbed through the skin

(5) a variety of host factors, such as age, genetics, use of respiratory protection, and comorbid illness. Overwhelming exposures to any irritant inhalant, however, can cause extensive damage throughout the respiratory tract.

Ammonia[9] and sulfur dioxide[10] are examples of substances that are highly soluble in water. Such highly soluble substances cause immediate irritation of the conjunctival mucosa and upper airways. This immediate onset of irritant effects provides warning symptoms that may prompt the victim to flee, thereby limiting exposure. In contrast, oxides of nitrogen,[11] ozone,[12] and phosgene[13] have relatively low water solubility. For this reason, exposure to one of these agents may *not* be characterized by immediate symptoms of mucous membrane irritation. This may lead to more prolonged exposure and delay in seeking medical attention. Both more-soluble and less-soluble irritant exposures can lead to distal lung injury but, in the case of highly soluble materials, a history of severe upper respiratory symptoms should precede the presentation of distal airway and alveolar damage.[14]

Irritants reaching the lower respiratory tract, either because of their inherent physical characteristics or because of exposures that overwhelm the absorptive capacity of the upper airway, can injure both the lung epithelium and its endothelium. Irritant injury at this level leads to a nonspecific pattern of *diffuse alveolar damage* (DAD) similar to that seen from a variety of different causes (see Chapter 8). The pathologic changes in fatal cases of irritant lung injury include focal and confluent areas of edema with protein-rich fluid in the alveolar spaces, hyaline membrane formation, and denudation of the alveolar epithelium. In addition, mucous membranes of the bronchial and bronchiolar walls may be denuded or destroyed. Pulmonary hemorrhage may be seen in irritant lung injury but is typically not the dominant clinicopathologic manifestation; prominent pulmonary hemorrhage should raise suspicion of other toxicant- or non–toxicant-mediated syndromes[15] (see Chapter 94).

On the cellular level, respiratory tract injury may be mediated through the deposition or formation of an acid, alkali, free radical, or other reactive chemical species. The precise cellular mechanisms of injury from irritant inhalants have not been fully delineated, even for relatively common irritants such as chlorine or the chemical warfare agent phosgene, substances for which extensive human and experimental animal data exist.[16–19]

OTHER PATTERNS OF RESPONSE

Acute irritant inhalation injury is the predominant, but not the only, pathophysiologic mechanism underlying acute toxicant-caused lung syndromes. In contrast to the anatomic distribution commonly seen in water-soluble, irritant chemical–related inhalant injury, it may be difficult to delineate a descending, hierarchical pattern from upper airway to lower lung injury following exposure to a diverse group of other agents. Many of these exposures, as with the water-soluble irritants, also lead to acute lung injury through nonimmunologic mechanisms (clinically, *acute respiratory distress syndrome* [ARDS]; pathologically, DAD), as detailed subsequently in this chapter. Other toxicant exposures produce various other syndromes of respiratory tract injury, such as heavy metal pneumonitis,[20] hydrocarbon aspiration,[21] or paraquat lung injury.[22,23] The inhalation fever syndromes are exceptions in that they do not involve obvious lung injury; the pathophysiology of this group of self-limited acute lung syndromes appears to be cytokine mediated.[24]

GENERAL MANAGEMENT PRINCIPLES

Symptoms and signs of acute inhalation injury can be delayed in onset. Following removal of the patient from exposure while safeguarding the rescuing personnel, the next most important management decisions include protection of the airway (i.e., preemptive intubation may be required to prevent precipitous airway obstruction from progressive airway edema) and treatment of hypoxemia. The nasopharynx and larynx may manifest injuries earliest because they are exposed to the highest concentrations of inhaled water-soluble toxicants. The upper airway may also be a primary target organ as a result of angioedema in selected toxicant ingestions.[25] Within a few hours of exposure, progressive airway edema, mucopurulent sputum production, and bronchorrhea may develop. Bronchoconstriction, peribronchial edema, and bronchial mucosal sloughing may produce atelectasis. In the distal airways and alveoli, epithelial and endothelial injury leads to permeability-induced edema, which can manifest ranging from mild interstitial edema to DAD. Pulmonary edema may be rapid following high-concentration toxicant exposure or may be delayed

up to 24 to 48 hours. Pneumothorax and pneumomediastinum can be acute complications of respiratory tract injury resulting from chemical toxicants.[26–31]

Acute toxicant lung injury manifest as DAD should be managed consistent with the basic management of acute lung injury from other causes. This includes utilizing lung-protective ventilation strategies for patients with ARDS and avoiding fluid overload.[32,33] Concomitant airway injury with acute bronchospasm often warrants treatment with bronchodilators because of the airway obstruction.

A beneficial role for systemic corticosteroids in the acute phase of irritant and other chemically mediated forms of acute injury to the lungs has not been established, either by controlled trials in humans or through studies using experimental animal models.[34,35] Inhaled steroids are more likely to have a better risk-benefit ratio in the therapy of acute inhalation injury (e.g., in the context of bronchospasm and concomitant use of bronchodilators, taking acute smoke inhalation injury as a paradigm).[36] Despite the lack of controlled evidence of efficacy, anecdotal reports of benefits of systemic corticosteroid use continue to appear.[30] For example, systemic corticosteroids may have a beneficial effect in the treatment of lung injury following zinc chloride inhalation.[31,37] Prophylactic antibiotic drugs have not proved to be efficacious in toxicant-induced lung injury; antibiotics should be reserved for those patients with clinical evidence of infection, including ventilator-associated pneumonia.[38,39] To date, convincing data do not support the use of other pharmacologic agents, such as antioxidants, in the generic treatment of toxic chemical lung injury, although this is the subject of experimental research.[34,40,41]

Certain exposure-specific management issues do occasionally arise. In paraquat-induced lung injury, for example, oxygen toxicity is a particular concern because of the specific mechanism of action of paraquat (i.e., high concentrations of oxygen may lead to more severe lung injury).[22] In addition, in paraquat-induced lung injury, immunosuppressive therapy has yielded some promising data but remains to be confirmed in randomized controlled studies.[23] Biologic therapy utilizing an anti-C5a antibody also has demonstrated promise for the treatment of paraquat-induced lung injury and the associated systemic inflammatory response.[42] In the case of certain metal toxins, chelation may have a therapeutic role, as is addressed later in relation to the specific exposures involved. Inhalation fever is self-limited, so the principal clinical management issue is to exclude other exposures with more serious outcomes.[24]

Nonspecific treatments for toxic lung injury include interventions to clear the airways of mucus, denuded mucosal tissue, and cellular debris. Such interventions may include chest physiotherapy, intrapulmonary percussive ventilation, inhalation of isotonic saline, aerosolized mucolytic agents such as *N*-acetyl cysteine, and, in some settings, therapeutic bronchoscopy.[43] Although a detailed discussion of mass casualty events is beyond the scope of this chapter, large-scale release of toxicant chemicals may result in widespread chaos and confusion that has the potential to overwhelm the public emergency system, including first responders and emergency departments (see also Chapter 59). A surge of highly exposed, acutely ill victims along with lower–exposure risk but anxious patients may present significant challenges to prehospital care and hospital-based emergency care.[44,45]

Companion animals (e.g., dogs, cats, and birds) often show symptoms and signs in advance of humans. An example of historical interest is that of coal miners bringing canaries into coal mines. This phenomenon may allow the clinician to identify occult exposure, test, and treat while human disease is mild or still subclinical.[45a]

CHRONIC SEQUELAE AND RESIDUAL EFFECTS

Persons surviving symptomatic exposure to acute irritants may have persistent structural and functional effects. Long-term consequences to the upper airways (nose, pharynx, and larynx) can be sequelae of acute inhalational exposures; upper airway complaints, including chronic rhinitis (reactive upper airway dysfunction syndrome, anosmia, and vocal cord dysfunction), have been reported.[46–50] Follow-up studies of more homogeneous populations evaluated after inhalation injury (with only a minority experiencing severe injury) suggest that airflow obstruction and nonspecific airway hyperresponsiveness are the most common persistent abnormalities of the conducting airways after irritant injury. Even so, epidemiologic data suggest that only a minority of those exposed will experience these outcomes.[51–53] The term *reactive airway dysfunction syndrome* has been applied to the persistence of airway reactivity after acute exposure to respiratory irritants.[54–57] The more general term *irritant-induced asthma* has also been used to describe this condition.[58,59] Insofar as this can represent a form of work-related asthma, it is addressed in Chapter 100.

Chronic injuries to the lower airways and lung parenchyma are unusual sequelae of acute inhalational exposure. Long-term follow-up evaluation after recovery from ARDS resulting from heterogeneous causes (predominantly associated with sepsis) suggests that residual deficits in lung volumes, airflow, and gas exchange may persist long after recovery.[60] *Bronchiolitis obliterans* (BO),[61–69] bronchiectasis,[9,68,70–73] and organizing pneumonia[74,75] may all develop, but are rare complications. Irritants, in particular nitrogen oxide and related exposures, have long been known to cause BO.[76] Yet even with nitrogen dioxide, BO is an infrequent event; for example, only one case was found in a series of 20 moderate to severe exposures.[62] The histologic manifestations of exposure-related bronchiolitis can include various subtypes.[63] Pathologically, acute or subacute irritant-induced bronchiolitis is usually characterized histologically as either proliferative bronchiolitis with organizing pneumonia (that is, a histologic pattern of organizing pneumonia) or constrictive bronchiolitis. The latter appears to be the pathologic correlate of diacetyl-caused popcorn worker's lung[2] and has been reported in one case of BO following exposure in the World Trade Center disaster,[77] in a case series of Iraq and Afghanistan military veterans (although no single toxic exposure has been implicated),[78] and in association with styrene-fiberglass boat construction, presumably with more indolent exposure, rather than acute exposure.[79] In addition to residual obstructive ventilatory deficits, restrictive deficits may also result from severe irritant inhalation injury.[70,80] There is also some indication that an isolated reduction in residual volume may be noted in the follow-up of such cases.[81,82] Finally, nonspecific respiratory signs and symptoms after

Table 103.2 Selected Toxic Agents Causing Pulmonary Responses After Acute Exposure

Agent	Common Exposure Scenarios	References
Acid aerosols	Plating; microelectronics; other manufacturing	123, 149–153
Acrolein	Structural or wildland fires; other combustion	292, 293
Ammonia	Industrial refrigeration leaks; fertilizers	9, 322, 326
Brevetoxin	Aerosolization of "red tide" toxin	311, 313
Bromine	Water treatment; chemical manufacturing	69, 328–331
Cadmium fume	Flame cutting of soldered or sheet metal materials	186–190
Chloramines and nitrogen trichloride	Bleach + ammonia mix; chlorination + ammonia	101–103
Chlorine gas	Gas leak; water treatment; bleach + acid mix	16, 87–96
Chlorine dioxide	Pulp paper bleaching	130, 131
Crowd-control agents (tear gas)	Military and police training and operations	174–177
Dimethyl sulfate	Industrial chemical yielding sulfuric acid	137, 138
Fluorocarbon polymers	Overheating polymers	145, 217, 223
Fluorocarbon sprays	Waterproofing and related aerosol sprays	256–260
Hydrocarbons	Aspiration of low-viscosity materials, "fire eating"	21, 267, 269, 275, 278
Hydrogen sulfide	Sewers and manure pits; fossil fuel and geothermal production	336, 340–342
Mercury vapor	Gold extraction, heating cinnabar	192–199
Methyl bromide	Pesticide fumigant	334, 335
Methyl isocyanate	Pesticide manufacturing	343, 345
Methyl isothiocyanate	Breakdown product of metam sodium fumigant	346, 347
Mustard gas	Chemical warfare agent	70, 155–157
Nickel carbonyl	Nickel processing, metal reclamation	200–204
Nitrogen dioxide	Silage; combustion; explosives; welding; nitric acid mixes	11, 62, 117, 118, 121
Organic dusts or aerosols	Contaminated dust or bioaerosol generation	24, 237, 242, 243
Organophosphates	Pesticide application; chemical warfare	170, 307
Ozone	Bleaching; water treatment; plasma welding	12
Paraquat	Herbicide skin contamination or ingestion	22, 282
Phosgene	Chlorinated solvent breakdown by-product	13, 18
Phosphine	Fumigation with aluminum or zinc phosphide, microelectronics	364–366
Sulfur dioxide	Refrigeration; cement manufacture; mining; pulp paper mills	10, 132–134
Tributyltin (bis[tributyltin] oxide)	Paint additive for mold inhibition	215
Vanadium	Ore processing; fossil fuel by-product, catalyst use	211, 212
Zinc chloride	Smoke bombs ("white smoke")	179, 183
Zinc oxide fume	Welding galvanized steel; brass casting	218, 219, 236

acute inhalation events can be somatic manifestations of psychological processes and can be further complicated by posttraumatic stress disorder comorbidity.[83–86]

SPECIFIC EXPOSURES

See Table 103.2 for a list of selected toxic agents causing pulmonary responses after acute exposure.

CHLORINE, CHLORAMINES, HYDROCHLORIC ACID, AND RELATED CHEMICALS

Among toxicants causing pulmonary responses, *chlorine* is a common and potent irritant inhalant accounting for substantial human morbidity.[17,87,88] Common forms of exposure include industrial leaks,[89,90] environmental releases primarily during transport,[91,92] water purification,[93] swimming pool–related events,[94,95] household cleaning product misadventures,[96] and even homemade chemical bombs[97] or intentional terrorist use.[98]

In the form of a yellow-green acrid gas, industrial and environmental releases typically have clear-cut exposure histories. Because the gas is heavier than air, higher contamination can be expected in low-lying areas (hence, its use in trench warfare in World War I).[99] Other environmental conditions, however, may supervene. Examples include one well-documented case of the gas rising along the heated outside wall of a factory where rooftop workers were exposed.[89] In another case, chlorine initially collected in a basement but then was sucked up into the central heating system of a dormitory.[100]

The history of exposure to chlorine may be less straightforward when the chlorine is generated after de novo generation from chlorine-containing products. Chlorine gas can be generated from liquid bleach containing hypochlorite or from dry powdered bleach containing chlorinated phosphate. In either liquid or powdered bleaches, the chlorine gas is liberated on contact with acids, which can be common in other household products (such as those containing muriatic [i.e., hydrochloric], phosphoric, or hydrofluoric acid[96]) or in industrial settings.[53] In contrast, mixing chlorine-containing products with ammonia leads to release of chloramines (monochloramine [NH_2Cl] and dichloramine [$NHCl_2$]) and related chemicals, especially nitrogen trichloride (NCl_3), chemicals whose irritant effects are attributed to in situ pulmonary reactions releasing chlorine, hypochlorous acid, and ammonia.[96,101,102] In aquatic venues, including swimming pools, inadvertent mixing of the chlorinated water with nitrogen donors can also happen, with potential irritant effects attributed to nitrogen trichloride in particular.[101,103] A report of a public aquatic venue mishap found that inadvertent mixing of sodium hypochlorite and hydrochloric acid led to toxic chlorine gas release resulting in a constellation of adverse health effects, including vomiting, coughing, and eye irritation, among several dozen affected bathers.[104] Chloramines evolved from mixing chlorine and ammonia should not be confused with Chloramine-T (sodium-*N*-chlorine-*p*-toluene sulfonamide), a disinfectant that can act as a chemical sensitizer leading to allergic asthma and other anamnestic responses.[105]

Irritant effects after inhalation of *hypochlorite* aerosols in confined spaces without a history of combining products (not an uncommon scenario when cleaning bathrooms) can also be associated with irritant effects. Similarly, in certain industrial operations, hydrochloric (hydrogen chloride in water) or hypochlorous acid aerosols are also respiratory irritants.

Chlorine exposure can also take place in specific industrial processes that use inorganic chlorine derivatives. Worthy of particular mention are chlorine dioxide (used in pulp paper processing),[106] chlorinated silanes (gases used in microelectronics),[107] reactive metal halides (e.g., titanium or antimony chlorides),[20] and thionyl chloride (which breaks down to yield hydrogen chloride and sulfur dioxide).[65,108]

For chlorine and related chemicals, there is a dose-dependent exposure-response relationship; that is, lung injury is largely a function of the dose of irritant gas entrained into the respiratory system. For chlorine, as for irritant gases generally, the dose response has been presumed to be equivalent for any given cross-product of concentration and exposure time (Haber's law), although experimental data indicate that this relationship may be more variable.[109]

All of these compounds appear to share a final common toxic pathway. As noted in the general discussion of acute toxicant inhalation, water solubility is an important determinant of the dose reaching the lower airways. For chlorine, chlorine dioxide, chloramines, and nitrogen trichloride, their lower solubility favors deeper penetration with a more effective delivered dose compared with an equivalent inhalation of agents with a higher solubility such as acid aerosols. Nonetheless, exposure to any of these compounds is associated with some degree of immediate mucous membrane and upper airway irritation. In fact, the absence of acute irritant effects is not clinically consistent with chlorine gas or related exposures.

Chlorine inhalation may manifest any of the full spectrum of respiratory tract irritant effects, from minor mucosal responses to upper airway responses to DAD.[89–99,110,110a] Persistent airway hyperresponsiveness after irritant exposure has been associated particularly with chlorine gas and chlorine-containing products, although this association may have more to do with the frequency of chlorine exposures than with any particular effect of chlorine on the airways.[16,43,58,59] Human experimental studies have provided inconsistent results about whether persons with underlying airway hyperreactivity may be more responsive to chlorine.[111,112]

Use of inhaled bronchodilators and inhaled steroids may be indicated for both acute and residual bronchospasm following chlorine inhalation, consistent with the general principles of management addressed previously. Although several case reports and series have touted the potential benefits of nebulized sodium bicarbonate inhalation in the acute treatment of chlorine or chloramine inhalation, the efficacy of this intervention has never been assessed in a controlled trial.[102,112,113] One small controlled trial administered inhaled bicarbonate 3 months or more after exposure in irritant-induced asthma and described some benefit.[114] Other potential therapeutics have been reported on the basis of published animal and human data, including intramuscular sodium nitrite, intramuscular ascorbic acid/deferoxamine, and sevoflurane (an inhalational anesthetic agent), although the efficacy of such interventions remains to be established.[115]

OXIDES OF NITROGEN, OZONE, SULFUR DIOXIDE, AND ACID AEROSOLS

These inhalants are major air pollutants; the effects of low-level exposure are discussed in detail in Chapter 102. When inhaled in high concentrations, these irritants can cause acute lung injury. Because of their lower solubility and thus their lower incidence of upper airway symptoms, ozone[12] and, even more commonly, nitrogen dioxide may be associated with a longer exposure with a greater predilection for lung injury.[116] With sulfur dioxide and acid aerosols, despite their high solubility, a sufficient intensity of exposure can also lead to DAD.

High-intensity exposure to *oxides of nitrogen* can take place through decomposition of organic matter and other sources. Examples of exposure scenarios include the following: nitrogen dioxide–induced lung injury among farmers (also known as silo filler's disease)[52,117,118]; use of internal combustion engines in enclosed spaces (with large outbreaks associated with ice resurfacing equipment used in indoor skating rinks)[11,119–121]; thermal degradation of polymers (e.g., in structural fires)[38]; toxicant gas produced by the detonation of explosives[67,122]; the release of gas through reactions of nitric acid breakdown in air or in reaction with metals or organic materials[123–125]; welding by-products, particularly when "gas-shielded" techniques are used (manual inert gas welding or tungsten inert welding)[124]; and the release of compressed nitrogen dioxide gas.[126] Historically, the detonation of explosives has been one of the most important sources of exposure to nitrogen oxides.[122] Work-related exposure to a mixture of nitric acid

and hydrofluoric acid, known as "pickling paste," used to clean welding joints in welded stainless steel construction, has been reported as a cause of ARDS.[127] Nitric oxide, an inhalant used therapeutically, breaks down to nitrogen dioxide in the presence of oxygen and thus must be monitored with appropriate delivery devices to avoid exposure to the potentially toxic nitrogen dioxide.[128]

High-intensity occupational ozone exposure is unusual, but it can happen with welding conditions similar to those associated with oxides of nitrogen.[129] More recently, ozone in water treatment and in pulp paper bleaching has also emerged as a health issue; in the latter industry, there is often concomitant exposure to chlorine dioxide.[130,131]

Important sources of exposure to high-level sulfur dioxide include mining and ore refining,[10] portland cement manufacturing,[132] sulfur treatment of fruit,[133] and industrial releases.[134] Sulfur dioxide has been and continues to be important in sulfite process pulp paper processing, where acute gas releases are superimposed on long-term lower-level exposure.[130,131,135] In the past, sulfur dioxide was also a common refrigerant.[136]

In ambient air pollution, sulfuric acid is an acid aerosol of primary concern; in various occupations, sulfuric acid can also be encountered at high levels. Workers can be exposed to sulfuric acid through both direct use and the breakdown of a highly toxic industrial chemical, dimethyl sulfate.[137,138] Certain other inorganic and organic acid vapors and aerosols are also important potential causes of acute lung injury, including chromic,[139] acetic,[140] formic,[141] and hydrofluoric acids.[125,142,143] *Hydrofluoric acid* (hydrogen fluoride) inhalation, in addition to nonspecific irritant effects, can induce clinically significant hypocalcemia, which is thought to result from the formation of insoluble calcium fluoride.[144] Persons can be exposed to hydrofluoric acid in manufacturing of both microelectronics and phosphate fertilizers, in household use of hydrofluoric acid rust removal agents (the mixture of which with hypochlorite bleach can evolve both chlorine and hydrogen fluoride), and in the incomplete combustion (pyrolysis) of fluorinated polymers.[145] Exposure to hydrogen fluoride is a long-term problem in the aluminum smelting industry.[146] Hydrogen fluoride is also released as a breakdown product of sulfur hexafluoride, an electrical insulating liquid chemical used in circuit breakers, cables, capacitors, and transistors.[147]

MILITARY AND CROWD-CONTROL AGENTS

Unfortunately, chemical warfare agent exposures are not of mere historical interest.[99,148,149] Not only can sporadic exposures result from contact with a discarded ordnance,[150] but also, and more importantly, exposure can be widespread through the use of chemical warfare agents in acts of terrorism or in conventional military conflicts. Such risks have raised the specter that the diagnosis and management of such toxicants will again become clinically relevant. Several reviews have addressed general aspects of this question.[151–153] The goal of this section is to address individual chemical agents, including other military and crowd-control agents that are not warfare chemicals per se, with a focus on their respiratory toxicity. Biologic warfare agents of relevance to the respiratory tract are covered elsewhere (see Chapter 59).

Sulfur Mustard

Of the major World War I chemical weapons, only sulfur mustard (so called "mustard gas," although not a true gas in physical state) has subsequently been used in warfare. Classified as a vesicant because of blistering induced by skin contact, mustard gas inhalation causes severe respiratory injury. Largely on the basis of the Iranian experience of their Iraqi war veterans, sulfur mustard survivors can exhibit residual tracheobronchitis, asthma, bronchiectasis, bronchotracheomalacia, BO, and fibrosis.[70,154–157] Nitrogen mustards were sulfur mustard derivatives originally developed for military purposes but later applied medically; nonetheless, occupationally related acute lung injury has been reported through industrial release.[158]

Phosgene

Another World War I toxicant gas, phosgene, currently is encountered as a chemical industry process chemical and as a thermal breakdown product or ultraviolet photoreactant of chlorinated solvents (e.g., methylene chloride).[13,159] An occult cause of exposure can be inadvertent phosgene production from welding metals "degreased" with solvents.[129] Phosgene is the prototypical deeply penetrating inhalant exhibiting a delayed onset of symptoms (12 to 24 hours after exposure).[19,32,160–162] Even victims of phosgene exposure who eventually develop fulminant respiratory failure may exhibit only mild initial symptoms and have a normal chest radiograph in the first 2 hours after exposure.[163] Methyl chloroformate ($C_2H_3ClO_2$) has chemical and structural similarities to phosgene ($COCl_2$), is used in industrial chemical synthesis, and is also a potent inhalation irritant associated with severe lung injury.[164]

Chloropicrin

Chloropicrin, another World War I gas, is a low-threshold irritant currently encountered in chemical manufacturing and as a component of fumigants; it is added to fumigants for its irritant warning properties to deter persons from entering and remaining in structures during or soon after fumigation.[165–167]

Neurotoxicants

The modern chemical warfare armamentarium is dominated by systemic toxicants developed from organophosphate pesticides (which are discussed later in the section "Pharmacologic Syndromes"); the nerve agent VX is prototypical.[168,169] These highly lethal neurotoxins have important respiratory effects, including manifestations of both muscarinic receptor stimulation (bronchorrhea and bronchospasm) and nicotinic receptor depolarization blockade (respiratory muscle paralysis); treatment is based on reversing enzyme inhibition and countering the effects of acetyl cholinesterase excess.[170]

Chloroacetophenone (Mace), Other Tear Gas Agents, and Zinc Chloride

Crowd-control agents ("tear gases"), as opposed to the war gases, are intended to incapacitate persons through immediate mucous membrane irritation.[171] The agents in greatest use worldwide are chloroacetophenone ("mace") and orthochlorobenzamalonitrile.[172,173] In addition to their

mucous membrane effects, these agents have also been implicated in lower respiratory injury and even in persistent effects following high-intensity exposures (e.g., in enclosed buildings).[174–177] Unlike tear gas, exposure to smoke bomb releases (sometimes referred to as "white smoke") can cause severe lower respiratory injury by exposure to the potent respiratory irritant, zinc chloride fume, created through a pyrotechnic reaction between hexachloroethane and zinc oxide.[178,179] Military, police, and others who are exposed, often during ill-conceived training exercises, are at risk.[29,178–183] In an analysis of 15 cases of overexposure to a hexachloroethane–zinc chloride smoke bomb during a military exercise, the serum zinc level correlated with later lung function impairment, a finding suggesting that serum zinc may serve as a biomarker of high exposure that may predict outcomes.[184]

TOXIC METALS

Inhalation of certain metal fumes or metal vapors can cause acute pneumonitis.[20] Dangerous exposures to toxic metal fumes arise in part because these agents are not immediately irritating, analogous to the delayed symptoms after phosgene or nitrogen oxide gas inhalation. Patients typically present in respiratory distress 12 to 48 hours after exposure. Indeed, the exposure history often remains occult unless aggressively pursued. Metal pneumonitis from these materials also can include fever as a clinical manifestation of this toxic syndrome. However, the term *metal fume fever* should not be used in this context.[185] The toxic mechanism generalizable in heavy metal pneumonitis is presumed to be inhibition of enzymatic and other critical cellular functions.

Cadmium, Mercury, and Nickel

The three metals most important in clinical lung injury are cadmium, mercury, and nickel (nickel in the form of nickel carbonyl). *Cadmium* exposure typically takes place through welding, brazing (high-temperature soldering), or flame-cutting metal, or in working with molten metal under conditions of inadequate ventilation.[186–189] In welding, brazing, and flame-cutting, the usual source of cadmium is the welding rod, brazing solder, or a metal coating, rather than the base metal itself.[129] In areas of the world where jewelry is made at a cottage industry level, cadmium use in silver working can present a particular exposure risk.[190,191]

Mercury is relatively volatile, and high levels can be generated effectively from many nonenclosed operations, most notably through heated metal reclamation processes (e.g., home refining of mercury-gold amalgams or reclaiming of mercury from electronic equipment).[192–199] Exposure has also been reported after burning mercury sulfide (Chinese red cinnabar) and mercuric oxide for medicinal purposes.[197] Chelation treatment for elevated systemic mercury typically is begun after the onset of pneumonitis, but its efficacy in ameliorating mercury pneumonitis has not been studied.[196]

Nickel carbonyl is an organic metal derivative and potent pulmonary toxicant, with exposure described during nickel refining, during manufacturing processes in which it is used as a catalyst or intermediate, and during metal recycling or reclaiming operations.[200–204] Cases of severe nickel fume inhalation from metal spraying operations that were nickel carbonyl free suggests that, under certain conditions, inorganic nickel also can cause acute lung injury.[205,206] The agent dithiocarb (diethyldithiocarbamate) has been used as a chelating antidote for nickel carbonyl pneumonitis, on the basis of supportive animal data, although its benefits are most clear-cut when it is administered soon after exposure (e.g., before the time clinical illness would be manifested); disulfiram has been suggested as a potential alternative treatment, although experimental data to support this practice are also weak.[207]

Other Metals

Other metals, including antimony, manganese, and beryllium, are sometimes cited as causes of acute lung injury consistent with metal pneumonitis, but there are few reports in the past 50 years providing documentation of such disorders.[9] A case report implicated copper dust inhalation as a cause of acute lung injury.[208] Osmium tetroxide is a potent respiratory irritant with terrorist weapon potential; fortunately, experience with human inhalation exposure has been limited.[209] Cerium oxide is another metallic exposure of theoretical concern because of its potential use as a fuel additive and its capacity to cause acute inhalation injury experimentally.[210]

Two other metal compounds are well-documented bronchial irritants in humans. Vanadium (typically as a metal oxide), which is encountered in metal processing and, in lower concentrations, as a fossil fuel by-product, causes acute bronchitis.[211] Among boilermakers, vanadium-rich fuel oil ash is suspected to be a key exposure related to acute respiratory symptoms.[212] In a single case report, high-intensity exposure to ash from an oil-burning furnace was associated with DAD; although vanadium was detectable in the residue, the toxic mechanism in this case was unclear.[213] In another case report, vanadium (as vanadyl pyrophosphate) was linked to pneumonitis.[214] Tributyltin (bis[tributyltin] oxide) is an organotin compound, which is an organic compound with one or more molecules of tin. Tributyltin, which is used as a mildew and mold retardant, is also an acute airway irritant.[215]

METAL FUME FEVER, POLYMER FUME FEVER, ORGANIC DUST TOXIC SYNDROME, AND OTHER INHALATION FEVERS

Certain febrile flulike pulmonary syndromes reflect similar clinical responses to a diverse group of acute inhalational exposures.[24,216] Their hallmarks are chills, fever, malaise, and myalgia, with onset 4 to 8 hours after intense inhalation of fumes or organic dusts.[24,185,217] Common respiratory signs and symptoms include cough or mild dyspnea, but chest radiographic opacities or hypoxemia are not seen and would be inconsistent with this disorder. Peripheral leukocytosis usually accompanies the syndrome; bronchoalveolar lavage shows a marked influx of neutrophils.[218–220] These syndromes are self-limited, resolving clinically within 12 to 48 hours. Inhalation fevers share a common feature of tachyphylaxis, with a blunted response to daily repeated inhalation (and hence the name "Monday morning fever" among both brass founders and cotton mill workers).[24,221,222]

Signs or symptoms of pneumonitis should suggest alternative, more serious diagnoses, such as cadmium pneumonitis,[187,188] HP (see Chapter 91), active infection (in the case of water-source aerosols), or inhalation of more toxic temperature-dependent fluoropolymer combustion by-products (which include hydrogen fluoride and perfluoroisobutylene, which is more toxic than phosgene).[223–225] Toxic pneumonitis caused by fluorocarbon-containing aerosol sprays is an exposure scenario distinct from polymer fume fever resulting from exposure to fluoropolymer combustion by-products or from acute lung injury and is dealt with separately (see the following section).

Metal fume fever is associated with zinc oxide inhalation from welding galvanized metal or brass working.[226] There is only limited clinical evidence that other metals (magnesium and copper) are capable of causing a similar response,[185,227] and experimental data further discount magnesium as a potential cause of fume fever.[228] Zinc oxide fume rarely has also been purported to cause an acute lung injury pattern in case reports of welding-related illness, but the likelihood of cadmium or nitrogen dioxide coexposures makes this uncommon association questionable.[229] Further, controlled experimental human exposure data do not support this disorder as a zinc oxide inhalation effect.[219]

Polymer fume fever is associated with thermal breakdown products of fluoropolymers (e.g., polytetrafluoroethylene [Teflon] and related materials).[217,230–232] The pathophysiologic mechanisms underlying the metal and polymer fume fever syndromes have not been established, but research suggests that pulmonary cytokines may play a key role.[233–236]

Organic dust toxic syndrome (ODTS) is associated with inhalation of materials contaminated with thermophilic bacteria and fungal spores, including wood chips,[237] straw,[238] silage,[239] seeds,[240] grains and flour,[241] and textile raw materials.[222] The increasing industrialization of agricultural processes, especially the use of animal confinement techniques or so-called *concentrated animal feeding operations*, is an additional source of exposure leading to ODTS, although these same settings also can produce irritant gases such as hydrogen sulfide and ammonia.[242,243] ODTS has gone by various names, including pulmonary mycotoxicosis,[244] silo unloader's syndrome,[239] and mill fever.[245] One of the best documented historical outbreaks of ODTS was among individuals who worked with contaminated cotton mattresses.[222] Inhalation of aerosols from contaminated water sources produces a self-limited febrile syndrome similar to ODTS. Some of these outbreaks are attributable to inhalation of *Legionella* species without actual infection (i.e., without clinical evidence of pneumonia) and are referred to as "Pontiac fever."[246–248] Contaminated aerosols causing inhalation fever syndromes can originate from saunas or hot tubs,[249,250] commercial (industrial) humidifying systems,[251,252] and metal machining cooling fluids.[253] Along with these heterogeneous exposure scenarios, various different names have been used for these syndromes, including humidifier fever,[252] sump bay fever,[254] and bath water fever.[249] Many of the same occupational and environmental exposures that cause ODTS can cause HP and respiratory tract infections, thus complicating diagnosis and treatment. Certain features help to distinguish ODTS from HP or infection. For one, ODTS is self-limited, typically resolving spontaneously. For another, ODTS has a relatively high attack rate over a fairly short time period; that is, in contrast to HP in which host susceptibility, including sensitization, plays a role in disease pathogenesis, ODTS does not require sensitization and may develop in a high proportion of all exposed individuals. As with metal fume fever and polymer fume fever, cytokines are presumed to be key mediators of the ODTS and water-borne aerosol–related inhalation fevers, with endotoxin and related factors being key exposure variables.[24,255]

FLUOROCARBON AEROSOL SPRAY PNEUMONITIS

Acute lung injury following inhalation exposure to commercial fluorocarbon-containing aerosol products is an important emerging syndrome first reported in the early 1990s.[256] This syndrome is distinct both from fluoropolymer fume fever, as previously discussed, and from exposure to irritant by-products from higher-temperature thermal breakdown of such polymers. A key feature of fluorocarbon aerosol pneumonitis is the onset of symptoms within several hours after using a spray product containing fluorocarbon polymers. Exposure can take place in an occupational setting (e.g., construction) or, commonly, from home use of over-the-counter products. These exposures can be relatively brief, with varying degrees of ventilation; importantly, exposure need not be in an enclosed space. Victims usually do not recall previous exposure; there is nothing in the condition to suggest a hypersensitivity mechanism. Application of multiple types of fluorocarbon-containing products has been linked to outbreaks; although waterproofing leather and fabric sprays have dominated the reports, other products include floor stain protector, rustproofing spray, grout sealer, and ski wax.[256–263] The clinical presentations manifest a range of severity consistent with varying degrees of nonspecific acute lung injury, including ARDS.[264] Management is based on standard supportive care. The various descriptive labels for this condition, such as "horse rug lung" and "hill walkers' lung," can obscure the consistent pattern of the syndrome.[259,265]

HYDROCARBON PNEUMONITIS AND FIRE-EATER'S LUNG

Hydrocarbon pneumonitis can follow oral ingestion of hydrocarbons and associated hydrocarbon aspiration. In the pediatric high-risk age group, aspiration can take place during ingestion from non–tamper-proof containers typically involving mineral spirits, mineral seal oil (common in furniture polish), lamp oil, kerosene (paraffin), turpentine (pine oil), gasoline, and lighter fluid.[21,266–268] In adults, hydrocarbon aspiration associated with fuel syphoning represents an occupational hazard among diesel-powered heavy equipment and tractor operators.[269–271] Even though these substances have systemic toxic effects such as central nervous system depression, life-threatening complications of ingestion are predominantly the result of concomitant hydrocarbon aspiration and subsequent pulmonary compromise, making the lung the target organ of concern in hydrocarbon ingestion. Pneumatocele is a recognized complication of hydrocarbon pneumonitis.[272] In contrast

to aspiration hydrocarbon pneumonitis, the toxicity of hydrocarbon (solvent) vapor inhalation manifests primarily in either the central nervous system or the heart. Major pulmonary damage associated with acute hydrocarbon exposure by inhalation is unusual but has been reported.[273] Importantly, the lung also appears to be the target organ for the toxicity of intravenously administered hydrocarbons, an unusual but well-documented suicidal scenario.[274]

Fire-eater's lung is an important variant of hydrocarbon pneumonitis.[275–277] This syndrome typically involves adolescents or young adults who become exposed through mishap during flame-blowing performances using a variety of different flammable materials. In addition to kerosene and gasoline, the toxicants include jet fuel and, in France, an aromatic hydrocarbon-enriched petroleum-distillate called "kerdan."[278,279] There has also been a case of citronella oil aspiration in a fire-eater.[275] As with hydrocarbon pneumonitis in children, fire-eater's lung can also be complicated by pneumatocele.[280] Although the term *acute lipoid pneumonia* has been used to refer to the fire-eater's lung syndrome, as well as in other acute aspirations, this is a misnomer.[281]

In both childhood and adult pneumonitis, hydrocarbons are aspirated at the time of the initial ingestion or subsequently with vomiting. The low viscosity of an ingested hydrocarbon is considered a major factor promoting aspiration, presumably for mechanical reasons.[21,267] Although it has been theorized that hydrocarbon toxicity may involve disruption of surfactant, the chemical pneumonitis of the syndrome appears to be nonspecific.

PARAQUAT

Paraquat is a widely used herbicide and a potent toxin. Ingestion, rather than inhalation, is the typical route of exposure associated with human toxicity. There have been systemic reactions following skin exposure after direct exposure to the skin (e.g., soaking of the skin with paraquat) or when the skin integrity has been breached (e.g., preexisting skin lesions or burn). The theoretical risk of smoking contaminated materials has never been established.

Most paraquat deaths result from suicidal intent.[22,282,283] Paraquat ingestion is a relatively uncommon method of suicide in the United States, but its incidence is greater in a number of other countries, perhaps related to patterns of crop utilization and ease of access.[282,284] Although paraquat ingestion leads to acute gastrointestinal tract necrosis and multiorgan failure, the lung is the target organ for toxicity among those surviving the immediate postingestion period. Diquat, a related dipyridyl herbicide, does not cause the lung injury associated with paraquat, although poisoning can lead to renal failure and cerebral hemorrhage.[285]

The pulmonary toxicity of paraquat, in contrast to its gastrointestinal effects, does not reflect caustic irritant injury. The major lung effect of paraquat toxicity is the development of pulmonary edema, usually observed 24 to 48 hours after ingestion. The pulmonary edema may evolve to a condition resembling ARDS, associated with histopathologic findings similar to those of DAD, which may progress to an accelerated, chemically induced pulmonary fibrosis. After stabilization following acute multiorgan toxic effects, disease progression is marked by rapidly worsening respiratory distress, hypoxemia, and a restrictive ventilatory defect, with decreased lung compliance and diffusing capacity, ending in death from ventilatory failure within days to weeks.[22,282] Survivors may demonstrate modest and slow improvement in lung function.[286]

The mechanism of paraquat toxicity is attributed to the generation of superoxide radicals that may be partly iron dependent. Consistent with an oxidant mechanism, supplemental oxygen and radiation therapy may worsen the outcome; there are no known antidotes for paraquat poisoning, and enhanced elimination such as by hemoperfusion has not demonstrated a clear benefit.[22,282] Plasma paraquat levels can be determined and may have a use in predicting outcome.[287] Data suggest a possible therapeutic benefit from immunosuppression, but this awaits confirmation through controlled clinical trials.[23,282] Death results from multiorgan failure, which usually happens within 1 to 2 weeks but may be observed up to 6 weeks after ingestion.

SMOKE INHALATION

The generic term *smoke inhalation* includes potential exposure to a wide array of substances because of the complex chemistry of heat decomposition and pyrolysis.[38,288] *Pyrolysis* refers to the thermal decomposition of organic material without the involvement of oxygen and is a common component of burning buildings where oxygen is limited. Pyrolysis produces a variety of gases and a physical product such as charcoal. Although anoxia from carbon monoxide, cyanide, and oxidants represents a major manifestation of toxic insult from acute smoke inhalation, this nonpulmonary target organ effect is not covered here. Nonetheless, some chemical irritants produced as pyrolysis by-products do have significant potential pulmonary toxicity. In contrast to thermal injury to the respiratory tract, which typically is limited to upper airways, with laryngeal edema the major potential medical management problem,[289,290] inhalation of the smoke from fires can affect the entire respiratory tract through irritant injury.

In certain cases, irritant chemicals are released in fires as preformed substances, but, most commonly, the toxins are formed de novo. These irritants are produced by the thermal degradation of both natural and synthetic polymers. The predominant by-products of heat breakdown are determined by the nature of the polymers consumed, the temperature of the fire, and the availability of oxygen.[291]

Generally, polymers do not break down to their monomer precursors, although residual monomers can evolve under certain circumstances. For example, when polyvinyl chloride is burned, hydrogen chloride is released rather than the monomer, vinyl chloride. Many of the specific chemical irritants that can be released as common thermal breakdown by-products are addressed elsewhere in this chapter. These include the following: hydrochloric acid (hydrogen chloride), hydrofluoric acid (hydrogen fluoride), and other acids; ammonia; phosgene; and oxides of nitrogen. The zinc chloride "smoke" of smoke bombs (in contrast to the heterogeneous character of "natural smoke") was discussed previously.

Aldehydes merit specific attention. They are a common cause of high-intensity irritant lung injury from the smoke from fires. These chemicals include formaldehyde,

acetaldehyde, and acrolein. The most severe irritant, *acrolein* (CH_2=CHCHO), is least familiar to health care providers. Acrolein, a highly reactive chemical and key toxicant in smoke inhalation injury, is formed as an important pyrolysis product of both synthetic (e.g., acrylic) and natural polymers.[292,293] In addition to de novo formation as a combustion by-product, acrolein is also intentionally manufactured and used as a pesticide; its use as an aquatic herbicide to facilitate water flow in irrigation canals can lead to human inhalation exposure with irritant effects.[294]

The general considerations concerning irritant exposure discussed previously, including air concentration and water solubility, come into play in smoke inhalation. These factors are further complicated by the potential interactive effects of multiple simultaneous exposures, as well as the modifying impact of physical cofactors such as airborne respirable particulates (e.g., soot) that may serve as adsorbent carriers facilitating deep lung penetration of toxicants. In practice, detailed exposure data delineating the irritant contents of a specific smoke exposure are rarely available. Information that may help to elucidate exposure conditions include identity of the products involved (e.g., specific synthetic polymers, if known), history of inhalation within an enclosed or confined space, evidence of thermal injury, and carboxyhemoglobin and methemoglobin levels as markers of inhalation severity based on other concomitant exposures (carbon monoxide and oxidants, respectively).

Firefighters (both urban and wildland) and nonoccupationally exposed victims of irritant smoke inhalation have proved to be important groups in which to study acute inhalational syndromes. Large-scale conflagrations (e.g., urban "wildland" fires[295,296]) can expose substantial numbers of persons to irritant combustion by-products, as can smoke drift from intentional burning of agricultural residue. Wildfire health hazards can be expected to increase as climate change creates longer, warmer, and drier seasons. Studies of such populations after smoke inhalation have demonstrated acute and persistent airflow obstruction and increased nonspecific airway hyperresponsiveness.[297–305] Bronchiectasis and BO have both been associated with combustion by-product exposure.[66,68] The acute respiratory effects and potential sequelae of exposure to the plume generated by the destruction of the World Trade Center may relate to other factors such as alkaline (high-pH) dust from concrete, gypsum, and glass fibers, rather than to standard smoke particulate.[306]

PHARMACOLOGIC SYNDROMES

Certain natural and synthetic chemical exposures affect the lung by specific mechanisms consistent with known pharmacologic actions. These chemicals are site specific for key cellular functions leading to adverse respiratory effects. As noted previously, the most potent chemical warfare agents act through acetyl cholinesterase inhibition, with profound impacts on respiratory function.[168,169] Similar, albeit less potent, agents have widespread uses as agricultural chemicals. Both organophosphate and carbamate pesticides lead to respiratory compromise as a principal toxic effect. For example, in one case series, a considerable number of poisonings from these pesticides led to respiratory failure, accompanied by a high case-fatality rate; in contrast, all the patients without concomitant respiratory failure survived.[307]

Inhaled capsaicin, of interest as a research tool to study substance P–mediated effects, is associated with cough in occupational settings (e.g., in chili pepper processing).[308] When used as a personal defense spray, respiratory irritation has been reported, although ocular problems are more common.[309,310]

Brevetoxin is a toxin produced by dinoflagellates associated with "red tides." Environmental inhalation exposure from airborne aerosols of red tide resulting from wind and surf action causes cough, sneeze, and wheeze.[311–313] For lifeguards, brevetoxin health effects represent a source of occupational respiratory morbidity, including work loss.[314] The toxin appears to act by stimulating sodium channels in the lung.

Palytoxin is another natural toxin produced by certain dinoflagellates, as well as by sea anemones and zoanthid corals. Human exposure may result from ingestion, dermal contact, or inhalation. Respiratory illness attributable to palytoxin inhalation has been described among aquarium hobbyists and among individuals in proximity to algal blooms in ocean water.[315] The palytoxin inhalational toxic syndrome includes dyspnea, cough, fever, and tachycardia.[316]

Respiratory irritation may also be a manifestation of *Pfiesteria* dinoflagellate toxin inhalation (although potential neurotoxicologic effects have been of greater concern).[317,318]

OTHER INHALANT EXPOSURES

Ammonia

Anhydrous ammonia is a gas at room temperature and ambient pressure, although ammonia is more commonly encountered in aqueous form, as in cleaning solutions. Potential sources of ammonia gas exposure include incidents in the chemical industry and in hazardous transportation, commercial refrigeration systems, and farming (e.g., fertilizer).[9,318–323] Anhydrous ammonia has also been released from illicit methamphetamine laboratory operations, although such exposures are often in the context of conflagrations with concomitant thermal burns and other coexposures.[324,325]

Ammonia has prominent irritant properties, such as burning eyes, that warn the exposed individual to escape. It is linked with lung injury chiefly in settings of overwhelming exposure or where immediate escape has not been possible. Both asthma and bronchiectasis have been documented after ammonia exposure.[9,322] Acute ammonia exposure has also been reported to have residual upper airway effects, including decreased olfactory acuity.[46] Death may result from laryngeal edema and airway obstruction, acute pulmonary edema, or complications of the pneumonic process (e.g., bacterial superinfection). Lung transplantation following ammonia inhalation has been reported, including in a patient who had severe lung injury following an explosion in a poultry plant.[326,327]

Bromine and Methyl Bromide

Bromine is an irritant halogen. It is usually handled as a liquid rather than as a gas, but it vaporizes readily. Sources of bromine exposure other than environmental releases include chemical synthesis and water purification.[69,328–331] Bromine is a more potent irritant than chlorine and is approximately 100 times more irritating than ammonia.[332] In a murine model of bromine-induced lung injury, high heme levels, possibly released from dead inflammatory cells or sloughed epithelial cells, correlated with a spectrum of adverse sequelae, including lung edema, increased airway resistance, and lung inflammation. Therapeutic reduction of heme levels improved lung function and survival, thus suggesting a potential role for heme attenuation as a treatment for victims of bromine inhalation, although this has not been studied in humans.[333]

Methyl bromide is a major industrial fumigant with far-greater potential for public exposure. Methyl bromide is also a potent respiratory irritant, but the central nervous system may represent the more important target organ in typical exposures.[334,335]

Hydrogen Sulfide

Hydrogen sulfide is a common by-product of petroleum extraction and refining, as well as a potential hazard from the breakdown of organic materials (hence, its common name, "sewer gas"); overexposure can result from work in confined spaces, submersion in manure pits,[336] or proximity to geothermal or volcanic sources.[337] Asphyxial death of several tourists exploring a volcanic crater was attributed to inhalation of mixed gases containing both hydrogen sulfide and carbon dioxide.[338] Hydrogen sulfide is a respiratory irritant, but it is an even more potent cytotoxic asphyxiant, impairing cytochrome oxidase and cellular respiration. Therefore, in cases of severe hydrogen sulfide exposure, rapid cardiovascular collapse and death often overshadow any pulmonary organ effects, although an acute lung injury pattern can be present in persons surviving long enough to receive intensive supportive care; irritant symptoms as a predominant feature may be of greater relevance in lower-intensity exposures.[337,339–342]

Methyl Isocyanate and Methyl Isothiocyanate

Methyl isocyanate (MIC) use is restricted to a narrow industrial application in the synthesis of pesticides. The mass fatalities at Bhopal, India, make MIC an important toxin for historical reasons. The toxicity of MIC was the result of its severe irritant properties leading to pulmonary edema.[343–345] No cyanide-mediated mechanism was involved. *Methyl isothiocyanate*, a breakdown product of the soil fumigant metam sodium, is an irritant chemically related to MIC that was also involved in a mass exposure episode, although less severe than the MIC release at Bhopal, and has also been associated with respiratory symptoms following agricultural application.[346,347] The isocyanates associated with urethane, such as toluene diisocyanate, diphenylmethane diisocyanate, and hexamethylene diisocyanate, are pulmonary irritants but are primarily of concern because of their induced sensitization (see Chapter 100).

MISCELLANEOUS EXPOSURES

Numerous other occupational and environmental agents result in acute pulmonary syndromes. Examples of such exposures include the following: diethylaminoethanol and cyclohexylamine (both anticorrosive boiler additives)[348,349]; amitrole and glyphosphate (both common herbicides)[350,351]; thiram (used as a fungicide in agriculture and as a vulcanization accelerator in the rubber industry)[351a]; sodium azide (used in a variety of chemical applications but important as a potential inhalant through automobile airbag deployment)[352]; diazomethane, which is explosive but also highly toxic to the lung, with a delayed onset similar to that of nitrogen dioxide[353,354]; diborane (an irritant gas used in manufacturing microelectronic equipment)[355,356]; barium (inhalation can cause bronchospasm and respiratory muscle weakness in addition to life-threatening hypokalemia)[357]; and hydrogen selenide (an irritant gas used in several industrial processes, as well as being a potential metal processing by-product).[358,359]

An outbreak of severe lung injury in Korea, particularly among young, peripartum women, was linked to treatment of room humidifier water with two biocides: polyhexamethylene guanidine and oligo(2-(2-ethoxy)ethoxyethyl) guanidinium chloride.[360,361] The overall mortality rate in what has been labeled "humidifier disinfectant–associated lung injury" is reported to be more than one-third of cases, with three-fourths of those patients requiring mechanical ventilation dying of their injuries.[362] After the original offending product was removed from the market, humidifier disinfectant–associated lung injury was described in twin sisters exposed to chloromethylisothiazolinone and methylisothiazolinone, thus broadening the spectrum of disinfectants associated with toxic lung injury.[363]

Phosphine is an important agricultural fumigant with pulmonary and systemic toxicity, which is generated on site as a gas given off by moisture coming in contact with solid-form aluminum or zinc phosphide (e.g., in grain storage facilities or railway grain transport cars, where bystanders can be exposed).[364,365] Ingestion of the parent material by animals can also lead to exposure among treating veterinary personnel.[366] Phosphine also has industrial applications, particularly in the production of microelectronics.

Acetic anhydride (used in making epoxy and other resins) has also been associated with acute lung injury following acute inhalation.[367] A distinctly different pattern of injury is associated with a related epoxy chemical, trimellitic anhydride, which causes severe pulmonary hemorrhage after subacute exposure.[15]

Carbon dioxide, although a bulk asphyxiant and not a respiratory irritant, causes shortness of breath and induces tachypnea; persons can be exposed through natural geologic sources and dry ice sublimation in an enclosed space.[368–370]

Baby (talcum) powder inhalation can cause pediatric acute pneumonitis within hours of heavy exposure; infant inhalation of nontalcum powders has also led to pneumonitis.[371–373]

Paraphenylenediamine is a dye used to color hair and can also be admixed with henna as a temporary tattooing agent; its ingestion as an agent of self-harm is common in

TABLE 103.3 Useful Resources for Information About Specific Toxins

- The Household Products Database (https://healthdata.gov/dataset/household-products-database) is a consumer guide that provides information on the potential health effects of chemicals contained in more than 7000 common household products used inside and around the home.
- WISER (Wireless Information System for Emergency Responders) (http://wiser.nlm.nih.gov) is a system designed to assist first responders in hazardous material incidents.
- The EPA CompTox Chemicals Dashboard (https://comptox.epa.gov/dashboard/) provides access to multiple types of data, including physicochemical properties, environmental fate and transport, exposure, usage, in vivo toxicity, and in vitro bioassay.
- The ECOTOXicology knowledgebase (ECOTOX (https://cfpub.epa.gov/ecotox/) is a comprehensive knowledgebase providing single-chemical environmental toxicity data on aquatic life, terrestrial plants, and wildlife.
- The ATSDR Toxic Substances Portal (https://www.atsdr.cdc.gov/) provides information on toxic substances and their health effects.

Asia and Africa. In addition to rhabdomyolysis and renal damage, this chemical has a particular propensity to cause angioedema leading to airway obstruction.[25]

Naturally occurring sources of exposure can also be associated with acute and subacute lung responses, although these syndromes are poorly characterized. Epidemiologically, *Stachybotrys chartarum (atra)* mold growth in water-damaged residential structures was initially linked to a cluster of cases of pulmonary hemorrhage in infants, although the association was later retracted in a follow-up review by the U.S. Centers for Disease Control and Prevention.[374,375] Other case reports have occasionally linked other molds or mold by-products with lung injury (as opposed to self-limited ODTS, discussed previously).[376]

Lycoperdonosis is a potentially severe, acute pulmonary syndrome following intentional inhalation (sometimes as a natural medicinal treatment) of puffball mushroom *(Lycoperdon)* spores; in addition to human illness, fatal inhalation in pet dogs is a well-characterized veterinary syndrome.[377–379] The pathophysiology of the syndrome is not understood, but its high attack rate with heavy exposure suggests a toxic rather than an allergic or infective mechanism.

Beginning in 2019, acute lung injury associated with "vaping" (use of electronic cigarettes or e-cigarettes) began to be widely observed.[380,381] These devices work by heating liquids to produce an inhalable aerosol. Such aerosols can contain multiple intended and unintended component toxicants, including potential thermal breakdown materials. The topic of vaping, as well as classic cigarette smoking lung effects, is covered in Chapter 65.

Additional information about toxicants and their effects can be accessed online from a variety of resources (Table 103.3).

Key Points

- Short-term inhalation exposures to toxicants have important effects on the lung as the target organ for damage.
- Acute lung toxicity results from a variety of exposures but nonetheless is manifest by a narrow repertoire of injury.
- Although modified by the solubility and other physical properties of the toxicant, injury largely depends on the intensity and duration of exposure.
- Extensive injury can lead to acute pulmonary edema and diffuse alveolar damage.
- Specific exposures of importance include chlorine, oxides of nitrogen, sulfur dioxide, acid aerosols, toxic metal fumes, and pyrolysis by-products.
- Aside from acute irritant or toxic lung insult leading to airway injury and diffuse alveolar damage, other patterns of acute responses include the inhalation fevers (which are self-limited and appear to be cytokine mediated) and certain target-specific effects, such as those elicited by cholinesterase inhibition.
- Exposure by *ingestion* of some substances (e.g., hydrocarbons and paraquat) can cause important acute pulmonary target organ toxicity.

KEY POINTS

THORACIC TRAUMA

INTRODUCTION

Among trauma victims, thoracic trauma is the second most common cause of death in the field and the third most common cause of death in patients who make it to the hospital. In civilian trauma, the most common mechanism is blunt trauma, and the most frequently encountered injuries (i.e., hemothorax and pneumothorax) are seen in 20% of patients.[1] The majority will require only tube thoracostomy for definitive treatment. However, up to 15% of these patients will require operative intervention,[1] whether immediate (resuscitative), urgent, or delayed. Overall mortality in patients with thoracic trauma is approximately 10%, with a low Glasgow Coma Scale score exerting the strongest influence on mortality.[1] Additional predictors of poor outcomes include increasing age, mechanism of blunt injury, increasing number of ribs fractured, and concomitant long bone extremity fractures.[1]

RESUSCITATIVE THORACOTOMY

Patients who arrive without signs of life may benefit from *emergency department thoracotomy* (EDT) or "resuscitative" thoracotomy, depending on the amount of time elapsed since the loss of vital signs (<15 minutes for penetrating trauma; <10 minutes for blunt trauma).[2,3] The goal of this procedure is to restore spontaneous circulation by rapid repair of intrathoracic injuries or release of pericardial tamponade and by occlusion of the descending thoracic aorta to divert perfusion to the brain and heart. Internal cardiac massage with injection of intracardiac medications may also be indicated. In cases of bronchovenous air embolism, clamping of the pulmonary hilum prevents further propagation. Because patients who undergo resuscitative thoracotomy should always proceed to the operating room for definitive repair, EDT should not be attempted without a surgeon immediately available. Rhee and colleagues[4] reported that the overall survival rate after EDT is 7.4%, with a survival rate of 15% among all patients with penetrating injuries and 35% among patients with penetrating cardiac injuries. In contrast, survival rates after EDT are very low (2%) after blunt traumatic arrest.[4]

It is important to perform an initial cardiac ultrasound examination because EDT can be considered futile if asystole is the presenting rhythm and pericardial tamponade is absent.[3] In patients with appropriate indications, aggressive efforts are justified because functional long-term outcomes in survivors are excellent. More than one-half of survivors are discharged home from the hospital, and more than 75% have normal cognition, are ambulatory, and have no posttraumatic stress disorder.[5] However, inappropriate EDT results in no survival benefit, wasted use of resources, and exposure of health care workers to needle-stick and bone fragment injuries.[6]

URGENT THORACOTOMY

Commonly accepted indications for urgent thoracotomy include any of the following: initial chest drain output of 1500 mL, greater than 1500 mL output in the first 24 hours after injury, more than 200 mL bloody output per hour for 3 consecutive hours, massive air leak (present during all phases of respiration associated with inability to reexpand the lung or affecting ventilation secondary to loss of tidal volume), or hemodynamic instability.[7] Rarely, a patient has sudden cardiovascular collapse or new neurologic symptoms, typically after the patient is placed on positive-pressure ventilation, which are consistent with air embolism, and require urgent thoracotomy.

DELAYED THORACOTOMY

Delayed thoracotomy is performed several days after injury in stable patients, usually for retained hemothorax, trapped lung, persistent air leak, or rib fixation (see also Chapters 110, 112, and 113).

THORACIC CAGE INJURIES

Rib Fractures

Rib fractures are seen in 10% of hospitalized trauma patients.[8,9] The morbidity of rib fracture pain is underappreciated; one-third of patients require hospitalization for pain control, and pneumonia develops in another one-third.[10] The true incidence of rib fractures is likely higher; a supine chest radiograph is 50% sensitive (at best) for detecting rib fractures. Chest *computed tomography* (CT) (eFig. 104.1) is much more sensitive and can also evaluate for other occult injuries.[8] In general, ribs tend to fracture at their weakest structural point (the posterior angle) or directly at the point of impact.[11] They are rarely the sole injury, and 50% of patients with rib fractures have other significant injuries.[10] In a patient with lower rib injury (ribs 9 through 12), abdominal solid organ injury (spleen or liver) should be considered.

Pressley and colleagues[12] developed a simple scoring system that was based on initial clinical findings (age, number of fractured ribs, severity of *pulmonary contusion* [PC], and unilateral vs. bilateral rib fractures) to predict the likelihood of requiring intubation and mechanical ventilation or *intensive care unit* (ICU) admission (Table 104.1). These investigators found that a patient with a total score greater than 7 had a high probability of death, need for ICU admission, and need for mechanical ventilation. Similarly, a total score greater than 4 predicted the need for a longer hospital stay and prolonged mechanical ventilation. Other studies have also found that an increasing number of rib fractures correlates with increasing ICU *length of stay* (LOS), hospital LOS, and mortality.[13,14] Additionally, vital capacity lower than 30% is independently associated with increased odds of pulmonary complication,[15] whereas a low incentive spirometry volume (500 mL or less) is predictive of acute respiratory failure.[16]

Treatment for most patients with rib fractures is supportive care, consisting of aggressive pain control and pulmonary rehabilitation. Deep breathing facilitates clearance of secretions to reduce the incidence of pneumonia. Analgesic options include oral analgesics (including opioids), intermittent intravenous analgesics, patient-controlled analgesia, *thoracic epidural analgesia* (TEA), intrapleural blocks, intercostal blocks, and *thoracic paravertebral blocks* (TPVBs).[17,18] Nonopioid analgesic options include acetaminophen, nonsteroidal anti-inflammatory drugs (including ketorolac), anticonvulsant agents such as gabapentin, and topical lidocaine patches.[19] Numerous small, single-center trials have reported that, compared with intravenous opioids, TEA results in less pain, improved pulmonary function, fewer ventilator days, fewer infections, fewer pulmonary complications, shorter ICU LOS, and shorter hospital LOS.[20–27] Furthermore, TEA may also attenuate the postinjury inflammatory response.[25–28]At present, TEA is the preferred analgesic modality for pain secondary to blunt thoracic injury.[29,30] However, there are other considerations. For one, TEA is underused, with studies reporting its use in less than 30% of eligible patients.[31] For another, epidural analgesia is not without risk; side effects include hypotension, epidural hematoma, urinary retention, and epidural abscess. Finally, TEA may be of benefit only in selected patients. For example, one pooled meta-analysis did not find any benefit of TEA for decreasing the duration of mechanical ventilation, ICU LOS, hospital LOS, or mortality.[32] For epidural analgesia to be of benefit, appropriate patient selection is paramount. Although the absolute number of fractured ribs is predictive of the need for TEA, it is important to examine the patient carefully to determine whether pain is severe enough to cause respiratory embarrassment. In fact, one review reported that, in older patients, epidural analgesia was associated with *increased* complications and prolonged LOS.[33] In sum, based on the existing evidence, the Eastern Association for the Surgery of Trauma conditionally recommends epidural analgesia and multimodal analgesia for patients with severe pain resulting from traumatic rib fractures.[29]

Another underused analgesic option is the TPVB or paravertebral block, which is easy to perform, has a greater than 90% success rate, and has a low incidence of side effects.[34,35] When successful, TPVB has been shown to improve pain scores and pulmonary function tests.[36] TPVB provides only unilateral pain relief and thus is usually used only for patients with unilateral rib fractures; however, it is also useful when there are contraindications to TEA, such as coagulopathy, spinal fractures, or altered mental status.

In addition to pain control, a formalized multidisciplinary pathway that includes aggressive respiratory therapy and nutritional support has been shown to decrease ventilator days, LOS, infectious morbidity, and mortality among patients older than 45 years of age and with more than four fractured ribs.[37]

Older patients with rib fractures are at especially high risk for complications: 15% require intubation, and pneumonia develops in up to 31%[31,38–40] (Fig. 104.1). In patients older than 45 years of age, morbidity sharply increases when more than four ribs are fractured.[41] Bulger and coworkers[31] reported that patients older than 65 years of age with fractured ribs have double the morbidity and mortality rates compared with younger patients with similar injuries. Bedside vital capacity measurement can predict hospital LOS and identify those patients requiring discharge to an extended care facility.[42]

Table 104.1 Chest Wall Trauma Scoring System*

Age (y)	Number of Rib Fractures
<45 = 1 point	<3 = 1 point
45–65 = 2 points	3–5 = 2 points
>65 = 3 points	>5 = 3 points
Score: _____	Score: _____
Pulmonary Contusion	**Bilateral Rib Fractures**
None = 0 points	No = 0 points
Mild = 1 point	Yes = 2 points
Severe = 2 points	Score: _____
Bilateral = 3 points	
Score: _____	
	Total Score: _____

*Total score is the sum of the scores of each of the 4 categories. A score >4 predicts a longer hospital length of stay; a score >7 predicts increased risk for mortality, admission to the ICU, and intubation/mechanical ventilation.
From Pressley CM, Fry WR, Philp AS, Berry SD, Smith RS. Predicting outcome of patients with chest wall injury. *Am J Surg.* 2012;204:910–914.

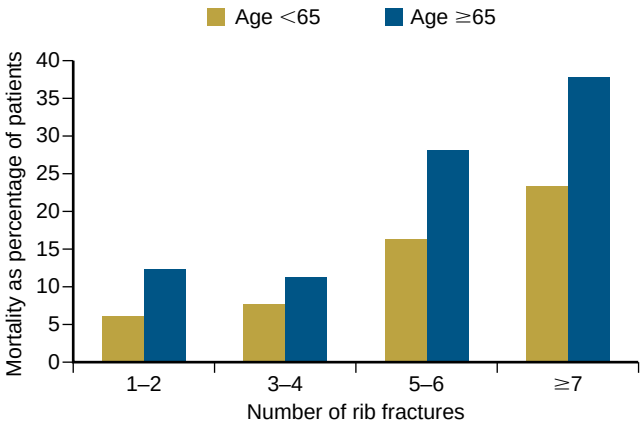

Figure 104.1 Relationship between the number of rib fractures and mortality. In a retrospective study of patients admitted to trauma centers, mortality increased with increasing number of rib fractures, an easily quantifiable measure of trauma severity. At each number of rib fractures, mortality for those patients older than 65 years was greater than that for those younger than 65 years. (From Stawicki SPG, Michael D, Hoey BA, et al. Rib fractures in the elderly: a marker of injury severity. *J Am Geriatr Soc.* 2004;52:805–808.)

Rib fractures continue to cause significant pain and disability long after hospital discharge. Typically, follow-up demonstrates that significant proportions of patients have chronic persistent pain and impairment of both work and personal life.[43,44] In one study, patients with rib fractures had more disabilities at 30 days after injury than did patients with chronic medical illness. These patients with rib injuries missed an average of 70 days of work.[45] Two months after injury, more than 75% of patients with rib fractures reported some form of disability.[46] Of patients who had blunt chest trauma and were admitted to the ICU, more than 60% reported chronic pain (requiring regular use of analgesics) 3 months after hospital discharge.[47] Interestingly, the single most important predictive factor for long-term disability after rib injury was the initial intensity of pain. The total number of rib fractures and the presence of bilateral injury was not predictive.[46]

Flail Chest. A flail chest, also known as stove-in or crushed chest, is the most severe form of blunt thoracic injury (see Chapter 131). The mortality associated with flail chest is as high as 40%.[48] Radiographically, it is defined as three or more consecutive ribs fractured in at least two locations. Clinically, a flail chest manifests as paradoxical incursion (rather than excursion) of the floating segment of chest wall during inspiration (Videos 104.1 and 104.2). Given the significant energy required to produce this injury, flail chest is almost universally accompanied by PC. Complications, especially pneumonia and *acute respiratory distress syndrome* (ARDS), are very common in this morbid condition.[49]

The management of flail chest has evolved over the past 50 years. Previously, it was believed that the paradoxical chest wall movement was the cause of the respiratory failure and hypoxemia. Now, it is understood that the respiratory impairment is secondary to the underlying pulmonary parenchymal injury. Historically, efforts were focused on correcting the paradoxical motion through external stabilization ("sandbagging") and, later, by internal pneumatic stabilization (i.e., positive-pressure ventilation).[50,51] Hence, in the mid-20th century, the predominant treatment method for all patients with flail chest was mechanical ventilation. Starting in the mid-1970s, some physicians found that these patients could be adequately managed without ventilatory support. At this time it was recognized that the underlying PC, rather than the chest wall instability, was the driving factor in outcome.[52] Currently, less than half of patients with flail chest require mechanical ventilation.[53] Abnormal gas exchange, not chest wall movement, should drive the decision to initiate mechanical ventilation.[54]

In the modern management of flail chest, optimal pain control is paramount. According to the Eastern Association for the Surgery of Trauma practice management guidelines,[55] TEA is the preferred pain treatment modality in the treatment of flail chest. When an epidural catheter is contraindicated, TPVB may be considered. If mild to moderate respiratory compromise is present, a trial of noninvasive ventilation in conjunction with TEA may be considered before proceeding to endotracheal intubation. However, in the absence of respiratory embarrassment, mechanical ventilation to treat paradoxical chest wall motion is not recommended.

The long-term outcome of flail chest managed nonoperatively is marked by disability, with 70% of patients reporting dyspnea and more than 50% reporting chronic chest wall pain.[55,56] Less than half of patients managed conservatively are able to return to work.[57] Surgical fixation of the floating chest wall segment has been practiced for decades in Europe and Asia, but it is underused in the United States, likely because of a combination of relative unfamiliarity with the procedure itself and unfamiliarity with the evidence supporting the procedure. In a survey of trauma surgeons, orthopedic surgeons, and thoracic surgeons, only 26% had ever performed or assisted on the procedure, and most were unaware of the published randomized trials supporting its use.[58] More recently, the use of surgical fixation for rib fractures has been increasing, although this change is inconsistent and varies according to region and by trauma center designation level.[59] Numerous techniques are described for rib fracture fixation, including the use of wire suture, staples, metal or absorbable plates, and screws.[10] A case-control study reported by de Moya and colleagues[60] concluded that rib fracture fixation significantly decreased the need for analgesia. Infection of rib fixation hardware is uncommon, reported to be approximately 2%.[10]

To date, three randomized controlled studies and a meta-analysis evaluating surgical fixation in patients with flail injury have been published supporting rib fracture fixation.[50] Tanaka and colleagues[61] reported that patients who underwent internal fixation of their fractured ribs had a shorter duration of mechanical ventilation, a lower incidence of pneumonia, a shorter ICU LOS, improved pulmonary function, and quicker return to employment. Granetzny and coworkers[62] also reported that patients randomized to surgical fixation had a decreased need for mechanical ventilation, a shorter ICU LOS, and a lower incidence of pneumonia. More recently, Marasco and associates[53] demonstrated that patients randomized to operative repair had a decreased ICU LOS and a reduced need for tracheostomy, with no difference in the duration of invasive mechanical ventilation. The optimal time for operative intervention is currently unknown, although a

multicenter observational study reported that early surgical fixation (<1 day) compared with late fixation (3 to 10 days after injury) was associated with decreased operative time and lower rates of pneumonia, prolonged mechanical ventilation, and tracheostomy.[63] No trial has compared surgical fixation with nonoperative management with TEA and chest physiotherapy. An economic analysis based on reported incidences of complications and outcomes concluded that, despite the additional cost of surgery, rib fixation for flail chest remained cost-effective compared with nonoperative management.[64] Long-term survey follow-up of patients treated by rib fixation revealed very high rates of satisfaction and return to work.[65]Currently, rib fixation is conditionally recommended by the Eastern Association for the Surgery of Trauma for the treatment of flail chest.[66]

Sternal Fractures. The most common cause of sternal fracture is motor vehicle crash (eFig. 104.2).[67] The presence of sternal fractures has traditionally been considered a marker of injury severity, especially in previous decades when seatbelt use was not as widespread. As such, some investigators advocate for hospital admission and close monitoring to rule out other serious injuries, such as blunt cardiac injury. Others report that sternal fracture by itself is not a significant cause of morbidity or mortality, and many believe that morbidity is mainly attributable to other associated injuries.[67–71] With increasing seatbelt use and more frequent use of diagnostic CT scanning, the incidence of sternal fractures has increased, whereas mortality has decreased.[72–74]

In the initial workup of a patient with sternal fracture, it is important to rule out a blunt cardiac injury by obtaining a 12-lead electrocardiogram and serum troponin level. A normal electrocardiogram and a normal initial troponin level essentially exclude the diagnosis of blunt cardiac injury, and no further workup is recommended.[75] However, arrhythmias, ST-segment changes, heart block, signs of ischemia, and elevated troponin levels are considered abnormal screening test results and should be followed by a confirmatory formal echocardiogram. Nuclear medicine studies are not useful in the diagnostic workup of blunt cardiac injury. As was discussed for rib fractures, adequate pain control is paramount for the treatment of sternal fractures. However, with isolated sternal fractures, pain can usually be treated on an outpatient basis.[76] Sternal fracture fixation is rarely indicated.

Clavicle Fractures. The clavicle is an S-shaped bone that acts as a strut between the shoulder and the axial skeleton. It protects the apex of the lung, brachial plexus, and subclavian vessels. Clavicle fractures follow direct impact to the extremity or chest and account for 44% of all fractures to the shoulder girdle.[77]

Fractures of the middle third are the most common, accounting for 69–81% of all clavicular fractures.[77] Diagnosis of clavicle fractures requires some type of imaging, usually radiography, although many fractures are visualized only on CT. Special radiographic views can be ordered to improve the evaluation for subtle fractures, fracture displacement, or sternoclavicular joint dislocations (eFigs. 104.3 and 104.4). These views include axillary views, 45-degree cephalic tilt, or a serendipity view, which is a 40-degree cephalic tilt.

Treatment generally is nonoperative, with a sling or figure-of-eight brace, and 2 to 6 weeks of immobilization, as well as avoidance of heavy lifting and contact sports for 4 to 6 months. Operative treatment is indicated for all open fractures, for skin tenting indicating a break that may result in an open fracture, and for any case with neurovascular compromise. A Cochrane meta-analysis of eight trials involving 555 patients examined the difference between conservative treatment and surgical fixation among patients with fractures of the middle third of the clavicle.[78] Unfortunately, because of heterogeneity between the studies and the overall high risk of bias, no strong conclusions could be made, and the investigators concluded that the decision to operate must be made on a case-by-case basis.[78]

LUNG PARENCHYMA INJURIES

Pulmonary Contusion

PC is a common injury, with an incidence of 30–75% in patients with blunt thoracic injury[55] and up to 17% of all trauma admissions. PC is most common after a blunt mechanism of injury, but it can also manifest adjacent to a missile tract through lung parenchyma. At the microscopic level, the contused lung displays edema, alveolar and intraparenchymal hemorrhage, and atelectasis, which results in intrapulmonary shunting, ventilation-perfusion mismatch, and decreased lung compliance.[79] This manifests as hypoxemia, hypercarbia, and increased work of breathing. The full effects of PC may not be obvious immediately; however, clinically significant PC becomes apparent within 24 hours. The natural history of PC is progressive dysfunction over the first few days and resolution within a week.[80]

Severe PC can produce systemic effects. Animal studies demonstrate that unilateral contusion can lead to capillary leak in *both* ipsilateral and contralateral sides, with increased edema and accumulation of inflammatory cells.[81] Inflammatory cytokines are increased both locally and systemically, and there is evidence of global immune dysfunction.[82–85] Additionally, PC may prime the immune system for an exaggerated response to a subsequent second hit, such as infection[81,86] (Fig. 104.2). Trauma patients with PC have twice the rate of ventilator-associated pneumonia as those without PC.[87] At 6 years after injury, more than half of patients with PC have evidence of lung fibrosis on CT scan,[88] and long-term lung function can be compromised.[43]

Because not all PCs are clinically significant, several groups have attempted to identify factors predictive of outcome. De Moya and associates[89] developed a simple scoring system, combining the initial CT findings, Glasgow Coma Score, and number of fractured ribs, to predict the need for mechanical ventilation. Interestingly, in this study, less than one-third of all PCs were evident on the initial chest radiograph (eFig. 104.5).[89] Other investigators have questioned the significance of occult PC (i.e., apparent only on CT; eFig. 104.6). In a prospective study of 255 patients with PC, Deunk and colleagues[90] reported that patients with occult PC fared no worse than those without PC, whereas patients with PC seen on both chest radiograph and chest CT scan had significantly worse outcomes. Others have attempted to correlate PC size (as a percentage of total lung volume) with outcomes. Studies have demonstrated that patients with PC volume greater than 20% of total lung volume are at increased risk for requiring mechanical ventilation, developing pneumonia, and developing ARDS.[91]

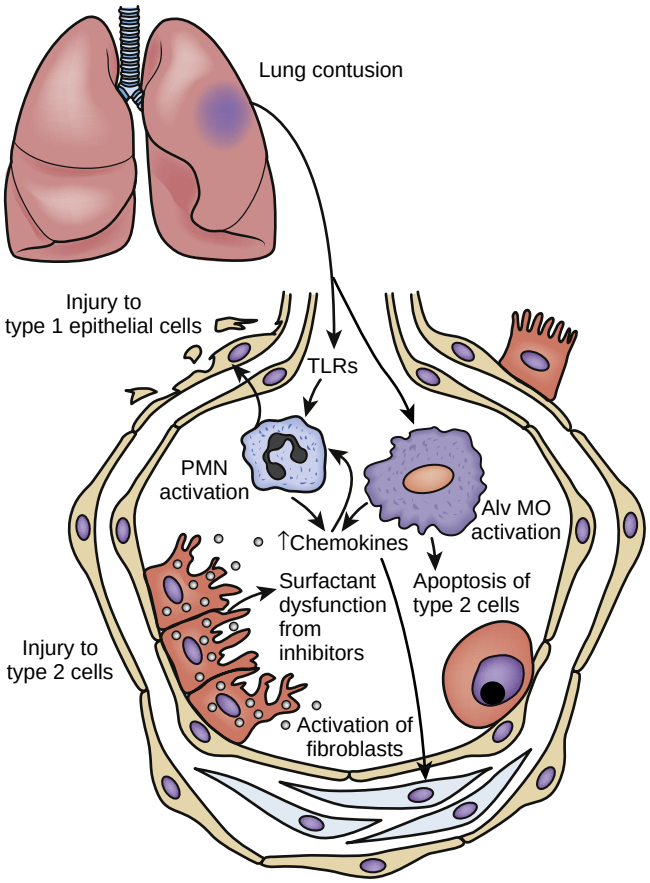

Figure 104.2 Inflammatory effects following pulmonary contusion. In the diagram, the potential interactions of the cells and mediators of the innate inflammatory response to contusion are shown. Although this inflammatory mechanism may amplify the injury of the contusion, it may also provide potential targets for therapeutic intervention. Alv MO, alveolar macrophage; PMN, polymorphonuclear neutrophil; TLRs, toll-like receptors. (Modified from Raghavendran K, Notter RH, Davidson BA, et al. Lung contusion: inflammatory mechanisms and interaction with other injuries. *Shock*. 2009;32:122–130.)

At this time there is no well-supported intervention to treat PC, and management consists mainly of supportive care and avoidance of iatrogenic injury. Steroids are not recommended, and prophylactic antibiotics are strongly discouraged. In 1973, Trinkle and coworkers[92] recognized that crystalloid administration increased the size of the contusion, whereas diuresis decreased it. Pharmacologic therapies being investigated include arginine vasopressin and dexmedetomidine.[93] In an animal study using a model of PC, dexmedetomidine infusion improved hemodynamic parameters, decreased inflammatory infiltration, and limited the extent of lung damage and pulmonary edema.[94] In patients with early, severe hypoxemia (ratio of arterial Po_2 to fractional concentration of oxygen in inspired gas <200), a trial of noninvasive ventilation may be attempted to avoid intubation; however, the development of pneumothorax must be carefully monitored.[95,96] In animal studies, the application of positive end-expiratory pressure has been shown to decrease the size of PCs. Small clinical studies have reported that recruitment maneuvers are successful in improving aeration ("open lung" strategy).[97] In patients with PC, the use of airway pressure release ventilation has been reported to decrease the incidence of ventilator-associated pneumonia; however, experience and evidence are limited.[87] For severe unilateral PC, lung isolation ventilation may be considered.[98] Although traumatic injury (with the attendant risk of bleeding complications) was previously considered a contraindication to *extracorporeal membrane oxygenation* (ECMO), increasing experience with ECMO without anticoagulation[99] and demonstration of improved outcomes compared with conventional mechanical ventilation for severe hypoxemic respiratory failure have made ECMO (with or without systemic anticoagulation) a viable rescue therapy in experienced centers.[100–103] The use of other rescue therapies such as high-frequency oscillatory ventilation and surfactant administration for the treatment of PC is poorly studied and considered experimental at this time.[104,105]

In sum, for the management of PC, the patient should be resuscitated to maintain signs of adequate tissue perfusion and achieve usual end points of resuscitation. Once this has been achieved, however, meticulous attention should be paid to the avoidance of excessive fluid administration, to the point of using a pulmonary artery catheter if necessary to help guide diuretic therapy.[55] Aggressive pulmonary toilet and adequate analgesia are extremely important in preventing pneumonia.

Pulmonary Laceration

Pulmonary laceration is the tearing of the pulmonary parenchyma, which disrupts the alveolar walls. Pulmonary lacerations result from several mechanisms, such as alternate compression and decompression of the chest wall or from a sudden, rapid increase in intrathoracic pressure with a closed glottis leading to high intra-alveolar pressure that produces shearing of pulmonary parenchymal tissue. Alternatively, pulmonary laceration may also result from direct puncture of lung tissue by a fractured rib, missile, or stab wound or from shearing of lung tissue fixed by previously formed pleural adhesions. The disrupted pulmonary tissue fills with blood and/or air and manifests on thoracic imaging as one or more pulmonary parenchymal cavities (eFig. 104.7), appearing as gas-fluid levels, frequently with surrounding pulmonary consolidation and ground-glass opacity related to hemorrhage and atelectasis.

Although only a small fraction of patients with thoracic injury will ultimately require urgent thoracotomy, of those patients who proceed to surgery, approximately one-third may require lung resection, usually to remove severely injured lung tissue, to control hemorrhage, or to remove irreparable proximal bronchus injuries.[106] The extent of resection can range from simple, nonanatomic wedge resection, to formal anatomic lobectomy, to the extremely morbid pneumonectomy.[107] For the majority of penetrating injuries, lung-sparing techniques such as simple suture or "tractotomy" (in which the tract of a penetrating injury is opened and damaged bronchi and vessels are ligated) are sufficient[106,108,109] (Fig. 104.3). Not surprisingly, there is a stepwise increase in mortality with increasing extent of lung resection for trauma: wedge resection (19%), lobectomy (27%), and pneumonectomy (53%).

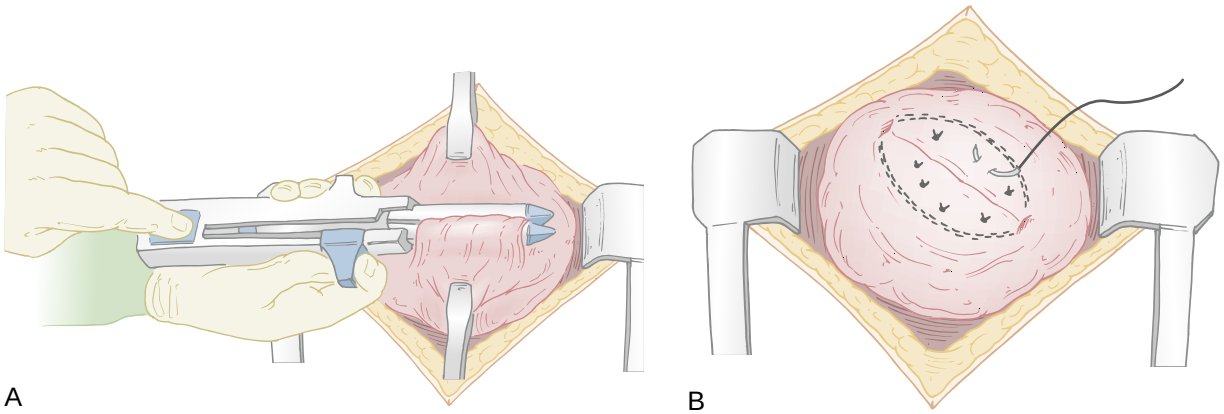

Figure 104.3 Lung-sparing "tractotomy" in which the tract of the penetrating injury is rapidly opened and injured vessels and bronchi are ligated. (A) The stapling device is advanced through the orifices of the entry and exit wound and is then closed and fired to staple the lung on either side and to open the tract ("tractotomy") for visualization of the injured vessels and bronchi. (B) The tractotomy exposes the bleeding vessels, which are then selectively ligated. The tractotomy approach preserves lung by avoiding wedge resection, lobectomy, or pneumonectomy. (From Asensio JA, Demetriades D, Berne JD, et al. Stapled pulmonary tractotomy: a rapid way to control hemorrhage in penetrating pulmonary injuries. *J Am Coll Surg.* 1977;185:486–487.)

Although most previously healthy patients who have experienced trauma can easily tolerate a minor wedge resection or even formal lobectomy, pneumonectomy can impose a tremendous physiologic burden to the unstable trauma patient, and patients often succumb to right ventricular failure.[110] Using a porcine model of hemorrhagic shock, Cryer and colleagues[111] demonstrated that pulmonary vascular resistance increases up to 500% within 4 hours after pneumonectomy. This phenomenon was not seen in animals subjected to pneumonectomy without preceding major blood loss.[111] Inhaled nitric oxide and prostacyclin have been demonstrated to restore pulmonary vascular resistance back to baseline and improve right ventricular function and oxygenation.[112,113] Postoperative complications in survivors are common and include pneumonia, bronchopleural fistula, empyema, or erosion into the pulmonary artery.

Bronchopleural Fistula

A bronchopleural fistula is a direct connection between the bronchus and the pleural space. Although most fistulas heal spontaneously, a persistent bronchopleural fistula may seriously impair the ability to ventilate a patient secondary to loss of tidal volume through the fistula. It is believed that air flowing through the fistula impedes healing, and therefore medical therapies are aimed at reducing bronchopleural fistula air flow.

Nonsurgical treatments include minimizing airway pressures (via lower tidal volumes, positive end-expiratory pressure, and inspiratory time), isolated contralateral lung ventilation, dependent positioning of the side with the bronchopleural fistula, and use of high-frequency oscillatory ventilation.[114–116] Bronchoscopy is useful to identify the injury directly (proximal) or the affected bronchial segment (distal). A balloon is used to occlude the segments sequentially until a reduction in air leak is noted. Once the affected bronchus is identified, agents such as silver nitrate, cyanoacrylate-based agents, gelatin, fibrin, and even fishing weights have been applied to occlude the bronchial segment and close the fistula.[117–121] Bronchopleural fistula refractory to medical therapy for more than 7 days may require pleurodesis, an endobronchial valve,[122,123] or operative intervention.

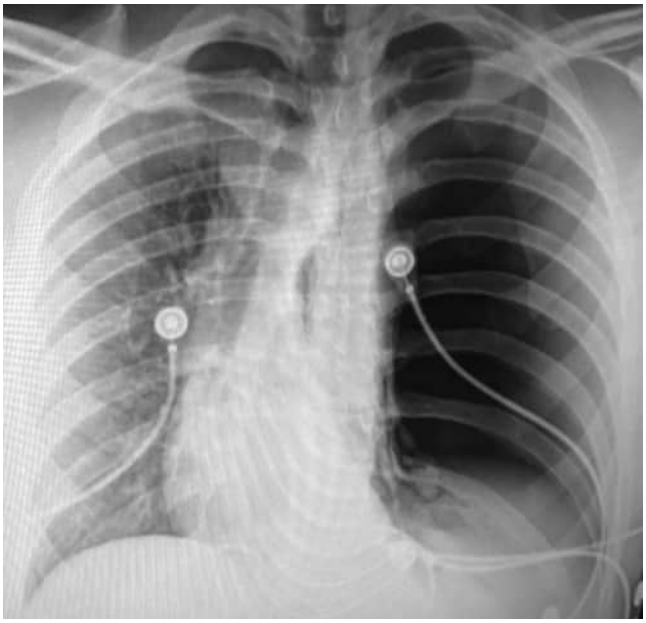

Figure 104.4 Chest radiograph showing tension pneumothorax. The free air in the left hemithorax is associated with a shift of the mediastinum into the right side of the chest, depression of the hemidiaphragm, and widening of the intercostal spaces. Hypotension follows as a result of impairment of venous return to the right side of the heart, both by the high intrathoracic pressure and perhaps by mechanical compression or kinking of the superior vena cava. Immediate decompression is required.

PNEUMOTHORAX

Pneumothorax, air within the pleural cavity, is present in 40% and 20% of patients with blunt and penetrating thoracic trauma, respectively (see Chapter 110).[124] The clinical consequence of pneumothorax ranges from asymptomatic to the most life-threatening manifestation, tension pneumothorax, whereby progressive air trapping in the thorax results in a contralateral mediastinal shift, compression or kinking of the superior and inferior vena cavae, and a precipitous drop in preload and cardiac output (Fig. 104.4). Clinically, this form of "obstructive" shock manifests as hypotension and hypoxia, although the mode of

presentation depends on the ventilator status of the patient. In a comprehensive review of the literature, Roberts and colleagues[125] reported that hypoxemia was nearly universal (92%) in ventilated patients with pneumothorax but present in only 50% of patients breathing unassisted. In those patients breathing unassisted, tension pneumothorax rarely progressed to respiratory arrest or cardiac arrest. Regardless of ventilator status, when diagnosed, tension pneumothorax should be treated with immediate thoracic decompression, either with needle thoracostomy or with tube thoracostomy. Current recommendations from the Advanced Trauma Life Support program[126] are to use longer needles and to insert the needle between the fourth and fifth intercostal space, the midaxillary line, instead of the traditional mid-clavicular line at the second intercostal space. This is because cadaver studies have shown that the midaxillary fourth and fifth intercostal space has higher likelihood of entering the thoracic cavity when compared with the mid-clavicular second intercostal space[127] because of decreased chest wall thickness in this location and greater needle stability during transport.[128,129] A systematic review of 15 studies describing chest wall thickness concluded that a 5-cm angiocatheter would have a significantly lower failure rate if inserted into the anterior axillary line at the fourth to fifth intercostal space compared with the mid-clavicular line at the second intercostal space (13% vs. 38%).[130] Additionally, lateral needle insertion avoids potentially life-threatening hemorrhagic complications such as laceration of the internal mammary artery, subclavian artery, or pulmonary artery.[131,132] Other investigators recommend inserting a chest tube at the outset instead of a needle because of frequent failure rates associated with the latter.[133]

An open pneumothorax, or sucking chest wound, is a special form of pneumothorax whereby a defect in the chest wall permits air entry through the wound with diaphragmatic movement. If the size of the wound approaches the size of the trachea, this may significantly hamper ventilation because air may preferentially enter through the wound rather than through the native airway.[134] Before operative repair, the wound should be covered with a one-way flutter (Heimlich) valve or an occlusive dressing with one side open to allow air egress.

For less severe pneumothorax, the decision to drain the pleural cavity should be made based on the degree of respiratory compromise and the potential for enlargement to a tension pneumothorax. In asymptomatic patients with a small (<2 cm in the largest dimension on upright chest radiograph) pneumothorax, selective conservative management without tube thoracostomy has been reported to have a high success rate.[135] Clinical significance of a pneumothorax depends not only on the absolute size of the pneumothorax, but also on the preinjury condition of the patient (e.g., presence of COPD) and other associated injuries.

Chest tube insertion is not without risk, and modern series report a 15–20% incidence of tube-related complications.[136] Complications can be broadly classified into one of five categories: insertional; positional; removal; infective and immunologic; and instructional, educational, or equipment related[137,138] (Fig. 104.5). The decision to place an additional chest tube should be based on

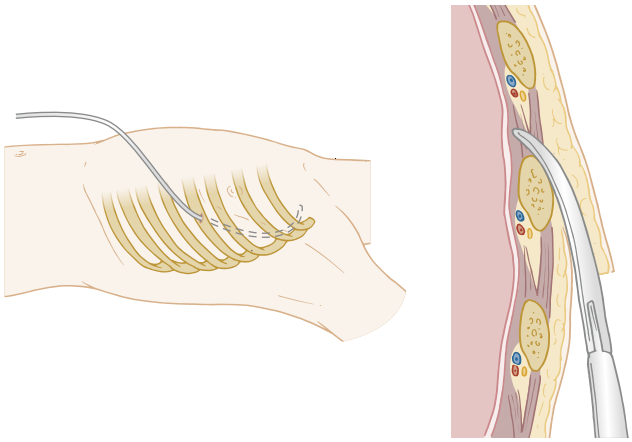

Figure 104.5 Diagrams illustrating tube thoracostomy placement. The thoracostomy tube is placed in the midaxillary line; the tube is directed anteriorly for drainage of pneumothorax. (From Van Way CW III, Buerk CA. *Surgical Skills in Patient Care.* St. Louis: Mosby; 1978.)

inadequate function of the initial chest tube, not based on the radiographic appearance of the trajectory.[139] As long as the sentinel port is within the thoracic cavity, nonkinked malpositioned tubes seem to function just as well as those with an "ideal" trajectory.[140] One rare complication following pneumothorax drainage is reexpansion pulmonary edema[141] (Fig. 104.6). Prophylactic antibiotics for the duration of dwell time of the chest tube are not recommended.[142] Accumulating evidence suggests that smaller, 14- to 16-French pigtail catheters are equally effective as traditional large-bore chest tubes (28 to 40 French), require less dissection, can be placed by the Seldinger technique, and may be less painful.[143,144]

An occult pneumothorax is defined as a pneumothorax that can be visualized only on chest CT scan; it is not detectable on chest radiograph, nor is it suspected on clinical examination (Fig. 104.7). Occult pneumothorax is present in up to 12% of seriously injured patients,[145,146] and it comprises more than 50% of all pneumothoraces diagnosed in injured patients.[147] Supine portable chest radiographs have been consistently shown to be only 50% sensitive for the detection of pneumothorax. Subtle findings on supine chest radiograph suggestive of pneumothorax include the deep sulcus sign (Fig. 104.8). Access to ultrasonography has increased dramatically, with most hospital areas having good access to ultrasound machines. As such, ultrasound is increasingly used to detect pneumothorax, especially because ultrasonography has higher sensitivity than chest radiography for its detection.[148–157]

The management of occult pneumothorax has evolved since the 1990s from mandatory tube thoracostomy for all occult pneumothoraces, progressing to selective drainage for only those patients undergoing positive-pressure ventilation,[158] to routine observation for all patients with selective drainage only for those demonstrating significant pneumothorax enlargement on chest radiograph or developing respiratory symptoms such as tachypnea or hypoxemia.[145,158] In a large, multicenter observational study of 569 patients with occult pneumothorax across 16 trauma centers, Moore and colleagues[159] reported that 21% required immediate tube thoracostomy. Of the remaining patients, observation failed in only 6% overall, and these patients required tube thoracostomy for pneumothorax

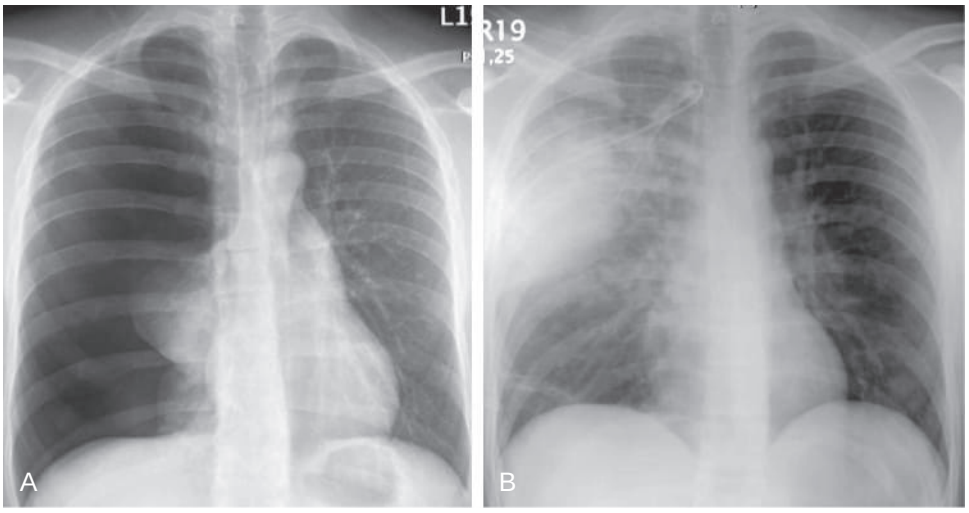

Figure 104.6 Chest radiographs showing pneumothorax and reexpansion pulmonary edema following evacuation of the pneumothorax. (A) Right-sided pneumothorax can be seen with subtotal lung collapse. (B) The same patient after expansion of the lung following placement of a thoracostomy tube. Peripheral right upper lobe opacity is now present, consistent with the development of reexpansion injury and edema in that region of lung. (From Malota M, Kowarik MC, Bechtold B, Kopp R. Reexpansion pulmonary edema following a posttraumatic pneumothorax: a case report and review of the literature. *World J Emerg Surg.* 2011;6:32.)

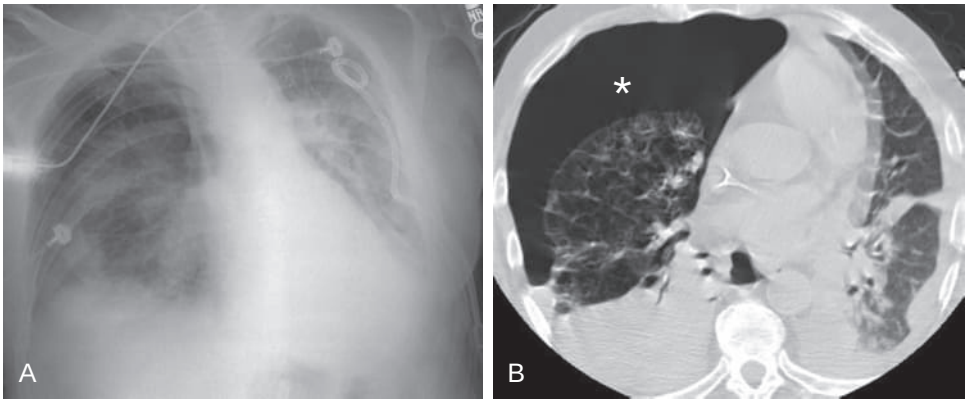

Figure 104.7 Imaging of radiographically occult pneumothorax. (A) Frontal chest radiography shows patchy bilateral opacity with a left-sided thoracostomy tube. No right pneumothorax is visible. (B) Axial chest computed tomography displayed in lung windows shows a moderate right-sided pneumothorax *(asterisk),* as well as basal lung opacity and pleural effusion bilaterally. (Courtesy Michael B. Gotway, MD.)

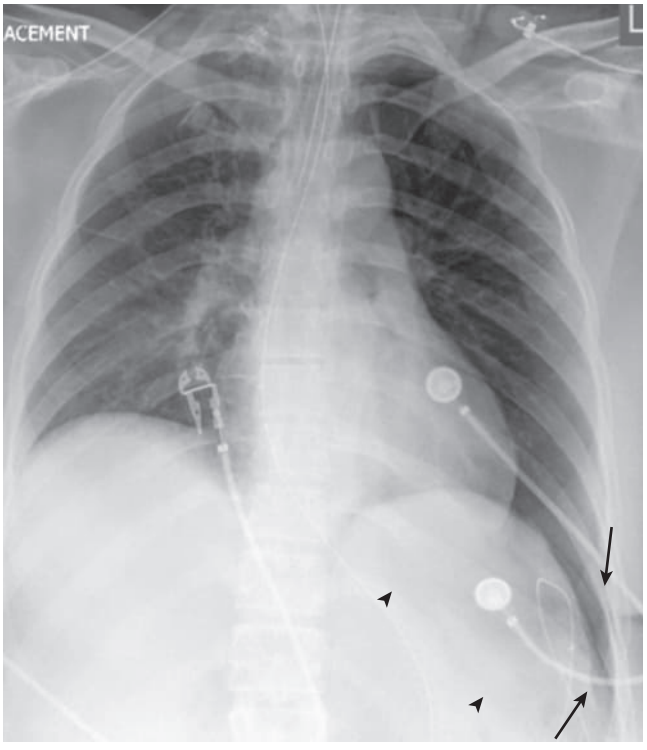

Figure 104.8 Deep sulcus sign on supine chest radiograph. In this supine patient, a pneumothorax on the left can be recognized by the depth of the diaphragmatic sulcus on the left compared with the right *(arrows)*. There is also lucency overlying the left hemidiaphragm that represents air anterior and lateral to the left hemidiaphragm and is seen as an air-tissue interface *(arrowheads)*.

enlargement, respiratory distress, or development of hemothorax. In this series, only 14% of patients undergoing positive-pressure ventilation required tube thoracostomy. Importantly, no patient in whom observation failed experienced an adverse event resulting from delay of chest drainage.[159] Thus, occult pneumothorax can be managed safely with observation, even in patients undergoing positive-pressure ventilation.

After drainage, standard management of the chest tube entails serial chest radiographs to document resolution of the pneumothorax. A bedside clinical examination should be performed to rule out an ongoing air leak, which is usually secondary to persistent alveolar-pleural fistula.[160] Air leaks may be graded according to increasing severity: forced expiratory, expiratory, inspiratory, and continuous. Most posttraumatic air leaks in stable patients are forced expiratory (coughing) or expiratory, and almost all resolve with time and patience.[160] Typically, the chest tube is placed at −20 cm H_2O suction and is advanced to water seal before removal.[161] In the trauma setting, chest tubes are generally not clamped. It is customary to obtain a chest radiograph after transitioning to water seal and after chest tube removal to monitor for pneumothorax reappearance. Pneumothorax recurs after chest tube removal in 11–24% of cases; however, if the pneumothorax is small and stable and the patient is asymptomatic, observation is frequently successful.[162–164] It is common practice to allow up to 24 hours between changes in chest tube management; however, Schulman and associates[165] reported that changes may be made at shorter intervals because clinically significant recurrent pneumothorax appeared within 3 hours.

After successful radiographic resolution of a pneumothorax, current guidelines from the Aerospace Medical Association[166] and the British Thoracic Society[167] recommend waiting at least 2 weeks before commercial airline travel, based on low-quality evidence (case reports and expert opinion) and the rationale that hypobaric conditions may cause expansion of a pneumothorax by up to 30%, thus potentially leading to life-threatening tension pneumothorax. However, a prospective study challenged these conservative recommendations. Majercik and colleagues[168] enrolled 20 patients with traumatic pneumothorax and submitted them to hypobaric conditions (554 and 471 mm Hg) within 48 hours of chest tube removal or resolution with high-flow oxygen therapy alone. Although an "in-flight" chest radiograph demonstrated an average pneumothorax expansion of 0.5 cm, no patients experienced cardiorespiratory symptoms, and all pneumothoraces returned to baseline within 4 hours after returning to normobaric conditions.[168] Zonies and associates[169] performed a retrospective review of patients transferred between medical facilities by air medical transport a median of 2.5 days after chest tube removal. Of the 73 patients (40% mechanically ventilated during flight), none experienced an in-flight emergency, and none experienced post-flight radiographic or clinical recurrences.[169]

HEMOTHORAX (See Chapter 113)

A hemothorax is blood in the pleural cavity. It can cause a wide range of consequences, from minor to life-threatening (eFig. 104.8). In general, a hemothorax evident on supine chest radiograph in the trauma bay is usually drained immediately, especially in the presence of hemodynamic instability. In stable patients, hemothorax is often diagnosed on CT of the thoracic cavity. Similar to occult pneumothorax, occult hemothoraces also exist, and the decision to drain the hemothorax should take into consideration the amount of blood present and the morbidity of chest tube insertion. For small (<300 mL) hemothoraces, initial observation without drainage in selected patients (younger age, no concomitant pneumothorax) is safe and may result in better outcomes.[170]

The initial treatment of hemothorax is tube thoracostomy. Based on the volume of initial output, the next step may be either urgent thoracotomy or observation. If the source of bleeding is the pulmonary parenchyma, hemostasis can sometimes be achieved simply through complete expansion of the lung. Because the pulmonary circulation is a low-pressure circuit, full inflation of the lung tissue can easily compress minor venous bleeding or raw surface oozing. However, bleeding from lacerated intercostal or internal mammary arteries is likely to persist and may require urgent thoracotomy for definitive hemostasis. Indications for urgent thoracotomy include hemodynamic instability, 1500 mL initial chest tube output, greater than 1500 mL over a 24-hour period, or greater than 200 mL/hr blood drainage for 3 consecutive hours.[171] Hemothorax secondary to major thoracic vascular structures (e.g., aorta, pulmonary artery) almost universally requires emergency thoracotomy for hemodynamic instability. Although some investigators have advocated for reinfusion ("autotransfusion") of blood collected from a hemothorax,[172] traumatic hemothorax blood may become hypercoagulable once remixed with the patient's own plasma.[173] Thus, caution should be applied when considering this practice.

Assuming adequate drainage and resolution of the hemothorax, it is customary to advance the chest tube to water seal before removal, similar to the chest tube management for a simple pneumothorax (see earlier). An additional factor to consider is the daily volume of bloody chest tube drainage. Although there are no standardized guidelines or recommendations, most trauma surgeons advance a chest tube once the daily output decreases to between 100 and 300 mL per day. A randomized trial comparing various thresholds after elective thoracic surgery did not show any difference in major pleural fluid accumulation or thoracocentesis rates when a threshold of 200 mL was used to trigger chest tube removal.[174]

The evacuation of a hemothorax may be incomplete in up to 20% of cases and can be a frustrating situation.[163,175,176] Untreated, a retained hemothorax may evolve into empyema; in one prospective observational trial of more than 300 patients with traumatic retained hemothorax, empyema developed in 26% and was more likely in patients with a greater number of rib fractures, a higher injury severity score, and a need for more interventions to drain the hemothorax.[177] Additional chest tube placement is usually ineffective for clot evacuation. For retained hemothorax, early *video-assisted thoracic surgery* (VATS) (<5 days after injury), compared with delayed operation or additional chest tubes, has been reported to decrease hospital LOS and decrease conversion to open thoracotomy.[178,179] Compared with open thoracotomy, VATS has significant advantages and should be considered as first-line operative treatment in the absence of contraindications.[180] According to the Eastern Association for the Surgery of Trauma guidelines,[181] there is level 1 evidence that a retained hemothorax should be treated with early VATS, not insertion of a second chest

tube. VATS should be considered within 3 to 7 days of hospitalization because this reduces the risk for infection and the requirement for thoracotomy (level 2 evidence). Retained hemothorax less than 300 mL by chest CT scan may be observed.[181] Currently, intrapleural thrombolytic agents are considered second-line treatment after VATS and can be considered in patients with subacute hemothoraces to improve drainage.[182,183] As a preventive measure, thoracic irrigation with 1 L of warmed sterile saline at the time of chest tube insertion may be considered to reduce the rate of retained hemothorax.[184,185]

Over the past decade, there has been a trend toward using smaller chest tubes for evacuating hemothorax.[186] When comparing the standard 36- to 40-French chest tube with 28- to 32-French tubes, Inaba and colleagues[186] found that the initial drainage volume and total indwelling time were similar, and there were no differences between groups in tube-related complications or the need for additional interventions. Animal studies of flow dynamics provide even further evidence that smaller tube size is equally effective for hemothorax evacuation. Niinami and coworkers[187] reported that a 19-French silicone drain is capable of draining 11 L/hr, and Russo and associates[188] demonstrated no significant difference in percentage of drainage when comparing a 14-French pigtail catheter with a 32-French chest tube. In that study, the pigtail catheter was able to drain almost 200 mL of fresh blood *per minute*. In human patients, a 14-French pigtail catheter seems to drain blood as effectively as larger-bore traditional chest tubes, with a similar incidence of complications.[189]

CHYLOTHORAX (See Chapter 111)

Traumatic chylothorax is an uncommon entity that results from disruption of the thoracic duct. Chylothorax manifests as a milky pleural effusion on resumption of oral intake, and the diagnosis is confirmed by finding fluid triglyceride levels greater than 110 mg/dL with or without lymphocytes predominating.[190] Initial treatment involves lung reexpansion and parenteral nutrition, with the possible addition of octreotide. If these measures fail, thoracic duct embolization or operative intervention is warranted.[191] However, the optimal duration of nonoperative management is unknown.

PNEUMATOCELE OR INTRAPARENCHYMAL HEMATOMA

Also termed a *posttraumatic pulmonary pseudocyst*, a pneumatocele is a traumatic cavitary lesion within the parenchyma following a pulmonary laceration (eFig. 104.9). Asymptomatic patients may be managed expectantly, and most pneumatoceles resolve within several weeks. For infectious complications, antibiotics and CT-guided catheter drainage may be attempted. Operative resection (VATS or thoracotomy) may be necessary if less invasive measures fail.

TRACHEOBRONCHIAL INJURIES

Tracheobronchial injuries are most commonly caused by penetrating injury,[192,193] and surgical intervention is usually required for the airway injury or for associated injuries in the neck or chest.[194] Tracheobronchial injuries from blunt trauma, conversely, manifest in one of two ways, depending on site, size, and communication with the pleural cavity: they are either immediately apparent, requiring immediate attention, or they are very subtle and difficult to diagnose.[195,196] Most are unrecognized for the first 24 hours and, in a few patients, there is no evidence of thoracic injury on physical examination or radiographs.[195] In those patients with delayed diagnosis, there is no discernible morbidity associated with delayed repair. Death is usually not from the tracheobronchial injury itself, but instead from fatal injuries to adjacent vascular structures.[197] Even with complete transection, the robust peritracheal connective tissue can splint the tracheal fragments, thus maintaining airway continuity. Blunt force likely injures the tracheobronchial tree by one of three mechanisms: rupture from tracheal compression against the rigid vertebral column, rupture from increased airway pressures secondary to compression of the chest with a closed glottis, or laceration from shearing forces.[198]

Most tracheobronchial injuries take place within 2.5 cm of the carina, with mainstem bronchial injuries comprising the majority (86%).[193,195,198] Clinically, the patient may have dyspnea or tachypnea (the most common symptom), hoarseness, stridor, hemoptysis, crepitus, or respiratory distress.[194] Radiographically, the "fallen lung" sign, first described by Oh and associates in 1969, is a highly specific finding for this injury.[199] This sign manifests when the patient has a pneumothorax. When pneumothorax is present without tracheobronchial injury, the lung falls *toward* the hilum (central displacement), whereas with tracheobronchial injury, the transected lung falls *away* from the hilum (peripheral displacement)[200] (Fig. 104.9). CT scanning may demonstrate bronchial wall discontinuity (eFig. 104.10 and Video 104.3) or mediastinal emphysema.[201] A tracheal or proximal bronchus injury should be suspected in a patient with pneumomediastinum or with a pneumothorax refractory to chest drainage. Bronchoscopy is the most effective method of diagnosis.[194]

Figure 104.9 "Fallen lung" sign seen on chest radiograph. Chest radiograph obtained 6 hours after initial presentation of acute dyspnea in an 8-year-old boy. Bilateral pneumothorax, more prominent on the right, is seen. Pneumomediastinum and soft tissue emphysema are observed. The right lung is seen to be collapsed inferior to the hilum ("fallen lung" sign), usually a sign of complete rupture of the main bronchus. A thoracostomy tube has been inserted on the right, yet a large right pneumothorax remains. (From Savas R, Alper H. Fallen lung sign: radiographic findings. *Diagn Interv Radiol.* 2008;14:120–121.)

Although the treatment for large or life-threatening tracheobronchial injuries is immediate repair, selective intubation beyond the injury alone (or even observation alone) may be successful in carefully selected patients with small or partial-thickness injuries.[7,202,203]

Delayed complications of unrecognized injury include bronchopleural fistula, bronchial stricture, atelectasis, bronchiectasis, and postobstructive pneumonia, as well as more serious sequelae such as mediastinitis or cervical abscess.[204]

DIAPHRAGM INJURIES

Diaphragmatic injury is a rare but morbid injury, manifesting in less than 1% of blunt trauma cases, and it is associated with a 21% overall mortality rate.[205] More than 90% of these injuries are seen after motor vehicle crashes. Two-thirds of diaphragm injuries develop on the left, perhaps because the liver cushions the impact on the right side. Because of the significant force required to rupture the diaphragm, these injuries are almost universally accompanied by other organ injuries, such as lung (77%), liver (52%), spleen (32%), and stomach (19%).[205]

The physical examination is inaccurate for the diagnosis of diaphragmatic injuries. For most victims of penetrating injury, there is no sign or symptom unique to diaphragmatic injury. For patients following blunt trauma, dyspnea and pain are common but nonspecific. Chest radiography is diagnostic in fewer than half of those patients with injury to the left hemidiaphragm (eFig. 104.11) and in only 17% of those with injury to the right hemidiaphragm[206] (Fig. 104.10). CT scan has a very high sensitivity for blunt diaphragmatic rupture. Imaging signs of injury include a nasogastric tube terminating above the diaphragmatic contour, discontinuity of the hemidiaphragm, herniation of the viscera into the thorax (eFig. 104.12), diaphragmatic thickening, the hump sign, the band sign, the dependent viscera sign (eFig. 104.13), the collar sign (eFig. 104.14), and the dangling sign.[207,208]

All acute diaphragmatic injuries should be surgically repaired. The natural history of traumatic diaphragmatic hernias is poorly studied, but it is presumed that the tendency of these hernias is to enlarge over time, with progressive herniation of abdominal viscera into the chest in response to the negative intrathoracic pressure and positive intra-abdominal pressure. For patients with left-sided penetrating thoracoabdominal wounds, if there is no immediate indication for operative exploration, it is recommended to perform diagnostic laparoscopy, because 20% of these patients will have diaphragm injuries.[209,210]

BLAST LUNG INJURY

INTRODUCTION

An increasing frequency of terrorist bombing attacks worldwide has resulted in a large number of civilian blast injuries.[211] Blast victims require a standard trauma workup as recommended by Advanced Trauma Life Support. Additionally, such victims may also present with a set of pulmonary injuries unique to the blast mechanism.[212]

Victims of blast injuries have different injuries depending on the type of the bomb, the location of detonation, and whether the targets were military or civilian. Typically, military victims have different injuries from civilian victims. Military personnel are young and healthy, and they usually have body armor that protects their thoracic and abdominal organs, whereas civilian victims range from children to older adults, and they are not wearing body protection. Thus, civilian victims present with more thoracic or lung and abdominal injuries than military victims. As a general rule, blast injury victims have multiple blunt and penetrating injuries, including traumatic amputations. Injuries from blast detonations are classified into the following categories: (1) primary, (2) secondary, (3) tertiary, and (4) quaternary.[212]

PRIMARY BLAST INJURIES

Primary blast injuries result from overpressure effects of the blast wave (see later). The blast typically injures organs that have interfaces between different densities, such as air and tissue or water and air. Examples include pulmonary barotrauma, tympanic membrane ruptures, gastrointestinal contusions or perforations, and traumatic amputations. Previously, tympanic membrane rupture was used as a marker of severity of illness from the blast wave. However, later studies showed that tympanic membrane rupture is not a reliable marker of severity because it has demonstrated poor sensitivity and specificity.[213] Instead, markers of severe blast injury include the following: (1) burns over more than 10% of total body surface area, (2) skull or facial fractures, and (3) penetrating injuries to the head or torso.[213]

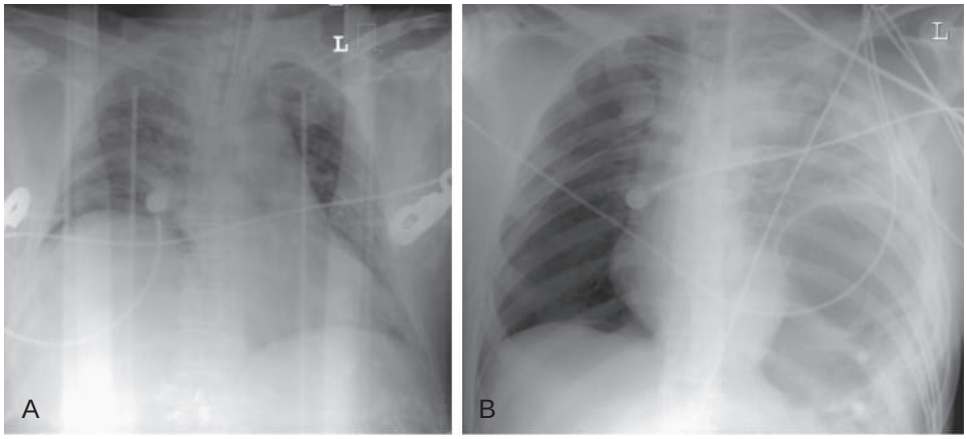

Figure 104.10 Hemidiaphragmatic injury in the setting of trauma. (A) Right hemidiaphragmatic injury. Frontal chest radiograph shows apparent elevation of the right hemidiaphragm, generally a nonspecific finding. However, in the setting of trauma, diaphragmatic injury with herniation of the liver into the thorax manifests similarly, as in this example. (B) Left hemidiaphragmatic injury. Frontal chest radiograph shows herniation of the stomach into the left thorax, consistent with a large tear of the left hemidiaphragm. *L*, Left.

SECONDARY BLAST INJURIES

Secondary blast injuries result when penetrating injuries are caused by flying debris, such as bomb fragments from the explosive device and fragments of bone and teeth from the bomber and victims. There are case reports of these biologic fragments transmitting hepatitis B.[214,215]

TERTIARY BLAST INJURIES

Tertiary blast injuries result when victims are physically propelled into hard surfaces by the force of the blast wave. Crush injuries from falling debris also fit into this category.

QUATERNARY BLAST INJURIES

Quaternary blast injuries encompass all other explosion-related effects such as burns, asphyxia, radiation poisoning, toxins, psychological trauma, and exacerbation of underlying medical conditions.

PHYSICS OF THE BLAST WAVE

Explosions result when a chemical reaction transforms a solid or liquid into gas within a very short time period and thus results in a massive release of energy. The explosion releases most of its energy as a blast wave, a positive-pressure front that travels faster than the speed of sound.[216] As a result, victims feel the blast wave before hearing the explosion. In the open air, the blast wave behaves in a predictable manner based on the physics of wave motion.[217]

Detonations within confined spaces or underwater cause blast waves that are accentuated and deadlier.[212,214] Under these conditions, blast waves are reflected back from surfaces with a different density, such as walls or air-water interfaces. The reflected wave superimposes and amplifies the outgoing blast wave, thereby causing a higher-intensity and much deadlier blast wave. Furthermore, the blast wave can reflect back from surfaces at an angle greater than 40 degrees, augmenting the incoming wave and creating a new blast wave. This phenomenon is known as a "mach stem formation."[218] Studies have shown that explosions detonated in corners can result in explosions that are up to eight times deadlier than explosions in the open air.[214]

The human body is damaged when the blast wave transmits energy directly to the body. This energy is transmitted unevenly through body tissues and, as described, reflects back when encountering changes in density. As a result, the majority of damage is done at interfaces of different tissue densities. For example, pulmonary blast injuries result when the blast wave rapidly changes in amplitude on entering and exiting the multiple air- and fluid-filled structures within the lungs. Other air-tissue interfaces include the gastrointestinal tract, tympanic membranes, and extremities, where greatly disparate density planes (e.g., air, soft tissue, and bone) all reside within a small space. The mechanisms causing these injuries can be classified physiologically into distinct categories: (1) spalling forces, (2) implosion forces, and (3) inertia forces.[212,217]

Spalling Forces

Spalling forces result when the blast wave displaces and fragments one tissue into another tissue, usually the higher-density tissue into the lower-density tissue. For example, spalling forces cause the forcible movement of blood from the capillaries into the alveoli, thus causing alveolar hemorrhage.

Implosion Forces

Implosion forces result when the highly compressed edge of the blast wave enters the victim. This results in gas that rapidly compresses and reexpands, causing injury. For example, implosion forces cause barotrauma by compressing and reexpanding the air in the alveoli. Furthermore, this rapid change in air density can cause an air embolism by forcing air into the circulatory system.

Inertia Forces

Inertia forces result when the blast wave causes the different tissue densities to absorb different amounts of energy. This results in different tissues moving at different velocities. The resulting shearing of tissue planes causes massive injuries, typically traumatic avulsions or amputations.

Results of Blast Injury

Blast lung injury results from the combination of all the forces described previously. The initial damage to the architecture of the alveoli leads to pulmonary hemorrhage. The free hemoglobin in the alveoli leads to the formation of free radicals, thereby worsening edema and an early inflammatory response.[219,220] This leukocyte accumulation and release of inflammatory cytokines cause further epithelial cell damage over 12 to 24 hours, as well as endothelial cell damage over 24 to 56 hours. This inflammatory cascade results in a lung injury syndrome similar to ARDS. Histologic examination of the lung damaged by blast injury reveals perivascular edema, extensive alveolar hemorrhage during the first 12 hours, and then further epithelial cell damage and detachment from the basement membrane.[219,220]

MANAGEMENT

Initial management of patients with blast lung injury should follow standard local trauma protocols and Advanced Trauma Life Support teaching. Pulmonary blast injury is the most common injury found in scene fatalities,[4] and survivors of the blast wave with primary blast lung injury represent a group of patients with very severe injuries. Clinical features include shortness of breath, cough, chest pain, hemoptysis, cyanosis, and tachypnea. Hypoxemia is a typical finding, but it may not develop until after the first few hours following presentation. One case series found that only 28% of patients had hypoxemia on initial presentation.[220]

All patients with suspected blast lung injury should receive a chest radiograph as soon as possible. Radiographic findings of blast injury may include not only the classic "bat wing" appearance on chest radiograph but also subcutaneous emphysema, pneumothorax, pulmonary interstitial emphysema, pneumopericardium, pneumomediastinum, and pneumoperitoneum.

The general treatment for patients with primary blast lung injury is similar to the treatment for patients with ARDS. This includes limiting fluid administration to reduce the chance of pulmonary edema and using low–tidal

volume lung-protective ventilation with permissive hypercapnia to minimize peak and plateau airway pressures.[221] Patients with refractory cases can be considered for rescue treatments for ARDS, such as inhaled nitric oxide, inhaled prostaglandins, and open-lung ventilation strategies. The underlying pathophysiology of blast lung involves alveolar hemorrhage, and the coagulopathy and anticoagulation usually started with ECMO can result in catastrophic pulmonary hemorrhage.[222] With increased use of ECMO, there is more experience in managing ECMO circuits safely without anticoagulation.[223] This opens up the possibility of using ECMO in patients with severe respiratory failure from blast injuries. However, caution should be taken because the ECMO circuit itself can lead to coagulopathy and an increased risk of bleeding, even without anticoagulation.[224]

In the rare case of air embolism from the blast lung injury, treatment aims to prevent further air emboli. The patient is placed in the left lateral decubitus position, with the head down and feet up in an attempt to contain the air embolism at the apex of the left ventricle. Peak pressures during positive-pressure ventilation should be minimized, and hyperbaric therapy should be considered. The diagnosis is clinical because CT scans, echocardiograms, and observations of retinal air bubbles on funduscopic examinations are unreliable.[212]

Patients who survive blast lung injury typically have excellent long-term pulmonary outcomes. One study found that, 1 year after the injury, survivors had normal pulmonary examinations, with minimal pulmonary complications.[225]

Key Points

- The majority of patients with pneumothorax and hemothorax may be adequately managed by tube thoracostomy alone.
- The cornerstone of treatment for rib fractures and flail chest is pain control.
- Pulmonary contusion is a major driver of morbidity and can cause systemic immune dysfunction.
- Occult pneumothorax may be safely managed with observation, even in patients undergoing positive-pressure ventilation.
- Blast lung injury is a unique form of lung injury most commonly seen in survivors of closed-space explosions.
- The diagnosis of blast lung injury is based on clinical observations and confirmed by plain chest radiograph.
- Management of blast lung injury is predominantly supportive and closely approximates the treatment of acute respiratory distress syndrome.

KEY POINTS

INTRODUCTION

Nearly 100 million persons live at altitudes greater than 2500 m across North America, South America, Asia, and Africa. These individuals have developed the ability to live and reproduce at elevations as high as 5000 m but, in some cases, they develop chronic medical problems attributable to their high-altitude residence. In addition, millions of lowlanders venture to high altitude for work and recreation each year, where they face a risk of acute altitude illness or altitude-related exacerbations of preexisting diseases. Given these large numbers of persons exposed to high altitude on a short- or long-term basis, medical providers must be able to provide guidance about minimizing risks and managing problems related to being in this environment.

This chapter reviews the adaptive and maladaptive responses to high altitude. Acute and chronic adaptation is discussed, and changes in common activities are explored, including sleep and exercise. The consequences of maladaptation—the acute and chronic illnesses of high altitude—are reviewed, as are strategies for managing these situations. Finally, an approach to the traveler with underlying medical problems who is planning a trip to high altitude is discussed.

ACCLIMATIZATION TO HIGH ALTITUDE

As altitude increases and barometric pressure declines (Table 105.1), the partial pressure of oxygen (P_{O_2}) decreases at each point of the oxygen transport chain from air to tissues. Compensatory processes involving ventilation, ventilation-perfusion matching, circulatory transport, oxygen diffusion from blood into tissues, and mitochondrial metabolism take place at each step at different rates to raise P_{O_2}, maintain oxygen delivery, and improve tolerance of the hypoxic environment.

The process of altitude acclimatization is vitally important to survival. Whereas a person who suddenly ascends from sea level to the summit of Mt. Everest (8848 m) by helicopter would become unconscious within minutes and die soon thereafter, some climbers using an appropriate ascent rate can complete the climb without supplemental oxygen because of adaptation to hypoxia. These adaptive responses been reviewed extensively elsewhere,[1,2] and a summary of the key features is provided in the following subsections.

PULMONARY ACCLIMATIZATION

Control of Ventilation

Acute Response. On acute hypoxic exposure, ventilation increases. This *hypoxic ventilatory response* (HVR), the magnitude of which varies among individuals, minimizes the drop in alveolar P_{O_2} (Fig. 105.1) and is mediated by carotid body peripheral chemoreceptors, which respond in a hyperbolic fashion to decreasing arterial P_{O_2}.[3] Ventilation increases immediately in response to a constant hypoxic stimulus (Fig. 105.2). With the initial rise in ventilation, the arterial partial pressure of carbon dioxide (P_{CO_2}) at medullary chemosensors decreases and partially depresses this ventilatory response.[4] In a process referred to as *ventilatory acclimatization*, ventilation then begins a steady rise over a period of days to weeks.[5] The classic explanation for this ongoing increase was the return of arterial pH toward normal through renal compensation and development of metabolic acidosis. However, the hypocapnic alkalemia persists as ventilation increases, thus suggesting that other mechanisms beyond renal compensation must be responsible for increasing ventilation. It was proposed that a relative cerebrospinal fluid acidosis at the medullary chemosensors triggers increased ventilation, but lumbar cerebrospinal fluid remains alkaline at 3100 m for 3 weeks, whereas hyperventilation persists even when arterial P_{CO_2} and blood and cerebrospinal fluid pH returns toward normal following descent.[6] Brain interstitial and intracellular fluid pH measurements also failed to show changes accounting for the increase in ventilation.[7] These results suggest that some mediators other than hydrogen

Table 105.1 U.S. Standard Atmosphere: Altitude, Barometric Pressure, and Inspired P_{O_2}*

Altitude (m)	Altitude (Feet)	Barometric Pressure (mm Hg)	Inspired P_{O_2} (mm Hg)
0	0	760	159
1000	3280	674	141
2000	6560	596	125
3000	9840	526	110
4000	13,120	463	97
5000	16,400	405	85
6000	19,680	354	79
8000	26,240	268	56
8848	29,028	253	43

*Values except 8848 m are taken for mid latitude (45°N). There is greater variation at higher latitudes.

Modified from Altman PL, Dittmer DS, eds. *Respiration and Circulation*. Bethesda, MD: Federation of American Societies for Experimental Biology; 1971:12–13.

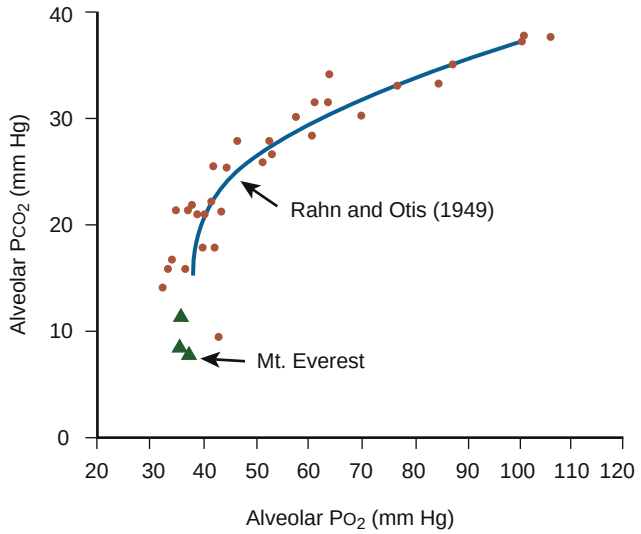

Fig. 105.1 Oxygen–carbon dioxide diagram demonstrating the alveolar gas composition in acclimatized subjects at high altitude. *Circles* represent data collected by Rahn and Otis (Rahn H, Otis B. Man's respiratory response during and after acclimatization to high altitude. *Am J Physiol.* 1949;157:445-449), and the *triangles* are measurements from three altitudes on Mt. Everest. At extreme altitudes, marked hyperventilation maintains alveolar P_{O_2} at approximately 35 mm Hg. (From West JB, Hackett PH, Maret KH, et al. Pulmonary gas exchange on the summit of Mt. Everest. *J Appl Physiol.* 1983;55:678–687.)

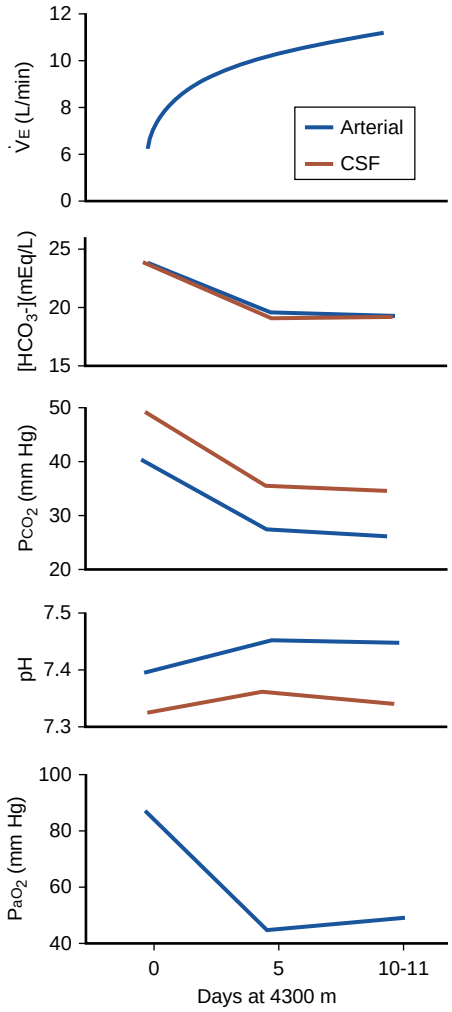

Fig. 105.2 Ventilatory acclimatization during 10- to 11-day sojourn to 4300 m. Ventilation continues to increase as cerebrospinal fluid (CSF) acid-base alterations parallel plasma changes. HCO_3^-, bicarbonate; P_{aO_2}, arterial P_{O_2}; $\dot{V}_E$, minute volume of ventilation. (From Forster HV, Dempsey JA, Chosy LW. Incomplete compensation of CSF [H^+] in man during acclimatization to high altitude [4300 m]. *J Appl Physiol.* 1975;38:1067–1072.)

ion sustain hyperventilation with ongoing hypoxic exposure. Other possible mechanisms include *erythropoietin* (EPO) signaling in the brain via EPO receptors,[8] carotid body hypertrophy,[9] or increases in carotid body sensitivity to hypoxia.[10]

Chronic Ventilatory Adaptation. High-altitude residents have lower ventilation and higher arterial P_{CO_2} than acclimatized lowlanders at the same elevation and have blunted ventilatory responses to acute hypoxia.[11] The blunted response develops despite carotid body hypertrophy and may be an adaptive phenomenon in which the disadvantages of lower arterial P_{O_2} are offset by decreased work of breathing associated with lower ventilation.

Pulmonary Function and Mechanics

Vital capacity decreases on acute ascent,[12] potentially as a result of a variety of mechanisms including airway narrowing and gas trapping secondary to interstitial fluid accumulation,[12] pulmonary vascular engorgement,[13] decreased respiratory muscle strength,[14] and decreased lung compliance caused by hypocapnia.[15] In contrast, in high-altitude residents, vital capacity is increased compared with nonnative residents,[16] with larger changes seen in those born and raised at high altitude compared with those who move to high altitude later in life.[17]

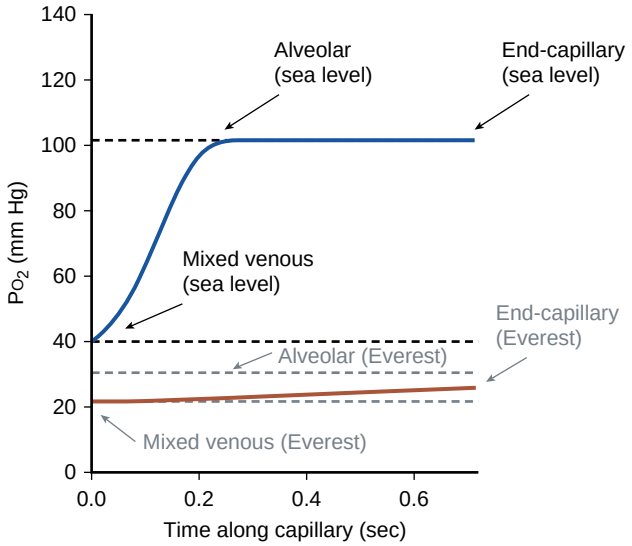

Fig. 105.3 Altitude-related diffusion limitation. Comparison of the calculated time course of P_{O_2} in the pulmonary capillary of a climber at rest on the summit of Mt. Everest (*orange line:* barometric pressure, 250 mm Hg; inspired P_{O_2}, 43 mm Hg; oxygen consumption, 250 mL/min; diffusion capacity of the alveolar capillary membrane, 40 mL/mm Hg) with sea-level values (*blue line:* barometric pressure, 760 mm Hg; inspired P_{O_2}, 150 mm Hg; oxygen consumption, 300 mL/min; diffusion capacity of the alveolar capillary membrane, 40 mL/mm Hg). At sea level, there is adequate time for equilibration of alveolar and end-capillary oxygen, whereas at extreme altitude, even at rest, when transit time for the red blood cell is presumably similar to that at sea level, full equilibration is not realized, resulting in end-capillary blood that is not fully saturated. (Modified from West JB, Wagner PD. Predicted gas exchange on the summit of Mt. Everest. *Respir Physiol.* 1980;42:1–16.)

Airway resistance is also reduced,[18] presumably because of decreased air density counteracting airway narrowing in response to hypoxia and hypocapnia.

Gas Exchange

Ventilation and Perfusion Matching. Increased ventilation during acute hypoxia is accompanied by greater cardiac output and pulmonary perfusion. Additionally, alveolar hypoxia triggers *hypoxic pulmonary vasoconstriction* (HPV), which increases *pulmonary vascular resistance* (PVR). These changes redistribute blood flow to recruit areas of the lung that are usually less well perfused during rest at sea level, thus potentially improving ventilation-perfusion matching and optimizing gas exchange. With exercise at high altitude, however, ventilation-perfusion matching is not improved by HPV.[19]

Diffusion. Hypobaria lowers alveolar P_{O_2}, which, in turn, decreases the pressure gradient for diffusion across the alveolar-capillary barrier so that, at altitudes higher than 2500 m, the estimated pulmonary capillary transit time at rest of 0.75 seconds may not be adequate for end-capillary oxygen equilibration (Fig. 105.3). This phenomenon is further exacerbated during exercise as a result of shortened capillary transit time and greater fall in mixed venous P_{O_2}. Because the low P_{O_2} lies on the steep portion of the oxygen-hemoglobin dissociation curve, a small decrease in arterial P_{O_2} causes a proportionately greater drop in arterial oxygen content than at sea level.[20] West and Wagner[20] modeled these factors for the summit of Mt. Everest (barometric pressure ~250 mm Hg) and demonstrated that alveolar-capillary oxygen equilibration is far from complete.

With many weeks at altitude and long-term residence, diffusing capacity has been shown to increase, possibly due to changes at the alveolar-capillary membrane from increased sympathetic activity.[21] Compared with sojourners, highland residents have a lower (A–a)P_{O_2} difference, increased diffusing capacity and, despite lower ventilation, a higher arterial P_{O_2} at rest and during exercise.[22,23]

CARDIOVASCULAR ACCLIMATIZATION

Cardiac Response

With acute hypoxia, cardiac output increases to maintain oxygen delivery, but the cardiac output-work relationship returns to sea level values over 1 to 2 weeks as hematocrit and arterial oxygen content rise. Increased cardiac output is largely the result of increases in heart rate rather than a change in stroke volume. In fact, stroke volume declines with ascent and remains lower than sea-level values despite acclimatization. The lower stroke volume is not caused by depressed myocardial function because contractility is maintained in hypoxia[24]; instead, it likely results from a decrease in plasma volume and venous return. Variable changes in systemic blood pressure have been reported following ascent, with some individuals experiencing small increases secondary to increased sympathetic stimulation and others experiencing either no change or a small decrease.[25–28]

Pulmonary Vascular Response

With ascent, *pulmonary artery* (PA) pressure increases because of HPV. This response is minimal until the arterial P_{O_2} drops to less than 70 mm Hg, at which point a more pronounced rise ensues (Fig. 105.4), although the magnitude of the response varies markedly among individuals.[29,30]

HPV remains relatively unchanged for several weeks,[31] but thereafter PVR and PA pressure rise further in response to the additional factors of polycythemia-induced hyperviscosity and vascular remodeling caused by smooth muscle hypertrophy and collagen proliferation. The time course of these changes is not clear. In a 40-day simulated ascent of Mt. Everest, Groves and associates[32] exposed individuals to progressively lower pressure of inspired oxygen and demonstrated a more than threefold increase in PVR after 40 days. PVR did not return to sea-level values on breathing 100% oxygen, a finding suggesting possible vascular remodeling. Depending on the severity of changes, particularly the degree of intimal fibrosis, reversal of pulmonary hypertension may require months or years at low altitude.[33]

HEMATOLOGIC ACCLIMATIZATION

Erythropoiesis

Hemoglobin concentration increases within 1 to 2 days of ascent and continues to rise over several weeks. The initial rise is caused by hemoconcentration from an early diuretic response, with further changes resulting from increased *red*

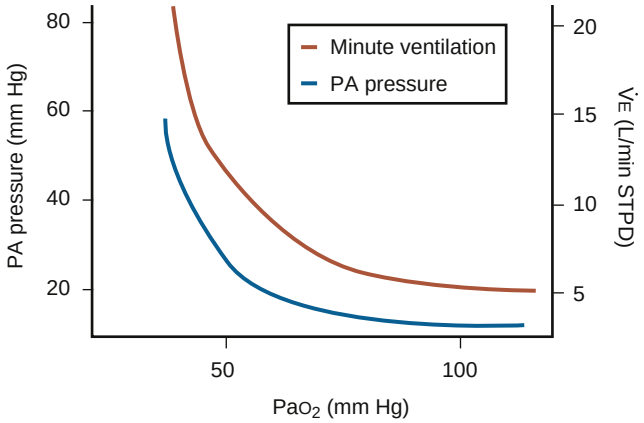

Fig. 105.4 Relationship of arterial P_{O_2} with minute ventilation and pulmonary arterial pressure. Although there is variability among individuals, both the ventilatory and the pulmonary vascular response do not increase until arterial P_{O_2} (P_{aO_2}) falls to less than 70 mm Hg. PA, pulmonary artery; STPD, standard temperature, standard pressure, and dry (conditions); $\dot{V}_E$, minute volume of ventilation. (From Reeves JT, Wagner WW Jr, McMurtry F, et al. Physiological effects of high altitude on the pulmonary circulation. In: Robertshaw D, editor. *International Review of Physiology: Environmental Physiology III.* Baltimore, MD: University Park Press; 1979:289–310.)

blood cell (RBC) production secondary to hypoxia-mediated renal EPO release and a hypoxia-mediated prolongation of RBC survival.[34] Although polycythemia augments arterial oxygen content, it may impair oxygen delivery if the hematocrit rises to more than 60%, because hyperviscosity can impair cardiac output and microvascular perfusion. Serum EPO increases within 24 to 48 hours before declining over 3 weeks as the hematocrit rises.[35] Erythrocytosis ceases on descent and the hematocrit returns to lowland values in approximately 3 weeks as a result of decreased RBC production and neocytolysis, a reactive oxygen species–mediated destruction of the youngest circulating RBCs.[36]

There is interindividual variability in the erythropoietic responses of both sojourners[37] and highlanders.[38] Similar variability is seen among different highland populations[39] because Andean natives demonstrate greater erythropoiesis than Himalayan or Ethiopian highlanders.[40] Whether greater erythropoiesis in Andean natives is secondary to genetic factors,[41] environmental exposures such as cobalt in mining regions,[42] or an up-regulation of the erythropoietic response to the renal sensing of hypoxia[43] is not clear. In Tibetan and Sherpa populations, the lower hematocrit results from a partial loss of function in the hypoxia inducible factor-2α gene responsible for renal EPO production.

Oxygen-Hemoglobin Affinity

A critical feature of oxygen transport at high altitude is that the hemoglobin-oxygen dissociation curve is much steeper as arterial P_{O_2} falls to less than 60 mm Hg. On ascent, with the P_{O_2} on the steep portion of the curve, arterial oxygen saturation (arterial S_{O_2}) falls precipitously with only a small decrease in P_{O_2}. Potential impacts on oxygen delivery are mitigated by adaptations in the dissociation curve. Because of the increase in ventilation and resulting respiratory alkalosis, the curve shifts leftward, enhancing oxygen loading and increasing arterial oxygen content, but at the expense of decreased tissue oxygen off-loading. Over several days, the dissociation curve shifts back rightward as RBC 2,3-diphosphoglycerate increases,[44] and the pH decreases because of renal compensatory responses.

Coagulation

There has long been a question whether acute hypoxia provokes a procoagulation state, and various studies have reported conflicting results regarding platelet function, bleeding times, and markers of thrombin and fibrin formation.[45–48] This uncertainty may be explained by the finding that most of the studies on this question have typically examined isolated portions of the coagulation process. In contrast, when thromboelastography, a functional test of all aspects of the clotting system, was used, Martin and colleagues[49] found evidence of slowed coagulation.

TISSUE ACCLIMATIZATION

The final stage of oxygen delivery is the movement of oxygen from the plasma to intracellular sites of oxidative phosphorylation. Driving pressures of 10 mm Hg may be needed for movement from plasma to the cytoplasm, whereas only 1 to 2 mm Hg will be necessary for diffusion from cytoplasm to the mitochondria. At extreme altitudes, capillary P_{O_2} may fall to levels at which diffusion from plasma to the cytoplasm and then to the mitochondria is impaired. Structural and biochemical responses may mitigate the effects of the low capillary P_{O_2}, including diminished muscle fiber size and reduced diffusion distance from blood to mitochondria, increased myoglobin concentration, and increased levels or activity of enzymes involved in oxidative metabolism favoring glucose utilization over fatty acid. Within mitochondria, changes in the oxidative cytochromes and a down-regulation of mitochondrial uncoupling protein increase mitochondrial oxygen utilization efficiency.[50] Much of this structural and metabolic adaptation may be driven by gene transcription via hypoxia inducible factor-1 and hypoxia inducible factor-2, which regulate nearly 1000 genes involved in hypoxia tolerance, such as EPO.[51] In addition, many cells express cytoglobins, heme oxygen binding proteins with transport characteristics similar to myoglobin.[52]

CENTRAL NERVOUS SYSTEM ACCLIMATIZATION

Cerebral Blood Flow and Other Changes

Acute hypoxia causes increased *cerebral blood flow* (CBF) that is partially offset by hypocapnic-mediated cerebral vasoconstriction. The net result is a modest increase in CBF[53] equally distributed between white and gray matter.[54] The acute response may be biphasic, with an initial decrease in CBF resulting from acute hypocapnia and the subsequent increase triggered by arterial hypoxemia.[55] After 4 to 5 days, CBF decreases but remains higher than at sea level.[53] Along with cytoglobin, intracerebral neuroglobin, another heme oxygen binding protein, is up-regulated during hypoxia and may limit neuronal dysfunction or injury.[56]

Cerebral Function

Motor, sensory, and complex cognitive abilities progressively decline with ascent. New tasks are learned with difficulty at 3048 m and, at 6100 m, sensory, perceptual, and motor performance suffers. Short-term memory is impaired

with ascent to greater than 8500 m without oxygen.[57] Even acute, modest decreases in arterial S_{O_2} to 85% impair mental concentration and fine motor coordination; further decreases to 75% cause poor judgment, irritability, and decreased muscle function.

Predicting who will develop neurologic dysfunction in hypoxia is difficult, but data from actual and simulated ascents of Mt. Everest demonstrate that individuals with a higher HVR and arterial S_{O_2} have more pronounced neuropsychometric dysfunction,[58] potentially because persons with greater HVR have more hypocapnic cerebral vasoconstriction and consequently lower oxygen delivery. Evidence suggests the transient deterioration in learning, memory, and verbal expression return to baseline within 1 year, although fine motor dyscoordination may persist.[58,59]

Whether these changes in cerebral function can be traced to structural changes in the brain following ascent is not clear. Fayed and colleagues[60] performed brain magnetic resonance imaging in climbers who ascended to between 5895 and 8848 m and demonstrated subcortical lesions suggestive of small infarctions. However, the investigators did not correlate these findings with evidence of neurologic dysfunction, nor did they perform follow-up studies to determine whether the lesions resolved.

FLUID HOMEOSTASIS AND RENAL FUNCTION

Diuresis and natriuresis happen after ascent, with a 10-fold variability in magnitude among individuals over the first 24 to 48 hours of exposure.[61,62] The mechanism underlying these responses does not relate to changes in renin, angiotensin, aldosterone, or atrial natriuretic peptide, but rather to a peripheral chemoreceptor response not involving renal sympathetic nervous tone.[61] Acute hypoxia causes a two- to threefold increase in urinary protein that increases further with acute altitude illness.

CHANGES IN COMMON SEA-LEVEL ACTIVITIES AT HIGH ALTITUDE

SLEEP

Difficulty sleeping is a common problem at high altitude. In studies examining pharmacologic prophylaxis of acute mountain sickness, for example, more than 70% of persons receiving placebo reported poor-quality sleep.[63] There is also objective evidence of poor sleep, with increased arousals, changes in sleep architecture, and an increased incidence of periodic breathing (Video 105.1).[64] In addition, all individuals experience an increase in hypoxemia during apneic periods.

Periodic breathing, one of the cardinal features of altered sleep at high altitude, develops from abnormalities in the feedback control system that governs ventilation. As a result of increases in ventilation, arterial P_{CO_2} falls below the apnea threshold, thus leading to a cessation of respiratory effort. With apnea, arterial P_{CO_2} rises and pH falls. In conjunction with decreases in arterial P_{O_2}, this leads to increased central and peripheral chemoreceptor stimulation. Excessive central chemoreceptor responses lead to overly large increases in ventilation, thereby lowering the arterial P_{CO_2} too far and initiating another cycle of apnea. As ventilatory acclimatization proceeds, periodic breathing diminishes over several days at moderate altitudes (<3000 m) but, at higher altitudes or with ongoing ascent, this breathing can persist.[65,66]

Periodic breathing can be eliminated by breathing supplemental oxygen (Fig. 105.5), and it can be reduced by using respiratory stimulants such as acetazolamide.[67] Acetazolamide may also improve overall sleep quality,[63,68] as can pharmacologic agents such as temazepam, zolpidem, and zaleplon. Of these agents, temazepam decreases periodic breathing,[65] whereas the latter two have no effect on this phenomenon.[69,70] Although periodic breathing is not dangerous by itself, it interferes with sleep quality.

EXERCISE

Exercise at high altitude is different in many respects from exercise at sea level.

Maximal Work

With acute and sustained hypoxia, maximal oxygen consumption and work capacity decrease relative to sea-level values,[71,72] at an approximate rate of about 10% per 1000 m of altitude gain. Because maximum oxygen uptake is decreased at high altitude, maximum minute ventilation and heart rate at end-exercise are also reduced compared with their sea-level values (Fig. 105.6).[71]

Ventilation

For any given work rate, minute ventilation is higher at high altitude than at sea level, with the magnitude of change varying as a function of both the altitude attained and the strength of the individual's HVR.[73] However, the increase in ventilation comes at a price because, at extreme altitude, the oxygen cost of breathing during exercise may be as high as 40% of the overall metabolic rate and may result in allocation of cardiac output to respiratory muscles instead of to muscles of locomotion. Extreme dyspnea with exercise may also limit the intensity and duration of exercise.

Gas Exchange

Unlike at sea level, where arterial S_{O_2} remains constant with increasing work, arterial S_{O_2} at high altitude decreases with exercise following either short[74] (Fig. 105.7) or long exposures.[71] Alveolar hypoxia decreases the gradient for

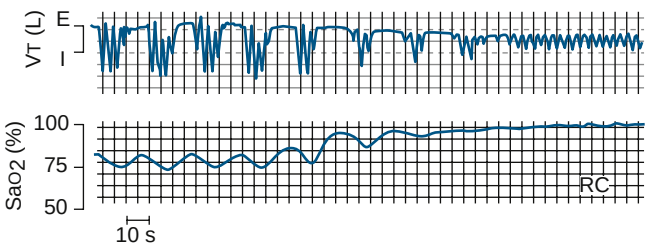

Fig. 105.5 Effect of altitude on breathing during sleep. Periodic breathing in a lowlander at 5400 m during sleep while breathing ambient air (*left half* of tracings) and oxygen (*right half* of tracings). *Top panel,* tidal volume (V_T, inspiration downward); *bottom panel,* arterial oxygen saturation (Sa_{O_2} [%]). (From Lahiri S, Maret K, Sherpa MG. Dependence of high-altitude sleep apnea on ventilatory sensitivity to hypoxia. *Respir Physiol.* 1983;52:281–301.)

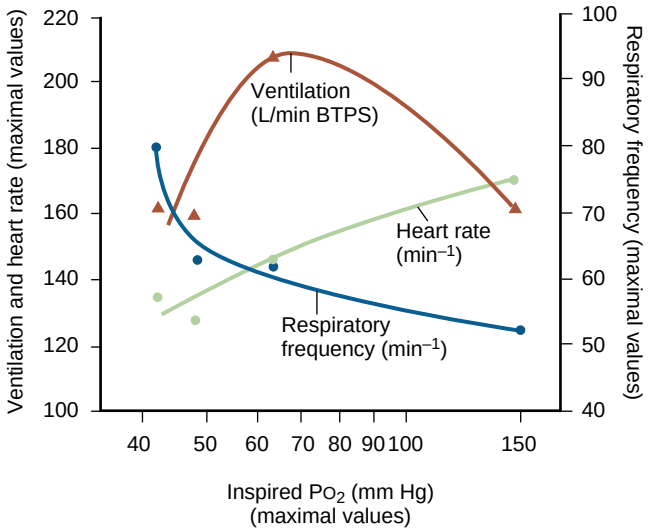

Fig. 105.6 Maximal ventilation, respiratory frequency, and heart rate versus inspired P_{O_2}. At a P_{O_2} of 64 mm Hg, equivalent to about 6300 m, maximal ventilation is increased because of the stimulation to ventilation from hypoxia, as well as a decreased density of the inspired air whereas, at a P_{O_2} of 43 mm Hg, equivalent to an altitude higher than 8000 m, maximal ventilation is decreased, probably as a result of a diminished metabolic demand from low work rates. Frequency continues to increase. Maximum heart rate decreases with increasing altitude. BTPS, body temperature ambient pressure, saturated with water vapor. (From West JB, Boyer SJ, Graber DJ, et al. Maximal exercise at extreme altitudes on Mount Everest. *J Appl Physiol.* 1983;55:688–702.)

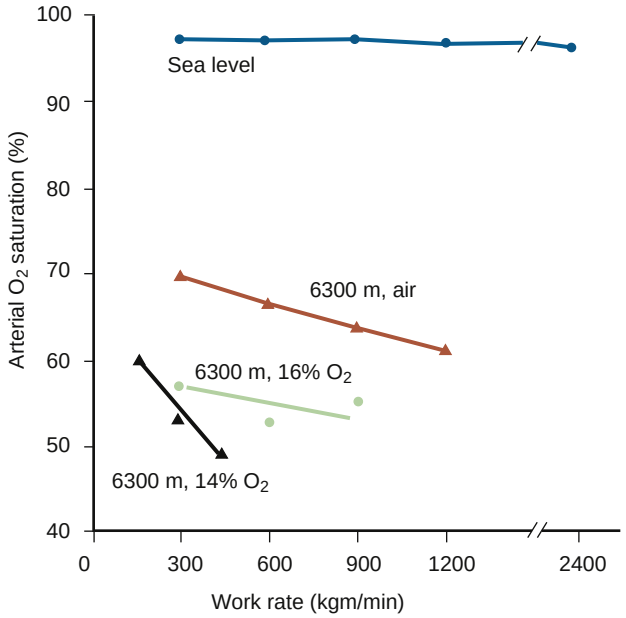

Fig. 105.7 Arterial oxygen saturation and altitude. Arterial oxygen saturation does not decrease with exercise at sea level but drops progressively with higher workloads at lower inspired P_{O_2}. At the 16% and 14% O_2 conditions, the inspired P_{O_2} was equal to that at 8050 m and 8848 m (the summit of Everest), respectively. The steep fall in O_2 saturation with the increasing work rate can be explained by diffusion limitation of oxygen transfer across the blood gas barrier. (From West JB, Boyer SJ, Graber DJ, et al. Maximal exercise at extreme altitudes on Mount Everest. *J Appl Physiol.* 1983;55:688–702.)

diffusion, while pulmonary capillary transit time is shortened as a result of the increase in cardiac output, thereby creating a true diffusion limitation (see Fig. 105.3). Ventilation-perfusion mismatching may also contribute to the observed gas exchange abnormalities[74] because nonuniform HPV may cause interstitial pulmonary fluid accumulation that, in turn, worsens ventilation-perfusion heterogeneity and impairs gas exchange.

Cardiovascular Response

For any given *submaximal* work rate, cardiac output and heart rate are higher during exercise on initial ascent compared with sea level. With acclimatization, cardiac output at submaximal workloads returns to sea level values, whereas heart rate remains elevated. However, because *maximum* exercise capacity is reduced, peak heart rate and cardiac output at altitude are lower than at sea level. Because acclimatization does not restore maximal exercise capacity to sea-level values, maximum cardiac output, heart rate, and stroke volume all remain decreased as well, despite acclimatization.[24]

PA pressure reaches high levels during exercise at high altitudes.[32] Whether this response limits exercise capacity at altitude is not clear. Because cardiac output is maintained at levels appropriate for the work rates attained, the increase in PVR in healthy sojourners to high altitude would not appear to limit exercise. However, in a field study of acclimatized individuals at 5245 m,[75] administration of the phosphodiesterase inhibitor sildenafil before a maximum exercise test lowered PA systolic pressure and improved maximum exercise capacity compared with placebo. This result has not been confirmed in other studies,[76] however, and it remains unresolved whether the rise in PA pressure contributes to exercise limitation at high altitude.

Exercise Performance at High Altitude

The effect of moderate altitude on exercise performance varies based on the type of activity and the duration of stay at high altitude. For running and throwing events of less than 2 minutes' duration, performance at high altitude is not impaired at altitudes lower than 3000 m and may even slightly improve because of decreased air density and resistance. However, for longer-duration events, performance is predictably diminished and can be restored only in part to sea-level capacity with prolonged stays at high altitude. Finally, as noted earlier, maximum oxygen consumption, peak heart rate, and minute ventilation are reduced at high altitude and do not return to sea level values regardless of the duration of stay or intensity of training.

Training at High Altitude

Ever since the 1968 Olympics in Mexico City (2200 m), there has been considerable interest in whether residence and training at high altitude improves performance at lower elevations. In the past, many elite endurance athletes relocated to and trained at moderate altitudes above 2000 m, but the beneficial effects on performance after return to sea level were generally not realized because, at high altitude, athletes could not attain the same maximum speeds and power output as when training at sea level. This problem led to interest in using intermittent hypoxia as an alternative means to apply the benefits of high-altitude acclimatization to sea-level performance. In a landmark study, Levine and Stray-Gundersen[77] used a randomized, controlled design and demonstrated that a combination of residence at high altitude (~3000 m) and training at lower elevation

(~1350 m) was associated with improvements in performance compared with those who lived and trained either at high altitude or at low elevation. This advantage was presumably the result of the modestly elevated hemoglobin from the altitude exposure, because there was individual variability in the erythropoietic response that correlated with improvement in performance.[78]

Because access to high altitude is limited for many athletes, interest has focused on "bringing the mountain to the athlete,"[79] by having the athlete spend time each day in oxygen-depleted tents that can be set up in the home or training center. Key questions that persist, however, are what "dose" of hypoxic exposure and what level of fitness are necessary to see a benefit in sea-level performance. A review concluded that athletes needed to reside at 2000 to 2500 m for 4 weeks or longer and for 22 hours or more per day to derive benefits from the live high–train low model,[79] but a subsequent placebo-controlled trial in which elite athletes were blinded to whether they were "living high" found no benefit to this strategy.[80] Approaches to altitude training and the data regarding their utility have been reviewed extensively elsewhere.[81,82]

MALADAPTATION

The physiologic adaptations described earlier give most individuals the ability to tolerate high-altitude exposure. However, regardless of the ultimate altitude achieved, individuals ascending too rapidly to altitudes higher than 2500 m may manifest maladaptive responses and develop one of three forms of acute altitude illness: *acute mountain sickness* (AMS), *high-altitude pulmonary edema* (HAPE), and *high-altitude cerebral edema* (HACE). Although long-term residents are not susceptible to these acute problems, several forms of chronic altitude illness—chronic mountain sickness and right heart failure—can affect these populations and represent important public health concerns.

PROBLEMS OF LOWLANDERS ON ASCENT TO HIGH ALTITUDE

Susceptibility to Altitude Illness

The incidence and severity of acute altitude illness depend on several factors, including the rate of ascent, the length of stay, and individual susceptibility. A trip to and from high altitude on the same day poses much less risk than an overnight stay because alveolar hypoxia is accentuated during sleep and because the overnight stay prolongs the duration of exposure. Susceptibility to altitude illness varies considerably among individuals but, for a single individual, the symptoms are often reproducible if the rate and other circumstances of the ascent remain roughly similar. Any individual who ascends too high and too fast can develop altitude illness, even if the person has never been sick at high altitude before.[83] Of note, being in good physical condition is not protective.[84]

At present, there is no way to predict who will get sick on ascent. Variables such as the HVR[85] and arterial S_{O_2} during hypoxic exposure[86] have been proposed as useful predictors for developing AMS, but they have not been validated in further studies, and specific genetic markers that predict susceptibility have not yet been identified.[87] Richalet and associates[88] derived and validated a model to identify patients with risk factors for severe high-altitude illness, but this model requires the use of cardiopulmonary exercise testing under hypoxic conditions to identify susceptible individuals and, as a result, is difficult to implement on a wide basis.

HAPE-susceptible individuals have been shown to have intense HPV and exaggerated pulmonary vascular responses to resting hypoxia and normoxic exercise,[29,89] but the presence of such responses alone is not sufficient to cause HAPE.[90] In the end, the only useful predictive tool remains the patient's prior experience at high altitude, particularly when the ascent rate and altitude of the prior and planned sojourns are similar.

Acute Mountain Sickness

AMS is the most common form of acute altitude illness, affecting 22–50% of travelers to altitudes between 1850 and 4240 m.[91,92] Given the increased awareness of the risks of altitude illness among the general population, the incidence of AMS has fallen in commonly traveled regions,[93,94] but very high rates (up to 70%) continue to be reported with rapid ascents to high elevations in certain regions such as Mt. Kilimanjaro.[95]

Clinical Presentation. AMS is marked by the presence of headache in addition to one or more other symptoms, including lassitude, anorexia, nausea, dizziness and, in severe cases, vomiting, although recent debate has developed on whether headache is required for diagnosis.[96,97] Difficulty with sleep was previously considered a primary symptom of AMS but was removed from the revised Lake Louise Acute Mountain Sickness Scoring System[98] after systematic studies showed it was not closely related to AMS.[99] Symptoms do not start immediately on ascent and instead come on over many hours following arrival at altitudes higher than 2400 m (8000 feet); the elevation at which symptoms begin varies significantly among individuals.

There are no characteristic physical examination findings, although mild increases in body temperature, crackles on auscultation, and peripheral edema have been documented in some reports.[100–102] S_{O_2} may be lower in individuals with AMS compared with those who remain healthy,[103,104] but AMS can still be seen in persons with what would be considered normal oxygenation.

The symptoms and signs of AMS are nonspecific, and other items must be considered in the differential diagnosis, including dehydration, hypothermia, hyponatremia, exhaustion, alcohol hangover, carbon monoxide poisoning, and central nervous system infection. The diagnosis is based solely on the clinical history, and there are no confirmatory laboratory tests. For a diagnosis of AMS, instead of HACE, the patient must have a normal neurologic examination and normal mental status.

Time Course of Symptoms. Symptoms develop after 6 to 10 hours at a given elevation, not immediately. In a study of a general tourist population traveling to 1900 to 2950 m in Colorado, Honigman and colleagues,[91] for example, reported that 65% developed symptoms within 12 hours of arrival at altitude, whereas 34% developed symptoms

between 12 and 36 hours following arrival. Onset after 36 hours at a given elevation is uncommon and should prompt a careful evaluation for alternative causes.

Symptoms are typically self-limited and resolve without treatment over a period of 1 to 4 days as the body acclimatizes to hypoxia although, in rare cases of individuals with very poor altitude tolerance, symptoms may persist for longer periods[100] and resolve only on descent. Even though symptoms resolve in most cases, they may recur with subsequent large gains in elevation if the individual does not take appropriate precautions. A small percentage of those with AMS proceed to develop HACE or HAPE, especially if ascent is continued despite illness.

Pathophysiology. Despite a considerable amount of research in this area, there is no coherent, unified explanation for why individuals develop AMS. Beyond the finding that hypoxemia is the key inciting factor that sets in motion a series of physiologic responses and pathophysiologic processes that ultimately cause AMS, the causal pathway leading from hypoxemia to that end point remains unclear. One challenge in interpreting the literature is that, although many studies have established associations between various physiologic derangements and AMS, they have failed to establish a causal relationship.

Because headache is the cardinal symptom of AMS, investigations of AMS pathophysiology often revolve around the pathophysiology of headache, with one of the leading concepts being the role played by trigeminovascular activation.[105] A long-standing concept in the literature is that symptom onset is related to the development of intracranial hypertension; however, increased intracranial pressure has not been consistently demonstrated in patients with AMS by using either direct or surrogate measures such as optic nerve sheath diameter. The *tight fit hypothesis*, which posits that individuals with a lower ratio of cerebral spinal fluid to blood and brain tissue volume have decreased ability to compensate for cerebral swelling or increased intracranial blood volume,[106] has long been an appealing theory from a theoretical standpoint, but supportive data are lacking. Various other factors have been considered to play a causal role, including ventilatory responses to hypoxemia,[107] alterations in CBF[108] or cerebral autoregulation,[109] subclinical pulmonary edema, abnormal fluid balance,[110,111] inflammation,[112] alterations in cerebral venous outflow,[113] and differences in mediators such as vascular endothelial growth factor,[114] free radicals, or reactive oxygen species.[115] Each of these factors may contribute in some way to the development of AMS, but as noted earlier, the particular causal links remain unclear.

Prevention. The pharmacologic and nonpharmacologic approaches to prevention and amelioration of AMS have been described in published guidelines.[116] Because overly rapid ascent to high elevation is the leading risk factor for altitude illness, gradual ascent, with rest days for acclimatization, is the single best way to prevent all acute altitude illness. Once higher than 3000 m, individuals should increase their sleeping elevation by no more than 300 to 500 m per night and should take an acclimatization day and sleep at the same elevation for two or more nights every 3 to 4 days or after any large gain in elevation. Although only a single study has demonstrated the benefits of slow ascent in a randomized, controlled manner,[117] considerable observational data support this approach. Strict adherence to published recommendations may be difficult, however, for a variety of logistic factors. Travelers should avoid overexertion and refrain from heavy alcohol consumption or opiate medication use, particularly before bedtime, to avoid hypoventilation, which can exacerbate hypoxemia. These strategies have not been systematically studied but represent common sense measures in light of the known physiologic changes at altitude. Staged ascent, in which an individual spends several days at a moderate elevation before ascending to the higher target elevation,[118,119] or preacclimatization, in which an individual undertakes repeated hypoxic exposures in the days and weeks before the planned ascent,[120,121] may be useful for preventing AMS. However, the precise recipe for implementing these strategies is unclear, and they can be logistically challenging to implement in practice.

Pharmacologic measures can also be used to prevent AMS in individuals deemed to be of moderate to high risk for AMS based on a prior history of the problem and/or features of their ascent profile[116] (Table 105.2). The most commonly used medication for this purpose is acetazolamide. Its principal action is renal carbonic anhydrase inhibition, which causes bicarbonate diuresis and metabolic acidosis, which, in turn, stimulates ventilation, increases alveolar Po_2, and enhances oxygen off-loading in the tissues. In effect, the drug speeds natural acclimatization by accelerating ventilatory acclimatization. Actions of acetazolamide on carbonic anhydrase elsewhere in the body, such as the peripheral and central chemoreceptors, may also contribute to its preventive role.[122] Acetazolamide is well tolerated, with the most common side effects being paresthesia involving the hands, feet, and lips and altered taste of carbonated beverages secondary to inhibition of hydration of carbon dioxide on the palate. Acetazolamide has a sulfonamide moiety and shares the cautions common to all sulfa drugs. The likelihood of cross-reactivity is very low,[123] but case reports do describe fatal anaphylaxis in persons with documented sulfa allergy who received acetazolamide.[124] For patients who do not tolerate or cannot take acetazolamide, dexamethasone is an effective alternative to AMS prophylaxis.[125] Although equally effective as acetazolamide,[126] dexamethasone does not hasten acclimatization, and symptoms may recur with abrupt discontinuation.[127] Attention has also focused on a potential prophylactic role for ibuprofen,[128] but it has yet to be proven equivalent to acetazolamide,[129] and it is not part of standard protocols at this time.[116]

Treatment. Descent leads to resolution of all forms of altitude illness, but patients with mild AMS usually recover by simply resting at the same elevation for a period of time. Descent is indicated in more severe cases or when symptoms fail to resolve with appropriate interventions and should continue until symptoms resolve. Logistic and other factors sometimes preclude descent, and alternative treatments may be necessary. Severely ill patients can be administered supplemental oxygen if gas tanks or oxygen concentrators are available or "low altitude" can be brought to the patient through the use of lightweight portable hyperbaric chambers (eFig. 105.1). These chambers, which can be pressurized to 2 psi and mimic a descent of approximately 1500 m,

Table 105.2 Dosing and Use of Altitude-Illness Medications

Medication	Indication	Route	Dosage
Acetazolamide	AMS, HACE prevention	Oral	125 mg q12h Pediatrics: 2.5 mg/kg q12h (maximum, 125 mg/dose)
	AMS treatment	Oral	250 mg q12h Pediatrics: 2.5 mg/kg q12h (maximum: 125 mg per dose)
Dexamethasone	AMS, HACE prevention	Oral	2 mg q6h or 4 mg q12h Pediatrics: Should not be used for prophylaxis
	AMS, HACE treatment	Oral, IV, IM	AMS: 4 mg q6h HACE: 8 mg once then 4 mg q6h Pediatrics: 0.15 mg/kg/dose q6h (maximum: 4 mg per dose)
Ibuprofen	AMS prevention	Oral	600 mg q8h
Nifedipine	HAPE prevention	Oral	30 mg ER version q12h or 20 mg ER version q8h
	HAPE treatment	Oral	30 mg ER version q12h or 20 mg ER version q8h
Tadalafil	HAPE prevention	Oral	10 mg q12h
Sildenafil	HAPE prevention	Oral	50 mg q8h

AMS, acute mountain sickness; ER, extended-release; HACE, high-altitude cerebral edema; HAPE, high-altitude pulmonary edema; IM, intramuscular; IV, intravenous.

have been shown to improve symptoms of AMS,[130,131] but they can be difficult to use with claustrophobic individuals or those who are vomiting. Relief of symptoms can be seen with as little as 1 hour of treatment, but the effects are not durable with such short treatment courses.[130]

Affected individuals can use aspirin,[100] acetaminophen, nonsteroidal anti-inflammatory drugs,[132] and antiemetics to relieve AMS symptoms. Individuals not responding to these conservative measures or persons with more severe AMS can add either acetazolamide[133] or dexamethasone[127,134,135] (see Table 105.2). The relative efficacy of these agents has not been studied, but clinical experience suggests that dexamethasone is a faster and more reliable intervention than acetazolamide.[116] Dexamethasone should never be taken to suppress symptoms of AMS while continuing to ascend.

High-Altitude Cerebral Edema

HACE is a potentially fatal form of acute altitude illness defined by the onset of mental status changes or ataxia in a person with AMS or by the presence of both neurologic signs in a person without AMS who has recently ascended to high altitude. It usually develops at altitudes higher than 3000 to 4000 m, although cases have been seen in conjunction with HAPE at more moderate altitudes in Colorado (~2500 m).[136] Although incidence rates of 0.26–1% have been reported,[92,137] the true incidence is difficult to assess because the boundary of progression from AMS is difficult to define, and the symptoms and signs may be similar to those of cerebral hypoxia secondary to severe hypoxemia from pulmonary edema. If HACE is not recognized and treated promptly, coma and death may ensue.

Based on findings on brain magnetic resonance imaging (discussed later), it has long been thought that HACE develops as a result of vasogenic, rather than cytotoxic, edema. More recent studies suggest that patients may progress from maladaptive ion transport to vasogenic edema and, in severe cases, hemorrhagic conversion,[138] whereas preliminary research suggests that the glymphatic system, consisting of a series of periarterial and perivenous channels associated with glial cell aquaporin channels, may also play a role in disease pathophysiology.[139]

In addition to symptoms of AMS, the most common signs include ataxia and altered mental status. Altered mental status may initially be subtle and include problems such as apathy, irritability, lassitude, and inability to eat or care for oneself before more obvious signs appear, including confusion, somnolence and, in the most severe cases, coma. Most cases are preceded by AMS but, in rare instances, HACE develops without preexisting AMS symptoms.

The physical examination demonstrates signs of global neurologic dysfunction rather than focal neurologic deficits, although the latter have been documented, along with abnormal reflexes, anisocoria, hallucinations, clonus, cranial nerve palsies, and seizures.[100,137,140,141] Retinal hemorrhages have been reported in HACE,[137] but they are common in otherwise healthy individuals at very high elevation,[142] and they are not a harbinger of the development of AMS or HACE. Hypoxemia is common in HACE and results from either poor ventilatory acclimatization or concurrent HAPE.

Because HACE is a global encephalopathy marked by onset over a period of hours, a sudden onset, and/or the presence of focal neurologic deficits, high fevers, or neck stiffness should prompt consideration of alternative diagnoses, including all other causes of encephalopathy, such as carbon monoxide poisoning, hypertensive crisis, hypoxic encephalopathy secondary to HAPE, meningitis, hypoglycemia, moderate to severe hypothermia, and severe migraine headache. Diagnosis in the field is based on clinical history and physical examination. Heel-to-toe walking along a straight line is an effective test for ataxia (see Video 105.2). When advanced diagnostic modalities are available, head computed tomography scans show nonspecific changes of diffuse edema, whereas magnetic resonance imaging reveals a pattern of reversible increased T2-weighted signal predominantly in the splenium and genu of the corpus callosum.[143] Microhemorrhages are common and specific findings,[143–145] and they may be present for up to 50 months following resolution of HACE, thus providing an

opportunity to confirm the diagnosis after symptoms have resolved following descent.[136,145]

Descent is the definitive treatment for HACE, although recovery in severe cases may take several weeks.[136,141] If descent is not feasible, oxygen and portable hyperbaric therapy (see eFig. 105.1) may be lifesaving temporizing measures. Although very early reports documented the use of furosemide and betamethasone,[100] dexamethasone is now the standard pharmacologic intervention for HACE (see Table 105.2). Mannitol and hypertonic saline are difficult to use safely in the field because of a lack of adequate monitoring, and they should be used only in a hospital or clinic setting.

High-Altitude Pulmonary Edema

The most common cause of death from high-altitude illness, HAPE was historically misdiagnosed as pneumonia, bronchitis, or congestive heart failure until reports by Hultgren and colleagues[89] and by Houston[146] revealed it to be a distinct form of noncardiogenic pulmonary edema.

Clinical Presentation. Typically manifesting within 2 to 4 days of ascent to altitudes higher than 2400 m, persons with HAPE usually present in the early stages with decreased exercise performance and increased time to recover from exertion, as well as fatigue, weakness, a persistent dry cough, and, in some cases, symptoms of AMS. As the disease worsens, individuals are dyspneic on minimal exertion and, in the most severe cases, dyspneic at rest. Even in the absence of concurrent HACE, severe hypoxemia may produce mental changes, ataxia, and altered levels of consciousness.

On physical examination, patients may have a low-grade fever to 38.5°C as well as tachycardia, tachypnea, and decreased oxygen saturation by pulse oximetry (Spo_2). Generalized pallor and cyanosis are often present, whereas crackles are initially heard in the right mid-lung fields and then more diffusely as the disease worsens. Radiographs[147] and computed tomography scans show patchy, alveolar opacities, which may be limited to one area (the right lung field predominating initially) or generalized, depending on illness severity (Fig. 105.8). Arterial blood gas measurements reveal severe hypoxemia. In a study at 4559 m, for example, individuals with HAPE had a mean arterial Po_2 of 23 ± 3 mm Hg and an average arterial So_2 of 48 ± 8% versus 40 ± 5 mm Hg and 78 ± 7%, respectively, for healthy control subjects.[148] Although not used as part of diagnostic protocols, right heart catheterization performed in a research setting demonstrates increased PA and pulmonary capillary pressure, but normal pulmonary capillary wedge pressure consistent with normal left ventricular function.[89,149]

Possible Mechanisms. HAPE is a form of noncardiogenic pulmonary edema marked by normal left ventricular function. Unlike the situation with AMS and HACE where the precise pathophysiologic mechanisms are unclear, it is well established that elevated PA pressure plays a key role in development of HAPE, because multiple investigations have shown that affected individuals have markedly elevated PA pressures compared with healthy controls.[89,149,150]

HAPE-susceptible individuals have exaggerated HPV, which likely accounts for their elevated PA pressures; multiple studies demonstrate that HAPE-susceptible individuals have abnormally high PA pressure responses during hypoxic breathing, during normoxic and hypoxic exercise, and on ascent to high altitude before the onset of edema.[29,30] The reasons for this exaggerated response are not entirely clear but may be related to differences in hypoxic ventilatory responsiveness,[151,152] lung volumes,[153] increased sympathetic tone,[154] or alterations in circulating vasoactive mediators including endothelin, nitric oxide, and free radicals.[155–159]

Given the central importance of elevated PA pressure in the pathogenesis of HAPE, the question is how this elevated pressure causes fluid accumulation when patients with severe pulmonary arterial hypertension at sea level do not typically have pulmonary edema. Hultgren[160] has suggested that edema results from uneven hypoxic vasoconstriction, leading to overperfusion of the microvasculature in areas of the lung where arteriolar vasoconstriction fails to protect downstream vessels. Uneven perfusion is suggested clinically by the typical patchy radiographic appearance (see Fig. 105.8) and by magnetic resonance imaging studies in persons breathing hypoxic gas mixtures,[161] which demonstrate more heterogeneous perfusion in HAPE-susceptible subjects.

Earlier work suggested that the leak in overperfusion edema was the result of *capillary stress failure* in which high shear forces cause biomechanical stress and injury in the precapillary arterioles and capillaries,[162,163] but other investigators[164] have argued that high pressures and shear

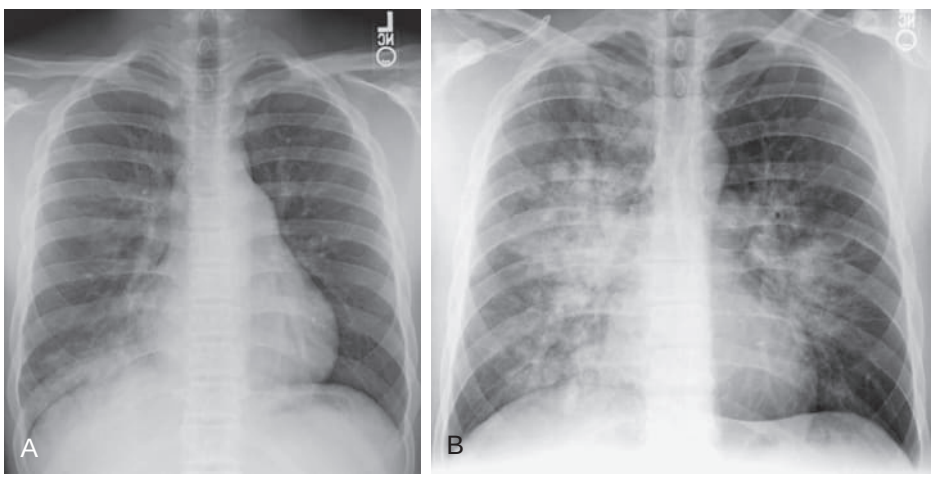

Fig. 105.8 Radiographs of high-altitude pulmonary edema. (A) Typical chest radiographic appearance of high-altitude pulmonary edema in a 15-year-old boy. Note that the edema is predominantly right sided. (B) Severe high-altitude pulmonary edema in a 27-year-old man. Note the normal heart size and the presence of bilateral opacities in this case. (Courtesy Peter Hackett.)

stress lead to a high permeability–type leak along a continuum of pressure-related phenomena by which plasma and even RBCs move from the intravascular space to the interstitium and subsequently into the alveolar space. At lower levels of pressure elevation, stretch on collagen and other supporting extracellular matrix elements may induce dynamic and quickly reversible changes in barrier permeability[165] that, with greater duration and further pressure elevation, may lead to capillary rupture and alveolar hemorrhage, as seen in severe HAPE.

Although the data largely establish a mechanical basis for HAPE, a role for inflammation was suggested by bronchoalveolar lavage studies in patients with HAPE that demonstrated increased cellularity and the presence of chemotactic (leukotriene B_4) and vasoactive (thromboxane B_2) mediators compared with control subjects.[166] Swenson and associates[150] further clarified the role of inflammation by performing bronchoalveolar lavage in HAPE-susceptible individuals and normal control subjects within the first 24 hours of arrival at 4559 m, earlier than the lavage samples obtained in the earlier studies. The lavage fluid demonstrated high protein and RBC content, the levels of which correlated with PA pressure estimated by echocardiography (eFig. 105.2), but no evidence of cytokine expression or neutrophil recruitment. These findings solidified the notion that HAPE arises from high intravascular pressure, rather than from inflammation. Inflammation may, however, play a role in certain situations, because viral respiratory infections may predispose children to HAPE,[167] and anecdotal reports suggest a similar role of viral infections in adults. These infections may trigger inflammation, which makes the capillary endothelium more vulnerable to increased pressures. This phenomenon may explain the cases of HAPE seen at atypically low altitudes (1500 to 2400 m).[168] Alterations in the alveolar epithelium may also contribute to HAPE. Hypoxia, for example, decreases alveolar transepithelial sodium transport[169] and fluid clearance,[170] with potential effects on alveolar fluid balance. In human studies, transepithelial potential differences across the nasal mucosa were studied as a model of alveolar epithelial function. In these studies, lower transepithelial nasal potentials in normoxia were indicative of decreased epithelial sodium channel transport in HAPE-susceptible individuals compared to control subjects.[171] A subsequent study confirmed the difference in nasal potential between HAPE-susceptible individuals and control subjects in normoxia, but the study could not attribute these differences to alterations in epithelial sodium channel activity.[172] Transalveolar sodium transport can be increased by β_2-receptor stimulation, and a field study reported successful prevention of HAPE with inhalation of the long-acting β_2-agonist salmeterol.[171] However, given the multiple actions of this drug, including increased ventilatory response to hypoxia, and tightening of cell-to-cell contacts, the contribution of enhanced alveolar fluid clearance to the study's positive outcome remains uncertain.[173]

Allemann and colleagues[174] documented an increased incidence of patent foramen ovale in HAPE-susceptible individuals at low and high altitude compared with healthy control subjects and argued that the presence of this anomaly may increase the risk of HAPE. It is not clear, however, whether the patent foramen ovale causes HAPE or is a sequela of prior marked rises in PA pressure during sojourns to high altitude or during normoxic exercise seen in HAPE-susceptible individuals.[175]

Prevention. The nonpharmacologic preventive measures previously described for AMS also apply to HAPE, with a slow ascent being the most important strategy. HAPE-specific pharmacologic prophylaxis is reserved for persons known to be HAPE susceptible based on a prior history of the disease (see Table 105.2). The mainstay of prevention is nifedipine, presumably via its action as a potent vasodilator, which was shown in a small study to be effective in individuals with a past history of the illness.[176] More recently, Maggiorini and colleagues[177] demonstrated that another vasodilator, the phosphodiesterase inhibitor tadalafil, can also prevent HAPE in known susceptible individuals. An unexpected finding of this study was that dexamethasone was also effective in this regard. Subsequent studies showed that dexamethasone decreases estimated PA pressure following ascent to 4559 m[178] but, because the mechanism of action remains unclear and clinical experience with dexamethasone for HAPE prophylaxis is limited, it is not part of standard HAPE prevention protocols.[116] A single study also established that inhaled salmeterol augments alveolar fluid clearance and may prevent HAPE,[171] but very high doses (2.5 times those used in asthma) were used in the study and may be associated with side effects that affect patient tolerance. For this reason, it is also not recommended as a primary option for HAPE prophylaxis.[116]

Treatment. Proper treatment depends on the severity of the illness and the clinical setting. In remote locations with limited access to care, the first priority is descent to lower elevation. Exertion should be limited during descent because this may increase PA pressure and worsen pulmonary edema. With early diagnosis, recovery is rapid with descents of only 500 to 1000 m, and the individual may be able to reascend cautiously 2 or 3 days later. If descent is not possible because of weather or other factors, supplemental oxygen or portable hyperbaric therapy should be initiated. If neither option is available, expiratory positive airway pressure may improve oxygenation, although the effect on outcomes has not been established.[179]

Given the reduced margin for error in remote settings, use of a pulmonary vasodilator such as nifedipine is warranted regardless of whether supplemental oxygen is available. The data supporting this practice are limited,[180] however, and the recommendation is based largely on extensive clinical experience. Other pulmonary vasodilators such as tadalafil and sildenafil have not been studied for HAPE treatment, but reports document their use, often in conjunction with calcium channel blocker therapy.[181,182] However, given the absence of data supporting benefit and the risk of provoking systemic hypotension, concurrent use of two pulmonary vasodilators should be avoided. Diuretic agents were used in the past,[183] but they are now avoided because patients with HAPE are typically volume depleted at the time of diagnosis and at risk for hypotension.

Individuals who can access well-supported medical facilities can typically be treated with bed rest and oxygen without the need for evacuation to lower elevation.[184,185] Well-selected patients with mild disease and adequate

support by family or friends can often be sent home or to their hotel with supplemental oxygen.[186] Addition of nifedipine or other pulmonary vasodilators to supplemental oxygen may not yield additional benefit,[185,187] and this treatment is generally reserved for those patients not responding appropriately to supplemental oxygen. A single series documented the use of continuous positive airway pressure to relieve dyspnea in HAPE,[168] but there are no controlled data demonstrating improved outcomes. Because fevers up to 38.5°C have been described in HAPE, a finding of elevated temperature should not prompt administration of antibiotics unless the clinical picture is consistent with pneumonia. Patients who do not improve with appropriate therapy should be investigated for other causes of hypoxemia and radiographic opacities.

PROBLEMS OF HIGH-ALTITUDE RESIDENTS

Chronic Mountain Sickness

First described in Andean dwellers by Monge[188] in 1928 and often referred to as Monge's disease, *chronic mountain sickness* (CMS) is a commonly described form of chronic altitude illness. It is seen in persons born and living at high altitude, as well as in lowlanders who move to high altitudes and stay for more than 1 year. Excessive erythrocytosis, defined as a hematocrit higher than 60–70% or more than two standard deviations above the average value for healthy residents at a given high altitude, is an essential characteristic of this syndrome. There are geographic and ethnic differences in the prevalence of CMS. It is rarely found in natives of the Tibetan plateau and Ethiopian highlands but is frequently encountered in the Andes, in the North American Rockies, and in other mountainous regions where lowlanders have moved as, for example, in Han Chinese who have been relocated to Tibet.[189–191] The reason for these regional differences is unclear, but they may relate to genetic polymorphisms affecting factors such as hypoxic pulmonary vasoconstriction and erythrocytosis that arose as a result of differences in duration of existence at high elevations between the Tibetan and Ethiopian highlanders compared with that of the Andeans and others who are more susceptible to the disease.

Clinical Presentation. Symptoms of CMS resemble those found in persons with polycythemia at low altitude: headache, dizziness, lethargy, impaired memory and mentation, decreased exercise tolerance, arthralgias, and poor sleep. Physical examination reveals deep cyanosis of the lips, mouth, and throat, digital clubbing, plethoric appearance, and hyperemic conjunctivae, whereas laboratory studies show the characteristic elevated hematocrit and hemoglobin concentration.[192] Chest radiography typically demonstrates enlargement of the right atrium and ventricle and pulmonary arteries, whereas electrocardiography reveals P pulmonale and right-axis deviation, among other findings.[193] The diagnosis is established by eliminating all other causes of polycythemia. Indeed, much confusion in the literature regarding incidence and other aspects of CMS may reflect inadequate validation of the diagnosis. For example, several studies have found evidence of respiratory disease in a high percentage of CMS patients in both Peru and Colorado.[189,194] The Qinghai score, which is based on the hemoglobin concentration and other signs and symptoms, can be used to quantify the severity of disease.[195]

Pathophysiology. The likely initiating factors for CMS are a blunted HVR and relative hypoventilation. Hypoventilation increases alveolar hypoxia and arterial hypoxemia. Alveolar hypoxia, in turn, triggers more HPV and greater pulmonary hypertension, whereas arterial hypoxemia leads to increased EPO secretion and more RBC production.[193,196,197] Serum EPO concentration may account for some of the excessive erythrocytosis because some CMS patients have EPO values that resemble those of healthy highlanders, rather than the low values one would expect in the setting of polycythemia, and thus they may not be able to "turn off" their EPO.[192] Instead of considering EPO levels, perhaps EPO availability, assessed as the ratio of serum EPO to its soluble receptor, an endogenous antagonist of EPO action, is the key factor.[198]

The precise cause and effect relationships among hypoventilation, polycythemia, and CMS are not entirely clear, however. For example, polycythemia has been shown to blunt ventilation and ventilatory responses,[199,200] whereas hypoxemia itself may contribute to the ventilatory depression, as evidenced by an increase in ventilation in some natives with CMS when given supplemental oxygen. Moreover, HPV may not be solely a function of increased alveolar hypoxia because CMS patients have also been noted to have accentuated PA pressure responses to modest exercise when compared with healthy individuals living at the same elevation,[201] a phenomenon also seen in HAPE-susceptible individuals.

Although the excessive polycythemia of CMS is likely the result of greater hypoxemia, the actual hematocrit is often higher than expected for the measured arterial So_2,[202] a finding suggesting that affected individuals have exaggerated erythropoietic responses to a given hypoxic stimulus.[196] Severe nocturnal desaturation may also contribute to the development of polycythemia because investigations in the Rocky Mountains revealed greater hypoxemia during sleep in patients with CMS compared with healthy controls.[203] Finally, Jefferson and associates[42] found that a majority of subjects with the most severe CMS and the greatest degree of excessive erythrocytosis in an Andean mining community had detectable serum concentrations of cobalt, a heavy metal known to stimulate renal EPO production. This may help explain the higher incidence of CMS in high-altitude regions where mining is common.

Once present, polycythemia may also contribute to the pulmonary vascular issues noted earlier because the increase in viscosity increases PVR. Along with impaired gas exchange and pulmonary vascular changes resulting from HPV, the onset of polycythemia represents a turning point in CMS that ultimately leads to the clinical deterioration and demise of these patients.[193,204]

Treatment. The keys to treating CMS are to reduce the hypoxic stimulus for RBC production and to decrease RBC mass. Although relocation to a lower altitude is the definitive means to achieve these goals, it is often not feasible, and other treatments are necessary. Phlebotomy with or without isovolumic hemodilution reduces symptoms and improves oxygenation and hematocrit,[205] but concerns exist about provoking iron deficiency with its potential effects on

PA pressure,[206] as well as a rebound effect on hematocrit whereby the hematocrit subsequently rises above the pretreatment values with return of symptoms.[192] Mild exercise may also be of benefit,[192] but care must be taken to avoid worsening pulmonary hypertension[201] or interstitial fluid accumulation.[207] Pharmacologic measures also have a role in treatment. Although studies have assessed the impact of angiotensin-converting enzyme inhibitors, medroxyprogesterone, and almitrine on oxygenation and hemoglobin concentration, the most promising agent appears to be acetazolamide, which has been demonstrated to reduce hemoglobin and serum EPO, as well as improve oxygenation, sleep disordered breathing, and PVR.[208,209]

High-Altitude Pulmonary Hypertension

An alternative form of altitude-related disease in long-term residents has also been described in areas outside the Andes Mountains. Referred to as high-altitude pulmonary hypertension, it is marked by pulmonary hypertension and right heart dysfunction *without* polycythemia. Based on consensus criteria,[195] high-altitude pulmonary hypertension is present if a resident at altitudes higher than 2500 m has a mean PA pressure greater than 30 mm Hg or a systolic PA pressure greater than 50 mm Hg, right ventricular hypertrophy, right heart failure, and moderate hypoxemia without excessive erythrocytosis (hemoglobin <21 g/dL in men and <19 g/dL in women). There is considerable overlap between this disease and subacute mountain sickness, a syndrome of pulmonary hypertension and right heart failure seen in lowlanders after weeks to months at high altitude,[210] with the major difference being the time spent at high altitude. There is also some debate about whether this truly represents a separate entity from CMS or is simply a variant of the same disease.[193]

Affected individuals manifest dyspnea, cough, cyanosis, peripheral edema, and physical examination findings consistent with right heart failure. Right-axis deviation, right ventricular hypertrophy, and P pulmonale may be present on the electrocardiogram, whereas chest imaging reveals right ventricular and right atrial enlargement and prominence of the pulmonary arteries.[195] The pulmonary hemodynamic findings are similar to those seen in patients with CMS.[193] The optimal treatment for the disorder is relocation to lower elevation, but that may not be feasible for many patients. A small placebo-controlled trial demonstrated that a 3-month course of the phosphodiesterase inhibitor sildenafil modestly lowered PA pressure (~6 to 7 mm Hg) and improved 6-minute walk distance,[211] but larger studies of this and other pulmonary vasodilators have not been performed, and there are no clear treatment guidelines.

Reentry and Resident Pulmonary Edema

Long-term residents who descend to lower altitudes may develop HAPE on reascent. Referred to as reentry HAPE, this phenomenon was originally described in Peru. In fact, many of the original cases of HAPE described in the literature were of the reentry variety. Since then, cases have also been widely reported in Colorado,[212] but only infrequently in the Himalayas.[213,214] No systematic studies have addressed the best means for prevention, but acetazolamide is commonly used for this purpose in children with history of reentry HAPE in Colorado.[215] No treatment trials have been conducted for reentry HAPE, and the disorder should be managed in the same way as for HAPE in unacclimatized lowlanders.

One report suggested that high-altitude residents may also be at risk for pulmonary edema even in the absence of a change in elevation. Ebert-Santos[216] documented multiple cases of high-altitude residents presenting to a clinic at 2800 m with hypoxemia and chest radiographs consistent with HAPE despite not having traveled to lower or higher elevations. All cases of what they referred to as mountain resident HAPE were seen in young children (ages 2 months to 15 years) and resolved readily with supplemental oxygen administration, although a few patients required up to 10 days of oxygen. The role of preceding viral infections in the development of pulmonary edema was not clear from this report, and physiologic data such as estimated PA pressure were not reported.

PREEXISTING ILLNESS AND HIGH ALTITUDE

Given the prevalence of many common diseases, such as hypertension and COPD, in the general population, it is likely that many high-altitude travelers have some underlying medical condition. This situation raises two important questions: (1) Will the underlying disease predispose these individuals to high-altitude illness? and (2) Will the stress of hypoxia at high altitude worsen control of their disease? To date, few studies have examined what happens to persons with respiratory and other diseases when they visit high-altitude destinations, and even fewer data are available on how to treat them before and after their exposure. Several major categories of respiratory diseases are discussed in the following subsections, whereas other major disease categories, including heart disease,[217–219] chronic kidney disease,[220] diabetes,[221,222] solid organ transplantation,[223] and chronic liver disease,[224] are reviewed elsewhere.

RESPIRATORY DISEASES

High-altitude exposure poses several challenges to patients with lung disease that have been reviewed extensively elsewhere.[225] Several important lung diseases are considered briefly here.

Chronic Obstructive Pulmonary Disease

Patients with COPD are at risk for exaggerated hypoxemia[226] and decreased exercise capacity[227] following ascent to high altitude. Spirometric measures of pulmonary function are unchanged,[226] and the risk of pneumothorax does not appear to be increased in those with bullous disease.[228,229] Patients with moderate to severe COPD (forced expiratory volume in 1 second <1.5 L) should undergo pretravel assessment of their risk of hypoxemia and need for supplemental oxygen. One of several published prediction rules can be used,[230,231] but the overall accuracy of these rules is not clear. A better test is the hypoxia altitude simulation test,[232] which allows one to observe actual physiologic responses to hypoxia. This approach is limited, however, by the short duration of exposure relative to the length of a high-altitude sojourn and the degree of hypoxia to which the patient can be exposed in a clinical testing environment. Those at risk for severe hypoxemia should travel with a portable oxygen concentrator or a

prescription for home oxygen that they can fill at their destination (e.g., a ski resort town). An alternative strategy in less severe disease is to monitor pulse oximetry following arrival and fill a prewritten home oxygen prescription if their saturation falls below a prespecified threshold.[233] Patients should travel with their controller medications and a supply of rescue medications in the event of an exacerbation.

Interstitial Lung Disease

Patients with various forms of interstitial lung disease are also at risk for exaggerated hypoxemia at high altitude that will worsen with even mild exertion.[231,234] From a theoretical standpoint, such patients may also have difficulty related to underlying pulmonary hypertension (described further later) and reduced lung compliance that may make it difficult to increase and maintain ventilation in response to hypoxemia at high altitude. Patients with severe restrictive physiology (total lung capacity <50% predicted) or a preexisting oxygen requirement should probably avoid high-altitude travel altogether, whereas those with less severe disease can travel to high altitude with adequate pretravel assessment to determine the need for supplemental oxygen.

Asthma

Changes in air temperature, humidity, and density may alter lung mechanics and airflow obstruction in patients with asthma, but field data demonstrate that patients with mild, well-controlled asthma have decreased bronchial hyperresponsiveness at elevations as high as 5000 m[235] and tolerate ascents as high as 6410 m without significant changes in their symptoms.[236,237] Asthma must be under good control before any trip to high altitude, and patients should travel with both their controller medications and an adequate supply of rescue inhalers and prednisone for use in the event of an exacerbation.

Pulmonary Vascular Disease

Only two studies have examined PA pressure responses to hypoxic exposure in patients with pulmonary hypertension. One study showed an increase in PA systolic pressure without deterioration in right heart function,[238] and the other showed no significant changes in mean PA pressure, PVR, or cardiac output.[239] Although these studies are somewhat reassuring, they involved very short exposures (≤20 minutes) to hypoxia, and multiple reports have documented HAPE in patients with various causes of pulmonary hypertension following ascent to high altitude.[240] Patients with New York Heart Association functional class III or IV symptoms or those who require continuous intravenous vasodilator therapy should avoid high altitude altogether. If travel is necessary, strong consideration should be given to using supplemental oxygen to blunt the rise in PA pressures. Patients with less severe disease may avoid problems but should consider adding or increasing the intensity of pulmonary vasodilator therapy and should monitor symptoms and pulse oximetry following arrival. Patients with congenital absence of a PA should also avoid high-altitude travel because these individuals are known to be susceptible to HAPE.[241,242]

Sleep Apnea

Although the decrease in barometric pressure and air density at high altitude could lead one to expect a decrease in the severity of obstructive sleep apnea following ascent, field studies suggest that obstructive sleep apnea persists following ascent to 2950 m and is accompanied by a marked increase in the number of central apneas, as well as impaired performance on simulated driving tasks, increased systolic blood pressure, and more frequent cardiac arrhythmias.[243] Given these issues, persons with moderate to severe obstructive sleep apnea should travel to high altitude with their continuous positive airway pressure machine when possible, assuming that reliable access to power sources can be arranged. In addition, for those using autotitrating continuous positive airway pressure, the addition of acetazolamide has been shown to improve the apnea-hypopnea index by decreasing the number of central sleep apneas and to improve nocturnal oxygenation.[244]

Thromboembolic Disease

Although many case reports document arterial or venous thromboembolic events at high altitude, many of the cases were in persons with underlying coagulopathy.[225] There remains no compelling evidence that the risk of thromboembolism is increased in normal individuals at high altitude. As a result, there is no need to screen for thrombophilia in asymptomatic persons before high-altitude travel and no indication to start anticoagulation in patients not previously taking such medication. Efforts should be made to maintain mobility and good hydration throughout a trip. The international normalized ratio may change with trips to and from altitude,[245] and patients taking warfarin should obtain follow-up values on returning from a long sojourn or periodically during prolonged stays at a new altitude. An alternative approach is to change to a direct oral anticoagulant agent for the sojourn, although reversal of coagulopathy is more challenging with those agents compared with warfarin.

UNDERLYING MEDICAL PROBLEMS AND ALTITUDE ILLNESS MEDICATIONS

The efficacy and safety of acetazolamide, dexamethasone, nifedipine, and the phosphodiesterase inhibitors in managing acute altitude illness have largely been established based on studies in healthy individuals with no underlying medical disease. However, given the increasing numbers of persons traveling to high altitude, it is possible that many of those using the foregoing medications for management of altitude illness will have underlying medical problems or will be using other medications that cause adverse drug interactions. Practical guidelines for the selection and dosing of the altitude illness medications in such patient populations have been reviewed elsewhere.[246]

Key Points

- At high altitude, important adaptations at every step of the oxygen transport chain maintain oxygen delivery in the setting of lower ambient oxygen levels. However, the magnitude of these changes varies among individuals and affects individual tolerance of this environment.
- Various aspects of sleep, including respiratory patterns, sleep architecture, and subjective impressions of sleep quality, are altered and contribute to poor sleep at high altitude.
- Maximum exercise capacity is reduced at high altitude and does not recover to sea-level baseline values even with prolonged time and acclimatization at high altitude.
- An overly rapid ascent to high elevation is the primary reason persons develop acute altitude illness, and a gradual ascent is the best nonpharmacologic means for prevention. Pharmacologic options are available to prevent or treat specific illnesses and can include acetazolamide, dexamethasone, or pulmonary vasodilators.
- Acute mountain sickness is the most common form of acute altitude illness and is marked by the onset of headache in addition to one or more other symptoms, including lightheadedness, gastrointestinal upset, and fatigue several hours following ascent.
- High-altitude cerebral edema and high-altitude pulmonary edema are uncommon and potentially fatal forms of severe acute altitude illness that can be avoided with prompt recognition and initiation of treatment.
- Long-term high-altitude residents are susceptible to two forms of chronic altitude illness, namely chronic mountain sickness and high-altitude pulmonary hypertension, for which the optimal form of treatment is relocation to a lower elevation.
- High-altitude travelers with underlying medical problems should undergo pretravel assessment to evaluate whether the underlying disease process may be worse at high altitude. The choice and dose of prophylactic medications may require adjustment based on the patient's underlying medical issues.

106 AIR TRAVEL

UMUR HATIPOĞLU, MD, MBA • JAMES K. STOLLER, MD, MS

INTRODUCTION
EPIDEMIOLOGY AND GENERAL RISKS OF AIR TRAVEL
PHYSIOLOGIC IMPACT OF COMMERCIAL AIR TRAVEL
PREFLIGHT ASSESSMENT OF FITNESS TO FLY
Assessing for In-Flight Hypoxemia in Patients with Respiratory Disease
Assessing for In-flight Hypoxemia in Patients Not Using Supplemental Oxygen at Sea Level
PRESCRIBING SUPPLEMENTAL IN-FLIGHT OXYGEN IN PATIENTS ALREADY USING SUPPLEMENTAL OXYGEN AT SEA LEVEL
PROVIDING SUPPLEMENTAL IN-FLIGHT OXYGEN
CONSIDERATIONS REGARDING SPECIFIC LUNG DISEASES AND AIR TRAVEL
Pneumothorax
Lymphangioleiomyomatosis
Birt-Hogg-Dubé Syndrome
Pulmonary Hypertension
Sickle Cell Disease and Trait
Restrictive Lung Disease Due to Chest Wall Deformity, Neuromuscular Disease, or Interstitial Lung Disease
Cystic Fibrosis
TRANSMISSION OF RESPIRATORY INFECTIONS DURING AIR TRAVEL
RISK OF VENOUS THROMBOEMBOLISM DURING AIR TRAVEL
PRACTICAL ASPECTS OF ASSESSING THE PATIENT WITH PULMONARY SYMPTOMS IN FLIGHT
KEY POINTS

INTRODUCTION

As air travel increases as part of the fabric of modern life and as more individuals with lung disease—perhaps most commonly COPD—travel by air, pulmonologists are increasingly called upon to assess their patients' fitness to fly. Also, when air travel is endorsed, pulmonologists must advise patients about how to avoid the hazards of travel and manage their supplemental in-flight oxygen prescription, when needed. In this context, the current chapter reviews pulmonary aspects of commercial air travel. First, the epidemiology of air travel and concomitant risks are discussed. Then, based on the physiologic effects of high-altitude exposure discussed in Chapter 105, the physiologic impact of air travel (e.g., on gas exchange) is discussed. Attention then turns to evaluating fitness to fly, followed by assessing in-flight oxygenation. When and how to prescribe supplemental in-flight oxygen is discussed next, including recommendations for oxygen-naive patients and also for those already using supplemental oxygen at home. Equipment to provide in-flight supplemental oxygen is then reviewed, as is the process of prescribing in-flight oxygen. The chapter concludes with a discussion of the risks of air travel on infection transmission, venous thromboembolism, and pneumothorax, followed by issues regarding air travel that pertain to individuals with a spectrum of diagnoses beyond COPD (e.g., lymphangioleiomyomatosis, pulmonary hypertension) and a discussion of practical aspects of assessing a patient with pulmonary symptoms in flight.

EPIDEMIOLOGY AND GENERAL RISKS OF AIR TRAVEL

Travel is integral to modern life and, in the context of increasing affordability and facilitative technology (e.g., *portable oxygen concentrators* [POCs], mobility-enhancing devices), travel by air is increasingly common, even for individuals with chronic medical conditions. World Bank data suggest that 3.7 billion individuals traveled by air in 2016, up from 2.1 billion in 2006.[1]

Even though individuals with chronic medical illnesses are flying more frequently, medical emergencies associated with commercial air flight are relatively uncommon. Death in flight has been estimated to take place in 0.3% of in-flight emergencies, which happen in 1 of every 604 flights or for 1 of every 33,600 to 39,600 passengers.[2,3] The worldwide estimated frequency of in-flight medical emergencies is 1:40,000 passengers[4] and a *U.S. Federal Aviation Administration* (FAA) study[5] estimated that there were 1132 in-flight medical events in 140,000 plane trips between 1996 and 1997. Though not all in-flight medical events prompt calls for ground-based medical assistance, among calls from commercial aircraft for ground-based medical advice, syncope or presyncope was most common (37.4% of cases), followed by respiratory symptoms in 12.1% and nausea and vomiting in 9.5%. Cardiac symptoms (7.7%), stroke (2%), and cardiac arrest (0.3%) were less common. Having respiratory symptoms in-flight was associated with a twofold increase in risk of admission to the hospital after landing.[2]

Diversions of commercial air flights due to onboard medical emergencies are expensive and result in significant inconvenience for other passengers. Recent estimates suggest a cost of diversion ranging from US $50,000 to over US $600,000, depending on factors like fuel costs, passenger rebooking, and accommodations.[6] Approximately 7–13% of all in-flight medical events led to a diversion, and respiratory symptoms were the third most common reason for diversion.[4,7]

Table 106.1 Hypobaric Conditions at Increasing Altitude

Altitude (ft)	Barometric Pressure (mm Hg)*	Atmospheric P_{O_2} (mm Hg)*	Tracheal P_{O_2} (mm Hg)	Gas Density†	Gas Volume‡
0 (sea level)	760	159	149	1	1

PHYSIOLOGIC IMPACT OF COMMERCIAL AIR TRAVEL

Commercial airplanes characteristically travel at altitudes of 30,000 to 40,000 feet, posing risks of hypobaric hypoxia and changes in gas density related to altitude.[8] Because exposure to such ambient altitudes is life-threatening, airplanes are pressurized to provide so-called cabin altitudes (the altitude equivalent inside the airplane) that are tolerable. The degree of pressurization reflects structural features of the airplane (e.g., fuselage diameter, airplane construction materials, and their ability to withstand transmural pressure gradients) and in-flight cabin altitudes are uniformly higher than sea level. By FAA regulations,[9] cabin altitude must be maintained at 8000 feet (2438 meters) with rare diversions to 10,000 feet (3048 meters) for safety (e.g., weather avoidance). Measured peak cabin altitudes on 207 U.S. domestic flights using 17 different aircraft was 4528 to 8154 feet, with only 11.2% of measurements showing altitude measurements greater than 8000 feet, indicating good regulatory compliance.[10]

The physiologic impact of exposure to cabin altitudes of 8000 to 10,000 feet largely relates to the decreased ambient pressure (which prompts a decrease in the partial pressure of oxygen) and to the increasing volume of trapped gas as ambient pressure decreases (Boyle's law [see Chapter 107]). As discussed later (see "Transmission of Respiratory Infections During Air Travel"), a third effect of exposure to the environment of a commercial airliner cabin relates to the internal cabin air quality.

The impact of high altitude on inspired oxygen tension (P_{IO_2}) is defined by the equation:

$$P_{IO_2} = F_{IO_2} \times (P_{atm} - P_{H_2O})$$

where P_{atm} is the atmospheric pressure (760 mm Hg at sea level and 564 mm Hg at 8000 feet).

In the context of the oxyhemoglobin dissociation curve (see Chapter 10), the consequence of this hypobaric hypoxia at a cabin altitude of 8000 feet is that the in-flight P_{IO_2} is generally between 108 and 122 mm Hg and the arterial P_{O_2} of healthy individuals is generally 53 to 75 mm Hg (7–10 kPa). In general, exposure to the hypobaric hypoxia of commercial air travel causes the sea-level oxygen saturation to decrease by 3–4%, maintaining values of 90% or above (arterial P_{O_2} of 60–70 mm Hg)[4] in most healthy individuals.

Physiologic responses to the hypobaric hypoxia of commercial air flight include increased minute ventilation, increased heart rate, increased cardiac output to maintain tissue oxygen delivery, and pulmonary vasoconstriction to preserve ventilation-perfusion matching and oxygenation. With regard to the impact of cabin altitude exposure on gas density (Boyle's law), gas trapped in confined spaces (e.g., in noncommunicating bullae, within congested middle ear) expands, causing sequelae like pneumothorax and ear pain. Consider the progressive distension of a bag of potato chips or the cover on a container of yogurt as the plane ascends.[11] At a constant temperature, 1 L of gas at sea level expands to approximately 1.3 L at 1500 m and to approximately 1.4 L at 2450 meters (≈8000 feet).[4,12] The expected changes in gas volume and pressure at various altitudes are summarized in Table 106.1.[13] Such gas expansion can also pose risks for wound dehiscence in patients who have recently undergone surgery[14] or vision loss after intraocular gas injections. Cabin humidity is characteristically low (10–20% humidity), which may prompt dryness and precipitate bronchospasm in asthmatics.

The effects of hypobaric hypoxia and of decreased gas density during commercial air travel are relatively mild among normal subjects. For example, an in-flight study of 84 passengers with no history of lung disease showed a reduction in oxygen saturation from 97% (93–100%) at ground level to 93% (85–98%) during commercial flights.[15] Another study of 502 normal subjects exposed in a hypobaric chamber simulating a cabin altitude of 8000 feet showed an approximately 4.4% reduction in oxygen saturation with mild discomfort after 3 to 9 hours of exposure.[16]

In contrast, individuals with lung disease may experience more profound degrees of desaturation during commercial

air flight. A study of 18 individuals with COPD exposed to a mean cabin altitude of 6000 feet for a 5 hour, 40 minute flight showed that saturation declined at rest by 6% (i.e., from 96 ± 1% to 90 ± 4%) and declined further during walking in the aisle of the plane (to 87 ± 4%).[17] Similarly, Kelly et al. reported that in 13 subjects with COPD, oxygen saturation decreased from 95 ± 1% at ground level to 86 ± 4% in flight at rest, worsening further to 78 ± 6% with in-flight activity.[18]

The risks of gas expansion in noncommunicating cavities (e.g., in bullae in COPD or in lung cysts in lymphangioleiomyomatosis) pose risk for in-flight pneumothorax (see "Lymphangioleiomyomatosis" later).

Notwithstanding these physiologic effects, commercial air travel is generally well tolerated among patients with lung disease who are evaluated for travel; the prevalence of in-flight medical events among such individuals is relatively low. Coker et al. prospectively studied 616 patients with lung disease who planned air travel on a commercial airline.[19] The cohort included patients with COPD (39%), diffuse parenchymal lung disease (23%), asthma (15%), bronchiectasis (8%), sarcoidosis (7%), and various other conditions (8%). In the subset of 431 travelers who completed air travel, fewer than 1% required in-flight medical assistance and, although 18% reported some respiratory difficulty in flight, there were no flight diversions or deaths.

Table 106.2 Assessing Fitness to Fly

FEATURES WARRANTING PREFLIGHT ASSESSMENT
History of significant respiratory symptoms associated with air travel
Severe COPD (FEV_1 <30% predicted), bullous lung disease, difficult-to-control asthma, cystic fibrosis, or pulmonary tuberculosis
Severe restrictive disease (vital capacity <1 L), including interstitial lung, chest wall, and respiratory muscle disease, especially if associated with hypoxemia and/or hypercapnia
Presence of a comorbidity with conditions made worse by hypoxemia (e.g., cerebrovascular disease, cardiac disease, pulmonary hypertension)
Recent pneumothorax or within 6 weeks of an acute respiratory illness
Risk of, or previous history of, venous thromboembolism
Preexisting requirement for oxygen, continuous positive airways pressure or ventilator support
CONTRAINDICATIONS TO AIR TRAVEL
Infectious tuberculosis
Ongoing pneumothorax with persistent air leak
Major hemoptysis
Need for supplemental oxygen at sea level with requirements exceeding 4 L/min

Modified from Shrikrishna D, Coker RK. Managing passengers with stable respiratory disease planning air travel: British Thoracic Society recommendations. *Thorax*. 2011;66(9):831-833.

PREFLIGHT ASSESSMENT OF FITNESS TO FLY

The goal of preflight assessment is to optimize the patient's fitness to fly and to minimize the risk of an in-flight adverse medical event. Careful assessment registers the prospective traveler's comorbidities, past experience of flying, and oxygenation, particularly as estimated in flight.

The first consideration regards which travelers require preflight assessment for fitness to fly. Table 106.2 lists the clinical features that warrant preflight assessment according to the *British Thoracic Society* (BTS).[20]

Practice varies in assessing patients for air travel. In the series reported by Coker et al.,[19] tests used in preflight assessment included pulse oximetry, pulmonary function tests, high-altitude simulation testing, and walking tests. Assessment of oxygenation, usually by pulse oximetry, is almost universally employed.

ASSESSING FOR IN-FLIGHT HYPOXEMIA IN PATIENTS WITH RESPIRATORY DISEASE

Once the traveler is deemed fit to fly, assessing for in-flight hypoxemia should proceed. Various methods for assessing in-flight hypoxemia have been reported, including predictive equations (frequently based on sea-level pulse oximetry oxygen saturation, pulmonary function test results, health status, and sometimes arterial blood gases) and *high-altitude simulation testing* (HAST; also called hypoxic challenge testing or hypoxia altitude simulation testing). HAST is performed most commonly by having a patient breathe a hypoxic gas mixture (i.e., normobaric hypoxia testing) and, less frequently, by hypobaric chamber testing (i.e., hypobaric hypoxia testing). Predictive equations have largely fallen out of favor, based on poor accuracy in determining in-flight oxygenation,[21,22] leaving HAST as the primary method for assessing in-flight hypoxemia when indicated (Fig. 106.1; see also following text).

The purpose of HAST is to assess whether the traveler's in-flight arterial Po_2 will be less than 50 mm Hg or oxygen saturation 85% or less, which are the threshold values at which supplemental in-flight oxygen is generally recommended. The Aerospace Medical Association sets this threshold at arterial Po_2 55 mm Hg.[23] Hypobaric chamber testing is perhaps the gold standard for HAST but is not commonly available and usually reserved for treating diving-related injuries or osteonecrosis, or for training personnel who will perform tasks at high altitudes. Thus, HAST usually involves administering a hypoxic gas mixture and assessing oxygenation. Inhaling a gas mixture of 15.1% oxygen (fractional concentration of oxygen in inspired gas 0.151) simulates the oxygen concentration at a cabin altitude of 8000 feet. The HAST is generally performed by providing 15.1% oxygen through a mouthpiece or tight-fitting face mask with a nonrebreathing valve for 20 minutes or, alternatively, placing the patient in a body box chamber containing 15.1% oxygen for the same duration. An infrequently used alternative involves using a 35% Venturi mask with nitrogen as the driving gas because this produces an oxygen mixture of 15–16%. Estimates of oxygenation using HAST with 15.1% oxygen compare favorably with hypobaric chamber testing in identifying patients who need in-flight oxygen.[24] Also, the results of normobaric hypoxic high-altitude simulation correlate well, though imperfectly, with actual in-flight measurements ($r = 0.84$).[18,21,22] However, the effects of in-flight hypobaric conditions (i.e., lower gas density and

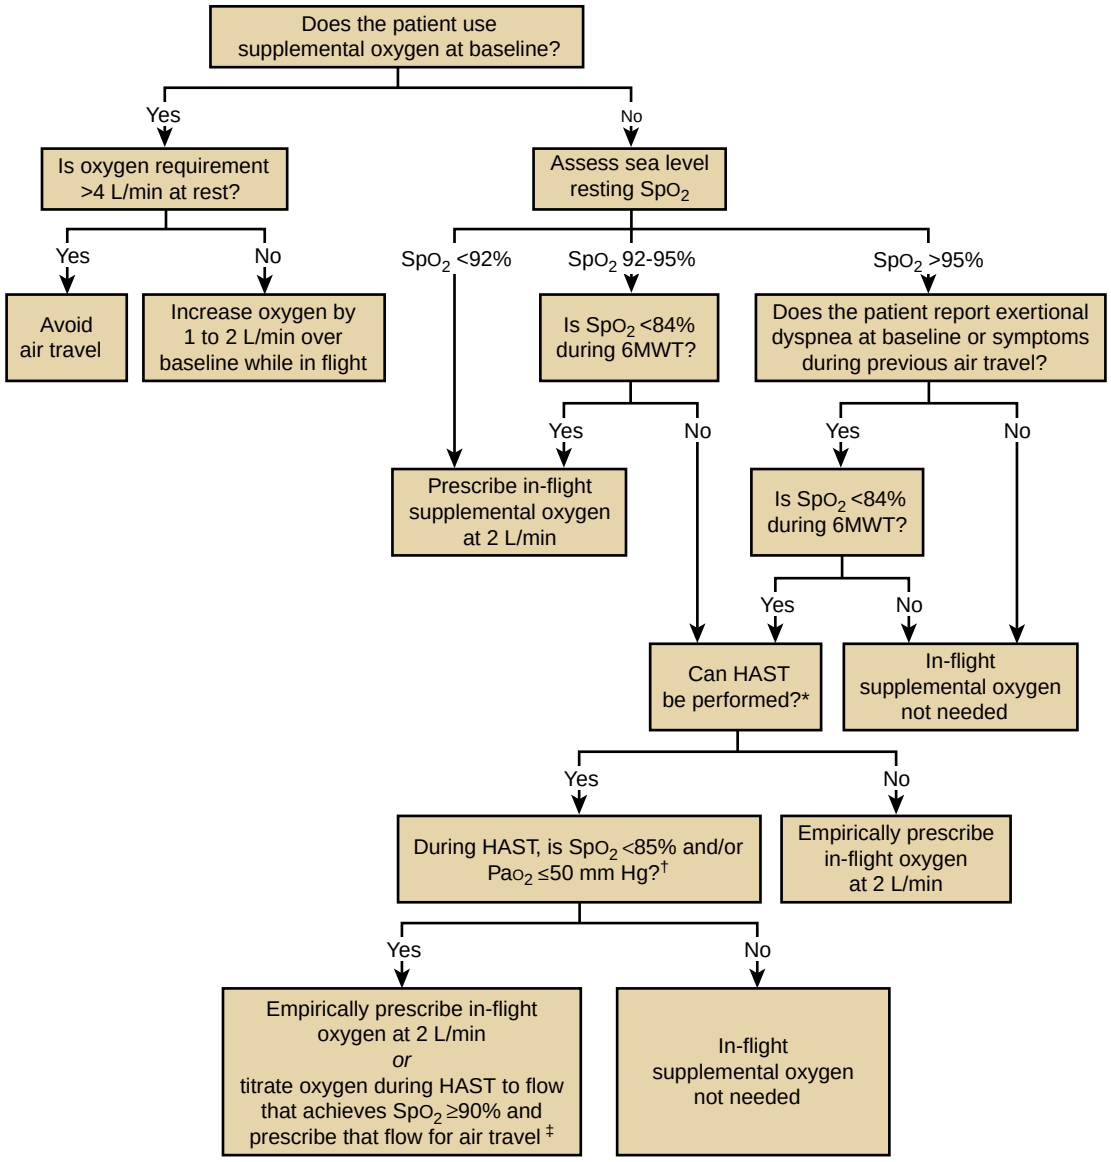

Figure 106.1 Algorithm to assess the need for supplemental oxygen before commercial air travel. The testing algorithm portion that applies to patients who are not on supplemental oxygen demonstrated 100% sensitivity and 80% specificity in identifying the need for in-flight oxygen when tested prospectively in 50 COPD patients.[25] Thus, using this algorithm allowed accurate identification of all patients who needed supplemental in-flight oxygen and led to overprescription of oxygen in 20% of the patients who did not need supplemental in-flight oxygen.[25,26] *HAST may not be covered by medical insurance. †During *high-altitude simulation testing* (HAST), assessment of arterial Po_2 is preferred if available. ‡HAST is less accurate than hypobaric testing but is more readily available. Determining exact supplemental oxygen requirement during HAST is technically difficult and may underestimate supplemental oxygen requirements. 6MWT, 6-minute walking test; Spo_2, oxygen saturation measured by a pulse oximeter. (Data from Stoller JK. Evaluation of patients for supplemental oxygen during air travel. In: Post TW (Ed). *UpToDate*. Waltham, MA: UpToDate; Akerø A, Christensen CC, Edvardsen A, Ryg M, Skjønsberg OH. Pulse oximetry in the preflight evaluation of patients with chronic obstructive pulmonary disease. *Aviat Space Environ Med*. 2008;79(5):518-524; and Edvardsen A, Akerø A, Christensen CC, Ryg M, Skjønsberg OH. Air travel and chronic obstructive pulmonary disease: A new algorithm for pre-flight evaluation. *Thorax*. 2012;67[11]:964-969.)

increased volume) can only be assessed preflight by using a hypobaric chamber.

ASSESSING FOR IN-FLIGHT HYPOXEMIA IN PATIENTS NOT USING SUPPLEMENTAL OXYGEN AT SEA LEVEL

The BTS guidelines suggest using pulse oximetry at sea level to identify individuals who need further assessment for supplemental in-flight oxygen.[20] These recommendations can be summarized as follows:

1. Patients with oxygen saturation less than 92% can forego further testing and be prescribed in-flight oxygen
2. Patients with oxygen saturation 92–95% at rest should undergo further testing with a *six-minute walk test* (6MWT) and HAST.
3. Patients with oxygen saturation greater than 95% do not require further testing and can usually fly without oxygen supplementation.

The first criterion (i.e., travelers whose sea-level oxygen saturation is less than 92% can forego further testing

and should be prescribed supplemental in-flight oxygen) is based on the observation that 83% of patients under this threshold desaturate during HAST.[25] Similarly, although a sea-level oxygen saturation greater than 95% generally predicts an in-flight arterial Po_2 greater than 50 mm Hg, thereby obviating the need for supplemental in-flight oxygen, up to 23% of patients with resting oxygen saturation greater than 96% still experience desaturation during HAST.[19] Therefore, clinicians should have a low threshold for ordering HAST for those patients with sea-level oxygen saturation greater than 95% who have additional risk factors for desaturation, such as a low diffusion capacity or previous respiratory symptoms during air travel.

Because exercise desaturation and aerobic capacity also correlate with in-flight desaturation, algorithms[26,27] for preflight assessment of in-flight hypoxemia often combine multiple tests to determine the need for in-flight supplemental oxygen (Fig. 106.1). The algorithm in Figure 106.1 suggests the following conclusions:

- Patients who have a sea-level oxygen saturation greater than 95% and 6MWT oxygen saturation 84% or greater can fly without oxygen and do not require further testing.
- Patients with a resting oxygen saturation less than 92% and those with a resting oxygen saturation 92–95% plus a 6MWT oxygen saturation less than 84% should be prescribed supplemental oxygen for air travel without further testing.
- Patients with a resting oxygen saturation of 92–95% and a 6MWT oxygen saturation 84% or greater or with a resting oxygen saturation greater than 95% and a 6MWT oxygen saturation less than 84% require further assessment with a HAST.

When the use of supplemental oxygen is recommended in flight, an oxygen flow rate (using continuous flow) of 2 L/minute generally suffices to assure adequate in-flight oxygenation.[28] A second study[29] suggested that providing oxygen in flight at 1.5 L/minute sufficed to reverse hypoxemia at a cabin altitude of 10,000 feet. Alternatively, the flow rate for supplemental in-flight oxygen can be determined by administering oxygen through nasal cannula during the HAST, though this method may underestimate the in-flight oxygen need.

PRESCRIBING SUPPLEMENTAL IN-FLIGHT OXYGEN IN PATIENTS ALREADY USING SUPPLEMENTAL OXYGEN AT SEA LEVEL

Patients who use long-term supplemental oxygen can fly with appropriate precautions. Management of their underlying lung disease should be optimized, of course. While the required liter flow for in-flight oxygen can be assessed during normobaric hypoxic testing (i.e., by administering oxygen through nasal cannula), supplemental oxygen needs are often underestimated in this manner.[30] As a practical matter, either doubling the sea-level flow rate during flight[20] or increasing the sea-level supplemental oxygen flow rate by 1 to 2 L/min will usually suffice. Notably, it is generally accepted that an oxygen requirement greater than 4 L/min at rest at sea level is a contraindication to air travel.

PROVIDING SUPPLEMENTAL IN-FLIGHT OXYGEN

The U.S. Department of Transportation's "Nondiscrimination on the Basis of Disability in Air Travel" final rule permits the use of respiratory assist devices, including POCs, on airplanes.[31] To date, over 20 POCs have been approved by the FAA.[32] The list will likely evolve over time, and prospective travelers are encouraged to check the FAA website for current approvals.[31] Passengers who need in-flight oxygen and who travel frequently may elect to buy a POC that is FAA approved. Travelers are also strongly encouraged to check with the individual airline to ensure their device is approved by the airline for use onboard their aircraft. For those not wishing to purchase a POC, the devices are often available for rental by the airlines and/or durable medical equipment providers. Notably, because POCs differ in performance characteristics, the weight, battery life, and maximum possible oxygen output should be considered when choosing a suitable system.[33] Furthermore, if the traveler plans to use pulsed flow during travel, preflight testing to determine the required in-flight flow rates should be performed with the traveler's own device.

Personal oxygen cylinders cannot be brought on board airplanes and are now very infrequently used for providing in-flight oxygen with the advent of POCs. When needed, oxygen cylinders that can be secured are sometimes provided by the airlines with prenotification by the traveler and with physician authorization. Charges may apply and may vary widely across carriers[34] so that the traveler hoping to use an oxygen cylinder should become well informed. Because policies regarding the use of in-flight oxygen and allowable equipment vary and may be confusing, various resources are available to the traveler in helping to plan air travel. In addition to individual airline sites, Table 106.3 lists websites available to help the traveler.

Clinicians should be aware of several practical considerations for the traveler and must be prepared to discuss these issues with their patients who are preparing to fly. These are summarized in Table 106.4.

CONSIDERATIONS REGARDING SPECIFIC LUNG DISEASES AND AIR TRAVEL

In addition to the challenges of traveling with COPD, other lung diseases pose specific issues for the affected air traveler. Table 106.5 summarizes some of these considerations according to BTS guidelines. Specific considerations are discussed below.

PNEUMOTHORAX

Pneumothorax may develop during air travel because of the expansion of gas at increasing altitude (see Table 106.1).

Table 106.4 Checklist for the Clinician to Inform Patients About Traveling on Commercial Airlines with Supplemental Oxygen

1. Inform the airline carrier of their intent to bring a POC on board at least 2 weeks in advance.
2. Ensure that the POC satisfies the maximum weight and dimension criteria of the airline and is labeled appropriately.
3. Inform the TSA official during screening about the POC.
4. Carry a clinician's letter or TSA notification card that describes the underlying lung condition, prescribed oxygen liter flow, instructions on when oxygen would be used (continuously or only during flight).
5. Ensure that the particular POC is approved for use in flight by the U.S. Federal Aviation Administration and the airline.
6. Bring enough batteries for the POC to last 1.5 times the anticipated duration of flight.
7. Ensure that arrangements for supplemental oxygen have been made at the destination if a delivery means other than a POC is planned (e.g., oxygen cylinders).
8. Bring adequate supplies of prescribed medications and medications that may be needed for emergencies (e.g., bronchodilators, corticosteroids, antibiotics). Such medications should be brought in the traveler's carry-on, and NOT in checked bags.
9. Identify local health care providers and hospitals at the destination in case of need.

POC, portable oxygen concentrator; TSA, Transportation Security Administration.

Though potentially dangerous during air travel, pneumothorax during air travel has only infrequently been reported. For example, an early FAA report documented only one confirmed and one suspected episode of pneumothorax among 2322 in-flight emergencies over 2 years.[35] No instance of pneumothorax was reported among a series of 431 travelers with lung disease[19] or in a series of 11,920 in-flight medical emergencies managed by a physician-directed medical communication center.[2] In-flight pneumothorax is also fortunately exceedingly rarely fatal; in a review of in-flight pneumothorax by Hu et al.,[36] only a single instance of fatal in-flight pneumothorax (in a woman with tension pneumothorax complicating treated tuberculosis) was reported. (see also Chapter 110).

Pneumothorax risk during air travel relates to the expansion of air within noncommunicating air collections, commonly present in cystic lung diseases or when mucous plugging obstructs communicating airways.[36–38] Specific conditions predisposing to pneumothorax include subpleural blebs,[39] *lymphangioleiomyomatosis* (LAM),[40–42] Birt-Hogg-Dubé syndrome,[43] congenital pulmonary airway malformation,[44] and bullae due to emphysema,[45] alpha$_1$-antitrypsin deficiency,[46] and tuberculosis.[47] As reviewed in Table 106.5, the BTS guidelines proscribe travel for patients with current pneumothorax and recommend delaying travel for 1 to 2 weeks following complete resolution of a prior pneumothorax.

Table 106.5 Disease-Specific Considerations and Recommendations for Air Travel

Condition	Considerations	Recommendation
Asthma and COPD	Hypoxemia, acute bronchospasm, or infectious exacerbation	■ Patients to use own bronchodilator (brought aboard with the traveler).
Bronchiectasis	Hypoxemia, infectious exacerbation	■ Nebulized bronchodilators and antibiotics not generally required.
Cancer	Risks related to anemia, neutropenia, pleural effusion	■ Correct symptomatic anemia before travel. ■ Pleural effusions should be drained before air travel, assuring no pneumothorax post-thoracentesis. ■ Travel within 24 hours of a seizure is not permitted.
Cardiac disease	Hypoxemia and tachycardia can increase risk	■ Patients who are status post percutaneous cardiac intervention may fly 2 days postprocedure. ■ Patients at low risk after STEMI (e.g., restored TIMI grade 3 flow, absence of heart failure and arrhythmia), can fly after 3 days; others may travel after 10 days unless awaiting revascularization or device implantation. ■ Patients may fly within 14 days following coronary artery bypass graft but should undergo a chest radiograph to exclude a pneumothorax. ■ Patients with unstable angina should not travel and those with stable angina at rest should be discouraged from traveling.
Cystic fibrosis	Hypoxemia	■ Assessment of in-flight oxygenation is recommended.
Interstitial lung disease	Hypoxemia	■ Careful preflight assessment is needed. ■ Supplemental oxygen is often needed, both in flight and on arrival at high-altitude destinations.
Neuromuscular disease and kyphoscoliosis	Hypoxemia	■ Assess for the need for in-flight supplemental oxygen.
Obstructive sleep apnea	CPAP machine use, availability of power to run machine	■ CPAP machines should travel with the passenger in the cabin; a physician's letter is often required. ■ Because A/C power may not be available in flight, dry cell batteries should be used. Also, ensure availability of a power source on arrival. ■ Avoid alcohol and sedatives during travel.
Pneumothorax	Risk of barotrauma and gas expansion	■ Patients with a closed pneumothorax should not travel (with the exception of a loculated or chronic localized air collection that has been carefully assessed). ■ Patients who have had a pneumothorax must have a chest radiograph to confirm resolution before flight; another 7 days should ideally elapse before air travel. ■ In the case of traumatic pneumothorax, a delay of 2 weeks after full resolution is recommended. ■ Definitive surgical intervention via thoracotomy is likely to be entirely successful and permit travel; intervention by video-assisted thoracoscopic surgery is also expected to have a high success rate but is not deemed definitive. ■ Patients undergoing other forms of pleurodesis are unlikely to experience recurrence, but consequences of recurrence precipitated by flight could be severe (e.g., tension pneumothorax); the risk of recurrence is higher in those with coexisting lung disease and does not fall for at least 1 year. Those not undergoing definitive treatment of prior pneumothorax may wish to consider alternative forms of travel. ■ Patients with lymphangioleiomyomatosis should be apprised of increased risk of pneumothorax and that any symptoms of chest pain or dyspnea should preclude travel until fully evaluated.
Pulmonary arteriovenous malformation	Hypoxemia, embolization	■ Considered to be at moderate or high risk of venous thromboembolism. ■ Patients with prior venous thromboembolism or history of embolic stroke should receive a single dose of low-molecular weight heparin before the flight. ■ If embolization is planned, defer long-haul travel until embolization is complete.
Pulmonary hypertension	Worsened pulmonary hypertension with hypoxemia	■ Those in NYHA class I or II can often fly without oxygen. ■ Those in NYHA class III or IV should receive in-flight oxygen. ■ Severe pulmonary hypertension is a contraindication to air travel.
Sinus and middle ear disease	Risks of barotrauma	■ Adults at risk for sinus or middle ear barotrauma should receive an oral decongestant before travel and a nasal decongestant during flight before descent. ■ Women in the first trimester of pregnancy may use intranasal steroids instead of topical decongestants. ■ Passengers who develop sinus barotrauma after flying should receive topical and oral decongestants, analgesics, and oral steroids. ■ Antibiotics are advised if bacterial sinusitis is thought to be the trigger and antihistamines if allergic rhinitis is suspected. ■ Symptoms and signs of barotrauma should have resolved before flying again; this usually takes a week and may take up to 6 weeks.

CPAP, continuous positive airway pressure; NYHA, New York Heart Association; STEMI; ST-segment elevation myocardial infarction; TIMI, Thrombolysis in Myocardial Infarction.

In general, the rarity of severe consequences of in-flight pneumothorax suggest that conservative in-flight management is appropriate (i.e., using supplemental oxygen and advising descent as soon as feasible). In the rare instance of suspected tension pneumothorax in flight, needle placement to decompress the pneumothorax may be needed. Given the scarcity of appropriate tools and the rarity of fatalities, needle decompression or use of improvised chest tubes should be reserved as a last resort and in the context of high diagnostic certainty.

LYMPHANGIOLEIOMYOMATOSIS

LAM (see Chapter 97) poses a significant (55–73%) lifetime risk of pneumothorax[48] and the risk associated with air travel has been estimated. Specifically, prevalence estimates of pneumothorax risk during air travel range from 1.1–2.8% per flight.[40–42] These rates are twofold higher than those observed in LAM patients traveling by car and the risk ratio of suffering a pneumothorax within 30 days of air travel in LAM patients was 3.6 (95% confidence interval, 1.4 to 7.5) compared to nonflight periods.[42] The BTS guidelines (see Table 106.5) specifically advise LAM patients with chest pain or dyspnea to seek evaluation in order to exclude a pneumothorax before traveling by air.

BIRT-HOGG-DUBÉ SYNDROME

Birt-Hogg-Dubé syndrome is also strongly associated with spontaneous pneumothorax; up to 24–38% of Birt-Hogg-Dubé patients experience a pneumothorax, with a 75% chance of recurrence.[49] The prevalence of pneumothorax within 30 days of air travel has been estimated to be 0.12–0.63% per flight.[43,49]

PULMONARY HYPERTENSION

Travelers with *pulmonary hypertension* (PH; see Chapter 83) may be particularly prone to the adverse effects of hypoxic pulmonary vasoconstriction.[50] Specifically, acute increases in pulmonary artery pressure may predispose to right ventricular failure and hemodynamic compromise.[51] Indeed, mean systolic pulmonary artery pressure, as estimated by echocardiography, increased by 6 mm Hg in healthy air travelers.[52] In a patient with increased hypoxic pulmonary vasoconstriction (due to a mutation leading to Chuvash polycythemia), an inflight echocardiogram showed the mean systolic pulmonary artery pressure increased by 15 mm Hg in response to a relatively mild reduction in oxygen saturation to 96% during a commercial flight.[53] Notwithstanding these theoretical risks, air travel has generally not been associated with severe complications in PH patients.[54,55] In a survey of 179 air travelers with PH,[54] most of whom were in *New York Heart Association* (NYHA) class II and III functional class (86%) and receiving pH-specific monotherapy or combination therapy (78%), only 20 (11.2%) of the travelers reported having in-flight symptoms (i.e., dyspnea, peripheral edema, exhaustion, palpitations or chest pain). Seven of the 20 required medical attention, and one patient required intensive care unit admission. In a second study of 34 air travelers,[55] most of whom (62%) carried a diagnosis of pulmonary arterial hypertension and who were receiving combination therapy (59%), nine (26%) of the patients experienced oxygen desaturation with a nadir oxygen saturation of 74%. Thirteen patients (38%) became symptomatic with chest pain, shortness of breath, and lightheadedness, but there were no severe complications or medical emergencies during the flights. The presence of pulmonary hypertension should increase the clinician's suspicion of hypoxemia in-flight and prompt HAST testing.[56]

Finally, the BTS guidelines recommend providing oxygen to PH patients in NYHA functional classes III and IV. Air travel is contraindicated for patients in NYHA functional class IV who also have risk factors for poor outcomes (e.g., decompensated right heart failure, recurrent syncope due to pulmonary hypertension). Because functional class correlates poorly with in-flight symptoms or in-fight medical events in travelers with PH, some authors have proposed assessing right ventricular dysfunction by performing an echocardiogram during the HAST in susceptible patients.[52]

SICKLE CELL DISEASE AND TRAIT

Patients with sickle cell disease are at risk for vaso-occlusive crises, commonly manifested as acute pain syndromes (e.g., acute chest syndrome [see Chapter 127], dactylitis), splenic infarction (usually early in life), acute ischemic stroke, priapism, and sequelae (e.g., pulmonary hypertension, hyposthenuria). Because air travel poses a risk of sickling prompted by hypoxemia, patients with sickle cell disease are at risk for such events during altitude exposure and air travel.

While patients with sickle cell trait and related hemoglobinopathies (e.g., HbSC, HbS, β- thalassemia) are characteristically less clinically affected, the hypoxic stress of altitude exposure and air travel can similarly precipitate vaso-occlusive events in these individuals, most commonly reported as splenic infarction, though instances of pulmonary infarction have been described as well.[57–60] A 2005 series summarized 47 cases of splenic infarction in patients with sickle cell trait at high altitude.[57] Compared to those with sickle cell disease, those with sickle cell trait have a distinctive in-flight risk for splenic infarction. Those with HbSS characteristically have infarcted spleens early in life, thereby averting further risk of acute splenic syndrome.[60] In contrast, those with sickle trait may only experience splenic infarction in the context of a hypoxic insult such as travel to high altitude or air travel. Indeed, many reports document workup for a previously unsuspected hemoglobinopathy prompted by in flight acute abdominal pain, diagnosed as splenic infarction.

Although sickle cell disease and sickle trait are not discussed in the otherwise comprehensive BTS guidelines on managing patients with stable respiratory disease who are planning air travel, preflight assessment should include eliciting a family history of hemoglobinopathy and diagnostic suspicion in appropriate ethnic groups. The clinician must be aware that the prevalence of sickle trait in the United States is 7–10% among African Americans and 0.046% in other persons.[60] For patients known or found to have sickle cell disease or trait, altitude exposure should be avoided if possible but, if required, such patients should likely receive supplemental oxygen in flight and be counseled to avoid dehydration and exertion at altitude.

RESTRICTIVE LUNG DISEASE DUE TO CHEST WALL DEFORMITY, NEUROMUSCULAR DISEASE, OR INTERSTITIAL LUNG DISEASE

Patients with restrictive ventilatory impairment are particularly prone to desaturation in flight, and physicians should have a low clinical threshold for performing HAST in such individuals. Christensen et al.[61] and Bandyopadhay et al.[62] showed that patients with interstitial lung disease and kyphoscoliosis with adequate oxygenation at sea level (i.e., oxygen saturation >95%), frequently desaturated during HAST. Like oxygen saturation, other clinical parameters (e.g., dyspnea score, lung function variables, and arterial blood gases at rest) failed to predict desaturation with HAST. Not surprisingly, patients with interstitial lung disease tend to desaturate more profoundly with light activity at altitude.[63] Though actual published experience with patients with restrictive chest disease who have flown is scant, reported experience suggests that such patients generally tolerate air travel well. For example, one small study of six patients with pulmonary fibrosis traveling for lung transplant evaluation showed no adverse in-flight events.[63,64]

CYSTIC FIBROSIS

Because improved care of patients with *cystic fibrosis* (CF [see Chapter 68]) has greatly enhanced life expectancy, such patients are traveling more frequently. Although patients with CF have been reported to desaturate frequently below the 50 mm Hg (6.6 kPa) threshold during hypobaric hypoxia,[65–68] symptoms during air travel or with exposure to simulated cabin altitudes are uncommon.[66,67] Furthermore, in contrast to what is observed in COPD patients, sea-level pulse oximetry or arterial Po_2 correlate poorly with either simulated or actual in-flight hypoxemia in CF.[66,67] The discordance between sea-level oxygenation and in-flight oxygenation has led some[67,68] to advocate using other parameters (e.g., FEV_1, looking for a threshold value less than 50% predicted; or cardiopulmonary exercise testing) or to perform HAST during light exercise in preflight assessment of patients with CF.

TRANSMISSION OF RESPIRATORY INFECTIONS DURING AIR TRAVEL

Features of the cabin environment alter the risk of transmitting airborne infection. On the one hand, cabin air is both filtered and recirculated with approximately 20 to 30 complete air exchanges within the cabin hourly. Furthermore, high-efficiency particulate air filters on commercial airplanes can effectively remove droplet nuclei carrying bacteria, fungi, and viral particles. Also, the side-to-side and top-to-bottom air circulation in the cabin prevents front-to-back airflow, thereby limiting dissemination of airborne particles between the rows.[69] On the other hand, seating within airliners places passengers in close proximity, thereby increasing the risk of transmitting respiratory infection through contact, large droplet transmission, or fomites.[69] As possible evidence of transmission during air travel, Coker et al. noted that among 468 patients with lung disease who flew, the prevalence of patients seeking medical treatment rose from 9% before the flight to 19% within 4 weeks of returning[19]; 65% of these patients received antibiotic treatment for lower respiratory tract infections.

Evidence that infection can be transmitted during air travel comes from the experience with tuberculosis. Available reports show that there were skin test conversions among fellow passengers traveling with an infected individual.[69–74] The overall risk of tuberculosis transmission has been estimated to be 0.1–1.3% among travelers on long-haul (>8 hours) flights.[75] World Health Organization and BTS guidelines both recommend against air travel by patients who have "infectious tuberculosis."[76] Patients who have completed 2 weeks of antituberculous therapy and who are not suspected to have drug-resistant tuberculosis are permitted to travel. On the other hand, those with multidrug-resistant tuberculosis or extremely or totally resistant tuberculosis are advised not to fly until two consecutive sputa are culture negative. Physicians should report to the local public health authority when they become aware of a patient with potentially infectious tuberculosis who intends to travel or has traveled within the previous 3 months. Airline companies are also instructed to deny boarding to persons known to have infectious or potentially infectious tuberculosis.

Incidents of viral transmission during air flight also underscore the risk of infection transmission during air travel. Instances of transmitting influenza,[77–79] coronavirus associated with the severe acute respiratory syndrome, and measles have been documented.[80,81] Sitting within two rows of an index passenger for more than 8 hours has been associated with an elevated risk of infection.[69] However, in one instance, patients who were sitting as far as seven rows from the index passenger contracted the severe acute respiratory syndrome.[80] Several reports now implicate aircraft transmission of COVID-19,[81a,81b] although, in one report,[81c] the virus was not transmitted to any of the 25 travelers sitting within two rows of a COVID-19–infected traveler or to the cabin crew. Prudence dictates that air travel by COVID-19–positive individuals should be avoided.

Measles transmission during commercial air travel has also been reported.[82,83] Due to the resurgence of measles and several severe cases associated with travel, the CDC recommends the MMR vaccine to travelers who have not been vaccinated or who have never had measles.[84]

RISK OF VENOUS THROMBOEMBOLISM DURING AIR TRAVEL

Air travel increases the risk for *venous thromboembolism* (VTE), presumably related to stasis from immobility and or hypercoagulability associated with air travel. Estimates from three major airports in Europe[85–88] suggest that the overall prevalence of VTE associated with air travel is 0.2 to 0.4 per 1 million travelers, though these rates may underestimate the actual prevalence because they do not account for connecting passengers or admission to hospitals other than the hospital from which the report originated and they lacked a systematic method for ascertaining VTE.

The main pathophysiologic factor predisposing to VTE during air travel is thought to be immobility. In this context, flights of distances greater than 5000 km have been associated with a much higher prevalence of VTE compared to shorter flights (1.5 cases per million vs. 0.01 cases/million).[85] A meta-analysis of VTE during travel[88] suggests that the risk of VTE increases by 26% for every additional 2 hours of air travel. The odds ratio for VTE in this study was 2.2 (confidence interval, 1.4 to 3.2). Furthermore, patients who are seated in non-aisle seats appear to be more prone to VTE.[89,90] Though attribution is unclear, VTE during air travel has been dubbed "economy class syndrome" due to the cramped nature of the coach class, which may further limit mobility compared to seating in other classes.[89]

Preflight assessment of risk for VTE should include consideration of other risk factors for VTE. In one series,[87] 87% of patients whose VTE was associated with air travel had other risk factors for VTE. On the basis of this risk, the BTS[20] recommends that travelers who are at moderately increased risk of VTE (e.g., family history of VTE, past history of provoked VTE, thrombophilia, body mass index greater than 30 kg/m^2, height greater than 1.90 m or less than 1.16 m, significant medical illness within the previous 6 weeks, cardiac disease, immobility, pregnancy or estrogen therapy, and postpartum patients within 2 weeks of delivery) should wear below-knee elastic compression stockings during flight. For travelers who are at higher risk of VTE (i.e., past history of unprovoked VTE, major surgery or trauma within 6 weeks, or active malignancy), the BTS recommends a preflight prophylactic dose of low-molecular-weight heparin with consideration of full therapeutic anticoagulation on an individual basis. After an episode of VTE, the BTS recommends deferring travel for 4 weeks or until complete clinical and symptomatic resolution of proximal deep vein thrombosis.

PRACTICAL ASPECTS OF ASSESSING THE PATIENT WITH PULMONARY SYMPTOMS IN FLIGHT

Most (≈70%)[91] in-flight medical complaints are managed by the cabin crew without the request for or intervention by an onboard medical professional. However, requests for assistance have been estimated at a frequency of 1 per 14,000 passengers.[91] When a request for assistance for an onboard medical professional is expressed, some practical information regarding available equipment and medications as well as the implications of serving as a Good Samaritan[92] is useful.

By FAA mandate, every commercial airliner must carry at least one first-aid kit (and sometimes multiple kits depending on the aircraft passenger capacity) as well as an automated external defibrillator.[93] The minimal contents of the onboard medical kit are dictated by FAA directives and are presented in Table 106.6. In our experience, passengers on the plane will have a variety of medications in their onboard luggage, so that if a need arises for a medication not available in the medical kit, asking the cabin crew to announce the need for a specific medication may be productive.

When deciding to respond to the cabin crew's request for medical help, it is useful to understand the culture and implications of stepping forward as "the doctor on the plane" when such requests come. While there is no clear legal requirement to step forward, there is a moral and professional obligation to serve a patient in need. By U.S. law, Good Samaritan provisions protect passengers who offer medical assistance in flight from liability

Table 106.6 Federal Aviation Administration Required Contents of an Onboard Medical Kit

Content	Number
Sphygmomanometer	1
Stethoscope	1
Airways, oropharyngeal (3 sizes): 1 pediatric, 1 small adult, 1 large adult or equivalent	3
Self-inflating manual resuscitation device with 3 masks (1 pediatric, 1 small adult, large adult or equivalent)	1 with 3 masks
CPR mask (3 sizes), 1 pediatric, 1 small adult, 1 large adult, or equivalent	3
Intravenous administration set:	
Tubing with 2 Y-connectors	1
Alcohol sponges	2
Adhesive tape, 1-inch standard roll adhesive	1
Tape scissors	1 pair
Tourniquet	1
Saline solution, 500 mL	1
Protective nonpermeable gloves or equivalent	1 pair
Needles (2–18, 2–20, 2–22 gauge, or sizes necessary to administer required medications)	6
Syringes (1–5 mL, 2–10 mL, or sizes necessary to administer required medications)	4
Analgesic, nonnarcotic, tablets, 325 mg	4
Antihistamine tablets, 25 mg	4
Antihistamine injectable, 50 mg (single-dose ampule or equivalent)	2
Atropine, 0.5 mg, 5 mL (single-dose ampule or equivalent)	2
Aspirin tablets, 325 mg	4
Bronchodilator, inhaled (metered-dose inhaler or equivalent)	1
Dextrose, 50%/50 mL injectable (single-dose ampule or equivalent)	1
Epinephrine 1:1000, 1 mL, injectable, (single-dose ampule or equivalent)	2
Epinephrine 1:10,000, 2 mL, injectable (single-dose ampule or equivalent)	2
Lidocaine, 5 mL, 20 mg/mL, injectable (single-dose ampule or equivalent)	2
Nitroglycerin tablets, 0.4 mg	10
Basic instructions for use of the drugs in the kit	

CPR, cardiopulmonary resuscitation.

as long as no gross negligence or willful misconduct was conducted. Gross negligence is defined as deviating from the care "ordinarily to be expected from a person undertaking his particular role and professing to have his particular skills."[91] The standard is usually met when other physicians attest that they would have acted similarly, with the caveat that there is clear understanding that care provided in the limited medical environment of an airplane cabin is very different than that provided in a medical facility. Overall, experience suggests that it is extremely rare for a passenger to take action against a Good Samaritan.[91]

One of the issues embedded in serving as a health professional in response to a request from the cabin crew is whether the patient's condition requires diversion of the plane to an earlier landing. Airlines generally have on-ground support with algorithms that help the captain determine the need for diversion. While the captain of the plane bears ultimate responsibility for the decision to divert, the input of a physician attending to the patient in flight may be sought.

SUMMARY

Assessing prospective air travelers with lung disease requires careful consideration of the effect of the special environmental conditions at cabin altitude on respiratory disease. Most of the available experience and hence current recommendations are based on travelers with COPD, particularly in the assessment of in-flight oxygen requirements. Thus, there is a need for studies that clarify the steps in assessing patients with other lung diseases who intend to travel by air. Awareness of the specific risks associated with conditions like pneumothorax, VTE, and pulmonary hypertension, among others, is critical for determining fitness to fly and for optimal preflight assessment.

Fortunately, recognizing that available experience with in-flight medical emergencies is biased somewhat by a "healthy traveler" effect, the frequency of in-flight medical events, diversions of aircraft, and in-flight mortality is very low in the context of the expansion of air travel and the increasing availability of air travel for individuals with pulmonary disease. As the science of preflight assessment improves, clinicians must continue to exercise careful expertise in balancing the appetite for travel with awareness of travel-related risks, with the goal of optimizing patients' ability to travel safely.

Key Points

- Consideration of special environmental conditions in the aircraft cabin, particularly hypobaric hypoxia, is key to the preflight evaluation of patients with lung disease.
- In particular, a preflight clinical assessment should be performed for all patients with history of respiratory symptoms during previous air travel, severe COPD, bullous lung disease, asthma, cystic fibrosis, severe restrictive lung disease, comorbidities that could worsen with hypoxemia, history of pneumothorax or venous thromboembolism, and preexisting need for oxygen.
- A high-altitude simulation test combined with a 6-minute walk test can identify patients with COPD who will need in-flight oxygen and provide guidance for other respiratory conditions.
- Patients with diffuse cystic lung disease with chest pain or dyspnea should seek evaluation in order to exclude a pneumothorax before traveling by air.
- The presence of pulmonary hypertension should increase the clinician's suspicion of hypoxemia in flight and prompt performance of a high-altitude simulation test.
- Preflight assessment of risk for *venous thromboembolism* (VTE) should include consideration of other risk factors for VTE. Patients with acute VTE should defer air travel for at least 4 weeks or until complete clinical resolution. Patients with risk factors and previous VTE history should be considered for prophylactic measures, including compression stockings and, for those with highest risk, prophylactic or full anticoagulation.
- Patients with active tuberculosis should not travel by air. In patients with established or suspected coronavirus infection (e.g., severe acute respiratory syndrome, COVID-19), air travel should be avoided.

INTRODUCTION

Diving and work in compressed air have provided an occupational exposure to hazardous environments for nearly 400 years. In the 1600s, diving bells were first reported in use for marine salvage. These inverted metal containers provided a pocket of trapped air to transport divers to depth and also served as a reservoir of compressed air in between excursions from the bell while at depth. In 1670, Sir Robert Boyle first described decompression disease in animal studies and, in the 1800s, surface-supplied diving gear emerged to provide new degrees of freedom for divers and also new risks. *Decompression sickness* (DCS) in humans was first reported in the mid-1800s, in coal miners and caisson workers who worked in underground cavities pressurized to keep out water.[1] The term "the bends" originated from the distinctive forward-bent posture caused by joint symptoms from DCS and was first used to describe construction workers for the Eads and Brooklyn Bridges in 1870.[2] Around the turn of the 20th century, seminal work by Paul Bert, J.S. Haldane, and E.W. Moir helped lay the groundwork for modern dive medicine.

Since the advent of the *self-contained underwater breathing apparatus* (scuba), diving has become a recreation for millions of individuals around the world. Any physician may encounter a recreational, scientific, or occupational diver for an illness related to diving or for medical clearance for diving. Occasionally, a physician may be confronted with an acute medical emergency related to diving, such as DCS, arterial gas embolism, or drowning. This chapter reviews fundamental diving physiology and disorders and provides the basis for initiating treatment, seeking consultation, or furthering education in this evolving area of environmental medicine.

ADAPTATION TO DIVING

Many air-breathing animals have developed remarkable adaptations for diving and survival underwater. Several aquatic species are among the most hypoxia-tolerant animals on the planet. Diving Weddell seals (*Leptonychotes weddellii*) have reached arterial partial pressures of oxygen (P_{O_2}) of 18 mm Hg during 27-minute dives and may reach much lower partial pressures during dives known to last nearly 45 minutes.[3] Some diving mammals (Cuvier's beaked whales [*Ziphius cavirostris*]) reach depths of nearly 3000 m on dives lasting more than 2 hours.[4] Many diving mammals have evolved to possess many specialized adaptations, including larger spleens, high mass-specific blood volumes (>200 mL/kg in sperm whales as compared with 70 mL/kg in human adults), enhanced myoglobin structure and distribution, anatomic adaptations of the middle ear and sinuses, and specialized intrathoracic anatomy.[5,6] Contrary to popular belief, increasing total lung capacity is not a uniform adaptation in diving mammals. In fact, some of the deepest-diving whales have markedly small lung volumes relative to body mass. Certain diving mammals (e.g., seals) even exhale before diving. Collectively, these adaptations and adaptive behaviors aim to increase oxygen delivery to the vital organs, minimize potentially fatal consequences of absorbing compressed oxygen or nitrogen at extreme depths, and avoid painful compression or rupture of air-filled structures.[7]

All diving mammals, including humans, have developed a characteristic physiologic response to diving. Triggered by apnea and cold-water facial immersion, this dive response includes bradycardia (which decreases oxygen consumption), peripheral vasoconstriction (which shunts blood to vital organs), and splenic contraction (which increases

circulating red blood cell volume). The Japanese Ama pearl divers and Bajau ("sea nomads") of Southeast Asia are two of the human populations most closely studied for their diving adaptations.[8] The Bajau, who spend up to 60% of their working day breath-holding at depths of more than 70 m, have genetic adaptations that increase spleen size and modify their human diving reflex.[9,10] Studies of competitive free divers have demonstrated increased total lung capacity, splenic volume, hypercarbia tolerance, and hemoglobin concentration.[11]

EQUIPMENT AND TECHNIQUES

BREATH-HOLD DIVING

Humans breath-hold dive (i.e., dive on a breath-hold without a source of compressed gas) for many reasons, including recreation, hunting, and competition. The record for the deepest competitive breath-hold dive without fins is 125 m, and the longest static apnea (breath-holding in a pool) is 11 minutes 35 seconds. Many breath-hold divers use no equipment or little more than a face mask and weight belt. In some competitive breath-hold diving categories, divers may use weighted sleds, specialized fins, and inflatable ballasts to assist with more rapid descent and ascent at depths of more than 200 m. Although hypocapnia decreases respiratory drive and increases breath-hold duration, extreme voluntary hyperventilation is ill advised and can lead to loss of consciousness or death during breath-hold diving, in part because of decreased cerebral blood flow.

OPEN-CIRCUIT SCUBA

The most commonly used breathing equipment in diving is the open-circuit scuba. This equipment (Fig. 107.1) consists of a metal cylinder containing compressed air connected to a pressure regulator that lowers pressure from the tank to ambient pressure. This device delivers ambient-pressure air only when inhalation is initiated and allows flow that matches the minute ventilation of the diver. Expired air is released directly into the surrounding water. A typical scuba cylinder can supply approximately 2100 L of air at the surface (1 *atmospheres absolute* [ATA]). This volume is reduced in direct proportion to ambient pressure. For example, at a depth of 66 *feet of seawater* (fsw) or 3 ATA pressure, the effective volume of air is decreased to 700 L. With a minute ventilation of 20 L/min, this air supply would last 105 minutes at the surface but only 35 minutes at 66 fsw. Open-circuit scuba is usually limited to depths less than 200 feet because of limited air supply, nitrogen narcosis, and oxygen toxicity, as discussed in subsequent sections.

REBREATHER DIVING

There are several types of rebreather devices, including the oxygen rebreather, semiclosed-circuit rebreather, and closed-circuit rebreather. The closed-circuit rebreather apparatus uses a carbon dioxide absorbent to remove exhaled carbon dioxide and replenishes the circuit with oxygen (Fig. 107.1 and eFig. 107.1). Inert gas is conserved

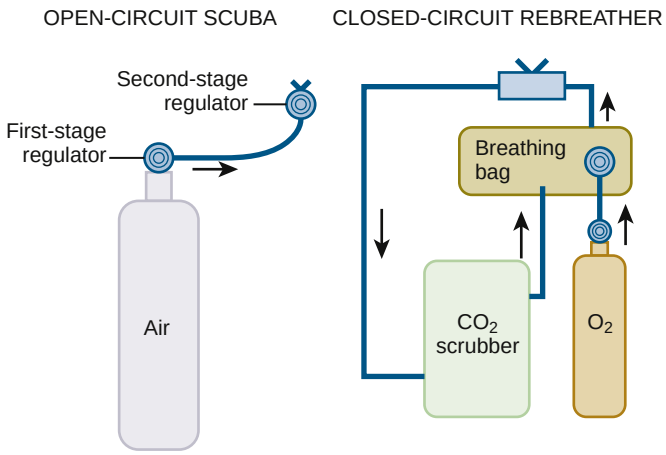

Figure 107.1 Two types of self-contained diving systems. The open-circuit scuba is the system commonly used for recreational diving. Air is exhaled into the surrounding water. Rebreather systems allow exhaled breathing gas to be recycled through a *carbon dioxide* (CO_2) scrubber, mixed with additional breathing gas, and returned to the diver through a breathing bag. Breathing gas is replenished through a demand valve. This system can be used with 100% *oxygen* (O_2) or oxygen-enriched air mixtures. Other forms of rebreather systems contain separate oxygen and inert gas supplies, and mixing is controlled with a small computer to maintain a constant oxygen partial pressure.

by recycling the exhaled gas through the carbon dioxide absorbent and then adding oxygen before the gas is rebreathed. Little gas is released into the surrounding water, exhaled heat and humidity are conserved, oxygen can be carried in volumes adequate for several hours of exposure, and gas consumption is independent of depth. Although use of rebreather diving in the past was confined to commercial and military divers, these systems are now becoming popular among technical divers and even some recreational divers. Dive incidents related to the use of closed-circuit rebreathers are often related to failures in equipment setup or maintenance, incomplete carbon dioxide scrubbing, and higher-risk dive profiles (i.e., dives lasting many hours at extreme depths) among many other factors.[12]

SURFACE-SUPPLIED EQUIPMENT

Commercial diving often uses surface-supplied gas equipment. The diver breathes compressed air or other gas mixtures pumped from the surface to a helmet or mouthpiece regulator. Diving helmets may be attached at the collar to a diving suit so that air can flow from the helmet into the suit to maintain an air layer for thermal protection. Modern systems contain a demand mask built into the helmet.

Surface-supplied equipment is also encountered in recreational diving although, contrary to popular belief, it has the same risks as scuba diving with tanks. Improvised surface-supplied setups (i.e., hookah diving support systems) are often used by fishermen in low- and middle-income countries. These setups can expose divers to unsafe gas pressures or hazardous gases (e.g., compressed carbon monoxide from an air compressor intake placed near the

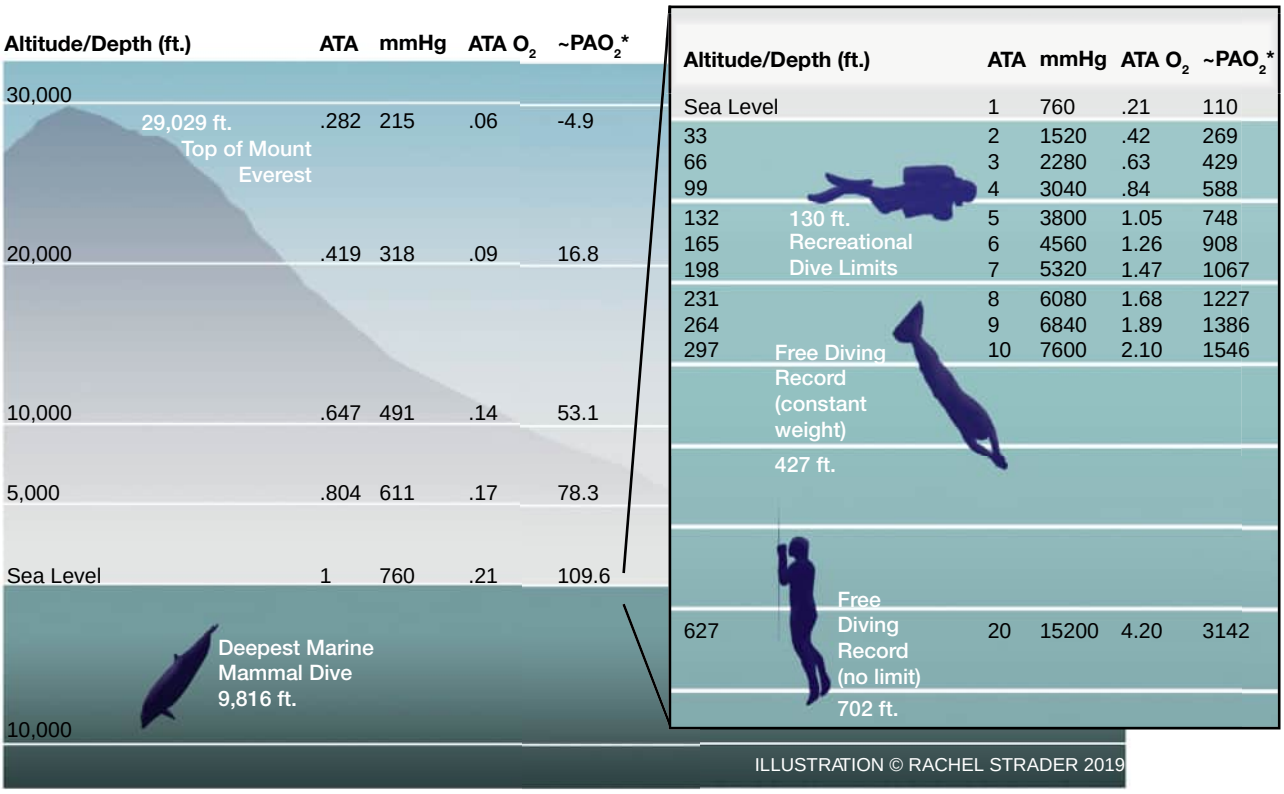

Figure 107.2 Pressure equivalents for high altitude and for depth. Relatively small changes in depth cause large changes in pressure, whereas extremely large changes in altitude are required for significant pressure changes. For example, descending from sea level to 33 *feet of seawater* (fsw) doubles the pressure, whereas one must ascend to nearly 16,000 feet to halve atmospheric pressure. *Hypothetical *alveolar partial pressure of oxygen* (P_{AO_2}) if breathing 21% inspired fraction of oxygen, assuming an *arterial partial pressure of carbon dioxide* (P_{aCO_2}) of 40 mm Hg and an ambient temperature of 15°C. Of note, at high altitude, climbers demonstrate profound hyperventilation to less than 10 mm Hg arterial P_{CO_2}, thus resulting in significantly higher alveolar P_{O_2} values than the hypothetical values shown if arterial P_{CO_2} remained at 40 mm Hg. ATA, atmospheres absolute. (Copyright Rachel Strader, 2019.)

engine exhaust).[13] Divers who use these setups in resource-constrained settings frequently experience decompression illness as a result of long dive durations and erratic depth changes.

SATURATION DIVING

The term *saturation* refers to a steady state when the diver remains at depth and is no longer increasing absorption of inert gas. Saturation divers delay surfacing and thus delay their decompression. In other words, divers who have reached saturation can remain at depth for a prolonged period of days or weeks without affecting the amount of time they must eventually spend decompressing (i.e., slowly ascending to release inert gas burden) at the end of the dive. To facilitate this, divers reach a working depth and then remain at that depth for the duration of the work period by entering a living habitat. In between working excursions, the living habitat may remain at depth or be transported to the surface; in either scenario, the habitat remains compressed at the working depth pressure. This type of diving was originally developed in the 1960s to facilitate dam repairs, although at present it is most commonly used in the open-water oil industry. These divers routinely spend 2 weeks "at depth," although saturation periods of up to 1 month have been reported. Once saturation is reached, the decompression time (which may last days or weeks) is the same for any duration of dive.

DISORDERS RELATED TO DIVING: NOMENCLATURE

Golding and coworkers[14] described disorders related to supersaturation of inert gases in tissues with subsequent bubble formation as *decompression sickness*. DCS is categorized as type I and type II: (1) type I, a nonsystemic (peripheral) form that involves only the skin, bones, and joints and (2) type II, a systemic form of DCS that involves the central nervous system, the lungs, the inner ear, and the circulation.

Arterial gas embolism (AGE) and pulmonary barotrauma are additional diving-related disorders with pathophysiology distinct from DCS. Francis and Smith[15] suggested the term *decompression illness* to describe DCS and AGE collectively because these disorders can be clinically difficult to separate and require similar therapy.[15] In fact, numerous dive-related disorders are attributable to the effects of dissolved gases or barotrauma.

PRESSURE EFFECTS AND BOYLE'S LAW

RELATION OF GAS VOLUME TO DEPTH

The terms *atmosphere* (ATM) and *atmosphere absolute* (ATA) both refer to pressure; ATM, however, can be used as a relative term (33 fsw depth is equivalent to 1 ATM of water), whereas ATA is always used for absolute pressure (33 fsw depth is equivalent to 2 ATA, or 1 ATM at the surface with an additional 1 ATM from the 33 fsw). *Atmosphere absolute* is the term used in this chapter and is always used for equations, such as Boyle's law. Boyle's law states that if the temperature of a fixed mass of an ideal gas is kept constant, then volume and pressure are inversely related. Consequently, when the pressure is doubled, the volume is reduced to one-half of the original volume. Because the gas volume is proportional to the absolute pressure, the volume change from the surface (1 ATA) to 33 fsw (2 ATA) is greater than the change from 33 (2 ATA) to 66 fsw (3 ATA).

Underwater exposure results in increasing pressure directly proportional to depth. Of note, relatively small changes in depth cause large changes in pressure, whereas extremely large changes in altitude are required for significant pressure changes. For example, descending from sea level to 33 fsw doubles the pressure, whereas one must ascend to nearly 16,000 feet to halve atmospheric pressure (see Fig. 107.2).

The relationship between pressure and depth holds true for all exposures to pressure, including hyperbaric chambers, pressurized tunnels, and caissons used for underwater construction. As depth increases, the diver breathes gas of increased density. Increased depth and pressure also lead to decreases in gas volume and increases in the amount of gas dissolved in body tissues. When human breath-hold divers descend to approximately 99 fsw, the lungs compress to a point at which the divers become negatively buoyant and actually sink.

BAROTRAUMA

Barotrauma is the most common medical problem in scuba diving and refers to tissue damage resulting from pressure imbalances in the body. Barotrauma may happen both during descent (pulmonary barotrauma, ear barotrauma, sinus barotrauma, and mask squeeze) and during ascent (pulmonary barotrauma, and AGE, alternobaric vertigo, reverse squeeze, gastrointestinal barotrauma).

Barotrauma of Descent

Pulmonary Barotrauma in Breath-Hold Divers. Lung barotrauma or lung squeeze is a rare consequence of breath-hold diving. This complication is not found in scuba divers and others breathing with an open glottis. When a breath-hold diver descends to such a depth that total lung volume is reduced to less than residual volume, transpulmonic pressure can exceed intra-alveolar pressure, thus leading to transudation of fluid and pulmonary edema, as well as rupture of pulmonary capillaries with bleeding. A diver with a total lung volume of 6000 mL and a residual volume of 1200 mL could theoretically dive to a maximum depth of 132 fsw (5 ATA) before developing lung squeeze. However, breath-hold divers have dived much deeper, probably because of central pooling of blood that would reduce the residual volume. Lung barotrauma can also take place at shallow depths and may be associated with inadequate training.[16,17]

Sinus Barotrauma. When a sinus orifice is occluded, pressure within the sinus becomes negative with respect to ambient pressure, and mucosal blood vessels become engorged and eventually rupture. Pain over the affected sinus during descent and epistaxis on ascent are usual symptoms. Headache following a dive may indicate sphenoid sinus barotrauma. Treatment includes topical and oral decongestants and maneuvers to drain the affected sinus. Persistence of blood in the sinus may result in bacterial sinusitis. This complication can be prevented by avoiding diving when the nasopharynx is congested and by using decongestants. If a maxillary sinus orifice is occluded, the maxillary branch of the trigeminal nerve may be compressed during ascent and result in infraorbital paresthesias that usually resolve in 2 to 3 hours.[22]

Less Common Forms of Barotrauma. Facial barotrauma ("mask squeeze") happens in the area of distribution of the diving mask. Facial edema, ecchymoses, and conjunctival hemorrhages can be noted after diving. The disorder is self-limiting, and no treatment is needed. Retro-orbital hematoma with diplopia or visual loss is a rare complication of face mask barotrauma.[23,24] A diver with suspected orbital hemorrhage must be referred for emergency imaging and ophthalmologic consultation.

Tooth barotrauma leading to severe toothache results when air pockets under fillings or areas of decay become compressed on descent. Careful dental work prevents this disorder.[25]

Barotrauma of Ascent

Pulmonary Barotrauma and Arterial Gas Embolism. The gas that a diver breathes is pressurized to the ambient pressure so that pressure gradients from the breathing supply to the airways are not altered as the diver descends. Behnke[26] and Polak and Adams[27] described lung barotrauma in ascending divers that resulted from inadequate exhalation during ascent and overexpansion of the lungs. Later studies provided further insight into mechanisms and prevention of pulmonary barotrauma.[28] Breath-holding during ascent from a depth as shallow as 4 fsw can result in fatal pulmonary barotrauma.[29] Patients with pulmonary blebs, cysts, or air trapping caused by obstructive disease can experience rupture on ascent that leads to pneumothorax.

PATHOPHYSIOLOGY. Under experimental conditions, transpulmonary pressures (i.e., the difference between intratracheal and intrapleural pressures) of 95 to 110 cm H_2O are sufficient to disrupt the pulmonary parenchyma and force gas into the interstitium.[28] Extra-alveolar gas can migrate through perivascular sheaths to cause mediastinal emphysema and pneumomediastinum. Less frequently, air can be vented through the visceral pleura and thereby cause a pneumothorax.[28] Gas can also dissect into the retroperitoneum and into the subcutaneous tissues of the neck. Extra-alveolar gas can pass into ruptured blood vessels, travel to the left side of the heart, and enter the arterial circulation as gaseous emboli, commonly referred to as an AGE. The

Middle Ear Barotrauma. Middle ear barotrauma is the most common diving-related disorder.[18] The middle ear undergoes barotrauma when the eustachian tube is blocked during descent, and the middle ear space cannot equilibrate with increasing ambient pressure. The tympanic membrane is displaced inward and may rupture. The middle ear may fill with blood from engorged mucous membranes. Infection and hearing loss are complications. Symptoms during descent include pain in the affected ear that increases with depth. Relief of pain without proper equalization of the middle ear pressure usually indicates that the tympanic membrane has ruptured. Cold water entering the middle ear when the tympanic membrane ruptures may cause vertigo because of unilateral vestibular stimulation. Late complications include bacterial otitis media, serous otitis media, and chronic tympanic membrane perforation.[18] In rare cases of middle ear barotrauma, the facial nerve is injured by the increased pressure, and temporary facial paralysis results.[19] A modified Valsalva maneuver is commonly used to equilibrate middle ear pressure. Because middle ear barotrauma causes edema and hemorrhage in the middle ear, equalization is usually impossible to achieve until healing is complete. The presence of middle ear barotrauma usually prohibits diving until it is resolved.

Inner Ear Barotrauma. Inner ear barotrauma may develop on descent in divers who perform a forceful Valsalva maneuver to equalize middle ear pressure. When the eustachian tube is blocked, middle ear pressure becomes progressively more negative relative to ambient pressure.[18,20] When a Valsalva maneuver is then performed, intrathoracic pressure, central venous pressure, spinal fluid pressure, and inner ear pressure rise to a level greater than ambient pressure, thereby increasing the gradient between the inner ear perilymph and the middle ear. Membranes separating the inner and middle ear (e.g., round and oval windows) can rupture, and perilymph can then leak from the inner to the middle ear.

Symptoms include vertigo, nausea, vomiting, tinnitus, and loss of hearing on the affected side. Severity may vary, and some divers report hearing loss, tinnitus, or vertigo only after diving.

Treatment varies from conservative therapy to surgical repair of ruptured membranes. Vertigo and nausea can be treated with benzodiazepine medications. Tinnitus and reduced hearing may become chronic, particularly without treatment. Divers who exhibit clinical evidence of inner ear barotrauma with intact round and oval windows may have a pressure injury to the organ of Corti and the vestibular system.[21]

dissemination of gas bubbles throughout the arterial circulation can injure numerous organs, including skeletal muscle, which may be manifest by a rise in serum creatine kinase level.[30]

Pulmonary barotrauma usually results from a rapid or uncontrolled ascent to the surface, typically caused by running out of air, panic, or sudden development of uncontrolled positive buoyancy. Occult lung disease may contribute to unexplained barotrauma and AGE.[31] Epidemiologic studies have not demonstrated a significant relationship between asthma and an increased risk for pulmonary barotrauma.[32]

Clinical Manifestations of Arterial Gas Embolism. The brain is commonly involved with AGE events. Within minutes of surfacing, the diver can experience loss of consciousness, hemiplegia, stupor, confusion, seizures, vertigo, visual disturbances, sensory changes, or headache. Circulatory collapse can result from filling of the heart and great vessels with air; these individuals may be unresponsive to cardiopulmonary resuscitation and advanced life support measures.[33] Most individuals with AGE fully recover if they are promptly recompressed.[34] Because AGE can lead to loss of consciousness on surfacing, a diver may aspirate water and drown. Chest radiographs may show a pattern of diffuse pulmonary edema (Fig. 107.3).[35] A report of 31 patients with cerebral air emboli from diving included the following findings: 25% demonstrated pneumomediastinum, 10% had subcutaneous emphysema, 6% had pneumocardium, 3% had pneumoperitoneum, and 3% had pneumothorax. Laboratory evaluation may show an elevated hematocrit level reflecting plasma extravasation from endothelial injury or an elevated creatine kinase from injury to skeletal muscle.[30,36]

Mediastinal emphysema is generally associated with mild substernal pain that may be exacerbated by inspiration, coughing, or swallowing. Unless massive, this condition is not usually associated with circulatory compromise.

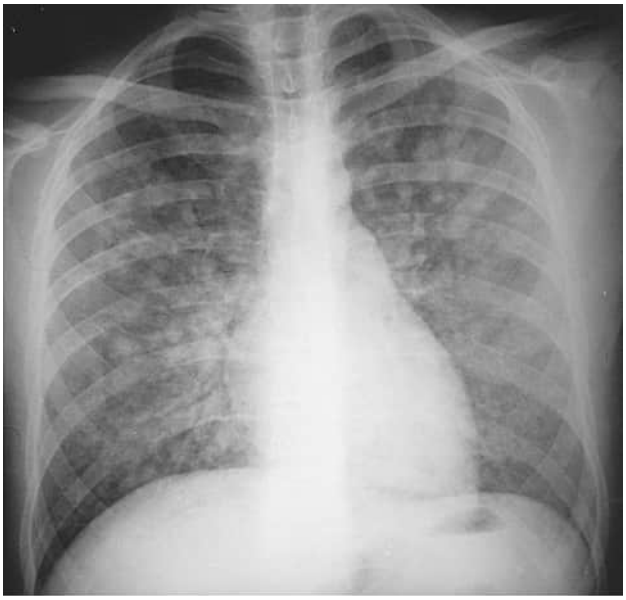

Figure 107.3 Chest radiograph from a diver who survived drowning. The diffuse pulmonary edema pattern is suggestive of water aspiration.

On physical examination, a crunching sound synchronous with the cardiac cycle may be auscultated (the Hamman sign). The chest radiograph confirms the diagnosis, and no treatment is usually necessary.

Subcutaneous emphysema may cause swelling and crepitus in the base of the neck and supraclavicular fossa, sore throat, hoarseness, and dysphagia. Radiographs may be helpful in detecting subtle cases, but *computed tomography* (CT) scans are more sensitive and can be useful to confirm the diagnosis of barotrauma in doubtful cases. Treatment of AGE requires recompression in a hyperbaric chamber (see later).

Alternobaric Vertigo. Vertigo may develop on ascent when the reduction of middle ear pressure is not uniform in both ears. The pressure imbalance causes differential stimulation of the labyrinths and results in what is called *alternobaric* vertigo. Although usually only transient, the sensation of vertigo rarely may persist for 1 to 2 hours after diving and gradually disappears without therapy. Symptoms are similar to labyrinthitis and can include nausea, vomiting, and generalized malaise. Some divers may be particularly susceptible to alternobaric vertigo if they have had previous injury or infection of the labyrinths. In susceptible individuals, use of moderate doses of antihistamines or decongestants may prevent symptoms. The disorder must be differentiated from vestibular DCS (see "Decompression Sickness"). The differential diagnosis of alternobaric vertigo may also include motion sickness, benign positional paroxysmal vertigo, and inner or middle ear barotrauma, among other potential conditions.

Reverse Squeeze. Inability to release increasing pressure from the middle ear during ascent can result in high-pressure translocation or rupture of the tympanic membrane, also known as reverse squeeze. This may result if the eustachian tubes are blocked by mucus or from incomplete equalization during descent. Reverse squeeze may be manifest by pain, sensation of ear fullness, or vertigo on ascent.

Gastrointestinal Barotrauma. Gastrointestinal barotrauma results when air enters the stomach during diving because of faulty breathing apparatus or air swallowing. On ascent, the expanding air distends the stomach or intestine. Gastric distention can occlude the esophageal-gastric junction or cause stomach rupture and pneumoperitoneum.[37] Divers with previous gastric surgery may be prone to gastric air trapping.[38]

DISSOLVED INERT GAS EFFECTS AND HENRY'S LAW

INERT GAS KINETICS

Gases dissolve in tissues, fats, and water according to Henry's law: $Q = c \times P$, where a solubility coefficient (c), and the partial pressure of the gas (P), determine the quantity (Q) of dissolved inert gas. Increased ambient pressure elevates the dissolved gas concentration in the tissues. The partial pressure of the gas and the solubility of the gas in the specific tissue (Table 107.1) determine dissolved gas content. Although Henry's law determines the amount of gas in the tissue, there is a finite time required for equilibrium to be achieved. Factors that affect the rate of entry

include blood flow and the rate of diffusion of gases into the tissue. During a dive, tissue gas concentration follows an asymptotic curve. When ambient pressure is reduced on ascent, similar kinetics control the washout of inert gas from tissues. Different body compartments have different gas exchange characteristics.[39] The lungs, blood, and brain equilibrate quickly relative to tissues that have high capacity for inert gas uptake or have relatively poor perfusion (e.g., ligaments, cartilage, and fat).

Because most diving is of short duration (i.e., minutes to hours) and shallow (i.e., in depths less than 200 feet), only a few tissue compartments reach equilibrium according to Henry's law. Divers can return to the surface from these short-duration dives by following a schedule of ascent based on depth and time.[39] When diving exposure is long enough, all tissues reach equilibrium at the new ambient pressure and are fully saturated with inert gas. Divers can spend prolonged periods (weeks) under pressure, with all tissues saturated at the increased pressure, without harm (see "Saturation Diving").[40]

INERT GAS SUPERSATURATION IN TISSUES

When the diver ascends after breathing pressurized gas, tissues become supersaturated with gas. When the degree of supersaturation becomes excessive, dissolved gas leaves solution and form free gas. Studies suggest that blood microparticles may act as a nidus for bubble formation in blood.[41]

DECOMPRESSION SICKNESS

On decompression, dissolved gases can change phase to the gaseous form.[42] DCS is the disorder caused by damage to organs and tissues as a result of free gas production.

Bert[43] first described the pathophysiology of DCS. Subsequent investigators in the early 20th century concluded from autopsies on divers and caisson workers that DCS is caused by free gas in blood and tissues.[44] Based on the volume and location of free gas on autopsy, they were able to explain the variety and severity of the symptoms. Paralysis resulted from free gas in the spinal cord, cerebral dysfunction was thought to result from free gas in the brain, and dyspnea was associated with free gas in the pulmonary circulation. Muscle and joint pain may be the result of free gas in ligaments, fascia, periosteum, marrow, or nerve sheaths.

Hallenbeck and colleagues,[45] as well as subsequent studies,[46,47] described a multitude of effects of free gas in blood and tissues, including platelet activation, intravascular coagulation, plasma leakage from the intravascular space, activation of the inflammatory cascade, hemoconcentration, and hypovolemia. More recent studies have outlined the role of cellular and biochemical changes involving inflammation, oxidative stress, and vascular endothelial cell activation in the pathogenesis of DCS.[41,48,49] The inflammatory response increases fluid leakage into the interstitial tissues of the systemic and pulmonary vascular beds.[50] Venous gas emboli are commonly present before overt symptoms of DCS appear (Fig. 107.4 and Video 107.1).[51,52]

Risk Factors

The use of ultrasonography for intravascular bubble detection has provided insight into the presence of bubbles following diving.[53] Many divers demonstrate venous gas emboli but no manifestations of DCS (see Fig. 107.4). The concept of a threshold or dose-response effect has been postulated, wherein a certain volume of free gas is needed to produce the clinical disorder, and divers with lesser amounts are asymptomatic.[54] Venous bubbles in asymptomatic divers and aviators are associated with increased risk for developing DCS after diving or altitude exposure.[55,56]

Symptoms can be prevented by keeping the degree of supersaturation lower than a certain level. The body can be considered as a set of tissue compartments with different rates of gas uptake and elimination.[57] Although these tissues do not represent discrete anatomic structures, they provide a convenient means for understanding the kinetics of inert gas exchange. In most decompression schedules, stops during ascent are selected to avoid excess

Table 107.1 Characteristics of Inert Gases*

Gas	Molecular Weight	Lipid Solubility†	Water Solubility	Narcotic Potential‡
Helium	4	0.015	0.009	0.23
Neon	20	0.019	0.009	0.28
Hydrogen	2	0.036	0.018	0.55
Nitrogen	28	0.067	0.013	1.00
Argon	40	0.140	0.026	2.32

*Solubility of the various gases in lipid is related to their narcotic potential. Helium is the least, and argon the most, narcotic gas in the list.
†Expressed as gas volume/solute volume at 1 bar.
‡Values relative to nitrogen.
Modified from Bennett PB: Inert gas narcosis and HPNS. In: Bove AA, ed. *Bove and Davis' Diving Medicine*. 4th ed. Philadelphia: Saunders; 2004:225–240.

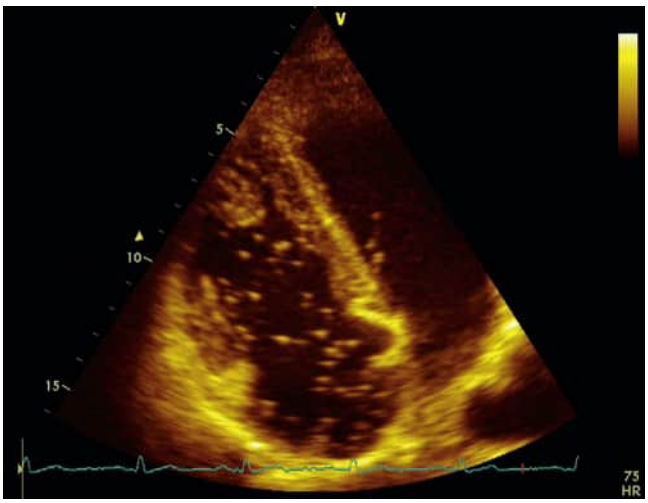

Figure 107.4 Gas bubbles after diving with compressed gases. Gas bubbles are commonly seen in the right side of the heart (*left*) after diving with compressed gases. Although the number of bubbles correlates with risk of decompression sickness, the presence of bubbles does not always imply decompression sickness and clinical symptoms (see also Video 107.1). (From Germonpré P, Papadopoulou V, Hemelryck W, et al. The use of portable 2D echocardiography and 'frame-based' bubble counting as a tool to evaluate diving decompression stress. *Diving Hyperb Med.* 2014;44:5–13.)

supersaturation in tissues with specific gas-exchange rates (Fig. 107.5). Decompression procedures are well defined for air and other mixtures of nitrogen and oxygen; helium and oxygen; nitrogen, helium, and oxygen (trimix); hydrogen and oxygen; and a few rare earth gases such as argon and neon.

There are several additional known risk factors for developing DCS, including exercise and temperature during decompression, decreased physical conditioning, lack of expertise, patent foramen ovale, older age, and subsequent exposure to high altitude (i.e., low pressure). Breath-hold divers can develop DCS from frequent repetitive dives.[58] Carturan and colleagues[59] found correlations among bubble formation, increased age, and decreased physical condition in sport divers. Klingmann and coworkers[60] reported an increased incidence of DCS in novice divers compared with more experienced divers. Blatteau and associates[61] reported that age and depth of dive exposure increased DCS risk. The presence of a *patent foramen ovale* (PFO) may be associated with a twofold to fourfold increase in the risk for DCS and is discussed further in the subsequent section on fitness to dive.[62] Risk for DCS in divers with PFOs may be mitigated by implementing conservative dive strategies.[63]

Exposure to altitudes higher than 18,000 feet (0.5 ATA) may increase the risk of DCS because of supersaturation of inert gases dissolved at atmospheric pressure.[64] Divers can develop free gas in tissues when going to higher altitude after diving even though they follow established protocols for ascent from depth to the surface. It is common for sport divers to fly in commercial aircraft (about 8000 feet equivalent altitude) shortly after diving, although special consideration is warranted and minimum preflight post-dive waits are recommended. Diving while at high altitude (e.g., in high-altitude lakes) can be more complex because of lower atmospheric pressure and the increased relative difference between atmospheric and underwater pressures.

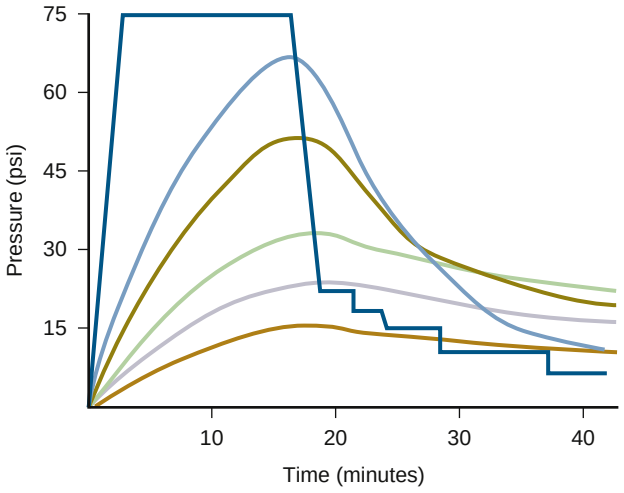

Figure 107.5 Theoretical nitrogen gas concentrations. Theoretical nitrogen gas concentrations are expressed in units of pressure for an exposure of 75 psi (5.1 ATA) following the depth-time profile indicated by the straight line. Curves are shown for five theoretical tissue compartments with different rates of gas exchange. Gas concentrations increase to different levels in the different tissue compartments during exposure to pressure. When pressure is reduced, gas concentrations in the different tissue compartments fall at different rates. Stops during return to baseline allow tissue concentration to fall to a safe level of supersaturation before reducing pressure further. (Data from Boycott AE, Damant GCC, Haldane J. The prevention of compressed air illness. *J Hyg [Lond].* 1908;8:342–443.)

Clinical Manifestations

The incidence of DCS in sport divers is estimated to be between 2 and 4 per 10,000 dives. In commercial divers, the incidence of DCS has been reported to be between 1 and 10 per 10,000 dives, although it can be as high as 35.5 per 10,000 dives.[65–70] Diving fishermen in low- and middle-income countries may have among the highest incidence of DCS, although data are limited.[72] Musculoskeletal DCS (type I) is the most common form of DCS in all divers.

DCS can mimic a variety of other disorders (Table 107.2). Free gas entering the venous system causes varying degrees of pulmonary vascular obstruction. A classic syndrome ("chokes") manifested by chest pain, dyspnea, and cough is described.[73] A common manifestation of DCS in divers is spinal cord dysfunction, usually at levels below the diaphragm.[74] Symptoms include paresthesias, muscle weakness, paralysis of the lower extremities, bowel or bladder incontinence, urinary retention, and sexual impotence.[75] A sudden ascent from deep depth ("blowup") can cause a massive DCS syndrome with both cerebral and spinal neurologic symptoms, unconsciousness, hypovolemic shock, pulmonary edema, and a high mortality rate.

The musculoskeletal form of DCS is manifested by pain in the extremities and joints.[76,77] Symptoms of local joint pain are often confused with pain from injuries, and the diagnosis of DCS may be missed. Exposure to high ambient pressures may cause aseptic necrosis of the bone, commonly seen in the juxta-articular femur and humerus. This condition, known as dysbaric osteonecrosis, is found in divers who have experienced musculoskeletal DCS in the distant past or who have experienced deep, prolonged exposures in caisson work, as well as in diving instructors and workers in commercial diving operations.[77,78] An erythematous or purpuric skin rash (cutis marmorata) may also be a manifestation of DCS. A systematic method for diagnosing DCS has been described by Latham and coworkers.[24]

Rare but important symptoms of serious (type II) DCS are sudden acute sensorineural hearing loss and vestibular dysfunction. DCS of this type usually follows deep,

Table 107.2 Frequency of Symptoms in 100 Cases of Decompression Sickness

Symptom	All DCS Symptoms (%)
Bone or joint pain	54
Spinal or neurologic	22
Respiratory	21
Fatigue or malaise	13
Spinal or back pain	11

DCS, decompression sickness.
Modified from U.S. Department of the Navy. *U.S. Navy Diving Manual*, vol 5, rev 6: *Diving Medicine and Recompression Chamber Operations* (NAVSEA 0910-LP-106-0957). Washington, DC: U.S. Department of the Navy; 2011.

prolonged diving exposures and, if untreated, can result in permanent deafness.[79] Inner ear DCS may be seen within 2 hours of surfacing and may include vertigo and hearing loss.[80] The mechanism is poorly understood but may involve formation of bubbles in the inner ear or embolism of systemic bubbles. Divers with inner ear DCS have been reported to have a higher prevalence of PFO, which increases the risk for right-to-left shunts of air bubbles and thus of decompression events. Such an association suggests that inner ear DCS may also result from air emboli.[81–83] The proper therapy for inner ear DCS is hyperbaric recompression.

Diagnostic Testing

Chest radiography can be used to diagnose pneumothorax, pneumomediastinum associated with pulmonary overpressure accidents, and the pulmonary abnormalities associated with aspiration or capillary leakage. Chest or abdominal CT can be used to diagnose pneumothorax, pneumomediastinum, or pneumoperitoneum. In cases of pulmonary barotrauma, a chest radiograph must be obtained prior to recompression to rule out a pneumothorax. If present, a chest tube will need to be inserted to prevent a tension pneumothorax from developing during a reduction in chamber pressure. Neurologic and psychological testing may be useful in determining response to treatment when brain injury is present. Electronystagmography and audiography may be useful in distinguishing inner ear DCS from inner ear barotrauma. Inner ear DCS requires recompression, whereas inner ear barotrauma is managed with bed rest, avoidance of straining, and possibly surgical intervention. The circumstances causing the two syndromes are distinct and are helpful in the differential diagnosis; the major difference is that inner ear barotrauma is caused during descent, whereas inner ear DCS is caused when surfacing. Central nervous system injury can be diagnosed by magnetic resonance imaging and correlated with clinical findings.[84,85] Magnetic resonance images of the brain in divers with no history of decompression-related disorders have also been found to be abnormal in some studies.[73]

Treatment

The clinical manifestations of DCS and AGE often overlap. The definitive treatment of DCS and AGE should ideally always be a return to pressure by recompression in a hyperbaric chamber and administration of oxygen at increased ambient pressure.[86,87] Timely fluid resuscitation, nonsteroidal anti-inflammatory drugs, and antiplatelet agents may also be part of the initial treatment.[88] Once stabilized with pressure and oxygen, the patient must be decompressed slowly to permit the inert gas to be carried away from tissues by the circulatory system and then to be exhaled by the lungs. With early treatment, DCS and AGE generally have an excellent prognosis for recovery. When treatment is delayed or when the injury is severe, there may be permanent injury to the brain or spinal cord.

Hyperbaric Therapy

Treatment of DCS and AGE should be instituted with recompression as soon as possible after the injury.[89] A history and physical evaluation, including a neurologic examination and cognitive assessment, should be obtained before treatment when possible. Therapy is provided by a trained medical team using either a monoplace (single-person) or multiplace (multiperson) hyperbaric chamber. A multiplace chamber allows medical personnel (also known as tenders) to be present in the chamber to administer additional therapies and tend to the patient. It is possible to place intubated patients in hyperbaric chambers. The usual practice is to follow the standard protocols for pressure treatment outlined in the *U.S. Navy Diving Manual,* which involves a pressure exposure equivalent to 60 fsw by using intermittent oxygen therapy (eFig. 107.2).[90] Oxygen breaks are used to limit potential for central nervous system oxygen toxicity. Most practitioners use a hyperbaric treatment protocol lasting approximately 5 hours for treatment of types I and II DCS. This treatment protocol reaches a simulated depth of 60 fsw (~3 ATA). Recompression therapy for cutis marmorata resulting from DCS has been recommended by some investigators, but most cases resolve spontaneously. Itching and erythema of the skin may also be noted following hyperbaric chamber exposures, but these skin findings alone do not require recompression therapy.

When a diver ascends from extreme depths with significant missed decompression, the practitioner may choose to use recompression tables that pressurize the diver to a "depth of relief," to use alternate gas mixtures (i.e., helium and oxygen), or to hold the diver for more than 24 hours at a single depth to stabilize the medical status (saturation treatment).[86] For surface-supplied air and scuba divers, the principal treatment gases are oxygen and air. For treatment depths greater than 60 fsw, enriched nitrogen-oxygen (nitrox) or helium-oxygen (heliox) may also be used to minimize unwanted effects of excess nitrogen exposure.

Repeated hyperbaric oxygen treatments can be given, although end points for repetitive therapy are not well defined. Treatments can be administered until complete resolution of symptoms, until no further change of symptoms is found or for a fixed number of exposures (e.g., five). Controlled trials to determine efficacy of repetitive treatments are not available. Treatment of AGE follows similar protocols. Recompression to 60 fsw and oxygen therapy are usually successful.[91] Recompression to 165 fsw depth equivalent (6 ATA) may be recommended if symptoms persist after recompression to 60 fsw.[90]

In selected cases of DCS when no hyperbaric chamber is readily accessible, the controversial practice of in-water recompression is sometimes used by specially trained teams. During in-water recompression, the diver descends to depths that are usually shallower than standard treatment tables and effectively begins decompression treatment immediately without delay encountered while transporting to a decompression chamber.[92] However, during in-water recompression, the diver is unable to receive supportive care and is subject to additional environmental risks. Central nervous system oxygen toxicity during in-water recompression can result in drowning.

Prehospital Care: Oxygen and Fluids. Early administration of 100% oxygen (10 L/min by non-rebreather face mask) on the surface and during transport is beneficial for treating both DCS and AGE.[93] Oxygen enhances the rate of absorption and resolution of inert gas bubbles and treats

hypoxemia if present. Intravenous fluid administration is also recommended as part of initial treatment. As discussed earlier, both DCS and AGE manifest with hemoconcentration caused by plasma leakage as a result of endothelial injury from gas bubbles. Measurement of hematocrit and urine output is useful to guide fluid replacement therapy. Central nervous system injury may be exacerbated by hyperglycemia, and glucose-containing intravenous solutions should be administered cautiously.

Several adjunctive medications have been proposed for the treatment of DCS and AGE, including heparin, aspirin, nonsteroidal anti-inflammatory drugs, corticosteroids, and lidocaine. However, experimental and clinical data do not support the use of these therapies. In the case of spinal cord DCS causing paralysis, subcutaneous low-molecular-weight heparin should be initiated to prevent thromboembolic disease.[94,95]

Arrangements for transfer to the nearest hyperbaric chamber must be initiated as soon as possible. The *Divers Alert Network* (DAN), a not-for-profit diving safety medical organization, offers medical assistance to the recreational, public safety, and scientific diving communities all over the world. DAN has a diving medicine physician available 24 hours a day, 7 days a week, who can help with the diagnosis and immediate care of an injured diver. DAN can provide the location of the nearest hyperbaric treatment facility and assist with arrangement of transport and treatment for all diving injuries. In the United States, the DAN hotline number is 919-684-9111.

INERT GAS NARCOSIS

Inert gas narcosis (e.g., "nitrogen narcosis"), another diving disorder related to dissolved inert gas, takes place after breathing air at depths greater than 100 fsw.[96] Symptoms include loss of fine motor control and high-order mental skills, inappropriate response to emotional stress, hostility, and unconsciousness. Symptoms increase with increasing depth greater than 100 fsw. At 300 to 400 fsw, unconsciousness may result from the anesthetic effect of nitrogen at this pressure. Fatigue, heavy work, and hypothermia can augment the narcosis effect of nitrogen, as can concurrent use of sedating medications (e.g., certain decongestants). Symptoms disappear immediately on ascending to a shallow depth. Often there is amnesia for the events.[96] Narcosis potential varies among the inert gases (see Table 107.1). Of note, the narcosis effect of nitrogen on human performance has been demonstrated even at sea level. If the nitrogen component of room air at sea level is replaced by helium, human performance measurably improves.[97] Stated differently, we are all partially sedated.

OTHER PHYSIOLOGIC AND PATHOPHYSIOLOGIC CONSIDERATIONS FOR DIVING

OXYGEN TOXICITY

Pulmonary oxygen toxicity is rare in diving but may be of some concern in prolonged hyperbaric oxygen treatments. This toxicity results from free radical–induced inflammation and cell death, manifest initially with symptoms of mild substernal pressure or pleuritic chest pain (i.e., tracheobronchitis), and it may be present after as little as 12 to 16 hours at 1 ATA, 8 to 14 hours at 1.5 ATA, or 3 to 6 hours at 2 ATA.[98,99] Pulmonary oxygen toxicity progresses with characteristic exudative and proliferative phases, similar to acute respiratory distress syndrome.

Oxygen toxicity in divers primarily affects the central nervous system.[100] Acute toxicity to the brain can develop when oxygen partial pressure exceeds 1.4 ATA (see Fig. 107.2). Higher partial pressures may be tolerated for brief periods especially while at rest. This is the case during hyperbaric therapy, which routinely reaches 2 to 3 ATA. A diver affected by central nervous system oxygen toxicity may experience auditory or visual hallucinations and commonly has a grand mal seizure. When a diver is underwater, a seizure can lead to drowning. For example, a 21% oxygen mixture will expose a diver to 1.4 ATA of oxygen at 187 fsw, and a 32% oxygen mixture ("enriched air nitrox") will expose a diver to 1.4 ATA of oxygen at 111 fsw. Divers have been known to develop seizures when using these breathing gases at greater depths. Hyperthyroidism, carbon dioxide retention, and exertion are among many factors that may increase the risk of oxygen toxicity.[101–103]

To avoid oxygen toxicity, recreational dive limits are set to avoid exposures to more than 1.4 ATA of oxygen (see Fig. 107.2). Commercial, scientific, or other specialized divers who exceed these limits must decrease the inspired oxygen concentration with increasing depth to keep the Po_2 lower than 1.4 ATA. For example, some scientific scuba divers routinely reach depths approaching 200 m and breathe trimix (helium, oxygen, and nitrogen). By lowering the oxygen concentration to approximately 7%, even at depths up to 200 m (20 ATA), the Po_2 remains less than 1.4 ATA.

THERMAL EXPOSURE

Most diving takes place in water colder than skin temperature, and the diver loses heat throughout the dive. Hypothermia happens rapidly in the absence of protective garments even in relatively warm water (e.g., 22–23°C). Cold stress evokes thermogenic responses, reflected by a rise in oxygen consumption to generate additional body heat and minimize core temperature change. Cold-water diving also leads to peripheral vasoconstriction; the magnitude of the vasoconstriction depends on the body core temperature, which, in turn, is affected by the amount of thermal protection and the water temperature. Heat loss is inhibited in divers doing moderate work in water warmer than 30°C and, in this situation, hyperthermia can develop.

Exertion at depth increases tissue temperature and increases gas solubility. During surfacing and decompression, the relative lack of exertion coupled with cold-water exposure causes decreased perfusion in the skin and extremities, as well as decreased gas solubility. The increased solubility at increased temperature followed by a decreased solubility at cooler temperatures can contribute to development of type I DCS; the nitrogen absorbed during a time of increased temperatures comes out of solution when the

HIGH-PRESSURE NERVOUS SYNDROME

Helium is used in diving as an alternative inert gas to replace nitrogen and avoid its narcosis effects at depth. However, at depths of more than 600 fsw (18 ATA), dissolved helium can also cause problems. At these depths, helium can cause a reversible state of excitation (i.e., high-pressure nervous syndrome) characterized by tremor, dizziness, and nausea, among other symptoms.[98]

temperature drops and is poorly eliminated in areas of low perfusion such as skin.

WATER IMMERSION

Intrathoracic blood volume increases with water immersion.[105] With the head above water, increased hydrostatic pressure during immersion decreases blood pooling in the peripheral veins, increases transdiaphragmatic pressure, and increases venous return.[100,106] The magnitude of the increase in intrathoracic blood volume during immersion with the head above water has been estimated to be 700 mL and may be augmented by colder water temperatures. In healthy divers, the central blood shifts result in increased cardiac output and an increase in venous return.[106] The increase in intrathoracic blood volume can cause diuresis resulting from release of natriuretic hormones and suppression of antidiuretic hormone. In patients with cardiac valvular disease, diastolic dysfunction, or systolic dysfunction, increased preload from immersion can result in volume overload. Water immersion has additional pulmonary physiologic considerations, including increased gas density and imposition of a restrictive deficit.

IMMERSION PULMONARY EDEMA

Diving can result in a condition known as immersion pulmonary edema. Immersion pulmonary edema has been reported in scuba divers at depth and surface swimmers undergoing heavy exertion, particularly military recruits and triathlon swimmers. Although the exact pathophysiology is uncertain, it is thought that increased pulmonary blood flow and vascular pressure can cause stress failure of the capillaries. A similar mechanism has been reported in race horses who develop extremely high pulmonary vascular pressures leading to stress failure at the capillary level.[107]

Immersion causes an increase in preload from central pooling of blood combined with increased sympathetic output leading to vasoconstriction and cold-induced vasoconstriction, all contributing to increased pulmonary vascular resistance, pulmonary capillary wedge pressure, systemic vascular resistance in the setting of increased venous return, and increased cardiac output. Symptoms include dyspnea, cough, tachypnea, frothy sputum, hemoptysis, and hypoxemia. In rare circumstances, immersion pulmonary edema can be fatal. Chest radiography typically shows evidence of pulmonary edema (i.e., Kerley B lines, cephalization of flow, air space consolidation) with a normal heart size. Conservative treatment is recommended because the symptoms usually resolve within 12 hours. Oxygen, β-adrenergic inhalers, and diuretics can be given, but the majority of patients will improve spontaneously.[108,109] Older patients with possible underlying cardiovascular disease should be evaluated for acute coronary syndrome.

Takotsubo cardiomyopathy has been reported in scuba divers who presented with pulmonary edema and transient myocardial systolic dysfunction. Gempp and colleagues[110] reported reversible myocardial dysfunction in 28% of 54 divers admitted for acute immersion pulmonary edema that was associated with age greater than 50 years, hypertension, and release of natriuretic peptides.[110–112]

MEDICAL CLEARANCE TO DIVE

GENERAL FITNESS FOR DIVING

Diving is a safe sport; however, certain physical conditions can lead to increased risk for injury while diving. Medical standards have been developed for the various diving communities (eTable 107.1). Recreational divers follow medical standards outlined in the Recreational SCUBA Training Council Medical Statement (http://wrstc.com/standards-downloads/). Medical standards for scientific divers fall under the auspices of the American Academy of Underwater Sciences (http://aaus.org/diving_standards). Commercial diving medical standards are governed by the Association of Diving Contractors International, Inc (http://adc-int.org).

Based on epidemiologic data of dive accidents and fatalities from DAN, many diving fatalities are associated with underlying cardiovascular disease. Disorders that limit cardiovascular or pulmonary function during exercise, physical deconditioning, metabolic disorders that limit exercise capacity, and certain physical disabilities can compromise diving safety (eTable 107.2). Contraindications to diving include (1) any condition that interferes with equalization of any air spaces within the body; (2) any condition that could lead to unconsciousness underwater; (3) any condition that impairs tissue diffusion of inert gas and increases the risk for DCS; (4) poor exercise tolerance; and (5) inability to tolerate the physiologic effects of diving (e.g., changes in preload, airway resistance, pulmonary arterial pressure, systemic vascular resistance, and myocardial metabolic demand).

PULMONARY DISORDERS

Primary Spontaneous Pneumothorax (see Chapter 110)

Primary spontaneous pneumothorax arises without trauma or an iatrogenic event and in patients with no apparent underlying lung disease. A history of primary spontaneous pneumothorax is widely considered a contraindication to diving because of the possibility that, with overinflation, lung defects may be susceptible to pulmonary barotrauma and AGE. Although risk declines over time or with pleurodesis, and has been associated with certain clinical and imaging findings, inadequate data exist to recommend a return to diving for most patients with a history of primary spontaneous pneumothorax.[113] A history of iatrogenic or traumatic pneumothorax is not a contraindication to diving. For individuals with a history of significant lung injury or surgery, in whom there is concern for air trapping, a high-resolution chest CT scan with inspiratory and expiratory views can confirm or rule out air trapping.

Asthma and COPD

Asthma has been a concern in diving because of possible bronchoconstriction, air trapping, and pulmonary overinflation during ascent. However, an increased risk for

ENERGY NEEDS

A scuba diver swimming underwater at a speed of 1.0 knot (about 100 feet/min or 1.15 miles/hr or 1.85 km/mile) consumes approximately 25 mL of oxygen/kg/min (eFig. 107.3).[90,104] A diver with a maximum oxygen consumption of 40 mL/kg/min would tolerate swimming at 1.3 knots for a few minutes but would become extremely tachypneic to compensate for lactate production. For this diver, a sustainable swimming speed, at 50% of maximum capacity, would be about 0.9 knots or 90 feet/min, whereas a diver with a maximum oxygen consumption of 25 mL/kg/min would be able to sustain a swimming speed of only approximately 0.55 knots or 55 feet/min. Safety considerations suggest that the sport diver should be able to tolerate a sustained workload of about 20 mL/kg/min (50% of maximum).[90,104] Poorly conditioned divers can experience severe dyspnea under even mildly stressful conditions that exceed their anaerobic threshold.

eTable 107.1 Criteria for Medical Clearance to Dive for Recreational, Scientific, and Commercial Diving

	Recreational Diving	Scientific Diving	Commercial Diving
Source	World Recreational Scuba Training Council (RSTC)	American Academy of Underwater Sciences (AAUS)	Association of Diving Contractors International (ADCI)
Provider	Evaluation performed by a physician	Evaluation performed by or under the direction of a licensed physician, preferably one trained in diving or undersea medicine	Evaluation performed by licensed physicians qualified to perform commercial diver medical examinations
Testing	■ Cardiac risk assessment if >40 yr old ■ Formalized stress testing encouraged if there is any doubt regarding physical performance capability ■ Further testing as indicated by history and examination	■ Urinalysis (all examinations) ■ Chest radiograph (first examination after age 40 yr) ■ ECG (all examinations after age 40 yr) ■ CAD risk assessment (history, blood pressure, hemoglobin A1c or fasting glucose, lipid profile) (all examinations after age 40 yr) ■ Exercise testing if indicated by history and CAD risk assessment	■ Urinalysis (annually) ■ CBC (annually) ■ CMP (optional) ■ Pregnancy test ■ Sickle cell test (optional) ■ TB screening (optional) ■ ECG stress testing if >10% Framingham risk score ■ PFTs (FEV_1, FVC, $FEF_{25\%–75\%}$ annually) ■ ECG (annually after age 35 yr) ■ Lipids (annually after age 35 yr) ■ Audiogram (annually) ■ Bone and joint radiographs (initial examination) ■ Chest radiograph (PA and lateral) (every 3 years) ■ Drug screen recommended ■ Visual acuity and field of vision testing
History and physical examination*	History and physical with RSTC Medical Statement Form, which includes structured questionnaire and guidelines for history and physical examination	■ History and physical with Diving Medical History, Evaluation and Examination forms, which include a structured questionnaire and guidelines for history and physical examination ■ <40 yr old: medical evaluation every 5 yr ■ 40–60 yr old: medical evaluation every 3 yr ■ >60 yr old: medical evaluation every 2 yr	■ History and examination forms provided ■ Request past medical records if available for chest radiograph, long bone radiograph, MRI, spine radiograph, PFTs, audiogram, ECG, stress testing ■ Annual examinations required

*Clearance to return to dive must be obtained for previously cleared divers who have subsequently experienced major injury or illness, conditions requiring chronic medication, or conditions that may be contraindications to diving.

CAD, coronary artery disease; CBC, complete blood count; CMP, comprehensive metabolic panel; ECG, electrocardiogram; $FEF_{25\%–75\%}$, mean forced expiratory flow between 25% and 75% of the forced vital capacity; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; MRI, magnetic resonance imaging; PA, posteroanterior; PFT, pulmonary function test; TB, tuberculosis.

eTable 107.2 Considerations for Medical Clearance for Recreational Diving

System	Severe Risk Conditions*	Relative Risk Conditions*	Temporary Risk Conditions*
Neurologic	■ Seizures (other than childhood febrile) ■ History of transient ischemic attack or cerebrovascular accident ■ History of serious decompression sickness with residual deficits (central nervous system or inner ear)	■ Complicated migraines ■ Head injury with sequelae ■ Herniated disc ■ Peripheral neuropathy ■ Multiple sclerosis ■ Spinal cord injury ■ Intracranial tumor or aneurysm	■ History of cerebral arterial gas embolism without residual pulmonary air trapping and low probability of recurrence (e.g., provoking event)
Cardiovascular	■ Intracardiac right-to-left shunt ■ Hypertrophic cardiomyopathy ■ Valvular stenosis ■ Heart failure ■ Impaired exercise tolerance resulting from cardiac disease	■ History of coronary artery bypass grafting ■ Coronary artery disease ■ History of myocardial infarction ■ Hypertension ■ History of dysrhythmias requiring ongoing treatment ■ Valvular regurgitation	■ Condition requiring a pacemaker (pacemaker must be certified by manufacturer to withstand increased pressure at depth)
Pulmonary	■ History of spontaneous pneumothorax ■ Intrapulmonary right-to-left shunt ■ Impaired exercise tolerance resulting from pulmonary disease	■ Asthma ■ COPD ■ Exercise-induced bronchospasm ■ Solid, cystic, or cavitary pulmonary lesions ■ Pneumothorax resulting from surgery, trauma, or overinflation injury ■ Obesity ■ History of immersion pulmonary edema ■ Interstitial lung disease	—
Gastrointestinal	■ Gastric outlet obstruction or gastroparesis causing recurrent vomiting ■ Recurrent or chronic small bowel obstruction ■ Severe gastroesophageal reflux ■ Achalasia ■ Paraesophageal hernia	■ Inflammatory bowel disease ■ Functional bowel disorders	■ Peptic ulcer disease with severe reflux ■ Unrepaired abdominal hernias
Metabolic and endocrine	■ Pregnancy	■ Diabetes mellitus	—
Otolaryngologic	■ Open tympanic membrane ■ Tube myringotomy ■ Middle or inner ear surgery ■ Tracheostomy ■ History of vestibular decompression sickness	■ Recurrent otitis externa, otitis media or sinusitis ■ Obstruction of external auditory canal ■ History of tympanic membrane perforation or round window rupture ■ History of tympanoplasty, mastoidectomy, neck radiation, or mid-face fracture ■ History of eustachian tube dysfunction ■ Significant hearing loss	■ Acute upper respiratory infection ■ Acute sinusitis ■ Acute otitis media ■ Recent or unhealed oral surgery
Orthopedic	—	■ Amputation ■ Scoliosis with impact on respiratory or exercise performance ■ Aseptic osteonecrosis	■ Back pain
Hematologic	—	■ Polycythemia vera ■ Hematologic malignancies ■ Coagulopathy ■ Sickle cell disease	—
Behavioral health	■ Inappropriate motivation to dive ■ Claustrophobia ■ Active psychosis ■ Untreated panic disorder	■ Use of psychotropic medications ■ History of psychotic episodes	—

*Severe risk conditions are generally considered contraindications to diving and imply a substantially elevated risk of decompression sickness, pulmonary or otic barotrauma, or altered consciousness with subsequent drowning. Relative risk conditions may be relative contraindications and imply a moderate increase in risk that requires individual consideration for fitness to dive. Temporary risk conditions are temporary or responsive to treatment, although they may be contraindications to diving and require careful consideration.

Data from the Recreational Scuba Training Council (RSTC) Medical Statement; wrstc.com/standards-downloads/ and Van Hoesen KB, Lang MA. Diving medicine. In: Auerbach PS, ed. *Auerbach's Wilderness Medicine*. 7th ed. Philadelphia: Elsevier; 2017.

pulmonary barotrauma has not been supported by accident data.[114] Although scuba diving can decrease peak expiratory flow rates, individuals with well-controlled asthma, known triggers that do not include cold or exercise, and normal pulmonary function test results with a reduction of less than 20% in peak midexpiratory flow with exercise can be cleared for diving.[115] The use of provocative inhalational challenges (e.g., hypertonic saline, cold dehumidified air, or methacholine) has been variably implemented, with no data to guide use. A current asthma exacerbation is a contraindication to diving. A more detailed discussion of issues related to asthma and diving has been published.[116]

Because patients with COPD by definition are unlikely to meet the functional or pulmonary function criteria discussed earlier, these patients generally should not be cleared for diving.

Bullous Lung Disease

Patients with COPD or risk factors for COPD have the additional potential for bullae. Individuals with known pulmonary cysts, blebs, or significant obstructive lung disease are not allowed to dive because of the potential for air trapping and subsequent pulmonary barotrauma.

CARDIAC DISORDERS

Coronary Artery Disease

Patients with coronary disease may experience angina pectoris, myocardial infarction, or sudden death while diving. The highest incidence of diving-related death from cardiovascular disease in divers is in the age range from 50 to 70 years.[117] In recreational divers, cardiac events are associated with approximately one-fourth of diving fatalities.[118] In the DAN Annual Diving Reports on Fatalities, Injuries, and Incidents, the data suggested that acute cardiac events are a leading cause of disabling injury.[119] More than one-half of the recreational diving fatalities were in divers older than 50 years, and heart disease, high blood pressure, and obesity were among the most common preexisting health conditions.[120] Diving candidates should be screened for cardiovascular risk factors (smoking history, hypertension, obesity) and undergo lipid profile, electrocardiogram, and exercise stress testing as indicated.

Atrial Septal Defect

Diving candidates with atrial septal defects that allow right-to-left intracardiac shunting are at risk for paradoxical embolism of gas bubbles that form in the venous circulation during decompression.[87,121] Patients with a right-to-left shunt and arterial hypoxemia will normally have severely limited exercise capacity and should not dive. Because of the lack of right-to-left shunting, a ventricular septal defect does not necessarily produce a risk for paradoxical embolization of bubbles. A detailed discussion of this topic can be found elsewhere.[122]

Patent Foramen Ovale

PFO is an active area of discussion in the diving medical community because of the potential for right-to-left shunting of bubbles. Community-based autopsy and transesophageal studies have revealed the prevalence of PFO at approximately 25%.[123,124] In a prospective community-based study of 588 randomly selected subjects, transesophageal echocardiography revealed PFO in 148 subjects (26%); of these, 84 had shunting at rest (57%), and 136 had shunting after Valsalva maneuver or cough (92%).[124] In a contrast echocardiographic study of 76 healthy volunteers, PFO was present in 14 (18%), and 4 (5%) subjects had shunting at rest.[125] In 30 divers with a history of DCS, Moon and colleagues[121] reported a higher prevalence of PFO (37%). Eighteen patients in this cohort had a history of serious DCS, and 11 (61%) of this subgroup had shunting through a PFO. Several studies suggest that presence of a PFO can increase the risk of serious DCS.[62,126–130]

However, the high prevalence of PFO in the population and the very low incidence of DCS suggest that a PFO likely plays only a minor role in the pathophysiology of DCS. DAN and the Undersea and Hyperbaric Medical Society held a consensus guideline workshop on PFO and diving.[131] Routine echocardiographic screening for a PFO is not indicated, and there is no routine need to close a PFO as a prophylactic measure.[129,132] Consideration should be given to testing for a PFO in a diver when there is a history of repeated episodes of neurologic, vestibulocochlear, or cutaneous DCS.

If a diver is known to have a PFO, closure of the PFO is controversial. Current data suggest that closure of a PFO does reduce the risk of neurologic DCS. Henzel and colleagues[133] followed 11 professional divers with PFOs who reported a total of 62 episodes of DCS before closure of their PFOs. All divers returned to unrestricted diving and made more than 3000 dives collectively; no episodes of decompression illness were reported after the intervention, and no diver reported complications from the procedure. Similarly, in a 2019 study by Anderson and colleagues,[63] 42 individuals underwent closure of their PFO or atrial septal defect and reported a significant decrease in DCS incidence rate compared with 23 individuals who continued diving without closure of the defect. Eight subjects reported an adverse event associated with defect closure.[63]

Dysrhythmias

Reflex bradycardia from diving has been described by several investigators and may be related to the mammalian diving reflex.[134,135] The autonomic adjustments to apneic diving in marine mammals appear to be an oxygen-conserving reflex, but this effect does not appear to be significant in humans. Drowning has been associated with the familial-inherited long QT syndrome in swimmers, and the same risk is likely to apply to divers. Individuals with benign dysrhythmias that do not interfere with exercise tolerance or with well-controlled atrial fibrillation can be cleared for diving.[136]

NEUROLOGIC DISORDERS

Seizure disorders are a contraindication to diving because a diver sustaining a seizure underwater is at risk for drowning and may compromise the safety of others who attempt a rescue. A diving candidate with a history of a seizure disorder should be seizure-free without antiseizure medications for 5 years and have a normal electroencephalogram before being considered for diving.[137] Many factors encountered in diving may lower the seizure threshold (e.g., exercise,

hypercapnia, hyperventilation, stress), whereas an elevated Po_2 theoretically may increase the risk of seizures in an individual with epilepsy.[138] History of unexplained syncope is also a contraindication to diving.

DIABETES

Insulin-dependent diabetes mellitus had traditionally been a contraindication for diving because of the risk of hypoglycemia, leading to unconsciousness and death underwater from drowning. However, guidelines developed through the YMCA and American Diabetes Association now exist for such patients to dive safely. Special training allows for safe diving for insulin-dependent sport divers.[83,139] Consensus guidelines for diving with diabetes are published by DAN and the Undersea and Hyperbaric Medical Society.[140]

DROWNING

For a detailed discussion of drowning, see ExpertConsult.com.

Key Points

- Middle ear barotrauma is the most prevalent diving injury, whereas pulmonary barotrauma, although uncommon, is the most severe form of barotrauma injury because of the risk of accompanying cerebral arterial gas embolism.
- Decompression sickness results when inert gas dissolved in the body at increased pressure forms free gas in blood and tissues on decompression.
- Clinical manifestations of acute decompression sickness include disorders of the brain and spinal cord, musculoskeletal pain, chest pain, dyspnea, and skin rash seen up to 24 hours following an exposure to increased pressure.
- Treatment of decompression sickness and arterial gas embolism should be instituted with recompression in a hyperbaric chamber as soon as possible after the injury. Assistance can be sought at all hours by calling the Divers Alert Network (919-684-9111).
- Assessment of fitness for diving includes consideration of the type of diving (recreational, scientific, commercial, or military) and of the number of comorbidities that can be aggravated by the diving environment. A history of primary spontaneous pneumothorax or the presence of an atrial septal defect is considered a contraindication to diving, although patent foramen ovale is not necessarily a contraindication. Obstructive pulmonary diseases require special consideration.
- Although drowning without aspiration is theoretically possible, most drownings are associated with aspiration of water into the lungs and accompanying hypoxemia.
- Goals of therapy for a drowning victim include reversing hypoxemia with positive-pressure ventilation and oxygen, treating metabolic acidosis, and managing accompanying cardiac arrhythmias.

DROWNING

Drowning is reported by medical examiners as the leading cause of death in the approximately 50 to 60 scuba fatalities in the United States each year; however, sudden cardiac death or AGE may be the precipitating factor or even the cause of death in many of these accidents.[119,141,142] Drowning (from all causes, not just diving) causes nearly 400,000 deaths per year and is the third leading cause of unintentional injury or death.[143]

Historically, the terms *drowning* and *near drowning* have been used to describe victims who either died or survived, respectively. The World Health Organization now defines drowning as "the process of experiencing respiratory impairment due submersion or immersion in liquid" with possible outcomes of death, morbidity, or no morbidity. It is simpler and preferable to use the term *drowning* for all individuals who experience submersion incidents.[141]

Among drowning victims from all circumstances, (i.e., not only diving), a significant proportion may survive with organ dysfunction, including persistent hypoxemic respiratory failure and neurologic injury. Intentional hyperventilation before breath-hold diving is associated with drowning episodes. Hyperventilation reduces the arterial partial pressure of carbon dioxide (P_{CO_2}), so the breath-hold breakpoint is prolonged sufficiently for hypoxemia to develop before the individual is forced to breathe. The hypoxemia in turn causes the individual to lose consciousness and then drown.[144] This is the hypothesized pathophysiology for what has been termed "shallow water blackout." Atrial and ventricular arrhythmias are known to happen during prolonged breath-holding experiments, but whether these arrhythmias play an important role in drowning incidents needs further study.[145.]

Hypothermia leading to drowning has been reported frequently; however, in diving fatalities this is unusual because of the almost universal use of thermal protection by divers. Hypothermia reduces a person's ability to function until the point of unconsciousness or helplessness is reached.[146] At that time, for someone at the surface, the head falls into the water, and drowning results. Maximum breath-hold times can drop dramatically in cold water, thus further compromising the ability to survive in rough water when intermittently submerged. In rare circumstances, hypothermia can have a protective effect on the drowning victim (see later). Hypothermia is only one of many conditions that can precipitate drowning by causing unconsciousness. As previously discussed, loss of consciousness caused by contamination of the diver's air supply with carbon monoxide and oxygen-induced seizures have been implicated as the cause of drowning in many diving-related incidents.

PATHOPHYSIOLOGY

Investigators have reported that 2–15% of drowning victims may not aspirate fluid during immersion.[147,148] It has been hypothesized that reflex laryngospasm that persists until reflex ventilatory activity ceases may account for this finding. However, review of early "dry" animal studies does not support the dry drowning hypothesis for fatal cases.[149] It is much more likely that these cases actually represent arrhythmic deaths, and the true number of drowning victims without aspiration is extremely low.

Unlike victims without aspiration, those who aspirate remain hypoxemic, even after being removed from the fluid medium and after ventilation is reestablished. As a result, the prolonged period of hypoxemia may cause secondary damage to other organ systems.[150,151]

There are many potential mechanisms contributing to oxygenation and ventilation defects after aspiration during drowning, including direct alveolar membrane injury by the aspirated fluid, altered ventilation-perfusion matching, increased airway resistance, washout of surfactant, volume overload, aspiration of particulate (e.g., vomit, mud, sand, algae), neurogenic pulmonary edema, and organization of proteinaceous exudate or secondary infection during recovery.[152,153]

Historically, the literature has emphasized a distinction between freshwater and saltwater aspiration, although more recently it is less clear that this difference has significant clinical relevance.[154] Aspiration of hyperosmolar fluid (i.e., saltwater) can cause transudation of fluid into alveoli, increased lung weight, increased serum osmolality, and hypovolemia.[155,156] Although this pathophysiology has been demonstrated in numerous animal studies and in exceptional circumstances in humans (e.g., aspiration of markedly hypertonic solution in the Dead Sea), it is uncommonly observed in drowning victims, especially those who survive.[151,156–158] Aspiration of fresh water can have the opposite effect, leading to intravascular volume overload and hypotonic serum. This requires aspiration of more than 11 mL/kg and is usually rapidly redistributed.[159–161] Human drowning victims rarely aspirate large enough volumes of water to produce life-threatening changes in intravascular volume or electrolytes.[158]

Aspiration of water (fresh water or seawater) during drowning causes washout of surfactant and often leads to noncardiogenic pulmonary edema as well as acute respiratory distress syndrome.[150] These abnormalities can persist until the lung damage resolves or until surfactant is regenerated.

In victims who swallow large amounts of fluid during the drowning episode, further impairment in ventilatory function can result from gastric distention. Profound acidemia may be present in response to concurrent hypercarbic respiratory failure and lactic acidosis caused by struggling during the drowning episode. Finally, if hypoxemia and decreased cardiac output persist long enough, there can be anoxic brain injury and cardiac arrest.[162,163]

Because cardiac arrest from downing is secondary to hypoxemia, it may be delayed by a significant amount of time. If the water is cold enough, if the surface area/mass ratio of the victim is large enough, and if the victim swallows enough water, then core temperature may decrease significantly. At low core temperatures. oxygen demand may be low enough that victims can occasionally survive even prolonged submersion.[164]

Postmortem evaluations of humans and animals after death by drowning reveal hyperexpansion of the lungs that can resemble acute emphysema. This finding may be attributable to rupture of alveoli secondary to marked changes in airway pressure during extreme ventilatory efforts in

the setting of a closed glottis or airway obstruction from water.[165,166]

CLINICAL PRESENTATION

The clinical presentation of drowning victims is highly variable. The patient who is unconscious and reported to be without vital signs at the site of the accident may be hemodynamically stable and neurologically intact in the emergency department, whereas the victim initially thought to be hemodynamically stable at the scene may deteriorate significantly before arrival at the hospital.

Cardiovascular System

Given the hypoxia associated with drowning, victims typically experience sinus tachycardia from the initial struggle, followed by bradycardia, pulseless electrical activity, and then asystole. Ventricular fibrillation is rare in near drowning victims.[167] Victims of significant drowning may suffer cardiac arrest and respond to on-scene resuscitative measures. Whether this represents premature cardiopulmonary resuscitation or a response to therapy is not certain. However, it is also not uncommon for a victim to be brought to the emergency department still requiring cardiopulmonary resuscitation. If the patient "responds" to cardiopulmonary resuscitation at the scene of the rescue with a stable rhythm or if the patient never has a cardiac arrest, supraventricular tachycardias are commonly seen. If the patient presents with a viable rhythm, it will most likely be supraventricular tachycardia secondary to hypoxemia and acidosis.[168] Patients with underlying cardiac disease may have primary cardiac arrest that may mimic a drowning episode.[142] The spectrum and frequency of cardiac channel defects such as prolonged QT syndrome in swimming-triggered arrhythmia events may be greater than previously suspected.[168,169] Pathologic diagnoses may be further complicated by terminal aspiration secondary to agonal breathing after cardiac arrest, and thus postmortem analyses that depend on the presence of aspiration may be misleading.[170,171]

Pulmonary System

Patients with water aspiration may present with few or no respiratory complaints or with severe pulmonary edema caused by direct lung injury.[172] Patients who have aspirated any significant quantity of water will likely have a widened alveolar-arterial P_{O_2} difference and anything from mild to severe hypoxemia. Arterial P_{CO_2} can be low or elevated depending on alveolar ventilation (eTable 107.3).

eTable 107.3 Average Blood Gas Measurements in Hospitalized Drowning Victims Breathing Room Air on Admission

	pH	$Paco_2$ (mm Hg)	Pao_2 (mm Hg)	Base Excess (mEq)
Fresh water	7.26	38	66	−9
Seawater	7.37	36	56	−5
All	7.30	37	62	−7

$Paco_2$, arterial partial pressure of carbon dioxide.
Modified from Modell JH, Davis JH, Giammona ST, et al. Blood gas and electrolyte changes in human near-drowning victims. *JAMA*. 1968;203:337–343.

Initial chest radiographs are often normal but can show patchy opacities, which are most common in the periphery or in the medial basal regions, or frank (noncardiac) pulmonary edema (see Fig. 107.3).[173] The clinical course cannot be predicted with certainty by the radiographic picture of lung injury. Victims with obvious respiratory symptoms may show minimal radiographic abnormalities, and those with minimal clinical signs may have markedly abnormal radiographic images.

Central Nervous System

The neurologic status of patients can also be quite variable. The central nervous system is extremely sensitive to hypoxemia and is the organ system most susceptible to the detrimental effects of drowning. Severe permanent neurologic injury is the most devastating long-term consequence for the victim of a drowning episode. Although a normal head CT scan on admission is of limited prognostic value, an initial abnormal CT scan that shows evidence of edema, focal infarct, or loss of gray and white matter differentiation is predictive of a poor outcome. The most important predictor of outcome is duration of submersion; in general, submersion times longer than 30 minutes suggest a poor prognosis. However, there are cases of good neurologic outcome despite prolonged submersions, especially in children younger than 6 years who drown in water temperatures less than 6°C (43°F), and with the use of advanced therapies such as extracorporeal membrane oxygenation.[174]

TREATMENT

Because cardiac arrest caused by drowning results from hypoxemia and acidosis, it is critically important to restore circulation, establish a patent airway, and provide oxygen rapidly. With a suspected drowning victim, the rescuer should provide cardiopulmonary resuscitation with rescue breathing in accordance with basic life support guidelines.[175–179] Establishing an airway and providing oxygen are priorities in the initial resuscitation. Rescue breathing may even be initiated during extraction from the water. Use of a subdiaphragmatic thrust (Heimlich maneuver) is no longer recommended because most water expelled by this technique originates from the stomach rather than the lungs and increases the risk of aspiration.[180,181] Endotracheal intubation is the preferred method for establishing an airway. This approach must account for the possibility of a concomitant unstable neck injury if there is associated trauma, as well as the risk for aspiration of gastric contents.[182] However, without a focal neurologic deficit or significant mechanism of cervical spine injury (e.g., diving into shallow water), the risk for an unstable cervical spine injury is low, and spinal immobilization should not take priority over resuscitation.[183]

A nasogastric tube should be inserted to decompress the stomach, and core body temperature readings should be obtained to diagnose and manage potential hypothermia. In the presence of a significantly lowered body temperature, rewarming measures should be instituted, although the rate of rewarming and temperature goals for drowning victims after cardiac arrest remain areas of active research. Although mild therapeutic hypothermia has been shown to decrease cerebral oxygen use and improve neurologic

outcomes in patients with return of spontaneous circulation after witnessed ventricular fibrillation arrest, there are no prospective studies comparing therapeutic hypothermia with normothermia after return of spontaneous circulation in drowning victims. There are several case reports of complete neurologic recovery after therapeutic hypothermia in drowning victims. Return of spontaneous circulation and hemodynamic stability take precedent over the decision to induce hypothermia.[174,184,185]

Occasionally, drowning patients will have marked hemodynamic instability, and resuscitation must be managed accordingly while accounting for the likelihood of concurrent pulmonary edema and acute respiratory distress syndrome. Positive end-expiratory pressure is extremely effective in reversing abnormal ventilation-perfusion matching leading to hypoxemia. Usually, pulmonary injury from drowning improves significantly over a period of 48 to 72 hours, and ventilatory support in most circumstances is relatively brief, unless infection develops. Consequently, if tolerated, noninvasive positive airway pressure ventilation strategies or a high-flow nasal cannula may be reasonable for short-term support. Oxygenation, ventilation, hemodynamics, and glycemic control should be managed in accordance with current critical care guidelines, including those for management of cerebral edema and post–cardiac arrest critical care, if applicable.

The use of antibiotics in drowning victims should be reserved for those who demonstrate signs of infection. Because most pulmonary infections in the near drowning victim appear to be hospital acquired, prophylactic antibiotics may serve only to select for more resistant organisms. If pneumonia is present, antibiotic therapy should be guided by microbiologic data, antibiograms, and standard protocols. If the victim aspirates heavily contaminated water with a known or suspected organism (as in the case of aspiration in a hot tub), the use of prophylactic antibiotics may be appropriate. Although bronchoscopy for the routine management of the drowning victim is not warranted, consideration of this procedure should be made when unexpected difficulties with mechanical ventilation arise, to evaluate for rare complications of drowning such as the aspiration of sand or gravel.[186]

Routine use of corticosteroids to treat the lung injury associated with drowning is unwarranted. Experimental evidence strongly suggests that steroids do not improve the short-term or long-term outcome.[187] Artificial and animal-derived surfactants, extracorporeal membrane oxygenation, cardiopulmonary bypass, and hypothermia have also been used to treat the pulmonary injury associated with drowning.[188–191] Any victim with more than minimal respiratory symptoms, an abnormal chest radiograph, or abnormal arterial blood gas measurements should be observed because pulmonary damage may not be clinically manifest for several hours after the incident.[192] Nearly all patients who will demonstrate significant problems of gas exchange will do so by 4 to 8 hours after the incident; therefore, consideration for discharge from the emergency department may be appropriate in people who can be observed in this fashion.[193] In a pediatric study, normal oxygen saturation and lack of field intervention after pediatric drowning were independent predictors of safe discharge from the emergency department.[194]

PROGNOSIS

The prognosis of the drowning victim depends mainly on the duration of immersion, the length of the anoxic period, and the degree of damage secondary to the anoxic episode. Restoration of normal neurologic function, although unusual, has been described even after prolonged drowning-induced cardiac arrest.[195] An apparent (i.e., undocumented) cardiac arrest does not in itself suggest a poor outcome; however, cardiac arrest that persists through the period of initial first aid and transport to the hospital is a poor prognostic sign. The presence of spontaneous respirations on presentation to the emergency department following cardiac arrest in the field is a good prognostic sign.[196] The duration of immersion correlates with the degree of damage secondary to the anoxic episode and therefore with the outcome. No prognostic test has shown to provide a reliable basis for treatment decisions, and predictions concerning outcome cannot be made in the presence of severe hypothermia, as discussed earlier. Multiple reports have described survivors of cold-water drownings after more than 20 minutes of submersion.[197,198] Notably, certain cold-water aquatic species such as the crucian carp can survive weeks or even months of anoxia (with concurrent hypothermia) and may hold the answers for many ongoing research efforts to improve human capacity to survive hypoxic and ischemic insults.[199]

KEY POINTS

INTRODUCTION

The pleural space is bounded by two membranes: the visceral pleura covering the lung and the parietal pleura covering the chest wall and diaphragm. Into this space, normal liquid and protein enter from the systemic circulation and are removed by the parietal pleural lymphatics. Pleural pressure is subatmospheric and ensures inflation of the lung. Because the mesothelial boundaries are leaky, excess liquid can move across into this lower pressure, high capacitance space and accumulate as a pleural effusion. Thus, pleural effusions are common and of highly diverse etiologies. These effusions can form based on disease of the pleural membranes themselves or of thoracic or abdominal organs. Depending on the protein and *lactate dehydrogenase* (LDH) concentrations of the liquid, these effusions can be categorized as exudates or transudates.

Other chapters cover the anatomy of the pleural membranes (see Chapter 1), the physiology of the pleural space (see Chapter 14), and the pleural diseases related to pleural infections (see Chapters 109) and pleural malignancy (Chapter 114). In addition, pneumothorax, chylothorax, pleural fibrosis, and hemothorax are covered individually in Chapters 110 to 113, respectively. This chapter covers effusions in general, with attention to transudates and exudative effusions caused by nonmalignant and noninfectious causes.

APPROACH TO PATIENTS WITH PLEURAL EFFUSION

Three common symptoms are associated with pleural effusion: dyspnea, cough, and chest pain. Dyspnea appears to be caused by mechanical effects, either due to the expansion of the chest wall and muscles of breathing and/or due to the inversion of the diaphragm.[1–4] Dyspnea due to an effusion can be quickly relieved by removal of the fluid, indicating

the return of improved mechanics. One consequence of this is that even a patient with a trapped lung that cannot reinflate can have improvement of dyspnea if removal of the fluid restores the chest wall and diaphragm to a more normal position. In a recent prospective trial, 73% of patients experienced an improvement in dyspnea with thoracentesis (median volume, 1.7 L); the improvement was greatest in those with baseline abnormal diaphragm movement. Of interest, the improvement in dyspnea was seen in those with or without trapped lung.[5] Cough is another symptom of large effusions and may be due to the distortion of the lung with volume loss. Pleuritic chest pain can be seen due to inflammation, infection, or malignant involvement of the pleura. Pain fibers are most likely those of the parietal pleura, but there are also pain fibers now recognized in the visceral pleura and in adhesions.[6]

Physical findings of a pleural effusion include dullness to percussion, decreased breath sounds, egophony at the upper level of the effusion, and decreased tactile fremitus. With large effusions, signs can include asymmetrical chest expansion or even bulging of the intercostal spaces. A systematic review concluded that the most useful physical findings were dullness to percussion and decreased tactile fremitus[7] (see Chapter 18).

The possibility of a pleural effusion should be considered in any patient with an abnormal chest radiograph. Increased opacity on chest radiography is frequently attributed to a parenchymal abnormality when it actually represents pleural fluid. Free pleural fluid gravitates to the most dependent part of the thoracic cavity, which, in an upright patient, is the posterior costophrenic sulcus. Therefore, if the posterior costophrenic angle is blunted or if the posterior part of the diaphragm is not visible on the lateral chest radiograph, an ultrasonic examination of the pleural space can be obtained to ascertain whether free pleural fluid is present (see Videos 23.10 and 23.11). If the effusion is small and difficult to obtain by thoracentesis, the pleural effusion is not likely to be clinically significant. If the effusion is larger and accessible by thoracentesis, an effort should be made to determine its cause. Various studies have shown that ultrasonic determination of the separation of the visceral from the parietal pleura correlates with pleural effusion volume. In one study, sonographic measurements were more accurate than lateral decubitus radiographic measurements for pleural fluid volume.[7a] In another study, the maximal distance separating the visceral and parietal pleura determined on a transverse section could be related roughly to the volume of pleural fluid removed by multiplying the distance (in mm) by 20. By this method, a maximal distance of 20 mm would allow the pleural volume to be estimated as 400 mL. In this study, a maximal distance less than 10 mm was considered too small to allow thoracentesis.[7b]

DIFFERENTIAL DIAGNOSIS OF PLEURAL EFFUSION

Many different diseases may have an accompanying pleural effusion (Table 108.1). The vigor with which various diagnoses are pursued should depend on the likelihood that the person has that particular disease. In several studies of pleural fluid etiology, *congestive heart failure* (CHF) and cirrhosis are responsible for almost all transudative pleural effusions.[8,9] Pneumonia, malignant pleural disease, *pulmonary embolism* (PE), and gastrointestinal disease account for at least 90% of all exudative pleural effusions (eTable 108.1).[9] Pleural effusions often have more than one cause; in one study, as many as 30% of patients could be shown to have more than one cause, with CHF as the most common contributing cause.[10] As proposed in Chapter 14, one disease may

TRANSUDATIVE PLEURAL EFFUSIONS

Congestive heart failure
Hepatic hydrothorax
Nephrotic syndrome
Peritoneal dialysis
Myxedema
Pericardial disease
Central venous occlusion
Pulmonary veno-occlusive disease

VERY LOW PROTEIN TRANSUDATES

Urinothorax
Subarachnoid-pleural fistula
Iatrogenic

EXUDATIVE PLEURAL EFFUSIONS

Neoplastic diseases (see Chapter 114)
- Metastatic disease
- Mesothelioma
- Primary effusion lymphoma
- Pyothorax-associated lymphoma

Infectious diseases (see Chapter 109)
- Pyogenic bacterial infections
- Tuberculosis
- Actinomycosis and nocardiosis
- Fungal infections
- Viral infections
- Parasitic infections

Pulmonary embolism

Abdominal diseases
- Esophageal perforation
- Pancreatic disease
- Intra-abdominal abscesses
- Postabdominal surgery
- Liver transplantation
- Bilious pleural effusion

Inflammatory diseases
- Rheumatoid pleuritis
- Lupus pleuritis
- Immunoglobulin G4–related disease
- Sarcoidosis
- Asbestos-related disease
- Uremia
- Post–cardiac injury syndrome
- Post–coronary artery bypass surgery
- Drug-induced pleural disease (see Chapter 99)
- Eosinophilic granulomatosis with polyangiitis
- Granulomatosis with polyangiitis
- Sjögren syndrome
- Acute eosinophilic pneumonia

Miscellaneous
- Lung transplantation
- Meigs syndrome
- Endometriosis
- Ovarian hyperstimulation syndrome
- Trapped lung (see Chapter 112)
- Yellow nail syndrome
- Misplaced catheters

Hemothorax (see Chapter 113)
Chylothorax (see Chapter 111)

eTable 108.1 Approximate Annual Incidence of Various Types of Pleural Effusions in the United States

Type of Effusion	Incidence
Congestive heart failure	500,000
Pneumonia (bacterial)	300,000
Malignant disease	200,000
■ Lung	60,000
■ Breast	50,000
■ Lymphoma	40,000
■ Other	50,000
Pulmonary embolization	150,000
Viral disease	100,000
Post–coronary artery bypass surgery	60,000
Cirrhosis with ascites	50,000
Gastrointestinal disease	25,000
Collagen vascular disease	6000
Tuberculosis	2500
Asbestos exposure	2000
Mesothelioma	1500

Modified from Light RW. *Pleural Diseases*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2013.

cooperate with another to produce an effusion, especially if one disease enhances fluid entry into the pleural space and the other compromises pleural fluid exit via lymphatics.

SEPARATION OF EXUDATES FROM TRANSUDATES

A diagnostic thoracentesis should be performed on nearly every patient with free pleural fluid that measures more than 10 mm on the lateral decubitus film, ultrasound, or chest CT scan (eFig. 108.1). If the patient has obvious CHF, consideration can be given to postponing the thoracentesis until the heart failure is treated. However, if the patient is febrile or has pleuritic chest pain or if the effusions are not of comparable size on both sides, CHF is an unlikely explanation for the effusion, and a thoracentesis should be performed without delay.

Thoracentesis is a safe procedure when performed by an experienced operator.[11] It may be even safer when performed with ultrasound guidance.[12] Because of the small-bore needle required, it can be safely performed in patients with coagulopathies and thrombocytopenia,[13] and in patients on positive mechanical ventilation.[14,15] Questions have arisen about safety of thoracentesis in patients on the potent antiplatelet agent clopidogrel; cases of hemorrhage are few,[16] and there are several reports of the safety of thoracentesis in patients on clopidogrel.[17–19] The Society of Interventional Radiology currently recommends withholding clopidogrel for 5 days before thoracentesis when possible.[20] Nonetheless, there are risks to withholding anticoagulants or reversing their effects, and no large studies or published guidelines have provided guidance.[21] Thus, the risks should be balanced and, if thoracentesis is needed, it should be performed by experienced clinicians using ultrasound guidance.

Descriptions of the technique emphasize proper positioning of the patient, identification of the area of decreased tactile fremitus, and use of ultrasound, as recommended by the British Thoracic Society 2010 guidelines.[12] Adequate local anesthesia means anesthetizing the parietal pleura and the skin. The needle should run over the top of the rib to avoid the neurovascular bundle that travels in each intercostal space. Of note, this bundle travels in the middle of the intercostal space for approximately 5 to 6 inches (13 cm) from the spine before taking its safer position beneath the upper rib (eFig. 108.2).[14] Thus, one should avoid thoracentesis medial to the midclavicular line. Doppler ultrasound is increasingly used to identify the intercostal arteries and possible collateral arteries.[22] Drainage of the pleural fluid by manual pumping using one-way valve tubing may be safer than by vacuum drainage, with less pain and fewer complications.[23]

Complications from thoracentesis include pneumothorax and hemothorax. Estimates of each complication from prospective studies are low (2–6% for pneumothorax; 1% for hemothorax), with only half of the pneumothoraces requiring chest thoracostomy.[24] In a more recent prospective cohort study of 9320 procedures over 12 years with the routine use of ultrasound, complications were even lower: 0.6% for pneumothorax, 0.2% for bleeding, and 0.01% for reexpansion pulmonary edema.[11] Pneumothorax is often associated with procedural events, such as aspiration of air, multiple needle passes, and development of new symptoms. The risk for pneumothorax appears to be higher in patients with prior radiotherapy to the chest, multiple prior thoracenteses, or the use of vacuum bottles. In an uncomplicated thoracentesis that is well tolerated by the patient, there appears to be no value for routine chest radiography postprocedure.[24,25] Ultrasound detection of lung sliding in the uppermost part of the chest (where air would collect) can also be performed to exclude pneumothorax. Even when performed, routine post-thoracentesis radiographs rarely show new findings.[24]

The first question that should be answered with the diagnostic thoracentesis is whether the patient has a transudative or an exudative pleural effusion (Fig. 108.1). The identification of transudates or exudates is made by analysis of the levels of protein and LDH in pleural fluid and serum. Exudative pleural effusions meet at least one of the following criteria, whereas transudative pleural effusions meet none[26]: (1) pleural fluid protein/serum protein ratio greater than 0.50, (2) pleural fluid LDH/serum LDH ratio greater than 0.60, and (3) pleural fluid LDH greater than two-thirds of the upper normal limit for serum. If none of these criteria is met, the patient has a transudative pleural effusion, and the pleural surfaces can be ignored while the CHF, cirrhosis, or nephrosis is treated. In the rare cases where malignancy has been associated with a transudate, extrapleural effects of the tumor or other causes such as concurrent CHF are the most likely cause, as evidenced by the rarity of a positive cytology in those effusions.[27,28]

The above criteria may misidentify a transudative effusion as an exudative effusion in as many as 25% of cases.[29] If a patient appears to have a transudative effusion clinically, additional tests can be assessed to verify its transudative etiology. If the difference between the protein concentration of serum and pleural fluid exceeds 3.1 g/dL or if the difference between the albumin concentration of serum and pleural exceeds 1.2 g/dL, the patient in all probability has a transudative effusion.[29,30] If pleural concentrations of *N-terminal pro–brain natriuretic peptide* (NT-proBNP) are elevated (>1500 pg/mL), the patient likely has a transudate from a cardiac cause.[31,32]

Most studies dichotomize pleural effusions into transudates or exudates based on a single cutoff point. However, it is more realistic to consider biologic variation on a continuum, in which very high or very low values are almost always indicative of exudates and transudates, respectively, whereas values near the cutoff levels can be associated with either transudates or exudates and can be considered *indeterminate*. Indeterminate values may indicate that more than one process is acting, as mentioned above,[10,33,34] or that the underlying process has been evolving, such as after diuresis of patients with transudates due to CHF (see later).

When dealing with a patient who has a high likelihood of having a transudative pleural effusion, the most cost-effective use of the laboratory is to order only protein and LDH levels on the pleural fluid and obtain other laboratory tests only if the fluid turns out to be an exudate.[35] If one suspects initially that the patient has an exudate or if the fluid turns out to be an exudate, additional specimens can be sent.

DIFFERENTIATING EXUDATIVE PLEURAL EFFUSIONS

Once it has been determined that the patient has an exudative pleural effusion, one should attempt to determine which of the diseases listed in Table 108.1 is responsible for the effusion, remembering that pneumonia, malignancy,

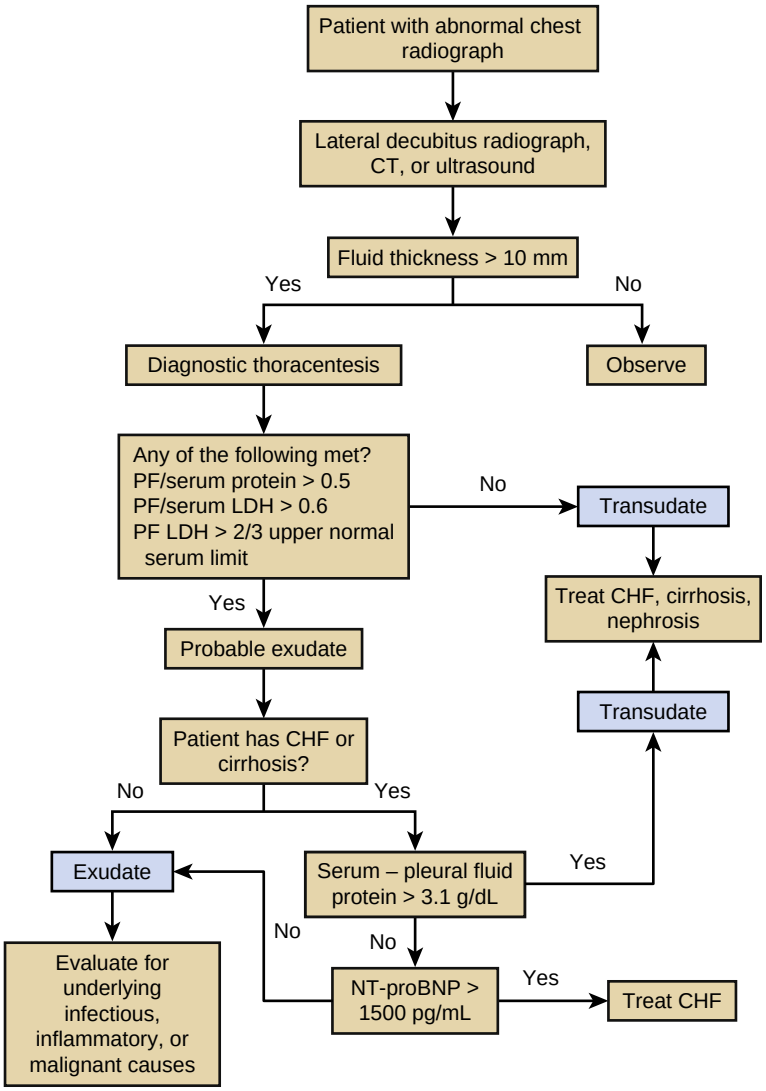

Figure 108.1 Algorithm for distinguishing transudative from exudative pleural effusions. With the results of the initial thoracentesis, one can usually determine whether the effusion is an exudate or a transudate. If a transudate, the treatment can be directed to the likely causes—*congestive heart failure* (CHF), liver disease, or kidney disease. If the protein and *lactate dehydrogenase* (LDH) results are borderline exudative and there is also CHF or cirrhosis present, there is a possibility that the effusion is still transudative. To determine this, one can use two additional tests: If the difference between the serum and pleural fluid protein concentrations is greater than 3.1 g/dL, one can assume that the effusion is transudative. If not, one can test the pleural or serum *N-terminal pro–brain natriuretic peptide* (NT-proBNP); if greater than 1500 pg/mL, one can conclude that CHF is at least one of the causes of the effusion. Once the effusion is determined to be exudative, one can focus on further evaluation of the underlying inflammatory, infectious, or malignant cause. CT, computed tomography; PF, pleural fluid.

and PE account for the great majority of all exudative pleural effusions. In all patients with undiagnosed exudative pleural effusions, the appearance of the fluid should be noted, and the pleural fluid protein and LDH levels (if not already obtained), glucose level, differential cell count, and microbiologic and cytologic studies should be obtained.[36] In selected patients, other tests on the pleural fluid, such as amylase, *antinuclear antibody* (ANA), rheumatoid factor, *adenosine deaminase* (ADA), lipid analysis, and so forth, may be of value. It is certainly not cost-effective, however, to obtain all these tests routinely on patients with undiagnosed exudative pleural effusions.

Appearance of Pleural Fluid

The gross appearance of the pleural fluid should always be described and its odor noted. If the pleural fluid smells putrid, the patient has a bacterial infection (probably anaerobic) of the pleural space. If the fluid smells like urine, the patient probably has a urinothorax. If the pleural fluid is bloody, a pleural fluid hematocrit or erythrocyte count should be obtained. To estimate the hematocrit, the erythrocyte count can be divided by 100,000.[37] For example, a pleural fluid erythrocyte count of 2,000,000/μL divided by 100,000 would give a estimated hematocrit of 20%. If the pleural fluid hematocrit is greater than 50% that of the peripheral blood, the patient has a hemothorax and the physician should strongly consider inserting chest tubes (see Chapter 113). If the pleural fluid hematocrit is less than 1%, the blood in the pleural fluid has no clinical significance. If the pleural fluid hematocrit is between 1% and 50%, the patient most likely has malignant pleural disease, a pulmonary embolus, or a traumatically induced pleural effusion.[38]

If the pleural fluid is turbid, milky, or bloody, the fluid should be centrifuged and the supernatant examined. If the pleural fluid is turbid when originally obtained and the turbidity clears with centrifugation, the turbidity is due to cells or debris in the pleural fluid; if the turbidity persists after centrifugation, the patient probably has a chylothorax or a pseudochylothorax. (eFig. 108.3A and Video 108.1) These two entities can be differentiated by the patient's history, examination of the sediment for cholesterol crystals (see eFig. 108.3B), and lipid analysis of the supernatant. With chylothorax, the disease process is acute, the pleural surfaces are not thickened, there are no cholesterol crystals present, and the pleural fluid triglyceride level is usually

greater than 110 mg/dL (1.24 mmol/L). With pseudochylothorax, the disease process is usually chronic, the pleural surfaces are usually thickened, there may be cholesterol crystals, and the pleural fluid triglyceride level is usually not elevated. (For further discussion of chylothorax and pseudochylothorax, see Chapter 111).

Pleural Fluid Protein

The pleural fluid protein level tends to be elevated to a comparable degree with all exudative pleural effusions and is therefore not generally useful in the differential diagnosis of an exudative pleural effusion. However, if the protein level is greater than 5.0 g/dL, the likelihood of a diagnosis of tuberculous pleurisy is increased. If the pleural fluid protein level is very low (<0.5 g/dL), the patient probably has a urinothorax, a leak of cerebrospinal fluid into the pleural space, or an effusion secondary to the misplacement of a central intravascular line.

Pleural Fluid Lactate Dehydrogenase

Whereas both pleural liquid protein and LDH arise from filtration from serum and thus serve as indicators of vascular permeability, LDH, as an intracellular enzyme, also indicates the level of inflammation and cell turnover within the pleural space. Nonetheless, the pleural fluid LDH level is increased to a comparable degree in patients with all categories of exudative pleural effusions and therefore is of no utility in the differential diagnosis of exudative pleural effusion.[26] Likewise, the pleural fluid LDH isoenzymes are of limited use in the differential diagnosis of exudative pleural effusions. However, pleural fluid LDH concentration should be measured every time a diagnostic thoracentesis is performed because the level of LDH in the pleural fluid reflects the degree of inflammation in the pleural space. If the pleural fluid LDH concentration increases with serial thoracentesis, the degree of inflammation in the pleural space is worsening, and the physician should be more aggressive in pursuing the diagnosis. Alternatively, if the pleural fluid LDH level decreases with serial thoracentesis, the pleural disease is resolving, and observation of the patient is indicated.[37] When an effusion meets exudative criteria on the basis of LDH but not protein, the effusion is usually malignant or parapneumonic.[26]

Pleural Fluid Glucose

A low glucose concentration probably indicates the coexistence of two abnormalities: a thickened, infiltrated pleura leading to an impaired diffusion of glucose into the pleural space plus increased metabolic activity leading to increased glucose utilization within the pleural space. The glucose level should be measured in all undiagnosed exudative pleural effusions because the demonstration of a reduced pleural fluid glucose level (<60 mg/dL, 3.33 mmol/L) narrows the diagnostic possibilities to seven: parapneumonic effusion, malignant effusion, tuberculous effusion, rheumatoid effusion, hemothorax, paragonimiasis, or *eosinophilic granulomatosis with polyangiitis* (EGPA).[37] If a patient with a parapneumonic effusion has a pleural fluid glucose level less than 40 mg/dL (2.22 mmol/L), tube thoracostomy should be considered. Many patients with rheumatoid pleural effusions have a pleural fluid glucose level less than 30 mg/dL (1.66 mmol/L).[39] In contrast, most patients with pleural effusion secondary to *systemic lupus erythematosus* (SLE) will have a pleural fluid glucose level greater than 80 mg/dL (4.44 mmol/L).[40] Patients with malignant pleural disease and a low pleural fluid glucose level usually have a positive pleural fluid cytology, maybe as a sign of more extensive pleural involvement. However, despite reports that low glucose or pH correlated with mortality or with failure of pleurodesis,[41,42] later studies have failed to confirm these findings.[43,44]

Pleural Fluid White Cell Count and Differential

Pleural liquid submitted for white cell count and differential should be sent in a tube with an anticoagulant to prevent the cells from clumping.[45] In the normal pleural space, the cell count has been reported to be 1700 cells/μL.[46] In effusions, the total cell count has limited diagnostic value. A pleural fluid white blood cell count of 1000/μL roughly separates transudative from exudative pleural effusion, whereas a pleural fluid white blood cell count greater than 10,000/μL is most common with empyemas and parapneumonic effusions but can also be seen with pancreatitis, PE, and collagen vascular diseases and, occasionally, with malignancy and tuberculosis.[38]

The differential cell count on the pleural fluid is much more useful than the total white cell count itself. The normal pleural space contains predominantly macrophages (75%), followed by lymphocytes (23%).[46] A change in differential from this normal distribution provides a clue to the underlying disease process. For the pleural fluid differential cell count, the cells should be partitioned into the following categories: polymorphonuclear leukocytes, eosinophils, small lymphocytes, mesothelial cells, and other mononuclear cells. Pleural effusions due to an acute disease process, such as pneumonia, pulmonary embolization, pancreatitis, intra-abdominal abscess, or early tuberculosis, contain predominantly polymorphonuclear leukocytes. Pleural effusions due to a chronic disease process contain predominantly mononuclear cells.

Pleural fluid eosinophilia (10% or more eosinophils by differential count) is most commonly due to a reaction to air or blood in the pleural space. On occasion, no pleural fluid eosinophils are found in the initial thoracentesis, but many eosinophils are seen in a subsequent thoracentesis, most likely due to entry of air or blood caused by the initial thoracentesis.[47] The eosinophilia appears to be due to production of *interleukin* (IL)-5 by CD4 T cells within the pleural space[48] and has been associated with a type 2 innate immune response.[49] At times, the pleural fluid eosinophilia associated with a hemothorax can be associated with eosinophilia in the peripheral blood.[50] The bloody pleural effusion complicating PE frequently contains many eosinophils.[51] With pneumothorax, pleural eosinophilia appears within 3 days of the pneumothorax and reaches a peak after 6 days.[52] With traumatic hemothorax, pleural fluid eosinophilia may not appear until the second week.

After excluding air or blood as the underlying cause, the etiologies of 392 cases of eosinophilic pleural effusions have been reported as follows: 40% idiopathic, 17% malignancy, 13% parapneumonic, 6% tuberculosis, 4% PE, 8% transudates, and 13% other.[53] A later review found that, of 135 patients with eosinophilic pleural effusion, the most common cause was malignancy (35%), followed by infections (19%).[54] A more recent review of 687 cases of eosinophilic pleural effusions identified malignancy as the most common cause (26%), followed by idiopathic (25%)

and parapneumonic effusions (13%).[55] Although malignancy appears to be common in eosinophilic effusions, it is not associated with a high eosinophil percentage.[54,55] If the etiology of the eosinophilia is not evident, several unusual diagnoses should be considered. Benign asbestos pleural effusions are frequently eosinophilic. In one series, 15 of 29 patients (52%) with benign asbestos pleural effusions had pleural fluid eosinophilia.[47] Patients with pleural effusions secondary to drug reactions typically have pleural fluid eosinophilia.[37] The pleural fluid of patients with pleural paragonimiasis is typically eosinophilic with low glucose, low pH, and high LDH level.[56] EGPA is the only other disease that produces this constellation of pleural fluid findings.[57]

Mesothelial cells line the pleural cavities. It is unusual to find mesothelial cells in effusions due to tuberculosis. However, the absence of mesothelial cells is also common with other conditions in which the pleura becomes coated with fibrin, such as a complicated parapneumonic effusion.

Lymphocytic pleural effusions by definition contain greater than 50% small lymphocytes. Most lymphocytic pleural effusions are due to malignancy or tuberculosis. In two series, 90 of 96 exudative pleural effusions (94%) with greater than 50% small lymphocytes were due to tuberculosis or malignant disease.[38,58] Because these two diseases can be diagnosed with needle biopsy of the pleura, the presence of pleural fluid lymphocytosis should alert the physician to consider needle biopsy of the pleura for diagnosis. In general, separation of pleural lymphocytes into T and B lymphocytes has not been useful diagnostically because most lymphocytic effusions contain a predominance of T cells (CD4) whether the diagnosis is malignancy or tuberculosis.[59] Such partitioning can be useful diagnostically, however, when a diagnosis of chronic lymphocytic leukemia or lymphoma is suspected. With these diseases, the pleural lymphocytes are usually of B-cell origin.[60] Lymphocytic effusions can also raise the possibility of chylothorax, sarcoidosis, rheumatoid pleuritis, post–coronary artery bypass graft surgery, and *immunoglobulin* (Ig) G4-related disease.

Pleural Fluid Cytology

A pleural fluid specimen from every patient with an undiagnosed exudative pleural effusion should be sent for cytologic studies. The first pleural fluid cytologic study is positive for malignant cells in up to 60% of malignant effusions.[38] If three separate specimens are submitted, up to 90% with pleural malignancy have positive cytopathology. The percentage of cases in which cytologic study of the pleural fluid establishes the diagnosis of a malignant pleural effusion ranges from 40–87%.[38,61,62] The frequency of positive pleural fluid cytologic tests is dependent on the tumor type. For example, fewer than 25% of patients with Hodgkin disease have positive cytology,[63] whereas most patients with adenocarcinomas have positive cytology.[62] The percentage of positive diagnoses is higher if both cell blocks and smears are prepared by standard protocols and examined by an experienced cytologist.[64] Each additional sample may increase diagnostic yield in part by providing a higher percentage of fresher cells. During thoracoscopy, pleural lavage has been found to increase the diagnostic yield, perhaps by harvesting more fresh cells for analysis.[65] The percentage of positive diagnoses is obviously dependent on the skill of the cytologist. Flow cytometry has been useful in the diagnosis of hematologic metastatic disease in the pleura and may have a role in nonhematologic malignant disease, where discovery of epithelial antigens not present on mesothelial cells can increase the confidence in a diagnosis of malignancy.[66]

Immunohistochemical stains of malignant cells are used to confirm a diagnosis and to specify tumor type, with many new markers available and being used in panels for optimal diagnostic efficacy; cell blocks can also be immunostained for programmed death ligand-1, although the cutoff values for initiating immunotherapy are not yet known.[64,67–69] Immunohistochemical detection of loss of BRCA1-associated protein 1 can now improve the sensitivity for diagnosis of mesothelioma.[70] Cytology can provide enough DNA to assess mutational analysis for *epidermal growth factor receptor* (EGFR)-activating mutations when extremely sensitive techniques including next-generation sequencing are used.[71–74] Cellular material, often from cell blocks but also from cell-free supernatant, may be used as a source of DNA or RNA.[74] In fact, "liquid biopsies" from pleural and other fluids closer to the metastatic site may be more sensitive than blood[75] and are an alternative to tissue biopsies, with a low risk of false negatives.[76]

Other Diagnostic Tests for Malignancy

Cytology may be nondiagnostic either because of a problem of specificity (e.g., the malignant cells cannot be differentiated from reactive mesothelial cells and "atypical" benign cells) or because of a problem of sensitivity (e.g., the malignant cells are rare). Several assays are being evaluated for their ability to increase the specificity of cytology for diagnosis of malignancy.[77] Fluorescent in situ hybridization with chromosome-specific probes can confirm abnormal numbers of specific chromosomes (aneuploidy), thereby confirming that abnormal cells are indeed malignant.[78] Fluorescent in situ hybridization now has value for detecting loss of p16 (CDKN2A) as evidence of pleural mesothelioma.[70] Early findings of malignancy, including DNA methylation, can be detected by methylation-specific *polymerase chain reaction* (PCR),[79] and gene expression patterns can help distinguish mesothelioma and adenocarcinoma.[80] EGFR mutations can predict response to EGFR tyrosine kinase inhibitors. On the other hand, biomarkers have generally been disappointing due to nonspecificity. However, pleural fluid mesothelin measurements hold promise for the diagnosis of mesothelioma; mesothelin measured in the pleural fluid is more accurate than serum mesothelin for the diagnosis of mesothelioma, and a low value in the pleural fluid can be useful in excluding the diagnosis.[81,82] At this time, routine use of mesothelin is not advised[82] (see Chapter 114).

Culture and Bacteriologic Stains

Pleural fluid from patients with undiagnosed exudative pleural effusions should be cultured for bacteria (both aerobically and anaerobically), mycobacteria, and fungi. A Gram stain should also be obtained. In the case of a probable complicated parapneumonic effusion with an initial negative Gram stain, the sediment of the pleural fluid should be stained because the bacteria will be precipitated in the sediment along with

the white blood cells and the debris. The yield of bacterial culture can be increased by using blood culture bottle cultures in addition to standard cultures; in 62 patients with pleural infection, the added inoculation of a set of aerobic and anaerobic blood culture bottles increased the identification of pathogens from 38–59%.[83]

One potentially useful adjunct is molecular detection of bacterial antigens or DNA. Such molecular tests can be rapid and accurate. Antigen-based assays have shown promise in diagnosing empyema caused by *Streptococcus pneumoniae*[84,85] and *Streptococcus pyogenes*.[86] Amplification and sequencing of bacterial 16S ribosomal RNA have identified bacteria in pleural empyema, showing, in one study, that the bacteriology of pleural infections differed from that of pneumonia[87] and, in another study, that a subgroup of empyemas had a bacteriology similar to that of brain abscesses, pointing to hematologic seeding from the oral cavity.[88] It is likely that use of species-specific PCR will become a more standard molecular test for a panel of organisms; it improves detection when compared to 16S PCR and has the potential to make specific diagnoses, although false-positive results are a potential limitation.[89]

OTHER DIAGNOSTIC TESTS FOR PLEURAL FLUID

N-Terminal Pro–Brain Natriuretic Hormone

Natriuretic peptides have proven useful in identifying CHF as the primary or contributing cause of pleural effusions. In one meta-analysis of 12 studies, a pleural fluid NT-proBNP level of greater than 1500 pg/mL was 94% sensitive and 91% specific for CHF-related effusions.[90] NT-proBNP has been shown to be superior to BNP for the purpose of identifying CHF as the underlying cause of the effusion.[31] It is useful to consider that NT-proBNP levels in the pleural fluid are very similar to those in the serum, and thus either can be used for this purpose.[91] NT-proBNP levels are not elevated in the other major transudative effusion, hepatic hydrothorax,[92] nor are they elevated in effusions due to coronary artery bypass graft surgery or PE.[93]

Pleural Fluid pH

The pleural fluid pH can be reduced to less than 7.20 with 10 different conditions: (1) complicated parapneumonic effusion, (2) esophageal rupture, (3) rheumatoid pleuritis, (4) tuberculous pleuritis, (5) malignant pleural disease, (6) hemothorax, (7) systemic acidosis, (8) paragonimiasis, (9) lupus pleuritis, or (10) urinothorax.[37] The decreased pleural fluid pH appears to result from lactic acid and carbon dioxide accumulation in the pleural fluid.[94] The pleural fluid pH is most useful in determining whether chest tubes should be inserted in patients with parapneumonic effusions.[95] A fall in the pleural fluid pH appears to be a sensitive indicator that the patient has a highly inflammatory parapneumonic pleural effusion that will require drainage.

The measurement of pleural fluid pH should be considered only in patients with parapneumonic effusions. In general, pleural fluids with a low pH also have a low glucose[94]; thus, pleural fluid glucose can be used as an alternative to the pH measurement. Although they have been found to have a nonlinear relationship and one cannot predict the other, they reach their diagnostic cutoffs similarly and thus either has been shown to be a valid test.[96] When the pleural fluid pH is used as a diagnostic test, it must be measured with the same care as arterial pH. The fluid should be collected anaerobically in a heparinized syringe and placed on ice. If the sample is left open to air, a spuriously high pH value can be obtained because of the rapid loss of carbon dioxide. The pH must be measured with a blood gas machine; a pH meter or indicator paper is not accurate.[97] Pleural fluid pH, but not glucose, may be significantly altered by residual air or lidocaine in the syringe.[98] In a 2012 study, 40% of pulmonologists did not appreciate that blood gas analysis was the only accurate method to measure pleural fluid pH, and nearly 40% of pulmonologists incorrectly believed their laboratory was using blood gas analysis.[99] The pleural fluid glucose is a preferable test when the accuracy of pH measurements cannot be ensured.

Pleural Fluid Amylase or Lipase

The pleural fluid amylase is elevated in patients with pleural effusions secondary to esophageal perforation, pancreatic disease, or malignant disease. However, because such a small percentage of effusions are due to esophageal perforation or pancreatic disease, the routine measurement of pleural fluid amylase is not indicated.[100] In the case of esophageal rupture, the origin of the amylase is the salivary glands.[101] In animal models of esophageal rupture, the pleural fluid amylase concentration is elevated within 2 hours of esophageal rupture.[102] In effusions due to pancreaticopleural fistulas, the amylase concentration is extremely high (>4000 U/mL), reflecting the concentrations in pancreatic secretions.[103] In approximately 10% of malignant effusions, the pleural fluid amylase level is mildly elevated. The site of the primary tumor in such patients is usually not the pancreas.[104] Malignancy can be differentiated from pancreatic disease with amylase isoenzymes because the amylase with malignant effusions is primarily of the salivary type.[105] Because lipase originates only from the pancreas, finding a high concentration of lipase in the pleural effusion should help identify the source as the pancreas.

Tests for Collagen Vascular Diseases

About 5% of patients with rheumatoid arthritis[106] and 50% of patients with SLE[107] have a pleural effusion sometime during the course of their disease. At times the effusions may be the first manifestation of the disease; therefore, these diagnostic possibilities should be considered in patients with undiagnosed exudative pleural effusion.

Measurement of the ANA titer is the best screening test for lupus pleuritis, although it is now evident that a positive pleural fluid ANA is not specific for the diagnosis. Although all patients with lupus pleuritis have a positive pleural liquid ANA (>1:40), the finding of a positive ANA has been found in 10–27% of all other effusions.[108,109] Neither the titer of ANA, ratio of pleural to plasma ANA, nor the pattern of staining has been found to increase the specificity for SLE.[110] A positive pleural fluid ANA in patients without SLE may be associated with malignancy, including mesothelioma.[110,111] In patients with SLE and a pleural effusion of uncertain etiology, a lack of ANA (e.g., double-stranded DNA, extractable nuclear antigens) in the pleural fluid argues against the diagnosis of lupus pleuritis.[112]

When a rheumatoid pleural effusion is suspected, the clinical picture usually establishes the diagnosis. If any question exists, the level of rheumatoid factor in the pleural fluid should be measured. Only patients with rheumatoid pleuritis have a

pleural fluid rheumatoid factor titer of 1:320 or greater and equal to or greater than the serum titer.[113]

Adenosine Deaminase

Adenosine deaminase (ADA), a product of activated lymphocytes, catalyzes the conversion of adenosine to inosine and is important for normal immune function. The pleural fluid ADA levels are elevated in almost all patients with tuberculous pleuritis but not generally with other conditions, even when associated with lymphocytic effusions.[114] Despite earlier concerns about false-negative values in human immunodeficiency virus–positive patients, ADA remains a sensitive marker for tuberculous pleurisy in patients with human immunodeficiency virus.[115] ADA levels can be elevated in other conditions and also in neutrophilic effusions; in one study, ADA greater than the cutoff (35 U/L) was seen up to 40% of parapneumonic effusions and in half of effusions due to lymphoma.[116] ADA has also been described as elevated in IgG4-related pleural effusions.[117] Because it is a highly sensitive test, the ADA can be a useful test to exclude the diagnosis of tuberculosis when the ADA level is low (<40 U/L).[118] A falsely low ADA, however, may be found in elderly or critically ill patients, for whom a low ADA should not exclude a diagnosis of tuberculosis.[119]

Other pleural fluid tests for *Mycobacterium tuberculosis* are discussed at ExpertConsult.com and in Chapter 109.

PLEURAL MANOMETRY

Measuring the pleural pressure at the time of a thoracentesis adds information on the pleural elastance, the change in pressure resulting from the removal of a certain volume. The normal elastance is considered to be less than 14 cm H_2O/L; in other words, with the removal of 100 mL, the pleural pressure should fall less than 1.4 cm H_2O. Much interest has centered on whether use of pleural manometry would help avoid complications of thoracentesis; currently, routine manometry has not been shown to be of value in avoiding chest pain[132] or *reexpansion pulmonary edema* (RPE), although the incidence of RPE is low enough that such a study would require larger numbers of patients. Probably the best use of pleural manometry now is to diagnose trapped lung,[133] which can be difficult to diagnose based on imaging alone, although there are also reports that the pressures do not always correlate with radiologic evidence of incomplete expansion.[134] At this time, pending ongoing studies, there is no established role for routine pleural manometry.

USEFUL RADIOGRAPHIC TESTS IN PATIENTS WITH SUSPECTED PLEURAL DISEASE

The possibility of a pleural effusion should be considered whenever a patient with an abnormal chest radiograph is evaluated. Two main factors influence the distribution of free fluid in the pleural space. First, the fluid collects in the most dependent part of the thoracic cavity because the lung is less dense than the pleural fluid. Second, because of their elastic recoil, the lobes of the lung maintain their traditional shape at all stages of collapse.

When the patient is upright, the fluid first accumulates between the inferior surface of the lower lobe and the diaphragm. If there is less than 75 mL of fluid, it may occupy only this position without overflowing into the costophrenic sinuses. When more fluid accumulates, it spills over into the posterior costophrenic angle and obliterates the posterior part of the diaphragm on the lateral projection. The possibility of a pleural effusion should be suspected whenever the posterior part of one or both hemidiaphragms is obscured or one hemidiaphragm appears elevated (see eFig. 20.14). The presence of a clinically significant amount of free pleural fluid can be excluded if both posterior costophrenic angles are clear. Pleural effusions on radiography can be missed in the setting of lower lobe consolidation and, in the setting of pneumonia, consideration should be given to seeking the presence of effusions with additional imaging.[135]

When there are larger amounts of pleural fluid, the lateral costophrenic angle on the frontal radiograph becomes blunted. Collins and associates[136] demonstrated that at least 175 mL of pleural fluid had to be injected into the pleural space of cadavers before the lateral costophrenic angle was blunted. In some of their cases, more than 500 mL of pleural fluid could be present without blunting the lateral costophrenic angle. As more fluid accumulates, the entire outline of the diaphragm on the affected side is lost, and the fluid extends upward around the anterior, lateral, and posterior thoracic walls, producing opacification of the lung base and the typical meniscus shape of the fluid. The changes just discussed are suggestive rather than diagnostic of the presence of pleural fluid. Lateral decubitus radiographs (see eFig. 108.1 and eFigs. 20.12 and 20.14) or more commonly ultrasonic examination (see Fig. 23.5) should be obtained in most instances when free pleural fluid is suspected.

Pleural fluid may become encapsulated by adhesions anywhere between the parietal and the visceral pleurae or in the interlobar fissures. Pleural fluid loculates most frequently in association with conditions that cause intense pleural inflammation, such as with a complicated parapneumonic effusion or tuberculous pleuritis. When the loculation is situated between the lung and the chest wall, there is a characteristic radiographic picture. The loculation is D-shaped, with the base of the D against the chest wall and the smooth convexity protruding inward toward the lung (see Figs. 20.37 and 109.4). The absence of air bronchograms helps differentiate a loculated pleural effusion from a parenchymal opacity. A definite diagnosis of loculated pleural effusion is best established by ultrasonography or *computed tomography* (CT).

Ultrasound

Ultrasound is used to identify and locate pleural fluid. In the presence of pleural fluid, the proximal echoes from the skin, intercostal muscles, and parietal pleura are separated from the distal echoes arising from the visceral pleura and the lung by a central echo-free space (see Fig. 23.5). The advantages of ultrasound over CT are the ease and speed with which the examination can be performed, the lack of ionizing radiation, the relatively low cost, and the ability to provide continuous guidance for thoracentesis or pleural biopsy[137] (see Chapter 23).

Interferon Gamma

Interferon gamma, a T-cell lymphokine, plays a critical role in the effective clinical response to *M. tuberculosis*. Pleural fluid interferon gamma appears to be almost as useful as ADA; because ADA is less expensive and has more evidence to support its cutoff values, ADA is preferred. Compared to ADA and interferon gamma, the interferon gamma release assays of pleural fluid, however, have not been shown to be of use in the diagnosis or exclusion of active pleural tuberculosis; these tests are not currently recommended for pleural fluid.[120–123]

Molecular Techniques for Diagnosis of *Mycobacteria tuberculosis*

Four molecular techniques are now available: PCR to detect specific mycobaterial DNA sequences in clinical specimens (pleural liquid or biopsy), nucleic acid probes to identify the organism in culture, restriction fragment length polymorphism to compare strains in epidemiologic studies, and gene-based susceptibility studies to screen for known genes associated with drug resistance.[124]

In theory, PCR tests such as Xpert MTB/RIF (Cepheid) have a great potential for providing a rapid, highly sensitive, and specific diagnosis of mycobacterial infection. In practice, PCR amplification of clinical samples has been limited by a low sensitivity,[125,126] which may be due to degradation of the target DNA by sample processing or by inhibitors of amplification in clinical fluids. Because of the low sensitivity (30% in a recent systematic review), the PCR test is of no value in excluding the diagnosis.[126] Nonetheless, PCR amplification assays show a high specificity and thus, when positive, can help make the diagnosis and detect rifampicin resistance.[127–129] Xpert MTB/RIF has been shown to have a higher sensitivity when used to test pleural biopsy material than pleural fluid.[130,131]

The appropriate site for a thoracentesis can be identified using ultrasound.[14] If a patient has a moderate or large effusion, the thoracentesis may be performed without ultrasound, but large studies have shown a lower incidence of pneumothorax when ultrasound is used.[138] Ultrasound should definitely be used if the effusion is small or if the patient has increased risks due to anticoagulation or comorbidity. When ultrasound is used to identify the site for thoracentesis, it is important to perform the thoracentesis at the time of the ultrasonic examination. If the skin is marked and the patient returned to his or her room, thoracentesis may be unsuccessful because the relationship between the skin and the pleural fluid may have changed. In addition, when the thoracentesis is performed at the time of the ultrasonic examination, the immediate feedback is valuable in improving the skill of the ultrasonographer. An additional advantage may be the use of color Doppler to identify the course of the intercostal artery before thoracentesis.[22] In the 2010 British Thoracic Society guidelines, ultrasound guidance is strongly recommended for all thoracenteses.[12]

Computed Tomography

Chest CT is currently the best way to visualize the entire pleural space.[137] Chest CT has its greatest utility in distinguishing parenchymal and pleural abnormalities.[139] With current protocols involving the rapid injection of intravenous contrast medium, the unaerated perfused lung parenchyma will enhance, whereas the pleural fluid will not.[140] The use of CT to discriminate transudates from exudates by their attenuation (Hounsfield units) has not been found to be clinically useful due to a great deal of overlap.[141] A CT with contrast enhancement has been recommended in the workup of a unilateral effusion if the diagnosis is still unclear after history, physical examination, chest radiograph, and thoracentesis that excludes a transudate.[142]

Chest CT is quite useful in distinguishing a parenchymal lung abscess located near the chest wall from an empyema with an air-fluid level. The most distinctive features are the margins of the abnormality. With empyema, the cavity walls are of uniform thickness both internally and externally, and the adjacent lung is usually compressed. The angle of contact with the chest wall may be obtuse. In addition, most empyemas have a lenticular shape (see Fig. 109.5) and demonstrate the "split pleura" sign (Fig. 108.2A).[143] With lung abscess, the walls of the cavity are not of uniform thickness, and the adjacent lung is not compressed (see Figs. 50.2 and 50.3). The angle of contact with the chest wall may be acute (see Fig. 108.2B).

In diffuse pleural disease, chest CT is useful in distinguishing malignant from benign causes. Features associated with malignancy include circumferential pleural thickening, pleural nodules (see Fig. 114.1), parietal thickening greater than 1 cm, and mediastinal pleural involvement (Video 108.2).[144] The distinction of metastatic disease from mesothelioma can be difficult, although hilar adenopathy is more common with metastatic disease.[137]

CT pulmonary angiography (CTPA) has become the first-line imaging test for the evaluation of PE[145,146] (see Chapters 20 and 81). The evaluation of a patient with a pleural effusion for PE can begin with a Doppler ultrasound of the lower extremities. If the ultrasound identifies thrombus, the patient can then be treated for thromboembolic disease. If it is negative, the patient may still have a PE. In the past, the standard approach was to proceed to lung ventilation-perfusion scanning. However, this has largely been replaced by CTPA. CTPA is highly sensitive and specific for pulmonary emboli in the proximal, segmental pulmonary arteries.[145] In contrast to ventilation-perfusion lung scanning, CTPA is generally more available, is less affected by the presence of a pleural effusion, and can establish alternate diagnoses as well[146] (see

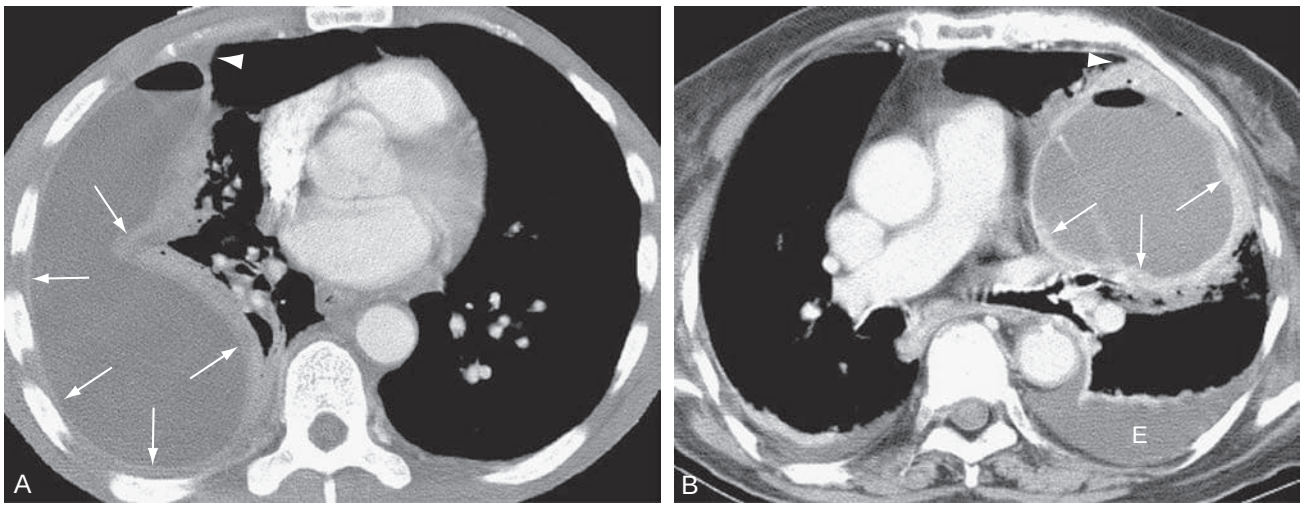

Figure 108.2 Typical *computed tomography* (CT) features of a pleural empyema versus a lung abscess. (A) Axial CT through the lower thorax in a patient with fever and pleuritic chest pain shows features typical of empyema, including the formation of obtuse angles between the lesion and chest wall (*arrowhead*), a lenticular shape, a smooth internal surface (*arrows*), and mass effect on surrounding structures (note slight leftward shift of the heart and great vessels). Note enhancement of the parietal and visceral pleura, representing the split-pleura sign (*arrows*) and the presence of an air-fluid level, indicating the presence of a bronchopleural fistula. (B) Axial CT through the midthorax in a patient with fever and cough productive of foul-smelling sputum shows features typical of a pulmonary abscess, including the formation of acute angles between the lesion and the chest wall (*arrowhead*), a round shape, a thick, irregular internal surface (*arrows*), and relatively little mass effect on surrounding structures, despite the large size of the lesion. The lack of mass effect results because pulmonary abscesses tend to destroy adjacent lung more than they displace it. An effusion (*E*), found to be an empyema, is also present. (Courtesy Michael B. Gotway, MD.)

Chapter 81). In addition, CTPA can be used to assess severity; measurements of right ventricle to left ventricle diameter greater than 1 are associated with a fivefold risk of death from PE and should increase concern for such a patient, although treatment guidelines do not currently incorporate these findings into clinical decision making.[147]

Magnetic Resonance Imaging

At the present time, *magnetic resonance imaging* (MRI) is less satisfactory than ultrasound or CT for the evaluation of pleural effusions.[148] It is possible that with improved MR technology, the characteristics of pleural fluid can be determined noninvasively. At the present time, respiratory and cardiac motion is the major limitation in evaluating specific intensity patterns of fluid collections of various compositions. MRI may have current value in delineating malignancy in the pleural space and may be better than chest CT for determining chest wall or diaphragmatic invasion.

Positron Emission Tomography and Computed Tomography

Positron emission tomography (PET) visualizes tissues that are metabolically active by their concentration of ^{18}F-fluorodeoxyglucose. Because most malignant cells have a higher metabolic rate than nonmalignant cells, PET can help differentiate malignant from benign lesions, help stage patients with malignancy, and help identify recurrence.[137] PET/CT integrates the metabolic information of PET with the detailed anatomic information of CT. Compared with CT or PET alone, PET/CT can allow detection of additional lesions, localize them more accurately, characterize them as highly likely to be malignant, and discriminate malignant from surrounding normal tissue[149] (see Chapter 114).

INVASIVE TESTS IN PATIENTS WITH UNDIAGNOSED EXUDATIVE PLEURAL EFFUSIONS

In the patient with an undiagnosed exudative pleural effusion, several invasive tests might be considered, including closed- or image-guided needle biopsy of the pleura, bronchoscopy, thoracoscopy or video-assisted thoracic surgery, and open biopsy of the pleura.

Nonspecific Findings on Invasive Testing

Nonspecific findings are common after invasive testing. After closed-needle biopsy, Poe and coworkers[150] reported that, of 207 patients with adequate biopsies, as many as 143 (68%) had nonspecific or normal results. In follow-up of these 143 patients at 12 to 72 months, 29 patients were diagnosed with malignant pleural disease and one patient was diagnosed with tuberculous pleuritis. In all 29 cases in which malignancy was eventually diagnosed, the diagnosis of malignant neoplasm was suggested by clinical criteria, such as weight loss, constitutional symptoms, or a history of previous cancer. These authors concluded that most patients with undiagnosed exudative pleural effusions in whom the clinical picture does not suggest malignancy are best managed by observation. In those with symptoms suggestive of malignancy, image-guided pleural biopsy or thoracoscopy are probably the procedures of choice.

Even thoracotomy often fails to provide a diagnosis in patients with pleural effusions. Over the 11-year period from 1962 to 1972, 51 patients with pleural effusion at the Mayo Clinic had no diagnosis after an open pleural biopsy.[151] In 31 of these patients (61%), there was no recurrence of the pleural effusion, and no cause ever became apparent. However, 13 of the patients were eventually proved to have malignancy: 6 had lymphoma and 4 had malignant mesothelioma. Thus, observation of patients with undiagnosed pleural effusions is often warranted unless there is compelling reason to pursue the diagnosis of malignancy. Since the time of this study, there have been many improvements in diagnostic tests that may increase the diagnostic yield of invasive procedures and the treatment options available.

If one looks to more recent data of outcomes after thoracoscopy and *video-assisted thoracic surgery* (VATS), the conclusions are similar. Two retrospective studies by Davies and colleagues[152] and McDonald and colleagues[153] yielded almost identical results. After thoracoscopy or VATS, 31% of patients in both studies (99/319 combined) had nonspecific findings. When these patients with nonspecific findings were followed for approximately 2 years, 11% in both studies (11/99 combined) were found to have malignancy. One can conclude that, in many patients with undiagnosed exudative pleural effusions, the problem will resolve. Thus, three factors should influence the vigor with which one pursues the diagnosis with invasive tests. (1) The symptoms and the clinical course of the patient: if the symptoms of the patient are minimal or if the symptoms are improving with time, a less aggressive approach is indicated. (2) The trend of the pleural fluid LDH level with time: if the pleural fluid LDH increases with serial thoracenteses, a more aggressive approach is indicated. (3) The attitude of the patient: if the patient is anxious about the cause of the pleural effusion, an aggressive approach should be taken. Furthermore, when an undiagnosed exudate resolves without treatment, two diagnoses should still be considered and excluded: PE and tuberculosis.

Needle Biopsy of the Pleura

Small specimens of the parietal pleura can be obtained with needle biopsy, also called blind or closed-needle biopsy. The needles most commonly used for this procedure are the Cope needle and the Abrams needle.[37] Because needle biopsy of the pleura is useful mainly to establish the diagnosis of malignant or tuberculous pleural effusions, this procedure should be considered when one of these diagnoses is suspected.

In malignant pleural disease, the needle biopsy of the pleura will be positive in 40–60% of patients.[154–156] Overall, the yield from pleural fluid cytology tends to be higher, probably because it samples cells dislodged from the entire pleura, whereas the needle biopsy can only sample from a localized area. In two series of malignant pleural effusions (n = 347), the cytology was positive in 58–69%, whereas the pleural biopsy was positive in 43–48%; the pleural biopsy added some diagnoses of malignancy in a few cases where the cytology was negative.[154,156] A prudent approach to the patient with a suspected malignant pleural effusion is to obtain a pleural biopsy only if the cytology obtained at the time of the initial diagnostic thoracentesis is nondiagnostic.

If the CT shows pleural thickening or nodularity, an image-guided pleural biopsy is an excellent option.[157,158]

Needle biopsy of the pleura has greater utility for the diagnosis of tuberculous pleuritis than of malignancy.[159] The initial biopsy is positive for granulomas in 50–80% of patients with tuberculous pleuritis.[160] Combining histology plus culture, the sensitivity of closed pleural biopsy for tuberculosis can be as high as 92%.[161] The demonstration of granulomas on the pleural biopsy is virtually diagnostic of tuberculous pleuritis; caseous necrosis or acid-fast bacilli need not be demonstrated. On rare occasions, fungal diseases, sarcoidosis, or rheumatoid pleuritis can produce granulomatous pleuritis. When tuberculous pleuritis is suspected, some of the pleural biopsy specimens should be cultured for mycobacteria.

The greatest value of needle biopsy for a patient with tuberculosis is in obtaining material for culture of *M. tuberculosis* for the determination of drug susceptibility. Often, the presentation of a patient with a recent purified protein derivative conversion and an exudative pleural effusion with lymphocytosis is classic and unlikely to be due to any diagnosis other than tuberculous pleurisy. The diagnosis can be further supported by measurements, where available, of pleural fluid ADA. In a patient with a recent skin test conversion, a lymphocytic exudate and an elevated pleural fluid ADA, treatment for tuberculosis can be offered with confidence without needle biopsy confirmation. However, when the patient may have been exposed to drug-resistant organisms, needle biopsy will increase the likelihood of obtaining organisms for culture and is recommended. Sputum induction can also be useful for culturing the organism, even when the patient is suspected to have only pleural involvement and the chest radiograph shows no pulmonary involvement; in this setting, sputum induction has been shown to have a yield similar to culture of the pleural biopsy (52% vs. 62%).[162] Medical thoracoscopy has a higher yield than closed-needle biopsy for obtaining pleural material for culture. When different approaches were compared in the same 51 patients, thoracoscopy obtained a positive culture of *M. tuberculosis* in 76%, whereas the Abrams needle obtained a culture in 48%.[163] If the need for obtaining positive cultures is high, the more invasive diagnostic tests, including medical thoracoscopy, may be preferred.

The two major complications of needle biopsy of the pleura are pneumothorax and bleeding. Pneumothoraces require a chest tube in only about 1% of pleural biopsies.[150,154,161] Many pneumothoraces likely develop because of leakage of air through the biopsy needle and do not necessarily indicate puncture of the lung. A hemothorax can result from inadvertent biopsy of an intercostal artery or vein. Although an older series reported two deaths from hemothorax in 227 biopsy procedures,[150] more recent series have not reported significant hemothorax.[161] The pleural biopsy needle can also be mistakenly inserted into the liver, spleen, or kidney, which can lead to hemorrhage in these organs. However, in general, bleeding complications are rare.

Image-Guided Pleural Biopsy

In patients with pleural abnormalities consistent with malignancy, CT-guided cutting-needle biopsies may supplant closed pleural biopsy for diagnosis, where image-guided technology is available.[164] In a randomized study of 50 patients with suspected malignant pleural effusions with negative cytology, those randomized to image-guided biopsy were more likely to be diagnosed (87% sensitivity) than those randomized to closed pleural biopsy (47%).[157] In situations where the effusion is small or where there is loculation or pleural thickening without an effusion, CT image-guided pleural biopsy is an excellent choice. Ultrasound guidance may also be used for closed pleural biopsy or transthoracic needle aspiration.[158] PET/CT may increase the yield further by improving interpretation and selection of biopsy targets (see earlier).

Bronchoscopy

Another procedure that should be considered in the patient with an undiagnosed pleural effusion is bronchoscopy. If the patient has an associated parenchymal lesion or hemoptysis, fiberoptic bronchoscopy will provide a diagnosis in nearly 75%.[165] On the other hand, if the patient has neither a parenchymal abnormality nor hemoptysis, a diagnosis for the pleural effusion is established less than 10% of the time.[166] At the present time, chest CT should be performed in all patients with undiagnosed exudative pleural effusions. Bronchoscopy should then be performed only if the CT scan demonstrates parenchymal abnormalities or if the patient has hemoptysis. At the time of bronchoscopy, special attention is paid to portions of the lung in which the parenchymal abnormalities were demonstrated.

Thoracoscopy or Video-Assisted Thoracic Surgery

Thoracoscopy may be useful diagnostically in patients in whom the origin of a pleural effusion remains unclear after routine fluid analysis and needle biopsy of the pleura. (See Chapter 29.) In many cases, especially for the evaluation of malignancy, thoracoscopy may supplant needle biopsy because of a greater diagnostic yield and the added ability to provide a pleurodesis. Thoracoscopy can be performed by pulmonologists using local anesthesia and conscious sedation for direct visualization of the pleural surfaces, tissue sampling, and pleurodesis; VATS, performed by thoracic surgeons, uses general anesthesia and single-lung ventilation by double-lumen intubation and allows greater access to the pleura and lung for surgical procedures.

Which patients with undiagnosed pleural effusions should undergo thoracoscopy? A diagnosis can be established in more than 90% of patients with malignancy, including those with mesothelioma.[167] Moreover, talc can be insufflated at the time of the procedure, which will control the effusion in the majority of patients. Nonetheless, thoracoscopy is not universally available, and there are risks of the procedure, a need for postprocedure chest tube(s), and a procedure cost that should be considered. Thoracoscopy is therefore recommended for the patient with a pleural effusion that remains undiagnosed after thoracentesis and needle biopsy of the pleura, and in whom the diagnosis of malignancy is strongly suspected and in whom one wishes to establish this diagnosis.

TRANSUDATIVE PLEURAL EFFUSIONS

Transudative pleural effusions accompany many common clinical disorders. It is noteworthy that the primary

abnormality in most cases of transudative pleural effusions originates in organs other than the pleura or lungs, especially the heart, liver, and kidneys. This association emphasizes the fact that although patients may visit their physicians for respiratory complaints, these symptoms may be caused by extrapulmonary disorders.

CONGESTIVE HEART FAILURE

CHF is probably the most common cause of pleural effusion.[37] The incidence of pleural effusion in patients with CHF is high. In one series of 60 patients with an exacerbation of stable CHF, chest CT scans demonstrated that 50 patients (83%) had a right-sided pleural effusion and 46 patients (77%) had a left-sided effusion. Approximately one-third of the effusions had a volume that exceeded 700 mL.[168] In a retrospective series of more than 3000 patients with acute heart failure, effusions were noted in 46%, of which most were bilateral.[169]

Pathophysiology (See Chapter 14)

The pleural fluid that accumulates with CHF is related to the clearance of pulmonary interstitial fluid across a leaky mesothelium into the pleural space.[170] In studies in which sheep lungs were isolated in situ, volume loading led to an increased transudation across the lung into the pleural space.[171] The pleural fluid had the same protein concentration as that of the lung lymph and the interstitial edema liquid in the lung. The volume of pleural fluid constituted about 25% of all edema formed in the lung.[171] In the clinical situation, patients with CHF are much more likely to have a pleural effusion if there is radiologically apparent pulmonary edema.[172]

Clinical Manifestations

Patients with pleural effusion resulting from CHF usually have symptoms and signs of heart failure, such as dyspnea on exertion, orthopnea, nocturia, peripheral edema, distended neck veins, crackles, and a cardiac gallop. The chest radiograph almost always reveals cardiomegaly in addition to the pleural effusion.

The pleural effusions seen with CHF tend to be bilateral, with larger effusions on the right (Fig. 108.3A). On CT imaging, interstitial and alveolar edema can often be detected by the presence of thickened septae and patchy opacities (Video 108.3, see Fig. 108.3B–C). Thickened septa represent interstitial edema, as seen in edematous lungs frozen to demonstrate the location of edema; the interstitial edema is continuous with the interlobular septa and the subpleural space, from which the edema has been shown to move across the visceral pleura to the pleural space (see Fig. 108.3D).[171]

CHF, either alone or as a contributing factor, is associated with bilateral and unilateral effusions. In an autopsy study of 250 patients with CHF and pleural effusion, 88% of the patients had bilateral pleural effusions, with the mean volume of pleural fluid in the right pleural space (1084 mL) slightly greater than the mean volume of fluid in the left pleural space (913 mL).[173] Of the 35 patients with CHF who had unilateral pleural effusions, 46% also had either PE or pneumonia.[173] Weiss and Spodick[174] reported that 73% of 51 patients with CHF had bilateral effusions, 19% had unilateral right-sided effusions and 9% had unilateral left-sided effusions. In a study of 100 patients with bilateral pleural effusions, the causes were often multiple; in fact, most of the effusions were exudative and, of these, CHF was the second most common cause.[33] In a study of unilateral effusions, of 130 prospectively studied patients, 30% had multiple causes, of which CHF was the most common contributing cause.[10]

The reason that effusions are generally larger on the right side may lie in the fact that they originate from the larger lung on the right side.[175] In volume-overloaded sheep, the rate of liquid leakage from the right lung was higher than from the left, likely due to the larger volume and surface area of the right lung.[171] In another study in awake sheep, there was no difference in the rate of absorption of effusions from the right and left pleural spaces,[176] suggesting that differences in formation are the cause of the difference in size.[175,176]

Although CHF is by far the most common cause of bilateral pleural effusions, an alternative explanation should be sought if there is no cardiomegaly. In one early series of 78 patients with bilateral effusions but a normal-sized heart, only 4% of the effusions were caused by CHF.[177]

Diagnosis and Management

The diagnosis is usually suggested by the clinical picture of CHF. A diagnostic thoracentesis should be performed if the pleural effusion is unilateral, if bilateral effusions are not comparable in size, if the patient is febrile, if the patient has pleuritic chest pain, or if the patient does not have cardiomegaly.[37] Otherwise, one can treat the CHF and observe; if the effusions do not resolve in a few days, a diagnostic thoracentesis should be performed.

The pleural fluid from a patient with CHF is usually a transudate.[26] However, if the patient has been on diuretics, the pleural fluid protein and LDH ratios may be increased sufficiently that the pleural fluid meets exudative criteria. A similar phenomenon has been described in the ascites literature.[178] The LDH ratio can also increase if intrapleural LDH increases due to injury from repeated taps and if serum LDH falls when diuresis reduces liver congestion.[178] In general, if the effusion protein and LDH values meet Light's criteria for an exudate, it is only by a small amount.[179] The transudative origin of the pleural fluids can be established in such patients if the serum minus the pleural fluid protein concentration is greater than 3.1 g/dL or the serum minus the pleural fluid albumin concentration is greater than 1.2 g/dL,[30] or by measurement of the pleural fluid NT-proBNP hormone.

Measurement of pleural fluid NT-proBNP is useful in this setting and may be more accurate, although more expensive, than the serum-to-pleural protein gradients for correctly classifying effusions from CHF.[31] Pleural fluid NT-proBNP is superior to BNP.[31] In a systematic review and meta-analysis of 10 studies, pleural fluid NT-proBNP was shown to be very useful for the diagnosis of pleural effusions due to CHF; the studies used different threshold values, but in this review the authors proposed a threshold for diagnosis of 1500 pg/mL (the average level was greater than 6000 pg/mL).[180]

Patients with CHF and pleural effusion should be treated with afterload reduction, diuretics, and inotropes, as needed. When the heart failure is successfully managed,

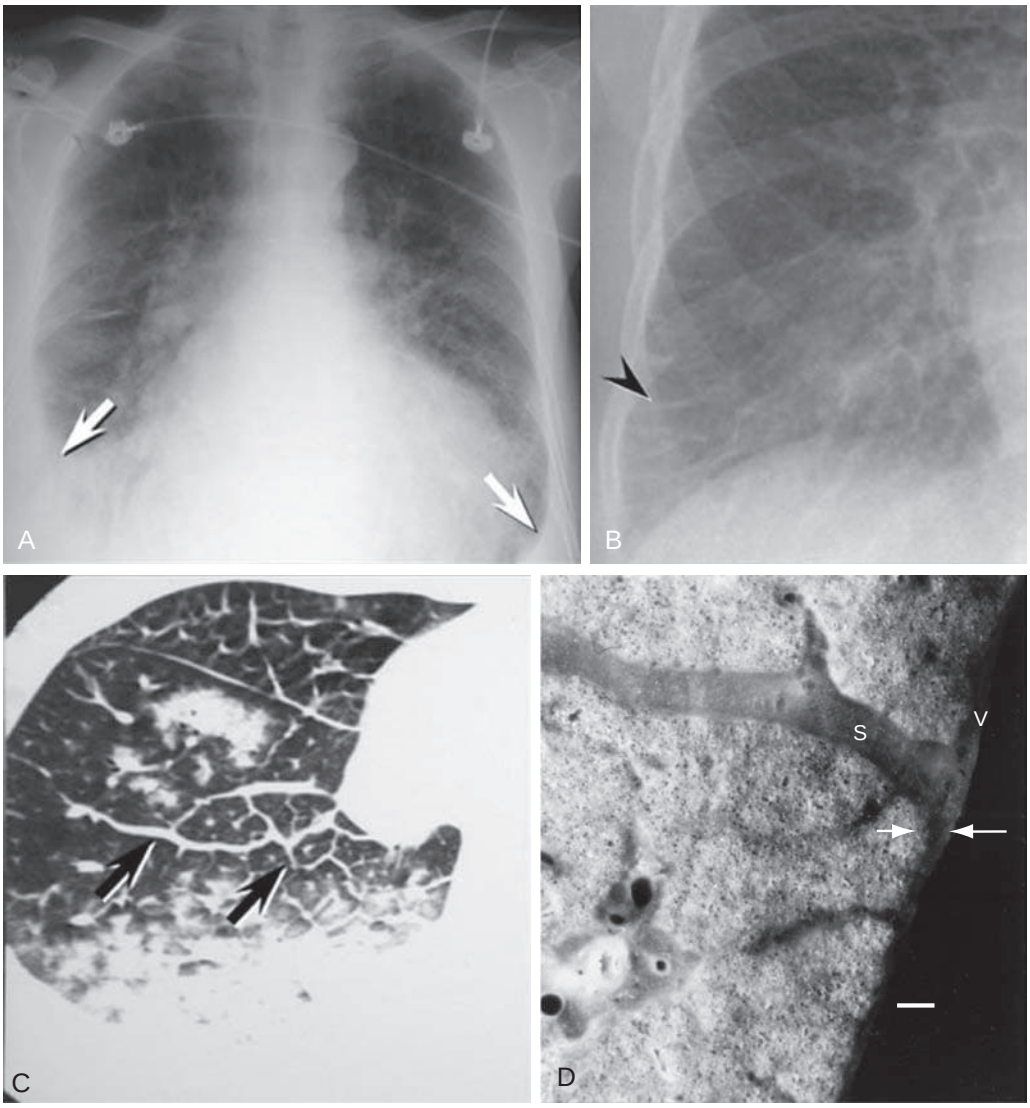

Figure 108.3 Pulmonary effusion from congestive heart failure. (A) Frontal chest radiograph in a patient with pulmonary edema shows cardiomegaly, bilateral pleural effusions (*arrows*), and central interstitial thickening. Note that the right effusion is slightly larger than the left effusion. (B) Detail frontal chest radiograph in a patient with increased pressure edema shows marked peripheral interlobular septal thickening (Kerley's B lines, *arrowhead*). (C) Chest computed tomography in a patient with pulmonary edema shows interstitial edema with smooth interlobular septal thickening (*arrows*). Bilateral pleural effusions are also present. (D) Frozen sheep lung after volume loading showing edema as a continuous band (*between arrows*) from the interlobular septa (S) to beneath the visceral pleura (V), which it can cross to enter the pleural space. Horizontal bar = 1 mm. (A–B, Courtesy Michael B. Gotway, MD. C, From Broaddus VC, Wiener-Kronish JP, Staub NC. Clearance of lung edema into the pleural space of volume-loaded anesthetized sheep. *J Appl Physiol.* 1990;68[6]:2627.)

the pleural effusion usually resolves. If the patient is markedly dyspneic when first evaluated, a therapeutic thoracentesis to relieve the dyspnea should be considered. Rarely, despite intensive therapy of the CHF, a patient has persistent large effusions; if such patients are dyspneic and if their dyspnea is relieved by a therapeutic thoracentesis, consideration can be given to controlling recurrent effusions with a pleurodesis using a sclerosing agent, such as talc, or the insertion of an indwelling pleural catheter.

HEPATIC HYDROTHORAX (See Chapter 126)

The incidence of pleural effusions with cirrhosis is approximately 6%.[181,182] The incidence appears to be much higher if ascites is present; however, in some patients with hepatic hydrothorax, no ascites can be detected, presumably because all ascitic fluid moves to the pleural space because of prevailing pressure gradients and low-resistance diaphragmatic defects (Fig. 108.4).[175,183]

Pathophysiology

The predominant mechanism leading to a pleural effusion in a patient with cirrhosis and ascites appears to be the movement of the ascitic fluid from the peritoneal cavity through defects in the diaphragm into the pleural space.[184] The decreased plasma oncotic pressure is only a secondary factor.

The diaphragmatic defects have been demonstrated in many ways. Lieberman and coworkers[181] introduced 500 to 1000 mL of air into the peritoneal cavity of five patients with cirrhosis, ascites, and pleural effusions and found that a pneumothorax developed in all patients within 48 hours. In addition, they were able to demonstrate air bubbles coming

through an otherwise undetectable diaphragmatic defect at thoracoscopy in one of their patients. In two of their patients, diaphragmatic defects were demonstrated at postmortem examination.[181] By thoracoscopy, different types of defects have been documented, such as blebs or fenestrations[185] (eFig. 108.4). Normally, there are no direct lymphatic connections between the peritoneal and the pleural spaces. Thus, the connections between the spaces are either preexisting developmental defects or are defects caused by trauma or stretching.

Clinical Manifestations

The clinical situation in patients with pleural effusions from cirrhosis is usually dominated by the cirrhosis. At times, however, the presence of a large pleural effusion may produce severe dyspnea. The pleural effusion associated with cirrhosis and ascites is frequently large and can occupy the entire hemithorax. The large effusions form because the diaphragmatic defect permits fluid to flow from the peritoneal cavity into the pleural cavity until the pleural pressure approaches the peritoneal pressure. The pleural effusions are usually right sided (80%) but occasionally are left sided (17%) or bilateral (3%).[184] Effusions can develop suddenly, presumably when the diaphragm becomes increasingly thinned and a rent develops (Fig. 108.4).

Diagnosis and Treatment

The diagnosis of hepatic hydrothorax is usually easily established from the clinical picture. If doubt exists, the diagnosis can be confirmed by scanning the chest after technitium-99m sulfur colloid is injected into the peritoneal cavity.[186] Both a paracentesis and a thoracentesis can be performed to confirm that the ascites and the pleural fluid are both transudates. Xiol and associates[187] performed thoracentesis on 60 patients with pleural effusion in the setting of cirrhosis and ascites. The pleural fluid analysis yielded a diagnosis other than hepatic hydrothorax in 18 (30%), including 9 spontaneous bacterial pleuritis, 2 tuberculosis, 2 adenocarcinomas, 2 parapneumonic effusions, and 3 undiagnosed exudates. The protein in the pleural fluid is usually higher than that in the ascitic fluid but is still less than 3.0 g/dL,

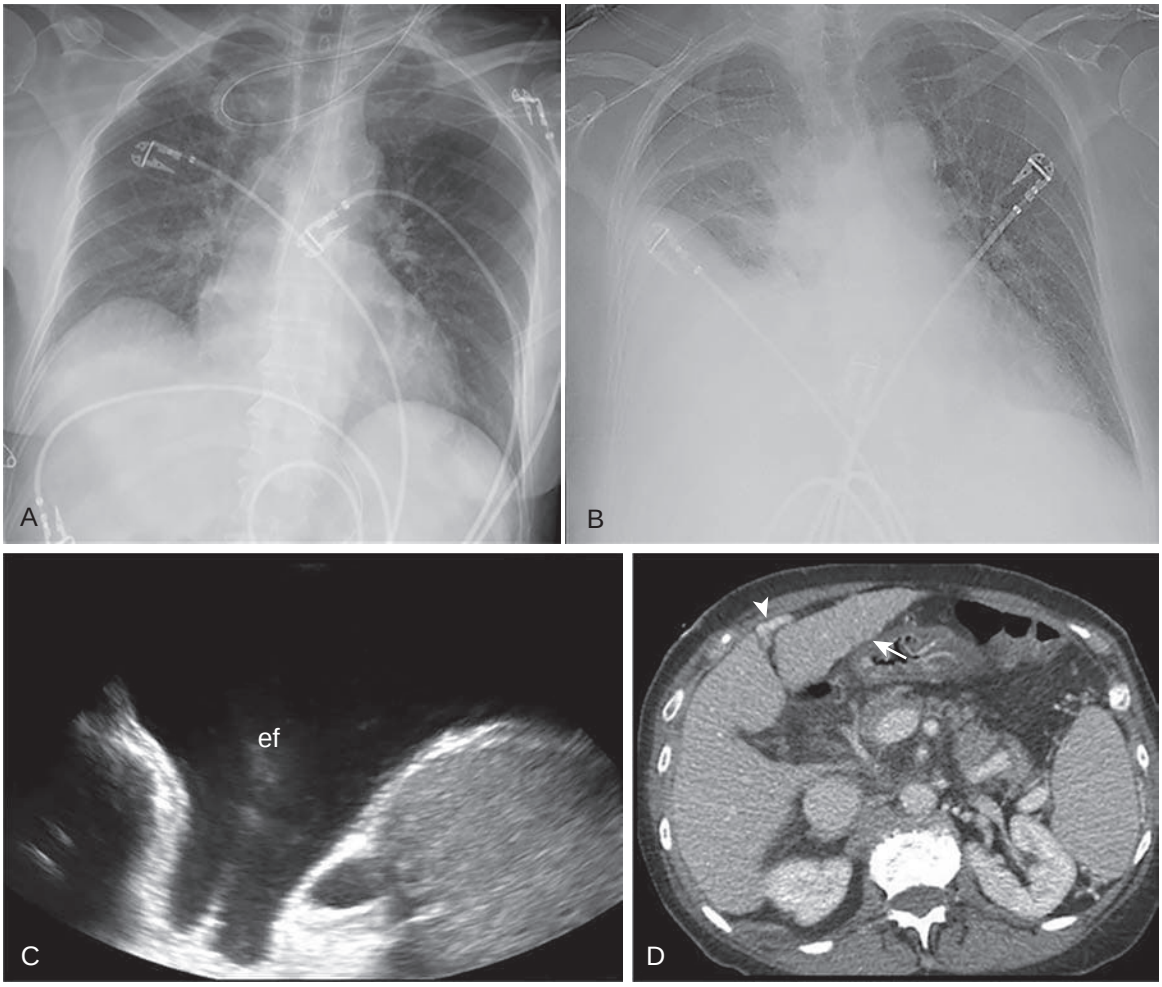

Figure 108.4 Rapid development of hepatic hydrothorax. (A) Frontal chest radiograph shows an elevated right diaphragm but no other significant findings. (B) Frontal chest radiograph performed about 30 hours after A shows a new large right pleural effusion, shown to be a transudate. (C) Thoracic ultrasound performed for thoracentesis shows a large right pleural effusion (*ef*). (D) Axial enhanced computed tomography of the abdomen shows a nodular liver contour (*arrow*) consistent with cirrhosis. A recanalized periumbilical ligament (*arrowhead*) is consistent with portal hypertension. No ascites is present in the upper abdomen, suggesting that it has all moved into the pleural space. (Courtesy Michael B. Gotway, MD.)

and the LDH is low.[181] If the polymorphonuclear cell count is greater than 500 cells/μL, the diagnosis of spontaneous bacterial pleuritis in conjunction with spontaneous bacterial peritonitis should be considered.[188]

The initial management of the pleural effusion associated with cirrhosis and ascites should be directed toward treatment of the ascites. Chest tube insertion should be avoided because the ascitic fluid will also drain through the chest tube, which can lead to massive protein depletion and even fatal cardiovascular collapse.[183] Instead, the patient should be given a low-salt diet and treated with diuretics, usually furosemide and spironolactone.

If diet and diuretics cannot control the effusion, the treatment of choice is liver transplantation.[183,189] Patients with hepatic hydrothorax have been found to do well posttransplant, at least as well as matched cirrhotic patients without hepatic hydrothorax[189]; however, although hepatic hydrothorax increases the mortality risk for patients with cirrhosis, this condition does not yet merit higher priority for transplant.[190] The next best approach is probably implantation of a *transjugular intrahepatic portal systemic shunt* (TIPS). Kinasewitz and Keddissi[183] summarized the literature on 115 patients who received TIPS for refractory hepatic hydrothorax and reported that the procedure controlled the hydrothorax in 80%, but 12% of the patients developed encephalopathy. In a study of TIPS with a long follow-up, 73 patients underwent TIPS with 59% complete response at 1 month and a 21% partial response; however, hepatic encephalopathy developed in 15%, and 30-day mortality was 19%. Survival was associated with the pre-TIPS *Model for End-stage Liver Disease* (MELD) score: with a MELD score less than 15, median survival was 875 days; with a MELD score greater than 15, it was 180 days.[191] Pleurodesis has been described in a few patients, but is complicated by rapid fluid movement into the pleural space.[192] If neither TIPS nor liver transplantation is feasible, the best alternative treatments are probably videothoracoscopy with closure of the diaphragmatic defects and pleurodesis[193,194] or placement of an indwelling pleural catheter.[195] An indwelling pleural catheter has been used as a bridge to liver transplant and as a palliative treatment; approximately 30% can experience a spontaneous pleurodesis, making this an attractive option.[192] Surprisingly, complications due to volume or electrolyte depletion have not been a problem, but infectious complications have been reported at 10–18%.[195,196]

Spontaneous Bacterial Pleuritis

Spontaneous bacterial pleuritis is, by definition, infection of a preexisting hepatic hydrothorax in which a parapneumonic infection has been excluded. Originally termed spontaneous bacterial *empyema*, we prefer the term *pleuritis* to emphasize its similarity to spontaneous bacterial peritonitis and to indicate that its treatment does not require tube thoracostomy. The diagnosis of spontaneous bacterial pleuritis is made if the pleural fluid culture is positive, the pleural fluid neutrophil count is greater than 250 cells/μL, and a pneumonic process has been excluded; the diagnosis of *culture-negative* spontaneous bacterial pleuritis is made if the pleural fluid cultures are negative and the pleural fluid neutrophil count is greater than 500 cells/μL.[188] They appear to be transudative. In one series in Spain, 16 of 120 patients (13%) admitted with a diagnosis of hepatic hydrothorax had spontaneous bacterial pleuritis; 10 of 24 episodes (43%) of spontaneous bacterial pleuritis were not associated with bacterial peritonitis.[188] Appropriate treatment of spontaneous bacterial pleuritis requires systemic antibiotics, but tube thoracostomy does not appear to be necessary. It remains to be seen whether spontaneous bacterial pleuritis is common in the United States.

NEPHROTIC SYNDROME

There is a high incidence of pleural effusion in patients with nephrotic syndrome. In one early study of 52 patients, 21% had pleural effusions.[197] The mechanism responsible for the transudative pleural effusion associated with nephrotic syndrome is probably the combination of decreased plasma osmotic pressure and increased hydrostatic pressure due to salt retention and hypervolemia. The pleural effusions in patients with nephrotic syndrome are usually bilateral and are frequently infrapulmonary in location.[197]

A diagnostic thoracentesis should be performed in all patients with nephrotic syndrome and a pleural effusion to prove that the pleural fluid is a transudate. Nonetheless, the possibility of PE should always be considered. In one series of 36 patients with nephrotic syndrome, 22% had pulmonary emboli.[198] If the pleural fluid is an exudate, a CTPA should be obtained.

The treatment of the pleural effusion associated with nephrotic syndrome should be aimed at increasing the level of protein in the serum by decreasing the protein loss in urine. If this is unsuccessful and patients are symptomatic from the pleural effusion, pleurodesis with a sclerosing agent or placement of an indwelling pleural catheter can be considered.

PERITONEAL DIALYSIS

Peritoneal dialysis is occasionally complicated by the development of an acute hydrothorax. In a review of 3195 patients receiving continuous ambulatory peritoneal dialysis in Japan, 1.6% developed a pleural effusion as a result of the movement of the dialysate from the peritoneal cavity into the pleural cavity.[199] The effusion developed within 30 days of initiation of the dialysis in 50% of the patients, but 18% had been receiving dialysis for more than 1 year before the effusion developed.[199] The effusions are right sided in about 90%.[199,200]

The pleural fluid in these patients is characterized by a glucose level intermediate between that of the dialysate and the serum, a protein level less than 10 g/L (1.0 g/dL), and a low LDH level. The LDH level is higher and the glucose level is lower in the pleural fluid than in the ascitic fluid.[200] Although the communication closes spontaneously in some patients, a surgical approach is usually required if continuous ambulatory peritoneal dialysis is to be continued. The treatment of choice is probably thoracoscopy with closure of the diaphragmatic defects, followed by pleurodesis. Alternative treatments are pleurodesis alone or thoracotomy with repair of the diaphragmatic defects.

MYXEDEMA

A pleural effusion sometimes arises as a complication of myxedema. Patients with myxedema and pleural effusion often have a concomitant pericardial effusion. In one early series of 25 patients with pericardial effusions secondary to myxedema, 13 of the patients (52%) had concomitant pleural effusion.[201] The isolated pleural effusion seen in conjunction with myxedema is generally borderline between a transudate and an exudate. Although the mechanism of formation of the effusion is unknown, a decrease in lymphatic function due to low thyroid levels or to deposition of mucopolysaccharides may contribute.[28,202] Thyroid replacement is the obvious treatment for pleural effusions associated with myxedema.

PERICARDIAL DISEASE

Pleural effusion is commonly seen in patients with pericardial disease (Video 108.4). Few of these effusions have been characterized but can be transudative or exudative. In one series of 35 patients with constrictive pericarditis, 60% of the patients had radiologically demonstrable pleural effusions.[203] Weiss and Spodick[204] reviewed 124 patients with pericardial disease and found that 35 (28%) had a pleural effusion. Of the group of 35 patients, 21 had only a left-sided pleural effusion (eFig. 108.5), 2 had only a right-sided pleural effusion, and the remaining 12 were bilateral. However, in another series of 21 patients with constrictive pericarditis and pleural effusion, the pleural effusion was right sided only in 9 (43%) and was bilateral in the remaining 12 (57%).[203]

The mechanism responsible for the pleural effusion associated with pericardial disease is not clear. In some cases, the pleura and the pericardium may be affected by the same systemic disease and develop effusions in concert; such conditions could include drug reactions, collagen vascular diseases, or IgG4-related disease. In constrictive pericarditis, one explanation for the effusions is that the pulmonary and systemic capillary pressures are elevated secondary to the pericardial disease, resulting in a transudative pleural effusion. However, one would expect these effusions to be bilateral. In inflammatory pericardial disease, however, the pleural effusion tends to be left sided (see eFig. 108.5) and, although the characteristics of the fluid have not been well described, it is probable that the effusion forms from extension of the pericardial inflammation to the adjacent pleura[204] or possibly from direct movement of the fluid across the pericardium into the pleural space.

CENTRAL VENOUS OBSTRUCTION

Central venous obstruction can cause large, persistent transudative effusions most likely due to increases in systemic venous pressure, leading to increased formation of liquid and to decreases in lymphatic clearance. Venous obstruction as a cause of persistent transudative effusions should be considered in situations with prior central venous instrumentation and have been reported from occlusions of the hemiazygous vein, brachiocephalic vein, and superior vena cava (eFig. 108.6). Relief of the obstruction can lead to resolution of the effusion.[205] Most cases have been reported in patients on hemodialysis, with an ipsilateral arteriovenous fistula, brachiocephalic stenosis or thrombosis, ipsilateral arm swelling, and a left-sided transudate.[206]

VERY LOW PROTEIN TRANSUDATES

Urinothorax

Obstruction of the urinary tract resulting in a retroperitoneal urine collection (urinoma) can lead to a pleural effusion.[207] The mechanism by which the urine accumulates in the pleural space is unknown, but it is thought that a retroperitoneal urine collection forms and then drains along pressure gradients into the pleural space. The fluid actually represents urine, and the pleural fluid smells like urine. Patients with urinothoraces have pleural fluid creatinine levels higher than those in serum, but about 10% of other effusions also meet this criterion.[207] When the urinary tract obstruction is relieved, the pleural effusion rapidly disappears. Although most are transudates, some with very low protein concentrations; in one systematic review of 88 patients, as many as 44% were exudates, usually because of the LDH value. The elevated LDH likely represented the effects of trauma, the most common cause of the urinary tract disruption in that review.[208]

Subarachnoid-Pleural Fistula

A subarachnoid pleural fistula allows accumulation of cerebrospinal fluid in the pleural space. The pleural fluid looks like cerebrospinal fluid with a very low protein and LDH level, although several have been reported to be exudates, perhaps because they arose postoperatively. Subarachnoid pleural fistula can follow ventriculopleural shunting or penetrating injuries, fractures, or surgery of the thoracic spine.[37] If there is doubt about the diagnosis, measurement of the pleural fluid β_2-transferrin or beta-trace protein is useful because only cerebrospinal fluid contains these proteins.[209,210] Patients often complain of headache or other neurologic symptoms. MRI has been used to identify the leak, although the leak may be missed if intermittent. There are several reports in which noninvasive positive pressure was used to slow and on occasion allow healing,[211] but, if such noninvasive measures fail to control the leak, surgical repair will be needed.

Iatrogenic

Transudative pleural effusions can result from misplaced catheters delivering intravenous fluids either directly into the pleural space or into the mediastinum, with leak or rupture into the pleural space. When the mediastinum is infiltrated, effusions can be bilateral.[212] Depending on the constituents of the infused material, the pleural fluid may have high fat content or high glucose concentrations; many are transudative.[213] These are probably underreported, and recognition depends on a high index of suspicion in any patients with indwelling lines or catheters. Once recognized, the offending catheter should be removed immediately (see "Pleural Effusions Due to Misplaced Catheters" later).

OTHER CAUSES OF TRANSUDATIVE PLEURAL EFFUSIONS

Pulmonary veno-occlusive disease frequently has small pleural effusions.[214] The characteristics of the pleural fluid have not been described, but it is probably a transudate because the effusions are likely related to the increased interstitial fluid. Patients with right heart failure secondary to pulmonary hypertension frequently have small bilateral pleural effusions.[215]

PE has been reported to be associated with a transudative pleural effusion. However, in a study of the pleural fluid findings in patients with PE, all 60 pleural fluids were exudates.[51] Pleural amyloidosis is associated with transudative effusions, probably due to a combination of heart failure and pleural infiltration with amyloid.[216] Cytokines such as *vascular endothelial growth factor* (VEGF) may play a role because, in a recent series, three out of four patients with persistent pleural effusions due to primary systemic amyloid improved with treatment with an antibody against VEGF, bevacizumab.[217]

Malignancy has been thought to cause transudates. If so, it is likely that the malignancy is extrathoracic, affecting the draining lymphatics, and exhibiting a negative pleural cytology.[218] It is also possible that there is another cause of the effusion, such as CHF (see also Chapter 14).

EXUDATIVE PLEURAL EFFUSIONS

Exudative pleural effusions are common clinical problems. These effusions may develop as a result of inflammation, injury, or malignancy, which can involve the pleural surfaces, the adjacent lung, or more distant tissues, such as mediastinal or abdominal organs. Further discussion of effusions due to infections can be found in Chapter 109; special types of effusions (chylothorax and hemothorax) are discussed in Chapters 111 and 113, respectively, and effusions secondary to pleural malignancy are presented in Chapter 114.

PULMONARY EMBOLISM

The diagnosis most commonly overlooked in the differential diagnosis of a patient with an undiagnosed pleural effusion is PE. It has been estimated that, due to the high incidence of PE and associated pleural effusion, one should expect to see more cases of pleural effusion secondary to PE than to bronchogenic carcinoma. Nevertheless, in most large series, PE accounts for less than 5% of pleural effusions. The diagnosis and treatment of PE are discussed in Chapters 81 and 82.

Clinical Manifestations

Patients with PE can be divided into three categories, depending on their presenting symptoms: (1) pleuritic pain or hemoptysis, (2) isolated dyspnea, and (3) circulatory collapse. In the *Prospective Investigation of Pulmonary Embolism Diagnosis* (PIOPED) study, 56% of the patients with pleuritic pain or hemoptysis had pleural effusion, and 26% of those with isolated dyspnea had pleural effusion, but none of the patients with circulatory collapse had pleural effusion.[219]

Approximately 50% of patients with paraembolic effusions have parenchymal opacities seen on chest radiographs[220] (Fig. 108.5). The opacities are usually in the lower lobes, are pleural based, and are convex toward the

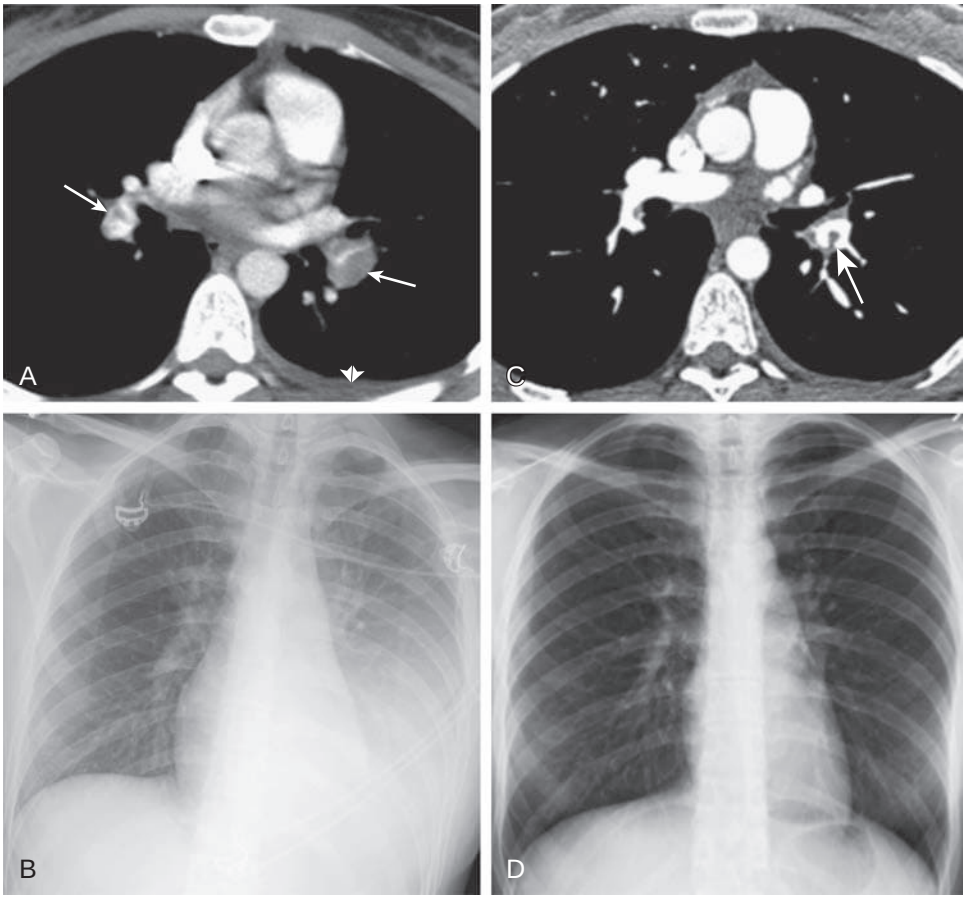

Figure 108.5 Pleural effusion related to acute pulmonary embolism. (A) Axial *computed tomography* (CT) pulmonary angiography shows bilateral acute pulmonary emboli (*arrows*); a trace left pleural effusion (*double arrowheads*) is present. (B) Frontal chest radiography performed 5 days after the CT pulmonary angiogram (A) shows left basal consolidation with a large left pleural effusion. (C) Axial CT pulmonary angiography performed more than 1 month after presentation, during treatment, shows near-complete resolution of the bilateral pulmonary emboli (*arrow*). (D) Frontal chest radiography performed more than 1 month after presentation shows complete resolution of the left basal consolidation and pleural effusion. (See also Videos 108.5A and 108.5B.) hilum. Paraembolic effusions are usually small; in one series, 48 of 56 patients (86%) had only blunting of the costophrenic angle, and no patient had an effusion that occupied more than one-third of a hemithorax.[219] The pleural effusions may be unilateral or bilateral. In one study of 63 patients with PE and pleural effusion, the effusions were bilateral in 16 (25%).[221] Of interest, in more recent studies using CTPA in patients suspected of having PE, patients found to have PE were no more likely to have pleural effusions than those without PE (50% vs. 58%,[222] 57% vs. 56%,[223] 55% vs. 53%,[224] respectively). However, in other studies using CTPA, those found to have PE were more likely to have pleural effusions than those without PE (48% vs. 34%[225], 20% vs. 9%,[226] respectively); nonetheless, effusions tended to be small and very few large enough to warrant thoracentesis. Of interest, in those with PE, pleural effusions have been found to be almost twice as common in those with pulmonary infarct (47% [29/62]) than without (24% [74/305]).[227] Patients suspected of having PE likely have other underlying conditions that predispose them to pleural effusions, such as CHF or pneumonia.

Pleural fluid analysis is of limited value in establishing the diagnosis of paraembolic effusion because there is nothing characteristic about the fluid. The pleural fluid is almost always an exudate.[51] The pleural fluid red blood cell count exceeds 100,000/μL in less than 20% and is less than 10,000/μL in at least 30%. The pleural fluid white blood cell count can vary from less than 100 to greater than 50,000/μL. The differential white blood cell count may reveal predominantly polymorphonuclear leukocytes or mononuclear cells; eosinophils may be present.

Diagnosis

The diagnosis of PE is discussed in Chapter 81. The possibility of PE should be considered in every patient with a pleural effusion, even if the patient has obvious CHF. In an early autopsy series of 290 patients with CHF and pleural effusion, 60 (21%) had PE.[173] When a paraembolic effusion is strongly suspected, the patient should be started on heparin treatment while the diagnostic evaluation for PE proceeds.[228] In the patient with an undiagnosed pleural effusion for whom PE is suspected, CTPA appears to be the preferred test compared to ventilation-perfusion scanning because it also provides information about the lung parenchyma, the mediastinum, and the pleural surfaces, which may provide clues to the etiology of the pleural effusion (Videos 108.5A and 108.5B) and may highlight incidental findings that may need urgent evaluation.[229]

Treatment

The treatment of the patient with a paraembolic effusion is the same as for any patient with PE (see Chapter 82). The presence of bloody pleural fluid is not a contraindication to the administration of anticoagulation or, if indicated, thrombolytic therapy.[220] Paraembolic effusions usually reach their maximum size within the first 3 days.[230] If the effusion increases in size after this time, the patient probably has recurrent emboli, a pleural infection, or a hemothorax, and a diagnostic thoracentesis should be performed. Hemothorax has been associated with pulmonary infarction, where the bleeding may be seen 1 to 2 weeks later.[231] If the pleural fluid hematocrit value is greater than 50% of the peripheral hematocrit, a hemothorax is present. In this instance, anticoagulation should be discontinued, and tube thoracostomy should be performed.

ABDOMINAL DISEASES

Many abdominal diseases can cause pulmonary signs and symptoms. This section describes the most important of these disorders that cause pleural effusion (see Chapter 126).

Esophageal Perforation

The diagnosis of esophageal rupture should always be considered in the differential diagnosis of exudative pleural effusions because, if this condition is not rapidly treated, the mortality increases, with current estimates ranging from 30–60%. Approximately 60% of patients with esophageal perforation have a pleural effusion, whereas about 25% have a pneumothorax.[232] The pleural effusion is usually left sided (Fig. 108.6), but it may be right sided[233] or bilateral.

The esophagus most commonly perforates as a complication of esophagoscopy and is more likely when there is an attempt to remove a foreign body or to dilate an esophageal stricture.[234] Overall, the incidence of esophageal perforation with esophagoscopic examination is 0.15–0.70%.[232] The insertion of a Blakemore-Sengstaken tube for esophageal varices can be complicated by esophageal rupture. Frequently, the diagnosis is missed in these patients because of the severity of their illness and the multiple coexisting problems.[232] Esophageal perforation may also result from transesophageal echocardiography, foreign bodies, esophageal carcinoma, gastric intubation, chest trauma, chest surgery, or vomiting (Boerhaave syndrome). In a review of 120 consecutive patients with esophageal perforation from all causes, the incidence of pleural effusion was 52% and pneumothorax was 11%.[235]

Clinical Manifestations. The symptoms associated with esophageal perforation result from the acute mediastinitis produced by contamination of the mediastinum by the oropharyngeal contents. Most of the morbidity from esophageal perforation is caused by infection of the mediastinum and the pleural space by the oropharyngeal bacterial flora.[102]

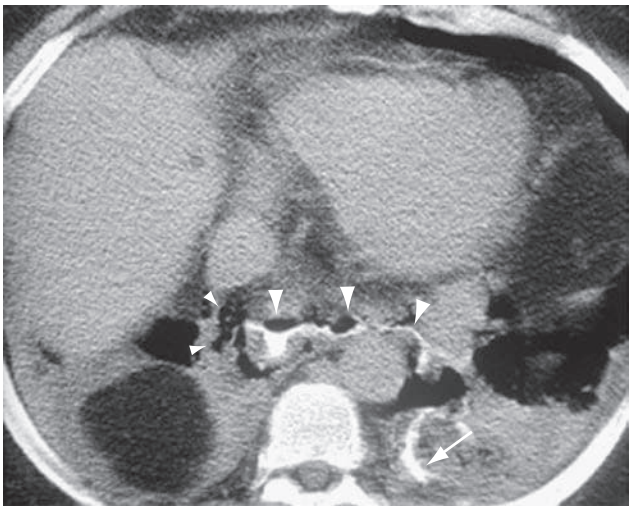

Figure 108.6 Effusion due to esophageal perforation. Axial computed tomography through the lower thorax in a patient with chest pain shows pneumomediastinum (*small arrowheads*) and leakage of water-soluble oral contrast from the ruptured esophagus (*large arrowheads*) through the mediastinum into the left pleural space (*arrow*). (Courtesy Michael B. Gotway, MD.)

A patient with an esophageal perforation is usually acutely ill. With a spontaneous rupture, there is frequently a sensation of tearing or bursting in the lower part of the chest or the epigastrium. The chest pain is characteristically excruciating and is often unrelieved by opiates. Greater than 50% of patients have small amounts of hematemesis. The presence of subcutaneous emphysema in the suprasternal notch is suggestive of the diagnosis. However, less than 10% of patients have subcutaneous emphysema within the first 4 hours of rupture.[236] When the esophagus is perforated during esophagoscopy, the endoscopist generally does not realize it; however, the patients usually develop persistent chest or epigastric pain within a few hours after the procedure.

Diagnosis. The diagnosis of esophageal rupture should be considered in all acutely ill patients with an exudative pleural effusion. The best screening test for esophageal rupture appears to be the level of amylase in the pleural fluid.[236] The pleural fluid amylase level is elevated owing to the amylase in saliva entering the pleural space.[101] The pleural fluid pH is usually decreased below 7.00 in patients with pleural effusion secondary to esophageal perforation due to the intense inflammatory response resulting from the mediastinitis and not the regurgitation of gastric juice into the pleural space. The demonstration of squamous epithelial cells or particularly of food particles in the pleural fluid is highly suggestive of the diagnosis. Other findings suggestive of esophageal rupture are a chest tube output greater than 500 mL/24 hr or polymicrobial flora in the pleural fluid. The diagnosis is established when esophageal perforation is confirmed by contrast studies of the esophagus (see Fig. 108.6).

Treatment. The treatment of the esophageal rupture may range from nonoperative stenting to primary repair to esophagectomy depending on the underlying disease of the esophagus and the size of the rupture.[235] Mediastinitis from esophageal perforation and other causes is discussed in detail in Chapter 116.

Pancreatic Disease

Three different types of nonmalignant pancreatic disease can have an accompanying pleural effusion: acute pancreatitis, chronic pancreatitis with pseudocyst, and pancreatic ascites.

Acute Pancreatitis. In two prospective reports a decade apart, exactly 50% of the nearly 200 patients admitted with acute pancreatitis had a pleural effusion on chest CT scan.[237,238] In both reports, patients with acute pancreatitis and a pleural effusion had more severe disease and a higher mortality rate than did those without effusions.[237,238] The exudative pleural effusion accompanying acute pancreatitis results from the diaphragmatic inflammation and transdiaphragmatic transfer of the exudative fluid arising from acute pancreatic inflammation. Even though small, pleural effusions may be a marker of significant inflammation.

The clinical picture is usually dominated by abdominal symptoms, including pain, nausea, and vomiting. However, at times, respiratory symptoms consisting of pleuritic chest pain and dyspnea may dominate the clinical picture. In addition to the small to moderate-sized pleural effusion, the chest radiograph may reveal an elevated diaphragm and basilar opacities. Demonstration of an elevated pleural fluid amylase level is highly suggestive of the diagnosis, but the diagnosis of esophageal rupture must be excluded. The pleural fluid is an exudate with predominantly polymorphonuclear leukocytes and a normal glucose level. It usually resolves as the pancreatic inflammation recedes.[239]

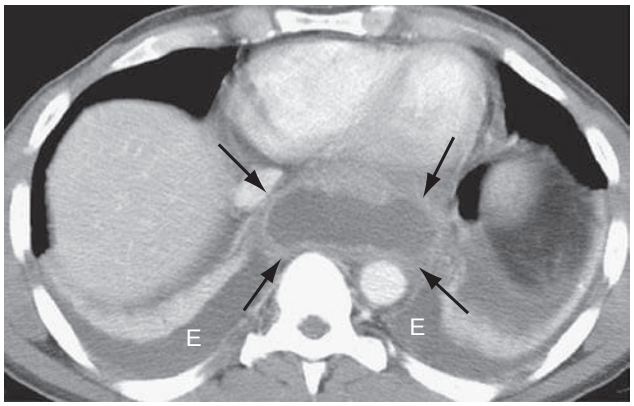

Figure 108.7 Effusion due to pancreatic pseudocyst. Axial computed tomography image through the lower thorax in a patient with chronic pancreatitis shows bilateral pleural effusions (*E*) and a cystic mass in the middle mediastinum (*arrows*) representing a pseudocyst. (Courtesy Michael B. Gotway, MD.)

Chronic Pancreatic Pleural Effusion. Patients with chronic pancreatic disease often have a large chronic pleural effusion. When the pancreatic ductal system is disrupted, a pseudocyst may form in the pancreas. A sinus tract can then extend from the pseudocyst through the aortic or esophageal hiatus into the mediastinum. Once the sinus tract reaches the mediastinum, the process may be contained to form a mediastinal pseudocyst, or it may rupture into one or both pleural spaces, resulting in a large chronic pleural effusion[103] (Fig. 108.7).

The clinical picture of patients with chronic pancreatic disease and pleural effusion is usually dominated by chest symptoms, such as dyspnea, cough, and chest pain. Most patients do not have abdominal symptoms because the pancreaticopleural fistula decompresses the pseudocyst. The pleural effusion is usually massive and recurs rapidly after thoracentesis.[103] The effusion is usually left sided but may be right sided or bilateral.

The key to the diagnosis is a markedly elevated pleural fluid amylase level, generally greater than 1000 U/L, whereas the serum level of amylase may be only mildly elevated. Patients with chronic pancreatic pleural disease are generally easily differentiated from those with malignant pleural effusion, who also may have an elevated pleural fluid amylase level, because the amylase level is much higher with the pseudocyst. In rare cases in which the differentiation is not obvious, the diagnosis can be made by measuring amylase isoenzymes, because the amylase associated with malignancy is of the salivary, not the pancreatic, type.[105] Both ultrasound and CT are useful in establishing the diagnosis of pancreatic pseudocyst. Endoscopic retrograde cholangiopancreatography usually documents the fistulous tract or other pancreatic pathology.

Interruption of the fistula and repair of pancreatic drainage will control the pleural effusion (see Chapter 126). Conservative therapy to suppress pancreatic secretion (nasogastric suction, no oral intake, somatostatin) may

be tried for minor leaks; however, if it fails, a more direct approach, usually by endoscopic means to drain internally or stent the pancreatic duct, is warranted.[240] Decortication of the pleura may be necessary for some patients to remove the thick pleural peel created by the intense inflammation caused by the presence of pancreatic enzymes.

Pancreatic Ascites. Some patients with pancreatic disease develop ascites characterized by high amylase and protein levels. If these patients should happen to have or develop a defect in their diaphragm, they develop a large pleural effusion as a result of the flow of fluid from the peritoneal cavity to the pleural cavity. The treatment for pancreatic ascites aims to stop the pancreatic leak, first with conservative measures (nothing by mouth, total parenteral nutrition, perhaps octreotide) and, if these measures fail, by endoscopic stenting.[240]

Intra-abdominal Abscesses

Pleural effusions are frequently seen with intra-abdominal abscesses. The possibility of an intra-abdominal abscess should be considered strongly in any patient with an undiagnosed exudative pleural effusion containing predominantly polymorphonuclear leukocytes, particularly when there are no pulmonary parenchymal abnormalities. The mechanism responsible for the development of the exudative pleural effusion is probably diaphragmatic irritation.

Subphrenic abscess is the intra-abdominal abscess most commonly associated with a pleural effusion; pleural effusions develop in approximately 80% of patients with subphrenic abscess.[241] The approximate incidence of effusions with other intra-abdominal abscesses is 40% in pancreatic abscesses, 30% in splenic abscess, and 20% in intrahepatic abscesses. With pancreatic abscess, the pleural fluid may have a high amylase level.

Clinical Manifestations. Subphrenic abscess most commonly develops as a postoperative complication 1 to 3 weeks after intra-abdominal surgery.[241] Splenectomy and gastrectomy are particularly likely to be complicated by left subphrenic abscess. There is no antecedent abdominal surgery in approximately 10% of patients with subphrenic abscess.[241] The abscess may result from perforation of the stomach, duodenum, appendix, colon, or a diverticulum, or from diverticulitis, cholecystitis, pancreatitis, or trauma. Most patients have fever, leukocytosis, and abdominal pain, but frequently there are no localizing signs or symptoms.

Most patients with pyogenic intrahepatic abscesses have fever and anorexia. Abdominal pain is common, but frequently it is not localized to the right upper quadrant. On physical examination, an enlarged, tender liver can be demonstrated. Laboratory tests reveal leukocytosis, anemia, elevated alkaline phosphatase levels, and hyperbilirubinemia.[242]

Pancreatic abscess usually follows an episode of acute pancreatitis. This diagnosis should be suspected if the patient does not respond to the initial therapy or if fever, abdominal pain, and leukocytosis develop within 3 weeks of the episode of acute pancreatitis. Splenic abscess is uncommon, usually seen in patients with systemic infection. Bacterial endocarditis is the most common underlying infection.

The pleural fluid that accumulates in patients with intra-abdominal abscesses is an exudate with predominantly polymorphonuclear leukocytes. The pleural fluid white blood cell count may exceed 50,000/μL, but the pleural fluid pH and glucose concentration usually remain greater than 7.20 and 60 mg/dL (3.33 mmol/L), respectively. Only rarely does the pleural fluid become infected.

Diagnosis and Treatment. The diagnosis of intra-abdominal abscess is best established with an abdominal CT scan (eFig. 108.7 and Video 108.6),[243] which should be obtained in every patient with an undiagnosed exudative pleural effusion characterized by predominantly polymorphonuclear leukocytes if there are no parenchymal abnormalities. The appropriate treatment for a patient with an intra-abdominal abscess and a pleural effusion is drainage of the abscess combined with parenteral antibiotics.

Post-abdominal Surgery

Approximately 50% of patients undergoing abdominal surgery develop a pleural effusion in the first few days after surgery.[244,245] The incidence of postoperative pleural effusion is greater in patients undergoing upper abdominal surgery, in patients with postoperative atelectasis, and in patients with free abdominal fluid at surgery.[244,245] Ultrasonography appears to be better at detecting pleural effusion than chest radiography in this setting, particularly with the difficulty in obtaining a true upright film.[246] The accumulation of pleural fluid within the first 72 hours after abdominal surgery is probably related to either diaphragmatic irritation or transdiaphragmatic movement of intra-abdominal fluid. A postoperative patient with a significant amount of pleural fluid, particularly when associated with fever, should have a diagnostic thoracentesis to rule out pleural infection as a cause of the effusion. In addition, the possibility of PE should be considered. If the effusion develops more than 72 hours after surgery, it is probably not related to the surgical procedure itself, and alternative explanations must be sought, such as PE, intra-abdominal abscess, and hypervolemia.

Liver Transplantation

Most patients who undergo an orthotopic liver transplantation develop a pleural effusion after surgery. In one study, 68% of 300 patients undergoing liver transplantation developed a pleural effusion, and the effusion occupied more than 25% of the hemithorax in 21 patients (7%).[247] Of the 206 patients with effusions, the effusion was unilateral right sided in 153 (74%) and bilateral in 53 (26%); none were unilateral on the left. The effusions are large enough to require therapeutic thoracentesis or tube thoracostomy in approximately 10%.[247] The natural history of these effusions is that they increase in size over the first 3 postoperative days and then gradually resolve over several weeks to several months. The pathogenesis of these effusions is probably related to injury or irritation of the right hemidiaphragm caused by the extensive right upper quadrant dissection. Those with pleural effusions requiring drainage have been found to have worse preoperative MELD scores and a worse outcome than those that without.[248]

Bilious Pleural Effusion

Bilious pleural effusions are due to a fistula from the biliary tree to the pleural space.[249] The fistula may be secondary to trauma, suppurative complications of biliary tract infections,

right-sided percutaneous transhepatic biliary drainage, or surgery, particularly when biliary obstruction is present. Percutaneous transhepatic biliary drainage can traverse the costophrenic sulcus, thereby connecting the bile duct to the pleural space.[250] The diagnosis should be suspected in any patient with an obstructed biliary tract or recent biliary interventions. The pleural fluid usually appears bilious or even black[251] but, at times, the diagnosis may depend on the demonstration that the ratio of pleural fluid to serum bilirubin is greater than 1.0. A pleural fluid glycocholic acid, a component of bile acids, can also identify the source.[252] Appropriate treatment consists of reestablishment of biliary drainage.

INFLAMMATORY DISEASES

Rheumatoid Pleuritis

The pleura is occasionally involved in the course of rheumatoid arthritis. Approximately 5% of patients with rheumatoid arthritis have a pleural effusion, and approximately 20% experience pleuritic chest pain.[106,253] Rheumatoid pleurisy has a striking male predominance, despite the higher prevalence of rheumatoid disease in women; greater than 10% of men, but less than 2% of women, with rheumatoid disease have a pleural effusion.[106,253]

Clinical Manifestations. Almost all patients with rheumatoid pleural effusions are older than 35 years. Approximately 80% are men, and approximately 80% have subcutaneous nodules. The pleural effusion usually develops only after the arthritis has been present for several years[106] but, on rare occasions, a patient may present with a pleural effusion.

Patients with rheumatoid pleuritis may be asymptomatic or symptomatic with pleuritic chest pain, fever, or both,[106,113] and some patients experience dyspnea secondary to the presence of pleural fluid. In most patients, the chest radiograph reveals a small- or moderate-sized pleural effusion. In approximately 25% of patients, the effusion is bilateral.[106] Over time, the effusion may alternate from one side to the other or may come and go on the same side. Other intrathoracic manifestations of rheumatoid disease are present in up to one-third of patients.[106]

Diagnosis. The diagnosis is suggested by the clinical picture of rheumatoid arthritis in the presence of a pleural effusion. The pleural fluid with rheumatoid pleuritis is distinctive, characterized by a glucose level less than 30 mg/dL (1.67 mmol/L), a high LDH level (>2 times the upper limit of normal), a low pH (<7.20), and a high rheumatoid factor titer (>1:320 and equal to or greater than the serum titer).[113] On occasion, the pleural fluid glucose is not low when the patient is first seen, but serial pleural fluid glucose determinations reveal progressively lower pleural fluid glucose levels. Another interesting characteristic of rheumatoid pleural effusions is their tendency to contain cholesterol crystals or high levels of cholesterol,[254] diagnostic of a pseudochylothorax, even without pleural thickening.[255] A unique cytologic appearance of elongated macrophages, called comet-tail cells, is also considered specific for the diagnosis[256] (eFig. 108.8).

With the characteristic pleural fluid findings, the primary alternative diagnosis to exclude is complicated parapneumonic effusion. The incidence of complicated parapneumonic effusion is high in patients with rheumatoid pleuritis,[257] so this differentiation is important. It is particularly important to examine the Gram stain of the pleural fluid and to culture the fluid both aerobically and anaerobically.

Prognosis and Treatment. The natural history of rheumatoid pleuritis varies. Most patients experience a spontaneous resolution within 3 months, but the effusion is persistent in an occasional patient, and massive pleural thickening sometimes develops. Rheumatoid pleural effusion may respond to systemic steroids or anti–tumor necrosis factor therapy; the results after intrapleural corticosteroids have been mixed.[37,258] There are case reports of response to newer anti-immune therapy (e.g., atabacept, tocilizumab).[259,260] Decortication can be considered in dyspneic patients with thickened pleura. This procedure is particularly difficult in patients with rheumatoid pleuritis because it is not easy to develop a plane of dissection between the lung and the fibrous peel.

Lupus Pleuritis

Approximately 40% of patients with SLE or drug-induced lupus have a pleural effusion during the course of their disease.[107]

Clinical Manifestations. Most patients with lupus pleuritis have arthritis or arthralgias before the development of a pleural effusion. Almost all patients with lupus pleuritis have pleuritic chest pain, and most are also febrile. Lupus pleuritis frequently develops in association with an exacerbation of the underlying disease. The pleural effusions secondary to lupus are usually small and are bilateral in about 50% of patients.[261]

Many medications have been incriminated for producing drug-induced lupus erythematosus (see Chapter 99).[37] Hydralazine, procainamide, isoniazid, phenytoin, and chlorpromazine are the ones most commonly associated with drug-induced lupus, but more than 70 other drugs possibly induce lupus. For the latest information on possible drug reactions, including lupus reactions, an excellent online source is www.pneumotox.com. The presenting signs, symptoms, and radiographic abnormalities are similar, whether the pleuritis is due to spontaneous or to drug-induced lupus. The symptoms associated with drug-induced lupus characteristically abate within days of discontinuing the offending drug.

Diagnosis. The possibility of lupus pleuritis should be considered in any patient with an exudative pleural effusion of unknown cause. The pleural fluid can contain a predominance of either polymorphonuclear or mononuclear cells, depending on the timing of the thoracentesis in relation to the development of the symptoms.[40] Elevated ANA titers in the pleural fluid (>1:160) are a sensitive test for effusions caused by lupus[108,112,262,263] but are not specific because elevated ANA can also be found in other conditions, particularly malignancy. The diagnosis of lupus pleuritis is based primarily on the clinical picture and the serologic findings for lupus. However, a low pleural ANA in a patient with SLE would argue for another cause for the effusion.[112]

Treatment. The pleuritis with systemic lupus responds to corticosteroid administration. It is recommended that patients with lupus pleuritis be treated with oral prednisone, with rapid tapering once the symptoms are controlled. At times, the effusion is large, is symptomatic, and does not respond to corticosteroid therapy. In such a situation, consideration should be given to chemical pleurodesis. Of

course, if the patient has drug-induced lupus, the offending drug should be withdrawn.

Immunoglobulin G4–Related Pleuritis

First reported in Japan in 2001,[264] IgG4-related disease is a systemic condition that can involve the lung and the pleura. It manifests as a fibroinflammatory disorder with IgG4-positive plasma cell infiltration into tissues. Pleural masses, pleuritis, and pleural effusion can be part of the disease or present by themselves, although pleural effusion appears in less than 5% of patients with this condition.[265] Despite its rarity, the reason to consider it is that IgG4-related pleural effusion presents as a lymphocytic exudate, often with a positive ADA, and thus can be mistaken for a tuberculous effusion.[117] In one retrospective study of idiopathic pleural effusions in Japan, IgG4 staining was positive in 34%, suggesting that, at least in Japan, this entity may account for one-third of otherwise undiagnosed effusions. The diagnosis requires a pleural biopsy showing plasma cell infiltration and staining positively for IgG4. Serum and pleural fluid levels of IgG4 may or may not be elevated.[266] Criteria for the diagnosis of respiratory disease have been published.[267] The condition responds to corticosteroids.[266] Its incidence and prevalence outside of Japan is unknown.

Sarcoidosis

The prevalence of pleural effusion with sarcoidosis (see Chapter 93) is about 1%.[268,269] Patients with pleural effusion due to sarcoid usually have extensive parenchymal sarcoidosis and frequently extrathoracic sarcoidosis[268] (Fig. 108.8). The symptoms of pleural involvement with sarcoidosis vary; many patients have no symptoms, although an equal number have pleuritic chest pain or dyspnea.

The pleural effusions with sarcoidosis are usually small and are bilateral in approximately one-third of cases. The pleural fluid is almost always an exudate, and its cell differential is characterized by predominantly small lymphocytes.[268,269] In the patient with known sarcoidosis, one can attribute the presence of the pleural effusion to sarcoid only when other causes of exudative lymphocyte-predominant pleural effusions, such as tuberculosis, are excluded.[270] The pleural effusion secondary to sarcoidosis may resolve spontaneously, or may require corticosteroid therapy for its resolution.

Asbestos-Related Disease

An otherwise unexplained pleural effusion may result years after exposure to asbestos, which may have been brief or intermittent, and in the immediate or distant past. Epler and coworkers[271] reviewed the medical histories of 1135 asbestos workers whom they had followed for several years and found that 35 (3%) of the workers had pleural effusions for which there was no other ready explanation. In general, the heavier the asbestos exposure, the more likely the patient is to develop a pleural effusion. The pleural effusion sometimes develops within 5 years of the initial exposure but, in one large series, the mean latency was 30 years.[272]

The pathogenesis of the pleural effusion arising after asbestos exposure is unknown.[273] Asbestos fibers, both long and short, move from the lung to the pleural space and lodge in the parietal pleura, where they appear to be concentrated in specific locations that correlate with lymphatic drainage.[274] Here their presence leads to a continuous low-grade inflammation. Now, with the ability to test different lengths of man-made nanotubes, it has been shown that the length of the fiber is important, presumably because the longer fibers are preferentially retained in the pleural space.[275] This chronic inflammation can either decrease the lymphatic clearance of the pleural space or increase the permeability of the capillaries in the parietal pleura, either of which could lead to the development of an exudative pleural effusion. An immune mechanism has been invoked to explain the fluctuations in the degree of pleuritis with time.[272]

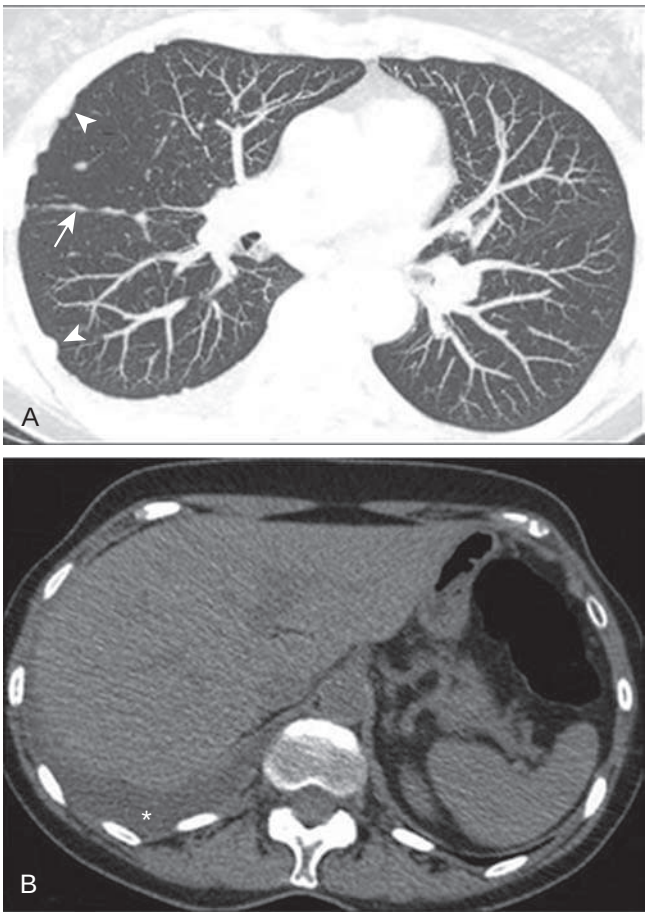

Figure 108.8 Sarcoidosis with pleural effusion. (A) Axial unenhanced maximum intensity projected computed tomography shows subpleural nodules along the costal (*arrowheads*) and fissural (*arrow*) pleural surfaces, consistent with the perilymphatic distribution of nodules in sarcoidosis. (B) Axial computed tomography through the lung bases displayed in soft tissue windows shows a small right pleural effusion (*asterisk*); biopsy of the pleura showed noncaseating granulomas. (Courtesy Michael B. Gotway, MD.)

Clinical Manifestations. Patients with pleural effusion secondary to asbestos exposure have surprisingly few symptoms. In the series of Epler and coworkers,[271] 66% had no symptoms. The chest radiograph usually reveals a small- to moderate-sized effusion, which is bilateral in about 10%. The pleural fluid is an exudate, and the pleural fluid differential can reveal either predominantly polymorphonuclear leukocytes or mononuclear cells. Of interest, pleural fluid eosinophilia was present in 15 (52%) of the 29 patients with asbestos pleural effusions for whom pleural fluid differentials were reported.[47]

Diagnosis. The diagnosis of benign asbestos effusion is one of exclusion. It requires the following criteria: history of direct or indirect exposure to asbestos; exclusion of other causes, notably infection, PE, and malignancy; and follow-up of at least 2 years to verify that the effusion is benign.[272] Biopsies via CT guidance or by medical thoracoscopy are useful to exclude mesothelioma and other potentially treatable conditions.[276]

Prognosis. The natural history of the patient with an asbestos pleural effusion is one of chronicity, with frequent recurrences and sometimes the development of extensive fibrosis of the parietal pleura.[271] On average, the pleural effusion persists for 3 months but eventually clears and leaves no residual pleural disease. Massive pleural fibrosis can develop in about 20% of patients, with ipsilateral blunting of the costophrenic angle in another 20%.[271] Rounded atelectasis also develops in about 10% of patients. There is no known treatment for asbestos pleural effusion. Further information about asbestos-induced lung disease is provided in Chapter 101.

Uremia

Uremia may be complicated by a fibrinous pleuritis and pleural effusion.[37] The pathogenesis of the pleural effusion associated with uremia is unclear. It is probably somewhat analogous to that for uremic pericarditis because more than half of the patients with uremic pleuritis also have uremic pericarditis (eFig. 108.9). The incidence of pleural effusions with uremia is approximately 3%, and there does not seem to be a close relationship between the degree of uremia and the presence of an effusion.[277] When patients are on chronic hemodialysis, the incidence of pleural effusion is high; with CT scanning, the incidence of pleural effusion in patients on chronic hemodialysis has been shown to be approximately 50%.[278] The etiologies of 100 effusions seen in hospitalized patients with uremia on hemodialysis in one study were as follows: heart failure, 46; uremia, 16; parapneumonic, 15; atelectasis, 11; and miscellaneous, 12.[279] In another study of 76 patients with effusions on hemodialysis, uremia was considered the cause in 24%, with parapneumonic effusion (24%) and CHF (20%) also common.[280]

The pleural effusion seen with uremia may occupy greater than 50% of the hemithorax and is bilateral in about 20% of patients.[277] Greater than 50% of patients are symptomatic from the pleural disease, with fever (50%), chest pain (30%), cough (35%), and dyspnea (20%) being the most common symptoms. The pleural fluid is an exudate that is frequently serosanguineous or bloody. The differential white blood cell count reveals predominantly lymphocytes.[277] Pleural biopsy specimens invariably reveal chronic fibrinous pleuritis.

The diagnosis of uremic pleuritis is one of exclusion in the patient with chronic renal failure. After beginning dialysis, the effusion gradually disappears within 4 to 6 weeks in about 75% of patients. In the remaining patients, the effusion persists, progresses, or recurs. An occasional patient develops marked pleural thickening that may require decortication[281] (see Chapter 112).

Post–Cardiac Injury Syndrome

Post–cardiac injury syndrome (PCIS), also known as postpericardiectomy or post–myocardial infarction (Dressler) syndrome, is characterized by combinations of pericarditis, pleuritis, and pneumonitis that develop after injury to the myocardium or pericardium.[282,283] In one report, noncomplicated PCIS was defined as the presence of temperature greater than 100.5°F, patient irritability, pericardial friction rub, and a small pericardial effusion with or without pleural effusion after cardiac trauma; a complicated PCIS was defined as a noncomplicated PCIS plus the need for hospital readmission with or without the need for pericardiocentesis or thoracentesis.[284] Imazio and colleagues[285] have recently defined PCIS as the presence of at least two of the following: fever without alternative explanation, pleuritic chest pain, pericardial friction rub, new or worsening pleural effusion, and new or worsening pericardial effusion. PCIS has been described after myocardial infarction (eFig. 108.10), cardiac surgery, blunt chest trauma, percutaneous left ventricle puncture, implantation of a pacemaker, and catheter ablation of arrhythmias.[282,286] The incidence of PCIS is approximately 1% after myocardial infarction and is somewhat higher after cardiac surgery.[37] The exact pathogenesis of this syndrome is unknown, but it appears to have an immunologic basis.

Clinical Manifestations. The syndrome typically develops about 3 weeks after the injury, but it can happen any time between 3 days and 1 year. The two cardinal symptoms are fever and chest pain. The chest pain often precedes the onset of fever and can vary from an agonizing crush to a dull ache. At times, it may have a pleuritic component. Most patients have a pericardial friction rub. Pulmonary opacities are present in about 50% of patients, and laboratory evaluation reveals leukocytosis with an elevated erythrocyte sedimentation rate.

A pleural effusion arises in about two-thirds of patients with PCIS.[282] The pleural effusions are bilateral and small in most patients. The pleural fluid is an exudate that is frequently serosanguineous or bloody. The pleural fluid differential may reveal either predominantly polymorphonuclear leukocytes or mononuclear cells, depending on the acuteness of the process.[282]

Diagnosis. The diagnosis of PCIS should be considered in any patient who develops a pleural effusion after injury to the heart. The diagnosis of the syndrome is established by the clinical picture and by excluding CHF, PE, and pneumonia.

Treatment. PCIS usually responds to treatment with antiinflammatory agents, such as aspirin, colchicine or indomethacin. Corticosteroids may be necessary in more severe cases.

Post–Coronary Artery Bypass Surgery

Although it is less commonly performed due to less invasive options, *coronary artery bypass graft* (CABG) surgery is the most commonly performed cardiac surgery in the world, with 200,000 cases in the United States each year.[287] Because approximately 10% of patients who undergo CABG surgery will develop a pleural effusion occupying greater than 25% of their hemithorax in the subsequent month,[288] CABG surgery is one of the more common causes of pleural effusions in the United States. The prevalence of small pleural effusions is high after CABG surgery. In one study, the prevalence of pleural effusions in 47 patients as detected by ultrasound was 89% at 7 days, 77% at 14 days, and 57% at 30 days.[289] In a study of 349 patients post-CABG, the

prevalence of pleural effusion on chest radiograph 30 days postoperatively was 62%; 40 of the 349 patients (11%) had an effusion occupying greater than 25% of the hemithorax.[288] The pleural effusions after CABG surgery tend to be left sided or bilateral, and if bilateral, the effusion is usually larger on the left.[288] They are a frequent cause for readmission to hospital.[290]

The primary symptom of a patient with a large pleural effusion post-CABG is dyspnea.[288] The presence of either chest pain or fever should alert the physician to an alternative diagnosis. When all patients with large pleural effusions after CABG surgery are considered, the effusions can be divided into those that are bloody and those that are serous. The bloody effusions are caused by bleeding into the pleural space; they reach their maximal size within 30 days of surgery, are frequently associated with pleural fluid or peripheral eosinophilia or both, have a high pleural fluid LDH level, and respond to one or two therapeutic thoracenteses.[291] In contrast, the cause of the serous pleural effusions is unknown. They tend to reach their maximal size more than 30 days after surgery, have greater than 50% small lymphocytes, and have a relatively low pleural fluid LDH level.[291] Most of these late effusions can also be managed with one or two therapeutic thoracenteses,[288] but some are refractory. It is unknown whether anti-inflammatory agents or diuretics are beneficial in the treatment of these effusions. A placebo-controlled, double-blind, randomized study of 360 patients undergoing cardiac surgery compared the effectiveness of colchicine with placebo in preventing postoperative effusions.[292] These investigators reported that the patients who received colchicine had a significantly lower incidence of pleural effusion (12.2% vs. 26.5%) and a significantly lower incidence of pericardial effusion (12.8% vs. 22.8%).

Drug-Induced Pleural Disease

Lupus-like syndromes arise in conjunction with the administration of many different medications, as discussed earlier in this chapter and in Chapter 99. Although many drugs have been associated with pleural disease,[296] several drugs are particularly well known to induce pleural disease, including nitrofurantoin, dantrolene, methysergide, and ergot drugs. Less common drugs include procarbizine and amiodarone. Newer drugs, such as IL-2 and dasatinib (a broad inhibitor of tyrosine kinases) cause pleural effusions.[297] In general, one should consider a drug etiology for every patient with an undiagnosed exudative pleural effusion. Referring to pneumotox.com can be helpful, especially for newer drugs without published reports. At the time of this writing, 100 drugs are listed on pneumotox.com as causing pleural effusions.

A discussion of some of these drugs is available at ExpertConsult.com.

Other Inflammatory Diseases

Pleural effusions occasionally develop in the course of EGPA (see eFig. 96.5), granulomatosis with polyangiitis, and Sjögren syndrome, which are described in detail in other chapters. Pleural effusions are found in most patients with acute eosinophilic pneumonia (see eFig. 96.4). The pleural disease seen with these diseases constitutes a relatively minor portion of the clinical picture.

MISCELLANEOUS

Lung Transplantation

With lung transplantation, the lymphatics that normally drain the lung are severed. In accordance, the fluid that normally exits the lung via these lymphatics may then exit into the pleural space. The presence of chest tubes in the first few days after lung transplantation prevents the accumulation of pleural fluid. Pleural complications such as hemothorax, empyema, and persistent air leak contribute substantially to the postoperative morbidity and mortality. The incidence of pleural effusions at 3 months posttransplantation is about 30–60%.[306,307] The incidence of effusion at 12 months is less than 10%.[307] The effusions are characteristically a lymphocyte-predominant exudate with a benign course.[306] However, patients who develop complications after lung transplantation are likely to develop pleural effusions. In one study, pleural effusions were seen with 74% of 19 episodes of acute rejection, 88% of 8 instances of chronic rejection, 55% of 11 episodes of infection, and 75% of 4 instances of lymphoproliferative disease.[308] Late effusions may also form due to constrictive pericarditis.[309] (More details about lung transplantation are provided in Chapter 140.)

Meigs Syndrome

Meigs and Cass[310] originally described a syndrome characterized by ascites and pleural effusion in association with solid benign ovarian tumors. Subsequently, it has become apparent that a similar syndrome can be seen with benign cystic ovarian tumors, with benign tumors of the uterus (fibromyomas), and with low-grade ovarian malignant tumors without evidence of metastases.[37] The ascites appears to result from the secretion of large amounts of fluid by the tumors. VEGF may play an important role in the pathogenesis of the ascites and pleural fluid because VEGF levels are high in both the ascites and pleural fluid.[311] It is thought that the pleural effusion results from the ascitic fluid passing through defects in the diaphragm into the pleural space, usually on the right side.

Patients with Meigs syndrome usually have a chronic illness characterized by weight loss, pleural effusion, ascites, and a pelvic mass. It is important to realize that not all patients with this constellation of symptoms have a disseminated malignancy. Approximately 70% of the effusions are right sided, and 20% are bilateral. The pleural fluid is usually an exudate with a relatively low white blood cell count (<1000/μL) and occasionally is bloody.[312] The level of cancer antigen-125 in the pleural fluid may be elevated and should not be taken as an indication of malignancy.[311]

The diagnosis of Meigs syndrome should be considered in all women who have a pelvic mass, ascites, and a pleural effusion. If the cytology of the pleural fluid is negative in such patients, a diagnostic laparoscopy or an exploratory laparotomy should be performed to determine whether there are peritoneal metastases. The diagnosis is confirmed when the ascites and the pleural fluid resolve after the primary neoplasm is removed and do not recur. The pleural fluid disappears from the chest within the first 2 weeks after surgery.

Nitrofurantoin. Pleuropulmonary reactions occasionally result from the administration of nitrofurantoin. Such reactions can have an acute or a chronic presentation.[298] The acute presentation is seen within 1 month of initiation of therapy and is manifested by dyspnea, nonproductive cough, and fever. About 20% of patients have an opacity and an effusion, and about 3% have only an effusion. Most patients have both peripheral eosinophilia (>350/μL) and lymphopenia (<1000/μL).[299] The chronic syndrome is seen when the patient has been taking nitrofurantoin for 2 months to 5 years and is much less common than the acute syndrome. Pleural effusion develops in less than 10% of patients, and no patient with the chronic syndrome has had a pleural effusion without an opacity.[298]

The diagnosis of nitrofurantoin pleuropulmonary reaction should be suspected in all patients with a pleural effusion who are taking nitrofurantoin. If the drug is discontinued, the patient usually improves clinically within 1 to 4 days, and the chest radiograph becomes normal within a week with the acute syndrome, whereas the time course is much longer for the chronic syndrome.[298]

Dantrolene. Dantrolene sodium is a long-acting skeletal muscle relaxant with a chemical structure similar to that of nitrofurantoin. Its administration can lead to the development of pleural or pericardial disease.[300] The pleural effusion is unilateral and develops 2 months to 12 years after the initial administration of dantrolene. Patients may be febrile and may have pleuritic chest pain. The pleural fluid is an eosinophilic exudate with a normal glucose level.[300] When dantrolene is discontinued, the patient improves symptomatically within days, but it may take several months for the pleural effusion to resolve completely.

Methysergide. The administration of methysergide can lead to a pleuropulmonary disease similar to that seen with nitrofurantoin.[301] Symptoms consisting of chest pain, dyspnea, and fever develop 1 month to 3 years after methysergide therapy is initiated. The chest radiograph commonly shows bilateral loculated pleural effusions and pleural thickening.[301] When methysergide is discontinued, the symptoms of the patients improve. However, in one series of 13 patients, severe pleural fibrosis persisted in two patients who had continued to take the drug for the longest period (18 and 36 months, respectively) after the onset of the pleurisy.[301]

Ergot Alkaloids. The administration of ergot alkaloid drugs, such as bromocriptine, ergotamine, dihydroergotamine, nicergoline, pergolide, and dopergine, in the long-term treatment of Parkinson disease can lead to pleuropulmonary changes.[296] As of 1988, a total of 23 patients had been reported. All the patients were men, and the drug had been taken for 6 months to 4 years before symptoms developed. From 2–5% of patients receiving long-term ergot alkaloid therapy develop pleuropulmonary disease. The incidence of pleural disease is higher if the patient has previous exposure to asbestos.[302] The chest radiograph reveals unilateral or bilateral pleural thickening or effusion in most patients. Analysis of the pleural fluid reveals an exudate with predominantly lymphocytes and frequently eosinophilia.[303] The natural history of pleuropulmonary disease during ergot alkaloid therapy is unclear. The disease progresses only in some of the patients who continue taking the drug.[303]

Procarbazine. There have been two detailed case reports of pleuropulmonary reactions consisting of chills, cough, dyspnea, and bilateral pulmonary opacities with pleural effusion after treatment with procarbazine.[37] In both cases, symptoms developed within hours after procarbazine therapy; in both instances, rechallenge with procarbazine again produced the opacities and pleural effusions. With discontinuation of the drug, the symptoms and radiographic changes resolved within several days.

Amiodarone. Amiodarone is an antiarrhythmic that may produce severe pulmonary toxicity. Pleural effusions are seen as a manifestation of amiodarone toxicity, but they are uncommon. Most cases have concomitant parenchymal involvement, but cases have been reported in which there is none.[296] The pleural fluid is an exudate and may have predominantly lymphocytes, macrophages, or polymorphonuclear leukocytes.[296]

Interleukin-2. Recombinant IL-2 is sometimes used in the treatment of malignancies, especially melanoma or renal cell carcinoma. One of the primary side effects of IL-2 administration is the development of pulmonary opacities and pleural effusion that are probably related to a generalized capillary leak syndrome.[37] The incidence of pleural effusion after IL-2 administration is approximately 50%.[296] The characteristics of the pleural fluid have not been described. After the IL-2 therapy is stopped, the effusions tend to disappear. However, in one study 17% of patients still had a pleural effusion 4 weeks after cessation of therapy.[304]

Dasatinib. Dasatinib, an inhibitor of multiple tyrosine kinase inhibitors, is used primarily for treating adults with chronic myeloid leukemia with resistance to prior therapy. Use of dasatinib is associated with a high incidence of pleural effusion.[297] Quintas-Cardama and associates[305] reported that the effusion developed in 35% of 135 patients receiving the drug and about half the effusions occupied more than 25% of the hemithorax. The effusions were bilateral in 80% of the patients. The effusions were mostly exudates. The effusions resolved when dasatinib was discontinued or when steroids were administered. The effusions are less common when dasatinib is administered once rather than twice per day.

Endometriosis

An occasional patient with severe endometriosis presents with massive ascites. In one review, 10 of 27 patients (37%) also had a pleural effusion.[313] The effusions are usually right sided but may be bilateral. The pleural fluid is a bloody or a chocolate-colored exudate. The serum carcinoembryonic antigen level may be elevated, suggesting ovarian carcinoma. Hormonal therapy, including gonadotropin-releasing hormone agonists, may be attempted, but frequently it is ineffective, and many patients require total abdominal hysterectomy plus bilateral salpingo-oophorectomy.[313]

Ovarian Hyperstimulation Syndrome

This syndrome is a serious complication of ovulation induction. The dramatic clinical picture is characterized by massive ovarian enlargement with multiple cysts, hemoconcentration, and the third-space accumulation of fluid.[311] The full-blown syndrome may be complicated by renal failure, hypovolemic shock, thromboembolic episodes, acute respiratory distress syndrome, and death. Although the pathophysiology of this syndrome is incompletely understood, it is likely that the increased capillary permeability is due to the upregulation of VEGF expression in the ovarian granulosa cells by the exogenous human chorionic gonadotropin.[311]

Patients with the syndrome present within 2 to 3 weeks of receiving the human chorionic gonadotropin. Patients typically present with abdominal pain and distention, nonproductive cough, and dyspnea caused by the ascites, pleural effusion, or both. The pleural effusion is usually right sided, and the pleural fluid is most often exudative with predominantly neutrophils and a relatively low LDH level.[314] The treatment of severe cases requires restoration of intravascular volume, correction of electrolyte abnormalities, and venous thromboembolism prophylaxis.[311]

Trapped Lung (See Chapter 112)

Effusions that are remarkably stable over time, that recur after thoracentesis, and that are resistant to diagnosis may be due to an underlying trapped lung (Fig. 108.9). After an earlier episode of inflammation, a fibrous peel may form over the visceral pleura and can prevent the underlying lung from expanding fully, thereby "trapping" the underlying lung. The resulting negative pleural pressure leads to the development of a chronic pleural effusion.[315,316]

Patients with a chronic pleural effusion secondary to trapped lung are often asymptomatic but may have symptoms of dyspnea. Symptoms of acute pleural inflammation, such as pleuritic chest pain and fever, are distinctly uncommon, but the patient often gives a history of such events in the past. One characteristic of the pleural effusion secondary to trapped lung is that the amount of fluid is quite constant from one study to another. With trapped lung, the pleural fluid is often a borderline exudate; the ratio of pleural fluid to serum protein is about 0.5, and the ratio of pleural fluid LDH to serum LDH is about 0.6.

The diagnosis of pleural effusion secondary to trapped lung should be suspected in any patient with a stable, chronic pleural effusion, particularly if the patient has a history of uremia, thoracic radiation, pancreatitis, collagen-vascular disease or prior thoracic surgery.[316,317] The thickened visceral pleura can be demonstrated if 200 to 400 mL of air is injected into the pleural space at the time of a thoracentesis. At some institutions, pleural manometry is used routinely during a therapeutic thoracentesis; if the pleural pressure falls rapidly (greater than 14 to 15 cm H_2O/L pleural fluid removed), air is allowed to enter the pleural space to return the pleural pressure to a more normal range (−5 cm H_2O) so that an air-contrast chest CT scan can be obtained to evaluate the visceral pleura.[316]

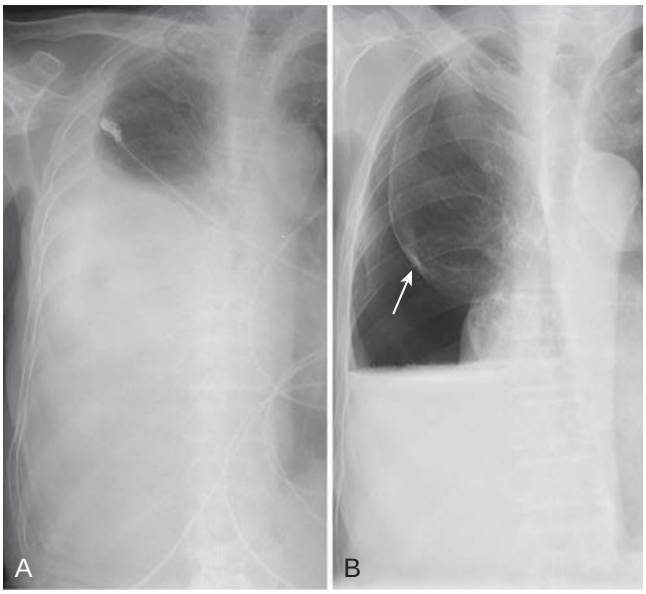

Figure 108.9 Effusion with trapped lung. (A) Frontal chest radiograph shows a large right pleural effusion. (B) On a subsequent radiograph, the effusion has been partially drained, revealing the underlying lung with some visceral pleural thickening (*arrow*). The lung failed to reexpand despite negative intrapleural pressures. The intrapleural air likely entered the pleural space from the atmosphere along the drainage track. (Courtesy Michael B. Gotway, MD.)

For symptomatic patients, decortication can be considered but is considered major surgery and may not benefit the patient, especially if the underlying lung is also diseased. If the patient is asymptomatic or minimally symptomatic, the patient can be observed if the clinical picture, pleural fluid findings, and pleural pressure measurements are all compatible with the diagnosis of trapped lung.

Yellow Nail Syndrome

This syndrome consists of the triad of deformed yellow nails, lymphedema, and pleural effusions.[318] The three entities may manifest at widely disparate times and therefore are not all present in every patient at the same time. The basic abnormality responsible for this syndrome appears to be hypoplasia of the lymphatic vessels[319,320] or a decrease in function of lymphatics.[321] The onset of the condition is after puberty (mean age of onset was 53 in one study[322] and 61 in another[323]). The condition may be acquired[322] and may resolve without treatment.[322]

Typically, the nails are pale yellow to greenish in color and are excessively curved from side to side (eFig. 108.11). They are also thickened and may show transverse ridging or onycholysis (separation of nail from bed). The pleural effusions are bilateral in about 50% of cases and can be massive; chylothoraces are also described.[318] Once a pleural effusion has developed with this syndrome, it tends to persist and to recur rapidly after thoracentesis.[319] The pleural fluid is usually an exudate with predominantly lymphocytes.[319] The

pleural fluid LDH tends to be relatively low relative to the pleural fluid protein level.[37]

The diagnosis is usually established by the presence of the triad of pleural effusion, lymphedema, and yellow nails. The diagnosis may be difficult to establish if the pleural effusion is the first manifestation of the syndrome. There is no specific treatment for the syndrome but, if the effusion is large and is producing symptoms, the effusion can be treated with pleurodesis.[37] Some reports suggest that treatment of associated bronchiectasis or rhinosinusitis can ameliorate the syndrome.[324,325]

Misplaced Catheters

Both internal jugular and subclavian vein catheterization can be complicated by misplacement of the catheter tip into the mediastinum or pleural space that results in a large unilateral (eFig. 108.12) or bilateral pleural effusion. The pleural fluid may have the characteristics of the intravenous fluid, or it may be bloody from laceration of the blood vessels.[213] If the patient is receiving lipids through a central line, the fluid may look chylous.[326] The diagnosis of a misplaced central venous catheter should be considered in all patients with such lines who rapidly develop pleural effusions, and the patients should be evaluated by diagnostic thoracentesis.

In the past several years, the development of soft, flexible, small-bore polyurethane feeding tubes has made nasogastric and nasoenteric feeding more practical and comfortable for patients. However, misplacement of these tubes can lead to serious pleural complications. Pneumothorax is the most common complication, but infusion of the enteral formula into the pleural space or the development of an empyema, or both, are also common.[327] These small flexible tubes are inserted with a stylet in place that enables easier advancement of the device. However, with the stylet in place, the tubing becomes stiff enough that it can perforate structures relatively easily. The risk is much greater if the patient has an endotracheal tube in place or is obtunded.[327] To prevent these complications, these tubes should be inserted only by experienced persons, and the tube should be immediately removed if the patient starts coughing. The tube should not be advanced if resistance is felt and, before feeding is initiated, the position of the tip of the tube should be confirmed radiographically.[328] If enteral solutions enter the pleural space, tube thoracostomy should be performed to remove the solution. In addition, the patient should be carefully observed for the development of an empyema.[327]

Key Points

- Transudates usually result from systemic changes in hydrostatic and/or osmotic pressures that lead to collection of a relatively low protein and *lactate dehydrogenase* (LDH) fluid (pleural/serum protein ratio < 0.5 *and* pleural/serum LDH < 0.6 *and* LDH less than two-thirds the upper limit of normal (Light's criteria).
- Transudates with a very low protein concentration (<0.5 g/dL) come from entry of cerebrospinal fluid, urine, peritoneal dialysis fluid, or intravenous fluids into the pleural space.
- Exudates result from pleural or extrapleural injury or inflammation due to a multitude of inflammatory, infectious, or malignant diseases, leading to an effusion with a relatively high protein and/or LDH concentration.
- Most transudates arise from *congestive heart failure* (CHF). When the cause is unclear or when the protein and LDH ratios are not clearly transudative, as can happen after diuresis, the pleural fluid *N-terminal pro–brain natriuretic peptide* (NT-proBNP) is a sensitive and specific marker for a cardiac etiology.
- Most exudates arise from either pneumonia, malignancy, or pulmonary embolism.
- Many effusions have multiple etiologies, often with CHF included. Pleural fluid NT-proBNP (>1500 pg/mL) can help identify an underlying contribution from CHF.
- Pleural fluid chemistries may be indeterminate, meaning not clearly transudative or exudative, a situation that may point to more than one etiology or to changes to a pleural effusion caused by diuresis.
- Pleural fluid glucose is as useful as pH but is an easier and a more reliable test.
- Pleural fluid and pleural cytology now have the potential for clinically useful molecular testing: detection of lung cancer treatment targets (epidermal growth factor receptor–activating mutations, programmed death ligand-1), metagenomics for bacterial and viral infection, and molecular testing for tuberculosis. The clinical role for these tests is evolving.
- No diagnosis is ever established for approximately 30% of all exudative pleural effusions, even after thoracoscopic biopsies, and many resolve spontaneously, leaving no residua. The degree to which a diagnosis is pursued by invasive procedures will depend on (1) the symptoms and the clinical course of the patient, (2) the trend of the pleural fluid LDH level with time, and (3) the eagerness of the patient for a diagnosis. Follow-up of such patients is warranted because 10–15% of these patients can later develop cancer.

INTRODUCTION

Of the approximately 1 million patients hospitalized with pneumonia each year in the United States, approximately 60,000 will develop frank empyema.[1] A further 25,000 are estimated to develop pleural infection for other reasons, including trauma and iatrogenic instrumentation.[2,3] The annual estimated hospital cost for treating these cases is in excess of $500 million.[2,3] The morbidity and mortality rates in patients with pneumonia and associated pleural effusions are higher than for those in patients with pneumonia alone, and one study suggested that the increased relative risk for mortality was 3.4 times higher.[4] The incidence of pleural infection has increased globally over the past decades, but despite continued advances in the management of this condition, morbidity and mortality have essentially remained static over the past decade.[5–8]

Bacterial pleural empyema is responsible for the majority of pleural infections, with tuberculous pleuritis common in countries with a high prevalence of tuberculosis.[9,10] Rarer bacterial pathogens, such as *Nocardia* and *Actinomyces,* can also affect the pleural space. Fungal lung infections can be complicated by spread of pathogens to the pleura, with serious consequences. Viruses are likely to be responsible for a significant proportion of undiagnosed pleural effusions, both in association with primary atypical pneumonias and in the absence of parenchymal opacification on chest radiographs. Finally, certain parasitic infections can involve the pleura.

BACTERIAL PLEURAL EMPYEMA

HISTORICAL PERSPECTIVE

Infection of the pleural space is an ancient disease, with the earliest recorded description more than 5000 years ago[11] and the first consistent description of its manifestations and treatment credited to the father of modern medicine, Hippocrates. Open thoracic drainage was the standard treatment for pleural infection before 1918; however, there was a 70% mortality rate associated with this treatment. Following an outbreak of hemolytic streptococcal infections in American military camps in the winter of 1917 to 1918, the U.S. Army Empyema Commission was formed to address the problem. The commission noted that dogs with empyema died more often if they were treated with early open drainage rather than with delayed intervention, and the commission recommended using the closed-tube drainage techniques described by Hewitt and Bülau.[12,13] The commission's summary recommendations were as follows: adequate pus drainage with a closed tube, avoidance of early open drainage, obliteration of the pleural space, and proper nutritional support. A landmark paper by Graham[14] charted the successes seen during this time, with short-term mortality plummeting to 4%. These treatment principles, described almost 100 years ago, remain essentially unchanged to this day. The discovery of penicillin in the 1940s was a major advance that led to a further reduction in mortality. Surgical techniques beyond open drainage were developed in the late 19th century, with thoracoplasty described by Estlander[15] and Schede[16] and with decortication described by Fowler.[17] More recently, however, the introduction of *video-assisted thoracic surgery* (VATS) has meant that increasing numbers of patients undergo this less invasive surgical procedure as the operation of choice for their pleural infection.

INCIDENCE

There have been some reports from the United States, Canada, Europe, and Asia, all showing a dramatic increase in the incidence of pleural infection over the past 2 decades.

This seems to be the case for both children and adults and, although most data are derived from populations in the developed world, this pattern has been replicated around the globe.[4–8,14–16,18–20] The incidence of pleural infection began to rise in the middle to late 1990s. This rather surprising increase was captured by Grijalva and colleagues,[7] who examined the trends in parapneumonic empyema in the United States over a 13-year period and demonstrated a doubling in the rates of empyema hospitalizations between 1996 and 2008, from 3.04 to 5.98 per 100,000. Similar results were demonstrated by a Canadian study, which also confirmed a significant disparity in empyema incidence between persons 65 years of age and older (17 to 20 per 100,000) and those 19 years of age or younger (2 to 4 per 100,000).[5] The finding of a higher incidence in older age groups has been replicated in more recent studies from Finland and Taiwan.[21,22]

Mortality rates from empyema also seem to be on the rise. A study looking at the population of Utah showed a sixfold rise in mortality from the period of 1950 to 1975 to the period of 2000 to 2005.[23] In a large series, inpatients were found to have a mortality up to 18% in the short term,[24] with patients in intensive care experiencing mortality as high as 41%.[25] In a large multicenter trial from the United Kingdom, patients (with an average age of 59 years) were shown to have a mortality rate from 8–20% 1 year after treatment for empyema.[26]

The explanation for the increase in empyema incidence and mortality is not clear. Following the licensing of the heptavalent *pneumococcal conjugate vaccine* (PCV7) for children and infants in 2000, there was concern that nonvaccine serotypes could replace vaccine serotypes in the nasopharynx.[8,27] Because PCV7 did not include the two pneumococcal serotypes commonly responsible for empyema (serotypes 1 and 19A),[27–29] the increase in pleural infection and invasive pneumococcal disease may be explained by this replacement phenomenon. Indeed, genetic sequence typing of pediatric empyema cases in Utah suggested that replacement with serotype 1 pneumococcus was a contributing factor in the increase in incidence following PCV7 introduction.[30]

However, vaccine effects are unlikely to be entirely responsible for the rising incidence of pleural infection, not least because subsequent pneumococcal vaccines (the 13-valent conjugate vaccine and the 23-strain polysaccharide vaccine) included serotypes 1 and 19A. Alternative explanations include aging populations,[31] emergence of new influenza strains causing pandemics,[32] and increasing antimicrobial resistance.[7] Increased detection resulting from wider availability of imaging techniques such as *computed tomography* (CT) may have also contributed.[7,33]

EPIDEMIOLOGY

Pleural infection is seen in patients of all ages but in a bimodal distribution, with a peak in childhood and a second rise in older adults. Men are affected twice as often as women,[34] as illustrated in Fig. 109.1, which shows the age and sex distribution of adult patients in the *Multicenter Intrapleural Sepsis Trial* (MIST) 1 study, the largest cohort in the literature to date.[35] Pleural infection is also more common in persons with diabetes, alcohol dependency or drug addiction, and rheumatoid arthritis.[34,35] Poor dentition and aspiration are also risk factors.[24]

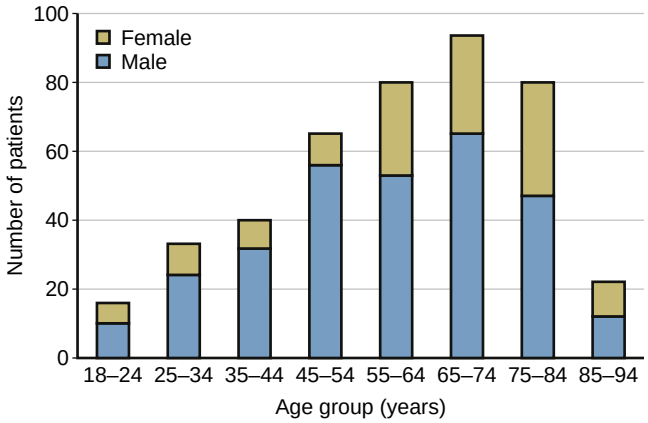

Fig. 109.1 Age and sex distribution of pleural infection in adults in a large UK cohort. The disease is more common in men, and the peak incidence in adults is in the 65- to 74-year age range. (Data from Maskell NA, Davies CW, Nunn AJ, et al. U.K. controlled trial of intrapleural streptokinase for pleural infection. *N Engl J Med.* 2005;352:865–874.)

The underlying etiology of pleural infection is varied, although most cases originate in the community.[36] Often this is a consequence of community-acquired pneumonia; however, many cases show no evidence of consolidation on CT imaging.[37] These cases are thought to have been acquired through hematogenous bacterial spread or by translocation of colonizing bacteria from the oropharynx, with the latter phenomenon being particularly relevant in the intensive care setting.[38,39] In the next largest group of patients, the infection develops in the hospital, often as the result of prolonged hospital admissions for other reasons, or complications following surgery or invasive procedures. For example, pleural infections and other pleural complications are common after lung transplantation.[40] Other potential causes include direct (transdiaphragmatic) spread of abdominal sepsis, blunt or penetrating chest trauma, esophageal perforation, or rupture of a peripheral lung abscess into the pleural space.[35,41,42]

PATHOGENESIS

The evolution of a pleural infection can be divided into three stages, which may overlap. The first, *exudative* stage is characterized by the rapid outpouring of sterile pleural fluid into the pleural space. Some of this fluid likely comes from the interstitial spaces of the lung and some from the parietal pleura due to increased permeability (see Chapter 14). The pleural fluid has a low white blood cell count and *lactate dehydrogenase* (LDH) level, together with a normal glucose level and pH.[43,44] At this stage, chest tube drainage is rarely required, and antibiotics alone should suffice.

The second, *fibropurulent* stage evolves if bacteria invade the sterile exudative effusion. During this stage, there is an accumulation of leukocytes, bacteria, and cell debris together with increased pleural fluid output. Fibrin is deposited over the visceral and parietal pleura, and there is a tendency for loculations to form within the pleural fluid, which may prevent or limit effective drainage via a chest tube. The pleural fluid pH and glucose level are lower, and the LDH level rises, often dramatically.

The final *organization* stage is characterized by thickening of the pleural surfaces to form a membrane called the "pleural peel." This may reduce lung functionality considerably, although it should resolve with time if the infection is controlled. The pleural fluid is often thick, consisting of pus and cellular debris.

In contrast to these three stages of parapneumonic empyema, primary empyema can arise from direct inoculation of the pleural space with bacteria, which can translocate from the oropharynx or via hematogenous spread. In these circumstances, bacteria invade the pleural space as the initial insult, leading directly to the fibropurulent stage.

CLINICAL PRESENTATION

The classic presentation of pleural infection is difficult to separate from that of pneumonia, whereby patients have dyspnea, cough, fever, malaise, and perhaps pleuritic chest pain, often over a prolonged period.[45] In fact, a significant number of patients with pneumonia will go on to develop a parapneumonic effusion without a change in symptoms to offer clues to its existence.

Parapneumonic effusions are often categorized as uncomplicated or complicated. An *uncomplicated* parapneumonic effusion is defined as an effusion with a glucose level higher than 40 mg/dL, pH greater than 7.2, and negative Gram stain and culture results without loculation on ultrasonography. A *complicated* parapneumonic effusion has a glucose level lower than 40 mg/dL or pH less than 7.2 or is loculated on ultrasonography (eFig. 109.1).[46,47] Although there is no symptomatic discriminator between patients with complicated effusions and patients with uncomplicated effusions, a high index of suspicion should be maintained for those patients whose conditions fail to improve within a few days of initiating antibiotic therapy[48] or who exhibit persistent fever or signs of sepsis. Further investigations should be undertaken swiftly in these patients because they may require urgent drainage.[49] With long-lasting infection, the course of patients with pleural infection can mimic that of a malignant process, with significant weight loss, sweats, and loss of appetite.

PLEURAL FLUID SAMPLING

Investigation and management of pleural infection are summarized in Fig. 109.2. Abnormal signs, symptoms, or blood test results in the context of a suggestive radiograph should lead to confirmation of the presence of an effusion and early sampling of the fluid. However, in a small retrospective series, Skouras and colleagues[50] suggested that parapneumonic effusions less than 2 cm in thickness on chest CT scan can be treated with antibiotics without sampling because these effusions are unlikely to become complicated or require intervention. Such patients would still require close monitoring and appropriate antibiotic therapy.

Confirmation of the presence of pleural fluid and identification of a safe and suitable site for aspiration require thoracic ultrasound guidance. Ultrasonography also provides useful information on the size and complexity of the fluid that can guide the need for further intervention.

BIOCHEMISTRY

In cases where overt pus is revealed on initial aspiration, no further biochemical analysis is necessary, and chest tube placement is required. Microbiologic analysis is still important, however.

Pleural fluid pH may be the best indicator of the need for chest tube insertion. Many studies have demonstrated better patient outcomes when drainage is instituted based on the early biochemical changes related to infection. In a meta-analysis by Heffner and coworkers,[51] the receiver operating characteristic for the diagnostic accuracy of pleural fluid pH showed that if the pH was less than 7.2, a chest tube was likely to be necessary. As a result, current guidelines regard a pH of 7.2 as diagnostic of complexity, thus making this the definitive cutoff below which drainage should take place.[52] A pH analysis (or glucose analysis) therefore should be performed in all cases where pleural infection is included in the differential diagnosis. The pH should be measured using a blood gas machine because pH strips and pH meters are not sufficiently accurate.[53] Some institutions rely on the glucose concentration instead and find it equally useful as pH and less prone to error.

Fluid pH values may be appreciably altered by minor variations in sampling and processing techniques, with significant subsequent effects on management strategy. In a study of pleural fluid pH, Rahman and associates[54] reproduced several common scenarios that could arise during testing. Small amounts of residual heparin or local anesthetic agent in a sample syringe could dramatically lower pH; residual air in the syringe could increase pH (if 1 mL of air was in the syringe with 2 mL of fluid, the pH rose by an average of 0.08).[54] These errors represented a clinically significant change in more than two-thirds of patients. These and other studies emphasize that the pH must be measured in a blood gas analyzer and the sample must be handled anaerobically, as one would handle an arterial blood sample; with exposure to the air, the loss of carbon dioxide will cause the pH to rise rapidly.[55,56] Thus, if clinical decisions depend on an accurate pH measurement, pleural fluid should be withdrawn anaerobically into a heparinized syringe and taken on ice immediately to the blood gas machine for measurement of the pH at 37°C.

As mentioned earlier, when pH measurements are not easily obtainable, a glucose level can be useful.[51] Samples should be collected in a blood glucose tube and sent to the laboratory, with a value of less than 2.2 mmol/L (40 mg/dL) indicating the need for chest tube drainage.[51,54] It should be noted that pH and glucose level can also be low in malignant pleural effusions, rheumatoid pleural effusions, and pleural effusions secondary to esophageal rupture. Therefore, their value for guiding chest tube drainage should be restricted to the setting of parapneumonic effusions.

LDH measurements tend to be high in all cases of complicated parapneumonic effusions and empyema. LDH tends to rise rapidly as the pleural infection progresses through the fibropurulent and organizing stages of the disease. When a patient is being treated with antibiotics alone, a rising LDH level on repeated thoracentesis may indicate that an effusion is not responding and chest tube drainage should be considered.

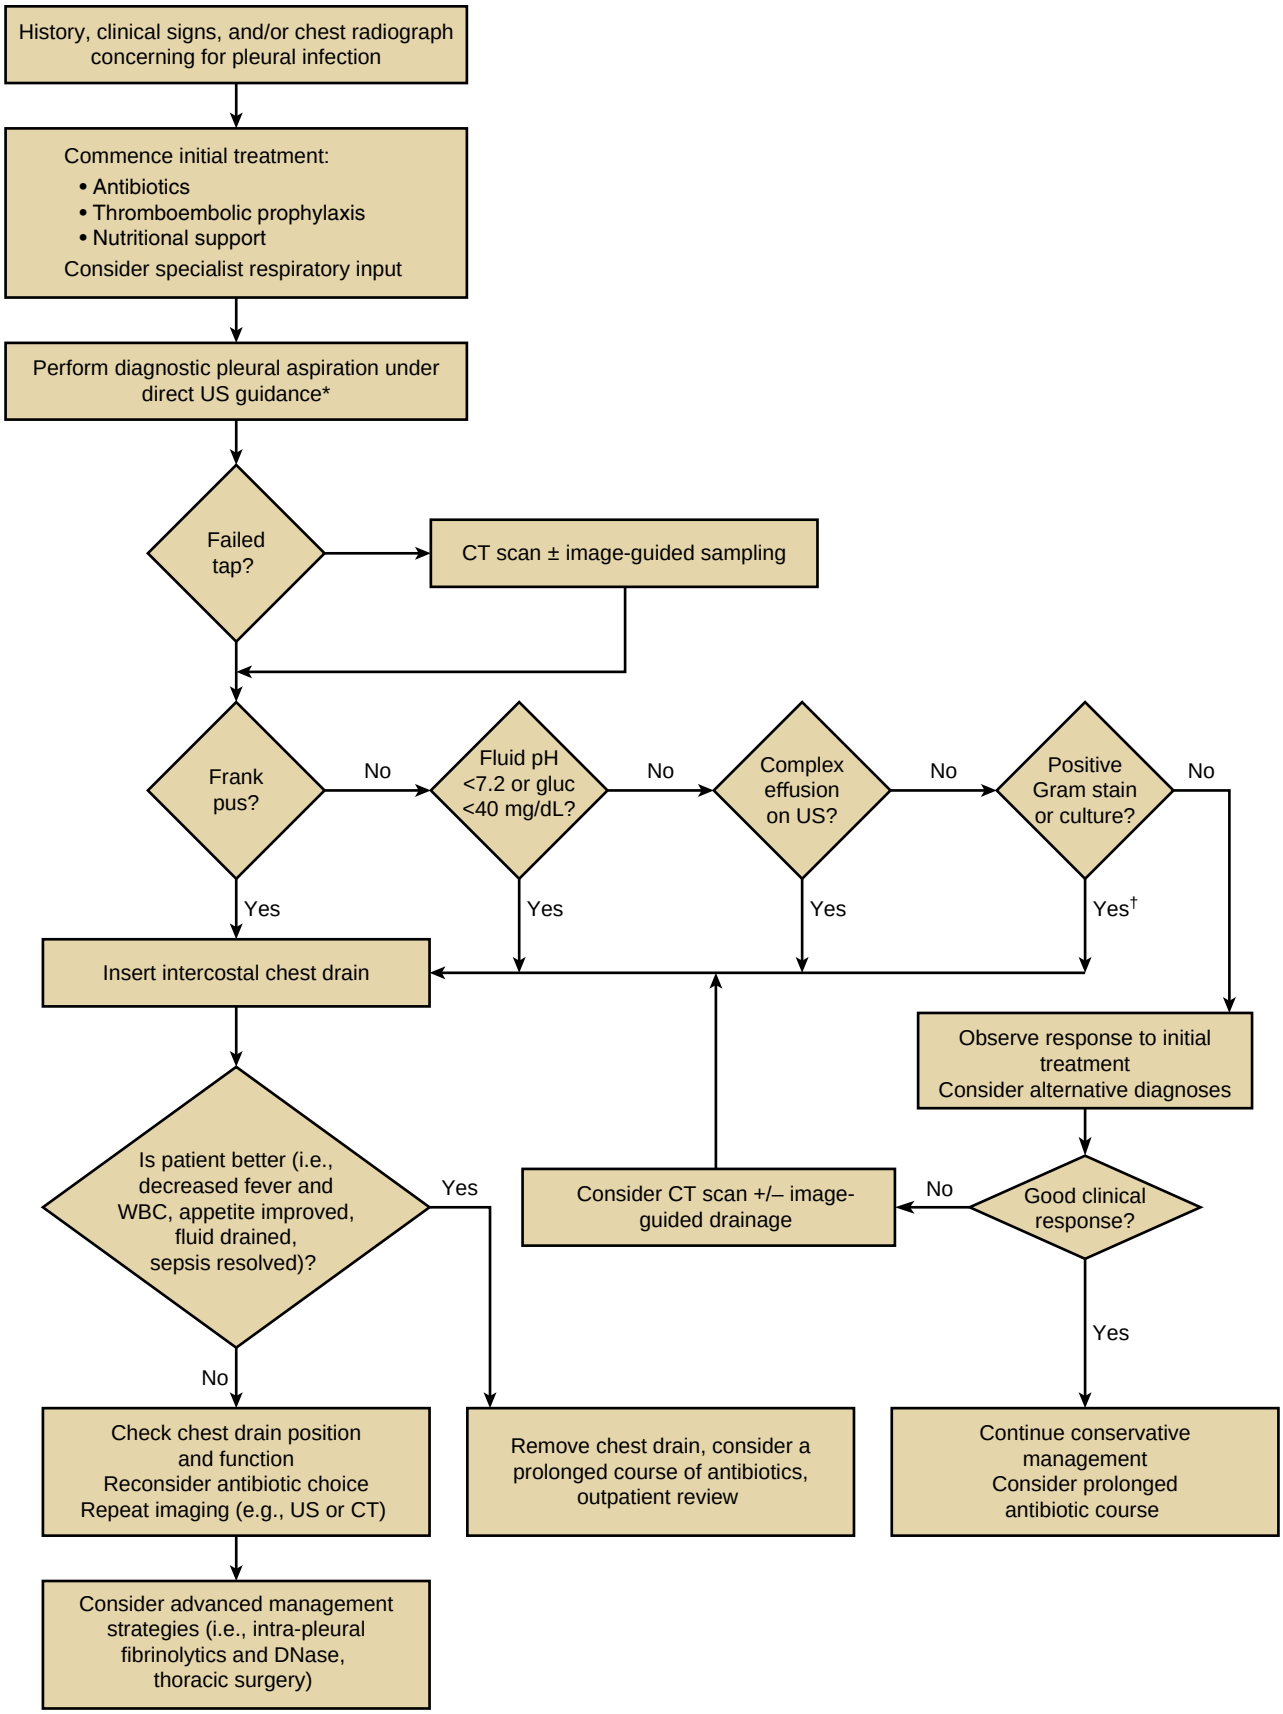

Fig. 109.2 Algorithm demonstrating the investigation and management of suspected pleural infection. *Ideally this should be performed before administration of antibiotics; however, treatment should not be delayed if aspiration cannot be performed immediately. †A positive pleural culture or Gram stain result usually means that a chest drain is required; however, the patient's clinical course should be considered when making this decision. CT, computed tomography; US, ultrasound; WBC, white blood cells.

MICROBIOLOGY

The bacteriologic features of culture-positive pleural fluid have changed since the introduction of antibiotics. In the pre-antibiotic era, the most common pathogens were *Streptococcus pneumoniae* and *Streptococcus haemolyticus*.[57] After this period, between 1955 and 1965, *Staphylococcus aureus* was the most common causative organism. Over time, there have been further shifts in the frequency and type of causative organisms, predominantly attributable to the introduction and evolution of antibiotics. There also appear to be global and regional differences in the frequencies and range of the causative organisms.

To increase the detection of causative organisms, standard culture methods can be combined with nucleic acid amplification, an approach that yielded a 74% overall identification rate in one UK-based pleural infection study.[58] Cloning techniques were also applied to a small number of cases (3%), limited by cost. Nucleic acid amplification identified an organism in 38% of the culture-negative samples, with the same organism found by both culture and nucleic acid amplification (or cloning) in 35% of cases. More recently, a study from Sweden found that DNA sequencing using 16S rDNA identified a causative bacterium in 94 of 152 (62%) patients with pleural infection, compared with 26 of 152 (17%) on standard microbiologic culture.[59] In patients with complex pleural effusions, detection rates were even higher, at 69 of 74 (93%) compared with 23 of 74 (31%) positive cultures. In both cohorts, which consisted of predominantly community-acquired pleural infections, the *Streptococcus anginosus* group (formerly *Streptococcus milleri* group) was the most frequently identified bacterial species.[58,59] These and other gram-positive aerobes were implicated in up to 65% of cases, thus confirming inherent differences in empyema etiology compared with pneumonia. Other organisms included staphylococci (11%), gram-negative aerobes such as *Escherichia coli* (9%), and anaerobes (20%). Polymicrobial samples were identified in 20% of cases, but this may be an underestimate of the true incidence, as suggested by the cloning results and the possibility that anaerobes, which have been identified in up to three-fourths of cases of community-acquired pleural infection in other series, may have been underrepresented here.[60]

Hospital-acquired pleural infections made up just 15% of the UK cohort but were markedly different from the community-acquired pleural infections. Most (58%) cases were attributed to gram-negative organisms or staphylococci, with more than 70% of the latter attributed to methicillin-resistant *S. aureus*.[58] This finding is likely to reflect the period over which the data were collected because infection control measures and antibiotic stewardship have reduced the incidence of methicillin-resistant *S. aureus* infections over subsequent years.[61] A systematic review and meta-analysis of 75 pleural infection studies published between 2000 and 2017 revealed methicillin resistance in 33% of community-acquired *S. aureus* infections (6% of all community-acquired infections) and in 58% of hospital-acquired *S. aureus* infections (22% of all hospital-acquired infections).[36] The bacteriology of hospital-acquired pleural infection is clearly very different from that of community-acquired pleural infections and therefore requires different empirical antibiotics.

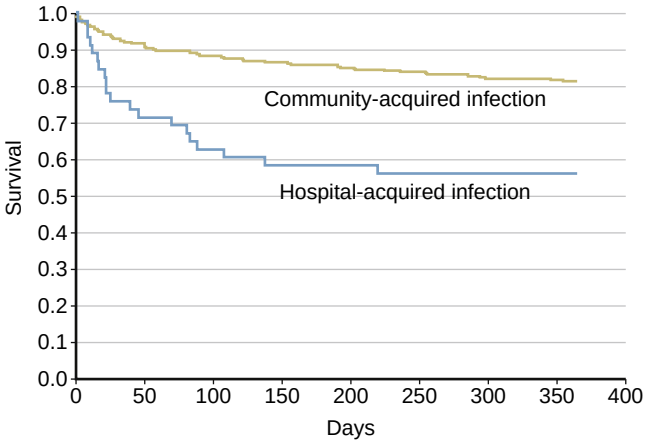

Fig. 109.3 Kaplan-Meier survival curves of patients with community-acquired and hospital-acquired pleural empyema. In the Multicenter Intrapleural Sepsis Trial cohort, there was a significantly higher mortality rate in patients with hospital-acquired pleural infection ($n = 46$) compared with patients with community-acquired infection ($n = 394$). (From Maskell NA, Batt S, Hedley EL, et al. The bacteriology of pleural infection by genetic and standard methods and its mortality significance. *Am J Respir Crit Care Med.* 2006;174:817–823.)

The use of blood culture bottles for culturing pleural fluid can increase yield. Menzies and colleagues[62] provided the first comparative, prospective evidence of increased microbiologic diagnostic yield in pleural infection by using the BACTEC blood culture bottle system (Becton Dickinson). Addition of blood culture bottle–inoculated pleural fluid to standard pleural fluid culture increased microbiologic diagnostic yield by 21% and, in a small proportion of cases (4%) where results of standard culture were positive, use of blood culture bottles suggested the presence of additional organisms that would alter antibiotic management. These findings are supported by the lack of false-positive culture results from noninfected control samples. In addition, results of standard cultures were positive in 29% of cases where blood culture bottle culture results were negative, a finding suggesting potential organism preference for certain growth media. As a result of this study, international guidelines recommended the use of blood culture bottles alongside standard culture techniques in the diagnosis of pleural infection.[52]

ANTIBIOTIC SELECTION AND DURATION

The initial empirical antibiotic selection at presentation should be based on whether the pleural infection is community acquired or hospital acquired. Hospital-acquired pleural infection has a different range of causative organisms and a considerably higher mortality (Fig. 109.3).

Because anaerobic bacteria are commonly seen in pleural infection and often fail to grow in culture, they should be covered empirically in all cases of presumed pleural infection. Liaison with local infectious disease specialists or microbiologists is invaluable in deciding the best combination of antibiotics to use because resistance patterns vary significantly from one geographic region to the next.

There are no robust studies looking at the optimal duration of antibiotics for pleural infection. In our experience, if

a patient is ill enough to require hospitalization, then intravenous antibiotics are usually indicated. Conversion to oral antibiotics should be based on clinical and biochemical parameters, specifically the presence of ongoing fevers and the C-reactive protein value. Radiologic appearance is less useful because it often lags behind clinical improvement, although thoracic ultrasound can be used to assess the volume of residual fluid in the chest and its appearance. An extended course of oral antibiotics, often up to 4 weeks in total, may be required if clinical parameters suggest residual fluid or ongoing infection.

There are no randomized controlled data supporting the use of intrapleural antibiotics. Because most intravenous antibiotics penetrate the pleural space in suitable concentrations, there is currently no role for intrapleural antibiotic use in pleural infection. However, intravenous aminoglycosides do not penetrate the pleural space well and should be avoided.

Fig. 109.4 Pleural empyema seen on a frontal chest radiograph. The D-shaped opacity, suggesting an extraparenchymal process, is commonly seen in cases of pleural infection.

NUTRITION

Patients with pleural infection, particularly those with empyema who have had a delayed presentation, experience the protracted catabolic consequences of chronic infection. A low albumin level has been shown consistently to be a marker of poor outcome.[63–65] Addressing the patient's nutritional status at presentation is often overlooked and should be an early priority alongside tube drainage and the prescribing of suitable antibiotics. Early nutritional assessment should be mandatory.

EARLY RISK STRATIFICATION

Although complex interactions are likely to exist between genetic and environmental factors that contribute to the development of pleural infection, these have not yet been determined.[66] There are, however, certain risk factors, particularly long-term alcohol excess and intravenous drug use, which likely increase the risk as a result of aspiration of gastric contents. In addition, Chalmers and colleagues[64] described four other independent risk factors associated with pleural infection: serum albumin level lower than 30 g/L, serum C-reactive protein greater than 100 mg/L, platelet count higher than 400×10^9/L, and serum sodium level lower than 130 mmol/L. Interestingly, patients with COPD appear to be at lower risk for developing pleural infection, perhaps because of a background level of generalized inflammation causing an attenuated response to a pleural bacterial challenge.[67]

A reliable and sensitive clinical prediction model of poor outcome in pleural infection would enable clinicians to triage patients according to risk and to select the most aggressive and expensive therapies for patients who may otherwise have the poorest outcomes. Chalmers and colleagues[64] proposed a risk scoring system based on the six factors outlined earlier; however, this score has not been independently validated. In contrast, Rahman and colleagues[65] used data from the UK MIST1 trial to develop an outcome score in patients with confirmed pleural infection and then validated the tool using a second cohort from the MIST2 trial. They found that five presenting factors (serum urea level, age, fluid purulence, likely origin of infection, and serum albumin level) could predict the eventual outcome, with patients divided into low-, medium-, or high-risk groups. At 3 months, patients in the lowest-risk group had mortality rates of less than 5%, whereas patients in the highest-risk group had mortality rates higher than 30%, with an odds ratio of 14.1 (95% confidence intervals, 3.5 to 56.8) for death. They named the score RAPID, a mnemonic for renal function, age, purulence, infection type, and dietary status.

The RAPID score was further validated in a prospective cohort of 551 patients enrolled in the Pleural Infection Longitudinal Outcome Study.[68] At 3 months, a low-risk RAPID score was associated with lower mortality than a high-risk score (2% vs. 30%). Further work is now required to determine whether targeting interventional therapies to high-risk groups can reduce mortality.

INVESTIGATIVE TECHNIQUES FOR PLEURAL INFECTION

Radiologic tests such as chest radiography, CT, and ultrasonography are vital in the initial diagnosis and management of pleural infection. Bronchoscopy is useful in selected cases, particularly for those patients with suspected airway obstruction.

Radiology

The presence of fever, pleuritic pain, and pleural effusion should always alert the physician to the possibility of pleural infection. Pleural fluid loculation can result in a D-shaped homogeneous peripheral opacity (Fig. 109.4 and eFig. 109.2A) on chest radiography. Posterior collections and posterior tracking of fluid in patients imaged in the supine position may result in generalized haziness of the hemithorax on the chest radiograph.

Thoracic ultrasonography (see eFig. 109.1) is advisable in all cases of suspected pleural infection because it can provide important information about the size and nature of the collection, as well as allowing accurate chest tube placement into the most appropriate site. Use of ultrasonography has also been shown to reduce iatrogenic injury.[69]

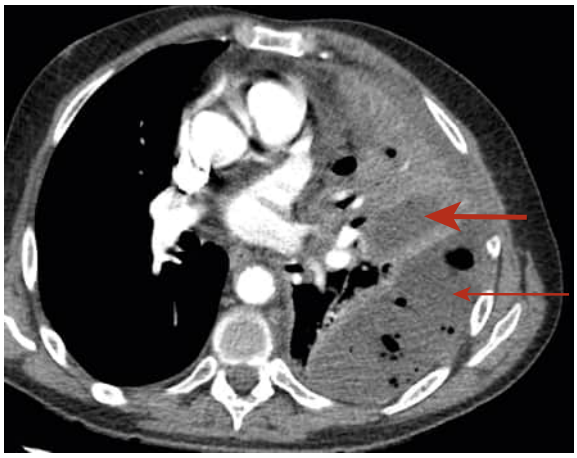

Fig. 109.5 Contrast-enhanced chest computed tomography showing both pleural empyema and a lung abscess. With contrast-enhanced computed tomography, pleural lesions can be discriminated from parenchymal lesions. The *thin arrow* shows empyema, and the *thick arrow* indicates a lung abscess. Note the lenticular shape of the empyema in contrast to the rounded shape of the abscess. The pleural collection does not have a visible "wall," whereas the abscess wall is thick and irregular. Within the empyema are multiple separate locules of gas, suggesting that the pleural collection is septated. Also see Table 109.1 for features that differentiate between empyema and lung abscess.

Table 109.1 Key Differences Between the Radiographic Appearance of Pleural Infection and Lung Abscesses

Empyema	Lung Abscess
Lenticular shape	Rounded
Surrounding lung often compressed	Boundary between lung and fluid indistinct, with necrosis of lung
Margins of collection creating obtuse angles with chest wall	Contact with chest wall made at acute angle
Thick smooth wall	Thick irregular wall
No vessels close by	Vessels seen passing through or near collection

Ultrasonography is also more accurate than CT imaging in detecting loculations and septations and can detect the presence of small quantities of pleural fluid not visible on chest radiography.[70]

Chest CT, particularly contrast-enhanced chest CT (eFigs. 109.2B–E and 109.3), is not necessary in all patients with pleural infection and should be reserved for those patients with persistent collections despite attempted chest tube drainage, those who may have a suspected obstructing lesion within the airway, and those in whom surgery is being considered. Chest CT provides detailed information about fluid loculation (Video 109.1), identifies chest tube position, and differentiates between empyema and lung abscesses when there is diagnostic uncertainty (Fig. 109.5, Fig. 108.2, and Table 109.1) (see also Chapter 50).

Magnetic resonance imaging is usually reserved for those patients who are unable to undergo CT imaging or for persons at high risk from irradiation. It is very good at visualizing septations and loculations within the pleural fluid (Fig. 109.6).

Bronchoscopy

Practitioners should be aware that a proximal airway obstructing lesion may be the cause of empyema. Although uncommon (<4% in one large series), this diagnosis should be considered in patients with a suggestive plain chest radiograph, for example, if the mediastinum is shifted *toward* the side of the effusion, or in patients failing to respond to simple first-line management. Bronchoscopy and chest CT are the investigations of choice if a bronchial obstruction is suspected. Aside from this situation, there is no role for routine bronchoscopy in patients with pleural infection.

When empyema is discovered distal to an obstructed bronchus, the underlying cause is usually either malignancy or aspirated foreign body, with malignancy the more common diagnosis. If a tumor is seen at bronchoscopy, histologic features should be confirmed and relief of the obstruction should be attempted using radiation therapy, laser resection, or stent insertion. Foreign objects are simply removed, often leading to reinflation of the distal lung and resolution of symptoms. In either setting, prolonged oral antibiotics may be required to prevent ongoing sepsis.

Chest Tube Drainage

Chest tube drainage is usually indicated in patients with loculated effusions, frank pus on aspiration, culture-positive pleural fluid or identification of organisms on Gram stains, or biochemical parameters suggestive of infection (pleural fluid pH < 7.2 or pleural fluid glucose < 2.2 mmol/L [40 mg/dL]). However, for some patients, particularly those with a small effusion or pneumococcal infection, conservative management with antibiotics alone can result in effusion resolution.[52,71] Observational data have suggested that repeat therapeutic thoracentesis may be an acceptable and effective alternative to chest drainage in some patients, with an associated reduction in inpatient hospital stay.[72,73]

Over the past decade, there has been a shift away from large-bore catheters to small-bore chest tubes inserted by the Seldinger technique. This change in practice is not so much the result of large, well-conducted, randomized controlled trials but more likely is due to the relative ease of the technique and the benefits of the smaller drains, which cause the patient less pain during insertion and while in place.[74] In the MIST trial, data were collected on the size of chest tubes placed in 405 patients. No difference between small- and large-bore tubes was found in the frequency with which patients either died or required thoracic surgery. However, patients with larger chest tubes reported significantly more pain both at the time of insertion and while the drain remained in place.[75] In another study of 103 patients with pleural infection, the small-bore chest tubes provided definitive treatment in 78% of cases,[76] similar to the success rates of two other series in which large-bore chest tubes were used.[77,78] In this study, radiologists guided tube placement, and this almost certainly helped the result.

The optimal drainage approach for an individual patient should be chosen at the time of treatment, based on clinical and patient-related factors. However, for most patients, initial placement of a small-bore (12-French) chest tube under ultrasonographic guidance in the largest locule in a dependent part of the pleural effusion is appropriate. Subsequent management with regular saline flushes may help ensure

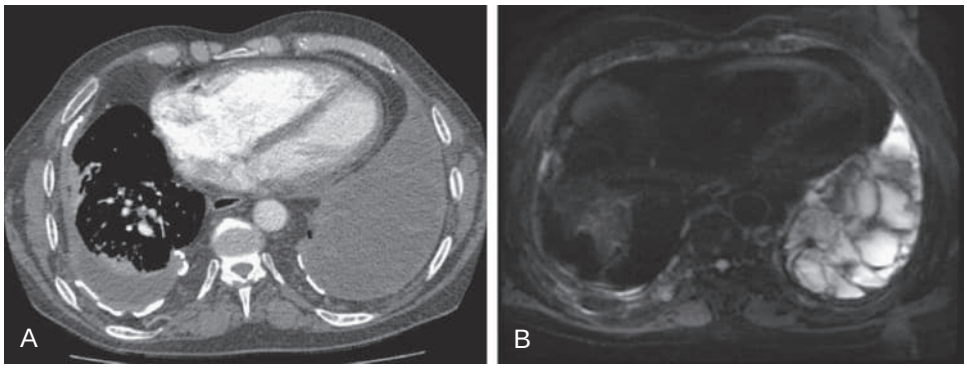

Fig. 109.6 Imaging of pleural empyema. (A) Contrast-enhanced chest computed tomography revealing a complex, large left pleural fluid collection secondary to pleural infection. (B) T2-weighted magnetic resonance imaging in the same patient that shows the presence of multiple septations and loculations.

that the drain does not become occluded. Guidelines recommend the instillation of 30 mL saline every 6 hours via a three-way stopcock.[52] If this fails to drain the effusion effectively, a large-bore drain may be necessary. It is more common for tubes to be replaced not because of obstruction but because they have become dislodged or have fallen out as a result of failure to secure the chest tube correctly.

FIBRINOLYTIC THERAPY

The use of fibrinolytic agents to disrupt fibrinous pleural septations was first described in 1949, by Tillett and Sherry,[79] who used partially purified streptococcal fibrinolysin that contained both streptokinase and streptodornase (a DNase) to drain infected postoperative hemothoraces. This approach was associated with immunologic side effects and did not become routine practice.

In a series of 24 patients, in 1997, Davies and coworkers[80] began to allay fears regarding intrapleural thrombolysis, which was found to be safe and also led to improvements in clinical outcomes. Other studies tended to focus more on the use of urokinase in loculated effusions, with benefits demonstrated of a reduction in treatment failure (as judged by surgical referral or death), reduced length of hospital stay, and better surgical outcomes.[81–83] However, these studies were often small trials or case series, which limited their ability to be generalized.

Thus, a large randomized study was designed to test the role of streptokinase in empyema. The 2005 MIST1 trial recruited 454 UK patients with pleural infection to receive either intrapleural streptokinase or placebo.[35] Entry criteria reflected real-world practice, with a strong reliance on local physician diagnosis, antibiotic choice, chest tube use, and surgical referral. The trial showed no significant benefit from the use of streptokinase in either surgical referral or death. There was also no improvement in the length of stay or in any signal in any subgroup analysis. The choice of single-agent streptokinase as the primary lytic may have contributed to these negative results because data from the subsequent MIST2 trial demonstrated that a combination of a fibrinolytic agent and a DNase was effective, whereas monotherapy with either agent was not.[26] In addition, streptokinase has several limitations compared with newer fibrinolytic agents, including antigenicity and the need for an additional step in its activation pathway.[84,85] However, a Cochrane review concluded that intrapleural fibrinolytic agents conferred benefit both in reduced treatment failure and reduced need for surgical intervention in pleural infection, but not reduced mortality.[86] Based on the Cochrane review, the 2010 British Thoracic Society guidelines advised that intrapleural fibrinolytic agents should not be used routinely, but may be considered in selected cases.[52]

Following the disappointing results with single-agent streptokinase, MIST2 was designed to test the *combination* of a fibrinolytic agent with a DNase. The combination approach was based on experimental in vitro and in vivo data that showed better lysis when a fibrinolytic agent was given together with DNase, a finding suggesting that the digestion of the long strands of DNA derived from degenerating cells facilitated fibrinolysis.[87,88] In this blinded, 2 × 2 factorial trial, 210 patients with pleural infection were randomly assigned to receive 1 of 4 study treatments for 3 days: intrapleural *tissue plasminogen activator* (tPA) and DNase, tPA and placebo, DNase and placebo, or double placebo.[26] The primary outcome was the change in pleural opacity, measured as the percentage of the hemithorax occupied by effusion on chest radiography on day 7 as compared with day 1. The mean change in pleural opacity was significantly greater in the tPA-DNase group than in the double-placebo group (−29.5% vs. −17.2%); the change observed with tPA alone and with DNase alone (−17.2% and −14.7%, respectively) was no different from that observed with placebo. In addition, the frequency of surgical referral at 3 months was lower in the tPA-DNase group than in the double-placebo group (4% vs. 16%). Finally, combined tPA-DNase therapy was associated with a reduction in the hospital stay as compared with double placebo (difference, −6.7 days), whereas the hospital stay with either agent alone was not significantly different from that with placebo. The study investigators concluded that intrapleural tPA-DNase therapy improved fluid drainage in patients with pleural infection and reduced the frequency of surgical referral and the duration of the hospital stay. Treatment with DNase alone or tPA alone was ineffective; indeed, by itself, DNase appeared harmful, with a threefold increase in surgical referrals.

The combination of a fibrinolytic agent with DNase was not associated with an excess of adverse events. Indeed, real-life data from centers across Europe and North America have confirmed that intrapleural tPA with DNase has an acceptable safety profile. In a report of 107 patients from 8 centers, the use of tPA with DNase showed benefit in patients who did not respond to antibiotics and chest tube drainage, with bleeding seen in just 2 patients (1.8%), both of whom had additional risk factors for bleeding, including preexisting coagulopathies.[89] Neither case resulted in fatality. In 3 further reports of a total of 209 patients in 4 centers,

the use of intrapleural tPA with DNase was associated with an overall 2.9% bleeding incidence.[90–92] All studies noted an increase in analgesia requirement following fibrinolytic administration. The cost of fibrinolytic agents, particularly tPA may be prohibitive in some health care settings.

Given that the dose of tPA with DNase used in the MIST trials (10 mg tPA and 5 mg DNAse) was chosen empirically, it may be possible to reduce the dose, thus lowering costs with no reduction in efficacy. Popowicz and colleagues[93] used 5 mg of tPA with 5 mg of DNase in 61 patients with pleural infection, with a 93% success rate (defined as survival to discharge and no need for surgery). Effective pleural drainage with 1 mg of tPA and 5 mg DNase has been reported in a single case, with studies underway investigating the efficacy of 2.5 mg tPA.[94] Pleural irrigation, in which saline is administered via the chest tube, may be an inexpensive yet effective alternative to fibrinolytic agents in patients with a persisting effusion after initial management. In their randomized trial of 35 patients, Hooper and colleagues[95] allowed 250 mL of normal saline to flow into the pleural space via gravity, three times a day for nine doses. Patients allocated to saline irrigation had a greater reduction in the volume of residual pleural collection on CT at day 3 compared with patients receiving standard care (which included small volume flushes of up to 20 mL of saline four times a day). Fewer patients in the irrigation group required surgery, with no serious adverse events noted in either arm of the study. Interestingly, the outcomes following pleural irrigation were comparable to those seen in patients who received tPA and DNase in the MIST2 trial, with a 32% reduction in radiologic opacification (compared with 29% in MIST2) and an odds ratio for referral to surgery of 0.14 (vs 0.17 in MIST2).[26]

MONITORING RESPONSE TO MEDICAL MANAGEMENT

Identifying patients who are not responding to medical management can be challenging. Radiologic appearances often lag behind clinical improvement and therefore, in our opinion, are not good indicators of the need for further intervention. The best markers of response to medical management include a falling C-reactive protein (halving in value and ideally falling to less than 100 mg/L) or a falling white blood cell count, the settling of a spiking temperature, and clinical signs associated with resolution of sepsis, such as improving energy levels and return of appetite. If these markers are all improving, then further interventions with additional chest tubes or surgery rarely become necessary. In sum, in assessing response to medical management, the most important factor is the patient's clinical condition, not the imaging.

When patients appear to have avoided surgery by the narrowest of margins, prolonged oral antibiotics (for 4 to 6 weeks) and close follow-up as outpatients with monitoring of the chest radiograph and C-reactive protein is advised.

SURGICAL OPTIONS

Patients are usually referred for surgical intervention if initial medical treatment fails or if they present late with highly organized empyemas that demonstrate significant pleural thickening and loculation. Practice varies, and some centers have a low threshold for early surgery.[96] The point at which medical management is deemed to have "failed" is necessarily ill defined, but one important indicator would be signs of ongoing sepsis despite attempted chest tube drainage and adequate antibiotic therapy. Another potential consideration is the risk for long-term respiratory embarrassment from the fibrin and loculated fluid, although observational evidence suggests that the pleural abnormalities usually resolve over time without acute surgical intervention.[97,98]

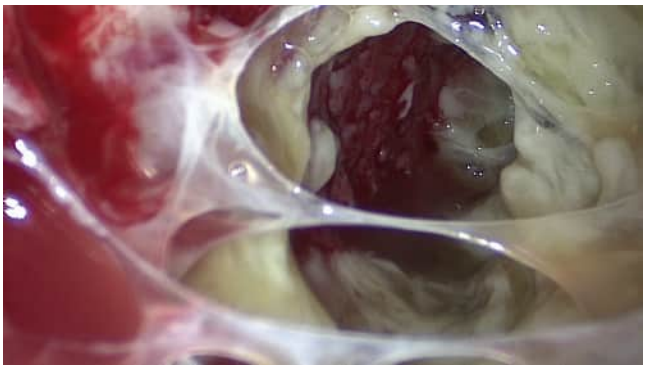

Fig. 109.7 Empyema during video-assisted thoracic surgery. Empyema in a 26-year-old woman at the time of video-assisted thoracic surgery shows thick pus within the pleural cavity, with inflammation and bleeding visible on the parietal pleural to the *left* of the picture. Septations are visible running between the visceral and parietal pleura.

It is currently unclear whether surgical intervention is better than medical management of pleural infection. A Cochrane review summarized the evidence and concluded that there was no difference in mortality between the two approaches, although surgery may be associated with shorter length of stay.[99] However, most studies were performed in pediatric populations, with only two small trials involving adults. Of these trials, one compared VATS with tube drainage and fibrinolytic agents,[100] and the other compared VATS with simple drainage without fibrinolytic agents.[101] To date, no randomized trial has directly compared all three approaches (simple drainage, tPA with DNase, VATS) to determine which is the most appropriate front-line treatment. The MIST3 trial is currently underway in the United Kingdom, aiming to assess the feasibility of such a trial, with a full-scale study potentially to follow.

Modern surgical options are varied and may be tailored to the individual. VATS typically requires general anesthesia and single-lung ventilation but can be performed using local anesthesia in patients deemed to be too high risk for general anesthesia (Fig. 109.7 and Video 109.2). Although originally used for thorough pleural débridement, VATS is now increasingly used to perform decortication in patients with particularly advanced or chronic empyema.[102,103] Studies show similar resolution rates following VATS compared with open surgery, with the added benefits of a minimally invasive approach resulting in reduced postoperative pain and other complications.[102,104] Overall success rates for VATS, based on resolution of sepsis and clinical stability, exceed 85%, with mortality rates of less than 1.5%.[105]

Open thoracotomy was formerly a mainstay of treatment for empyema, but its role has diminished as VATS has

superseded it as the standard of care.[102] It is now used when less invasive approaches have failed, with open thoracotomy more likely to be necessary in patients with a delayed presentation, a longer duration of illness, or resistant gram-negative infection.[106,107] A study from 2009 described a mortality of approximately 3.5% for this operation.[108]

Decortication via thoracotomy allows complete mobilization of the lung and is therefore particularly useful in cases of trapped lung.[109] However, in patients in the acute stages of pleural infection, decortication should be considered only for the control of infection. Decortication should not be performed just to remove thickened pleura because such thickening usually resolves spontaneously over the subsequent 4 to 6 months.[97,98]

For patients who have recurrent or particularly complex empyema, small prosthetic devices may be inserted between the ribs to maintain a drainage route. The more permanent way to achieve this effect is to perform an open-window drainage. This involves the resection of two or three ribs to create a direct opening to the thoracic cavity, which affords the opportunity to pack the pleural space.[110] The advantage of this open flap (Eloesser flap) (eFig. 109.4) is that it creates a skin-lined fistula that provides drainage without tubes. Should methods such as these fail, thoracomyoplasty may become necessary, whereby a large muscle is used to pack the thoracic cavity. This is usually reserved for patients with bronchopleural fistulas, trapped lung, or postoperative empyema.[109]

A more conservative approach, which may be applied in highly selected patients who have high risks for surgery, is the insertion of an indwelling pleural catheter together with long-term oral antibiotic therapy.[111,112] In our experience, this approach can occasionally be extremely useful and certainly warrants further research.

PLEURAL TUBERCULOSIS

In many parts of the world, the most common cause of an exudative pleural effusion is *tuberculosis* (TB). However, in the United States, tuberculous pleuritis is relatively uncommon, with only 7549 cases reported in the 10 years from 1993 to 2003; these pleural TB cases represent only 3.6% of the total number of cases of TB seen over this period.[113] In some African countries, the incidence of pleural involvement in TB appears to be much higher because pleural TB represents more than 30% of the total number of TB cases.[114] This high incidence may be a result of coinfection with *human immunodeficiency virus* (HIV) because TB effusions are much more prevalent in areas of high HIV prevalence.[115,116]

PATHOGENESIS

A tuberculous pleural effusion can either be a sequel to a primary infection acquired 3 to 6 months previously or can represent reactivation TB. A molecular epidemiologic study confirmed that tuberculous pleurisy is usually an early manifestation of TB infection.[117]

Pleural TB may manifest as tuberculous pleuritis or TB empyema. Historically it was thought that tuberculous pleuritis was caused by a delayed hypersensitivity reaction to mycobacterial antigens, whereas TB empyema was a result of fulminant TB infection of the pleural space. This theory was based on animal studies, in which the intrapleural injection of tuberculin protein in sensitized guinea pigs resulted in the rapid appearance of an exudative pleural effusion.[118] When the animals were given antilymphocyte serum, the development of the effusion was suppressed.[119] The observation that pleural fluid culture results are negative in approximately 80% of patients with tuberculous pleuritis supported the contention that delayed hypersensitivity played a role in the development of tuberculous pleural effusions in humans.

However, improvements in microbiologic techniques and culture media have refuted this theory. One study showed that combining liquid culture of pleural fluid and pleural biopsy tissue resulted in identification of bacilli in more than 60% of patients.[120] This finding suggests that tuberculous pleuritis actually reflects paucibacillary infection of the pleural space, with subsequent immunologic reaction.[115] The initial, neutrophil-predominant acute inflammatory response evolves into a chronic lymphocyte-driven immune reaction, with associated granuloma formation and containment of viable mycobacteria. The study demonstrated that the percentage of lymphocytes in pleural fluid was inversely correlated with the likelihood of obtaining positive culture results.[120] This finding suggests that with sufficient lymphocyte activity, it is possible to suppress all active bacilli and sterilize the pleural space, thus explaining why tuberculous pleuritis resolves spontaneously in some patients.[121]

By this theory, tuberculous pleuritis and TB empyema are different stages on an immunologic spectrum, rather than two distinct disorders. In TB empyema, a high mycobacterial load leads to an exaggerated and sustained acute inflammatory response, with neutrophil leukocytosis and pus formation. This gives rise to a culture-positive, purulent pleural effusion unlikely to resolve without clinical intervention.

CLINICAL MANIFESTATIONS

Tuberculous pleuritis manifests as an acute illness in about two-thirds of cases and as a chronic illness in the remaining one-third. The acute illness, marked by cough and chest pain in approximately 75% of patients, often mimics the presentation of bacterial pneumonia with a parapneumonic effusion (Fig. 109.8A). The chronic form is characterized by low-grade fever, weakness, and weight loss.

Effusions secondary to tuberculous pleuritis can manifest in a similar fashion as malignant effusions, being almost always unilateral, and usually small to moderate in size, although they may be large to the point of occupying the entire hemithorax.[115] Up to 86% of patients will have coexisting parenchymal disease (see Fig 109.8). In such patients the pleural effusion is almost always on the side of the parenchymal opacity and usually indicates active parenchymal disease. It is likely that, even in cases with no radiographic evidence of parenchymal involvement, the effusion is associated with a subpleural focus of infection. Evidence to support this contention is provided by a study in which the microbiologic yield of *Mycobacterium tuberculosis* from induced sputum was as high in patients with no radiographic evidence of parenchymal involvement (55%) as in patients with

Fig. 109.8 Tuberculous effusion and pneumonia resembling bacterial parapneumonic effusion and bacterial pneumonia. (A) Frontal chest radiograph shows left apical consolidation and a hazy left base with a well-delineated fluid collection visible in left costophrenic area. The patient also has a metabolic bone disorder creating abnormal appearances of the humeral heads. The findings are nonspecific, but the upper zone distribution of the infective change raises the possibility of mycobacterial infection. Drug-sensitive *Mycobacterium tuberculosis* was cultured from both the pleural effusion and bronchoalveolar lavage of the left upper lobe. The patient improved after 6 months of treatment for tuberculosis. (B) Chest computed tomography in the same patient shows an encapsulated effusion posteriorly in the left hemithorax, with fluid tracking along the fissure. Tree-in-bud changes are visible anteriorly in the left lung, thus indicating pulmonary infection. (C) Mediastinal windows show lenticular, smooth pleural thickening, with division of the parietal and visceral pleural clearly visible (*arrows*), representing the "split-pleura" sign.

parenchymal disease (45%).[122] Occasionally, dense parenchymal consolidation can rupture into the pleural space and cause TB empyema, often with concomitant pneumothorax (eFig 109.5). The risk of bronchopleural fistula is high in these patients. Rarely, TB empyema may decompress percutaneously, giving rise to empyema necessitans.

In patients with HIV infection, tuberculous pleuritis is more likely to manifest with systemic features of illness (i.e., significant weight loss and high fevers). In addition, in HIV-positive patients, concomitant parenchymal opacities and culture-positive pleural fluid are more common than in HIV-negative patients.[115,116] In addition, the cellular and cytokine profile of TB effusions in HIV-positive patients differs from that of HIV-negative patients, as a reflection either of the underlying immunocompromise or of a different pathogenic pathway.[116] Despite this, delayed hypersensitivity remains implicated in the development of TB effusions in HIV infection because the prevalence of tuberculous pleurisy is higher in patients with CD4 counts greater than 200 cells/μL than in patients with lower CD4 counts.[123]

PLEURAL FLUID

The pleural fluid from patients with tuberculous pleuritis is an exudate that usually contains predominantly small lymphocytes. This is not universally seen; in a series from 2012, 17% of confirmed cases were found to have less than 50% lymphocytes in pleural fluid,[120] and in approximately 11% of cases, the fluid has a polymorphonuclear leukocyte predominance, a pattern more likely in the earlier stages of the disease.[124] The pleural fluid glucose level is usually similar to that of serum, but it can also be reduced. A pleural fluid protein level higher than 5.0 g/dL is suggestive of tuberculous pleuritis, perhaps because of the intense inflammation and leakiness of the pleural capillaries.

DIAGNOSIS

The possibility of tuberculous pleuritis should be considered in every patient with an undiagnosed exudative pleural effusion, even though TB causes only a small percentage of such effusions in the United States.[113] For the past 40 years, the most common way to establish the diagnosis of tuberculous pleuritis has been with biopsy of the pleura, and this remains the gold standard test. However, more recently, pleural fluid tests have been developed that may be useful in establishing or excluding the diagnosis of tuberculous pleuritis. The pleural fluid tests found to have the most utility, especially in combination, are (1) the level of adenosine deaminase, (2) polymerase chain reaction for mycobacterial DNA, and (3) interferon-γ levels.[125,126] The last test requires direct measurement of the levels of interferon-γ with an enzyme-linked immunosorbent assay because interferon-γ release assays on pleural fluid are insufficiently sensitive to be of diagnostic benefit in tuberculous pleuritis.[126,127] The performance of these tests varies depending on the prevalence of TB, with higher specificity than sensitivity. Consequently, interpreting results in combination can enhance the diagnostic accuracy.

All patients with an undiagnosed exudative pleural effusion should undergo mycobacterial culture of their pleural fluid. An induced sputum sample should also be sent for smear and culture because results will be positive in approximately 50% of patients, even when there is no evident pulmonary involvement.[122] A *microscopic observation drug susceptibility* (MODS) assay, in which the TB is grown in liquid culture with drugs included to provide drug susceptibility information, can be applied to sputum or pleural fluid and has diagnostic accuracy similar to that of standard solid media culture, but it is less expensive and faster, and it provides information on drug resistance patterns.[128] The MODS assay is of particular benefit in resource-poor settings, where its use is approved by the World Health Organization.

If the culture of fluid or sputum becomes positive, standard treatment for TB should be initiated. If the culture result is negative, the decision to start antituberculous therapy should be based on the presence of other supportive test results, the overall index of suspicion for TB infection, and the balance of risk and benefit of starting treatment. In areas with a high incidence of resistant TB, the importance of obtaining an organism and testing drug susceptibility is

higher; thus, it may be appropriate to obtain pleural tissue for cultures. Thoracoscopic biopsies remain the ideal way of obtaining tissue but, if this resource is not available, then traditional blind pleural biopsy remains an important diagnostic modality,[129] especially when used in combination with adenosine deaminase and differential cell count.[130] Blind pleural biopsy with an Abrams needle may be preferable to other forms of blind biopsy when combined with ultrasonographic guidance.[131] If the patient does not respond to therapy, then further investigations for alternative causes are warranted.

TREATMENT

Patients with tuberculous pleuritis should be treated with antituberculous medications using the same treatment regimens as for patients with pulmonary TB. With treatment, patients generally become afebrile within about 2 weeks, and the pleural effusion resolves within 6 weeks. On occasion, the pleural effusion worsens after antituberculous therapy is initiated, or a pleural effusion develops while patients are being treated for parenchymal TB.[132,133] In these situations, the possibility of a wrong diagnosis must be considered, but paradoxical worsening can be seen with the correct diagnosis and appropriate antituberculous medications.[132,133] Mild degrees of residual pleural fibrosis are present a year after therapy is begun in approximately 50% of patients. Some investigators have used fibrinolytic agents in tuberculous effusions, with resulting improved drainage of fluid and less residual pleural thickening in the long term.[134,135] However, the clinical consequence of residual pleural thickening following tuberculous pleuritis is unknown; therefore, the utility of fibrinolytic agents in this scenario is not certain.

Systemic corticosteroids may reduce the time to resolution of TB effusions and reduce the degree of residual pleural fibrosis, although the evidence supporting these observations is of low quality.[136] Adverse events are more frequent in persons treated with corticosteroids, and there is some anxiety that, in HIV-infected patients, Kaposi sarcoma is more likely following prednisolone treatment, although this suggestion is based on observations in just four patients.[136,137] If corticosteroid treatment is contemplated, it should be initiated after antituberculous therapy has been commenced.

ACTINOMYCOSIS

More than 50% of patients with thoracic actinomycosis have pleural involvement.[138] In a series of 15 patients, 6 had pleural effusions and an additional 6 had marked pleural thickening.[139] The characteristic chest radiographic finding is a localized lung lesion extending to the chest wall with pleural thickening or effusion. The pleural fluid with actinomycosis may be either frank pus with predominantly polymorphonuclear leukocytes or serous fluid with predominantly lymphocytes.

The diagnosis of actinomycosis should be considered when a chronic infiltrative pulmonary lesion extends to adjacent lobes through intralobar fissures. The presence of chest wall abscesses or draining sinus tracts suggests the diagnosis, as do bone changes consisting of periosteal proliferation or bone destruction (see eFig. 46.42). The definitive diagnosis is established with the demonstration of *Actinomyces israelii* by anaerobic cultures. Patients with pleural actinomycosis should be treated with high doses of penicillin or another suitable antimicrobial agent for prolonged periods. The management of the pleural effusion is similar to that for patients with any other bacterial pneumonia.

NOCARDIOSIS

Patients with pleural effusion secondary to nocardiosis almost always have an associated parenchymal opacity (eFig. 109.6). The pleural fluid can range from serous fluid to frank pus, and pleural fluid culture results may or may not be positive. Because most patients who develop nocardiosis are immunosuppressed,[140] this diagnosis should be considered in the immunosuppressed patient with a parenchymal opacity and a pleural effusion. The diagnosis is usually established with aerobic cultures, although polymerase chain reaction has been successfully used for diagnosis in some cases.[141] Cultures should be observed for at least 2 weeks because *Nocardia asteroides* is a slow-growing organism. Patients with pleural nocardiosis should be treated with sulfonamides or suitable alternative antimicrobial agents, and the pleural effusion should be managed as any pleural effusion that complicates pneumonia.

FUNGAL INFECTIONS

Fungal infections of the lungs are discussed in Chapter 56. This section considers the pleural complications of aspergillosis, blastomycosis, coccidioidomycosis, cryptococcosis, and histoplasmosis. In addition, *Pneumocystis jirovecii* has been included.

ASPERGILLOSIS

The pleural space occasionally becomes infected with *Aspergillus,* usually *Aspergillus fumigatus*.[142] Pleural aspergillosis usually arises in one of two settings: in patients who were treated in the past with artificial pneumothorax therapy for TB and, less commonly, in patients following lobectomy or pneumonectomy, in which case a bronchopleural fistula is almost always present. Pleural aspergillosis has been described in a healthy individual.[143]

The diagnosis of pleural aspergillosis should be suspected in any patient with a history of artificial pneumothorax therapy for TB who has signs and symptoms of a chronic infection, such as weight loss, malaise, low-grade fever, and chronic cough. The chest radiograph reveals increasing degrees of pleural thickening and usually an air-fluid level in the pleural space, thus indicating the presence of a bronchopleural fistula.[142] In some patients, fungal balls may be evident in either the lungs or the pleural space. The diagnosis is confirmed by the demonstration of *Aspergillus* on fungal cultures of the pleural fluid. Patients with pleural aspergillosis almost always have positive precipitin blood test results for antibodies against *Aspergillus*.

The optimal treatment for pleural aspergillosis is likely to be a combination of surgical removal of the involved pleura and resection of the involved lobe or the entire ipsilateral lung and concomitant medical therapy, which may take

the form of systemic therapy or intrapleural antifungal treatment.[144] Lung resection is usually necessary because the infection tends to invade and destroy the underlying lung. Surgery, if appropriate, should be performed as early as possible to avoid progressive destruction of the lung. Some patients with pleural aspergillosis are too debilitated to undergo a major surgical procedure. Such patients can undergo open drainage (Eloesser flap) with daily insertion of gauze impregnated with amphotericin B.[145]

Systemic medical treatment is usually given both before and after surgery. A potential regimen is an initial 2- to 4-week period of therapy with amphotericin B, followed by longer-term administration of a more modern agent such as an azole. Treatment should continue for at least 6 months, although some patients may require much longer periods of treatment.[144] Topical pleural antifungal treatment may be used as an adjunct to systemic therapy.[144–146]

BLASTOMYCOSIS

Infection with *Blastomyces dermatitidis* produces a pleural effusion in approximately 10% of patients, and an additional 40% or more have pleural thickening.[147] Patients with pleural blastomycosis have signs and symptoms similar to those seen in tuberculous pleuritis. The pleural fluid is usually an exudate with predominantly small lymphocytes, although polymorphonuclear leukocytes may predominate. Because pleural biopsy results may reveal noncaseating granulomas, one should consider the diagnosis of blastomycosis in patients with a clinical picture compatible with tuberculous pleuritis and granulomas on pleural biopsy. The diagnosis is established by demonstrating the organism in secretions, pleural fluid, or histologic sections. Patients with pleural blastomycosis should be treated with itraconazole or amphotericin B.

COCCIDIOIDOMYCOSIS

Two types of pleural disease are seen in association with coccidioidomycosis. The first is associated with a primary benign infection and may or may not have concomitant parenchymal involvement. The second develops when a coccidioidal cavity ruptures to produce a hydropneumothorax.

Primary Coccidioidomycosis

The incidence of pleural effusion in hospitalized patients with primary coccidioidomycosis is approximately 15%.[148] Most patients are febrile and have pleuritic chest pain. The pleural effusion is almost always unilateral and can occupy more than 50% of the hemithorax.[148] There is a coexisting parenchymal opacity in approximately 50% of patients. The pleural fluid is an exudate containing predominantly small lymphocytes and frequently eosinophils.[148] At times the pleural fluid can be pus. Pleural fluid culture results are positive for *Coccidioides immitis* in only approximately 20%, with poor results also from polymerase chain reaction.[149] Culture results of pleural biopsy specimens, however, are almost always positive. Most patients with primary coccidioidomycosis and pleural effusion require no systemic therapy. Because the complement fixation titers are usually high in patients with coccidioidal pleural effusion, a high titer alone should not be used as an indication for treatment. Only patients with prolonged or severe symptoms, evidence of dissemination, or at high risk for dissemination should be considered for first-line treatment with an azole.

Rupture of Coccidioidal Cavity

Hydropneumothoraces develop in 1–5% of patients with chronic cavitary coccidioidomycosis (see Fig. 56.6). The rupture of the cavity into the pleural space is usually heralded by the development of an acute illness with systemic signs of toxicity. These patients should undergo tube thoracostomy immediately to drain the air and fluid from the pleural space. Most patients require thoracotomy with partial or total lobectomy, and most require some degree of decortication.

CRYPTOCOCCOSIS

Pleural involvement in patients with cryptococcosis appears to result from extension of a primary subpleural cryptococcal nodule into the pleural space. Approximately 50% of patients with pleural cryptococcosis have disseminated disease, and most have an accompanying parenchymal abnormality. Most patients who have a cryptococcal pleural effusion are immunosuppressed, and many of the patients have *acquired immunodeficiency syndrome* (AIDS).[150] The pleural fluid is an exudate, usually with a predominance of small lymphocytes. Pleural cryptococcosis is treated with systemic antifungal therapy, with corticosteroids required in severe disease or disease in immunocompromised hosts.[151] Cryptococcal antigen titers can help confirm the diagnosis and evaluate response to treatment.[152]

HISTOPLASMOSIS

Pleural effusion is rare in patients with histoplasmosis. In a review of 259 patients with pulmonary histoplasmosis, only 1 patient had a pleural effusion.[153] Patients with pleural effusions secondary to histoplasmosis may have a subacute illness characterized by low-grade fever and pleuritic chest pain. The chest radiograph usually reveals an opacity or a subpleural nodule in addition to the pleural effusion.[154] The pleural fluid is usually a lymphocytic-predominant exudate, and the pleural biopsy may reveal noncaseating granulomas. No systemic treatment is generally necessary for a pleural effusion secondary to histoplasmosis because the effusion normally resolves spontaneously over several weeks. Systemic therapy should be administered if the effusion persists more than 3 to 4 weeks or if the patient is immunosuppressed.

PNEUMOCYSTIS JIROVECII

Pleural effusions are rare in patients with *Pneumocystis jirovecii* pneumonia, but they have been reported. There is, however, no evidence to support the routine testing of pleural fluid for *P. jirovecii,* except in severely immunocompromised patients.[155] When pleural effusions are present, they appear to be extensions of the pulmonary process, and concurrent pneumothoraces are common. The pleural fluid is an exudate with a relatively low protein level but an LDH level higher than the upper normal limit for serum. At times, organisms can be visualized in the pleural fluid.

VIRAL INFECTIONS

Viral infections are believed to account for a sizable percentage of undiagnosed exudative pleural effusions. However, the diagnosis is rarely established because it usually depends on the isolation of the virus or the demonstration of a significant increase in antibody titers to the virus. Molecular sequencing has been applied to pleural fluid, thereby identifying respiratory viruses in 20.7% (12 of 58) of children with a parapneumonic effusion or empyema.[156] However, these tests are not routinely performed on patients with undiagnosed pleural effusions.

PRIMARY ATYPICAL PNEUMONIA

The incidence of pleural effusions in patients with so-called primary atypical pneumonia (usually caused by *Mycoplasma* or viruses) is as high as 20%.[157] The effusions associated with atypical pneumonia are usually small, exudative, and contain predominantly neutrophils. If there is sufficient fluid, as described earlier, thoracentesis should be performed to exclude a complicated parapneumonic effusion.

OTHER VIRUSES

Viral infection is probably responsible for a much higher percentage of pleural effusions without parenchymal opacities than is generally recognized. In one epidemic, 559 soldiers in Turkey had an acute febrile illness characterized by pleuritic chest pain and a mononuclear cell–predominant pleural effusion without parenchymal opacities. No pathogens were demonstrated, and it was assumed that this self-limited disease was caused by a virus, although serologic studies were not performed.[158]

Almost all patients with the hantavirus pulmonary syndrome have a pleural effusion. Initially the fluid is a transudate, probably resulting from cardiac dysfunction, but subsequently the fluid becomes exudative.[159] Almost all patients with severe cases of dengue hemorrhagic fever have pleural effusions. Pleural effusions have also been reported to result from infection with hepatitis virus, Epstein-Barr virus (the agent of infectious mononucleosis), respiratory syncytial virus, influenza viruses, measles after the administration of inactivated virus vaccine, cytomegalovirus, herpes simplex virus, and Lassa fever virus. Pleural effusions can be seen after infection with Ebola virus, usually secondary to vascular leakage.[160]

ACQUIRED IMMUNODEFICIENCY SYNDROME

Pleural effusions are seen in patients with AIDS but are less common than are parenchymal opacities. In a series of 1225 consecutive hospital admissions of patients with AIDS in Jacksonville, FL, the incidence of pleural effusion was 15%.[112] The distribution of the diseases responsible for pleural effusions in patients with AIDS varies widely. In series from industrialized countries that included predominantly intravenous drug users, the most common cause is parapneumonic effusions; in series with predominantly homosexual patients, the most common cause is Kaposi sarcoma; in series from Africa, the most common cause is TB. Other causes of pleural effusions in patients with AIDS include primary effusion lymphoma (see eFig. 123.36), *P. jirovecii* infection, opportunistic infections, renal failure, and congestive heart failure.

In pulmonary Kaposi sarcoma, the incidence of pleural effusion is approximately 50% (eFig. 109.7). Most patients with a pleural effusion secondary to Kaposi sarcoma have bilateral parenchymal opacities (see eFig. 109.7B). The diagnosis of pleural involvement is difficult and often depends on the demonstration of pulmonary Kaposi sarcoma by bronchoscopic examination, high-resolution CT, or thoracoscopy. The pleural fluid is an exudate that is usually serosanguineous or hemorrhagic. Pleural fluid cytologic examination results are invariably negative with pleural Kaposi sarcoma; pleural biopsy results are also usually negative because the parietal pleura is generally not involved.

Patients with AIDS with an exudative pleural effusion should have a diagnostic thoracentesis that includes bacterial, mycobacterial, and fungal cultures and measurement of the pleural fluid adenosine deaminase level. If this does not establish a diagnosis, consideration should be given to performing thoracoscopy, at which time pleurodesis may be considered in symptomatic patients. A patient with AIDS and parapneumonic effusions should be managed as any patient with a parapneumonic effusion would be managed, while recognizing that the incidence of complicated parapneumonic effusion is higher in patients with AIDS.[113]

PARASITIC DISEASES

Parasitic infections of the lungs are discussed in Chapter 58. Those parasitic infections that may also involve the pleura—amebiasis, echinococcosis, and paragonimiasis—are also considered in this section.

AMEBIASIS

Approximately 20% of patients with amebic liver abscess will develop pleuropulmonary complications.[161] Pleural effusions arise by two different mechanisms. First, an amebic liver abscess may irritate the diaphragm and produce a sympathetic pleural effusion in a manner analogous to that caused by a pyogenic liver abscess. Second, a pleural effusion develops when an amebic liver abscess ruptures into the pleural space through the diaphragm (see eFig. 46.61).[162]

The sympathetic effusion in amebic liver abscess is the more common of the two presentations. The pleural fluid has not been well characterized. The diagnosis can be established by positive gel diffusion, indirect hemagglutination, or enzyme-linked immunosorbent assay tests, the results of which are positive in more than 98% of patients with extraintestinal invasive amebiasis.[162] Patients with amebic abscess and a sympathetic pleural effusion should be treated with antiamebic drugs.

The transdiaphragmatic rupture of an amebic liver abscess is usually heralded by an abrupt exacerbation of pain in the right upper quadrant and may be accompanied by a tearing sensation.[161] Shortly thereafter, progressive respiratory distress, sepsis, and occasionally shock develop. The pleural effusion is frequently massive, with opacification of the entire hemithorax and shift of the mediastinum to the contralateral

side.[161] The diagnosis of amebic abscess with transdiaphragmatic rupture is suggested by the discovery of "anchovy paste"– or "chocolate sauce"–like pleural fluid on diagnostic thoracentesis. Patients with transdiaphragmatic rupture should undergo urgent tube thoracostomy. These patients should be treated with the same antiamebic drugs (e.g., metronidazole) recommended for patients with amebic sympathetic effusions. Although the pus in amebic empyema is sterile,[163] microbiologic cultures of the pleural fluid should be obtained because bacterial infection of the pleural space complicates the process in about one-third of patients. If bacterial infection is present, appropriate antibiotic therapy should be initiated.

ECHINOCOCCOSIS

Pleural involvement with hydatid disease can develop in one of three situations: (1) a pulmonary hydatid cyst may rupture into the pleural space, (2) a hepatic hydatid cyst or rarely a splenic cyst may rupture through the diaphragm into the pleural space, or (3) a hydatid cyst may slowly enlarge into the pleural space.[164] When a cyst ruptures into the pleural space, either empyema or pneumothorax can result.[164] In a series of 474 patients with pulmonary hydatid disease, 6% had pleural thickening or effusion.[165]

When a hydatid cyst ruptures into the pleural space, the patient develops acute symptoms, with sudden tearing chest pain, dyspnea, and shock from the antigenic challenge to the body. The cyst can also rupture into the tracheobronchial tree, thus producing a bronchopleural fistula with hydropneumothorax that may become secondarily infected.[164]

The diagnosis of pleural echinococcosis is established either by the demonstration of echinococcal scolices with hooklets in the pleural fluid or in the pleural biopsy specimen or by a combination of serologic testing and radiology. Lobulated cystic lesions in the pleural space may be seen on CT or magnetic resonance imaging.[163] Eosinophils are frequently present in the pleural fluid unless it is secondarily infected. Patients with pleural echinococcosis should be immediately subjected to thoracotomy to remove the parasite, to excise the original cyst, and to close the bronchopleural fistula.[164] Patients with hydatid cysts should be treated with antiprotozoal therapy if all the cysts cannot be removed or if a cyst has ruptured. An alternative nonsurgical approach is PAIR therapy (puncture of the cyst, aspiration, injection of 95% ethanol or hypertonic saline for a period of time, and reaspiration), although this can cause allergic reactions.[163]

PARAGONIMIASIS

Pleural disease is common in patients with paragonimiasis. In a series of 71 patients, 43 (61%) had pleural disease, including 20 with unilateral pleural effusions, 6 with bilateral pleural effusions, 6 each with unilateral and bilateral hydropneumothorax, and 5 with pleural thickening.[166] Paragonimiasis can be found in natives of the United States who have never left the country.

Patients with pleural paragonimiasis present with a chronic illness. There is a concomitant parenchymal opacity in approximately 50% of patients. The pleural fluid in paragonimiasis is characteristic: exudative with a glucose level less than 10 mg/dL (0.56 mmol/L), an LDH level more than three times the upper limit of normal for serum, a pH lower than 7.10, and a high percentage of eosinophils on cell differential.[167] In addition, cholesterol crystals[120] or chyle[121] may be present. Pleural paragonimiasis is one of only two conditions in which the pleural fluid is characterized by a low pH, a low glucose level, and many eosinophils; the other is eosinophilic granulomatosis with polyangiitis. Usually, there are no ova in the pleural fluid.

The diagnosis of pleural paragonimiasis is strongly suggested by the unique pleural fluid findings, although in some cases lung biopsy may become necessary. The diagnosis is established definitively by demonstrating the typical operculated eggs in sputum, stool, or pleural fluid. A complement fixation titer greater than 1:8 for *Paragonimus westermani* is strongly suggestive of the diagnosis.[167]

Key Points

- The incidence of pleural infection and the mortality associated with it are increasing globally in both adults and children, for unclear reasons.
- Standard bacterial culture results are positive in only approximately 60% of pleural infection cases. Blood culture bottles can be combined with standard cultures to increase the yield.
- The organisms causing pleural infection often differ from those causing pulmonary infection.
- Community-acquired pleural infection is caused by a different range of organisms from hospital-acquired pleural infection and should be treated with different empirical antibiotics at presentation.
- The cornerstones of pleural infection management remain intravenous antibiotics, adequate drainage of the pleural collection, and adequate nutrition.
- A parapneumonic effusion with a pH of less than 7.20, a glucose level lower than 40 mg/dL, or a significantly loculated pleural collection generally requires chest tube drainage.
- Surgical techniques such as video-assisted thoracic surgery have become widely available and can be offered to most patients if less invasive approaches are unsuccessful.
- Intrapleural tissue plasminogen activator in combination with DNase has been shown to improve the chest radiographic evidence of empyema and to decrease hospital length of stay. The role of fibrinolytic therapy needs to be evaluated further before its routine use can be recommended.

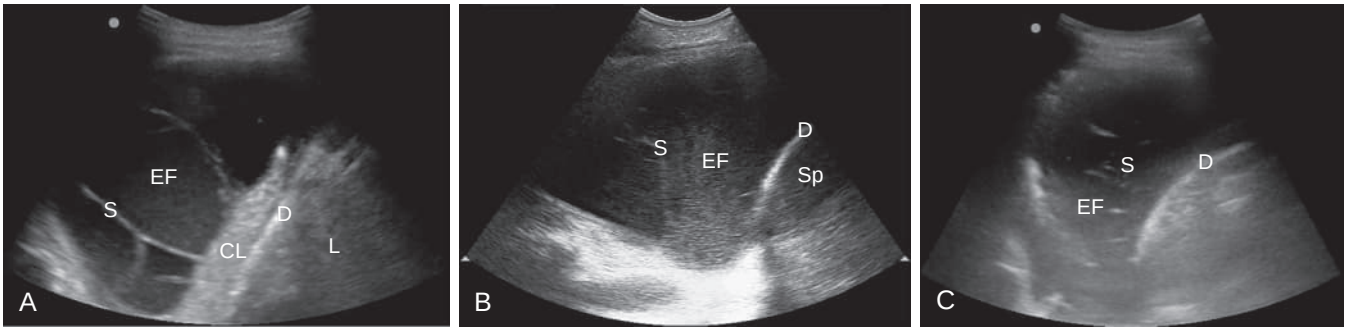
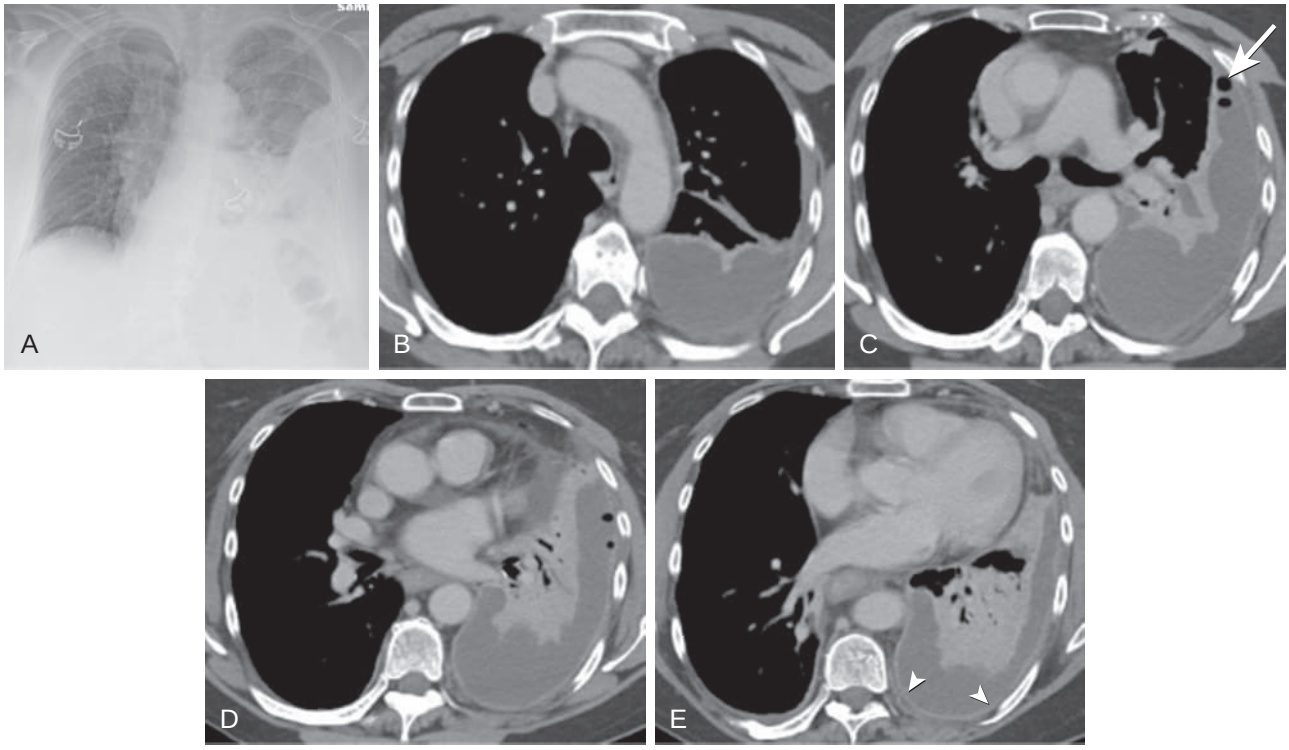
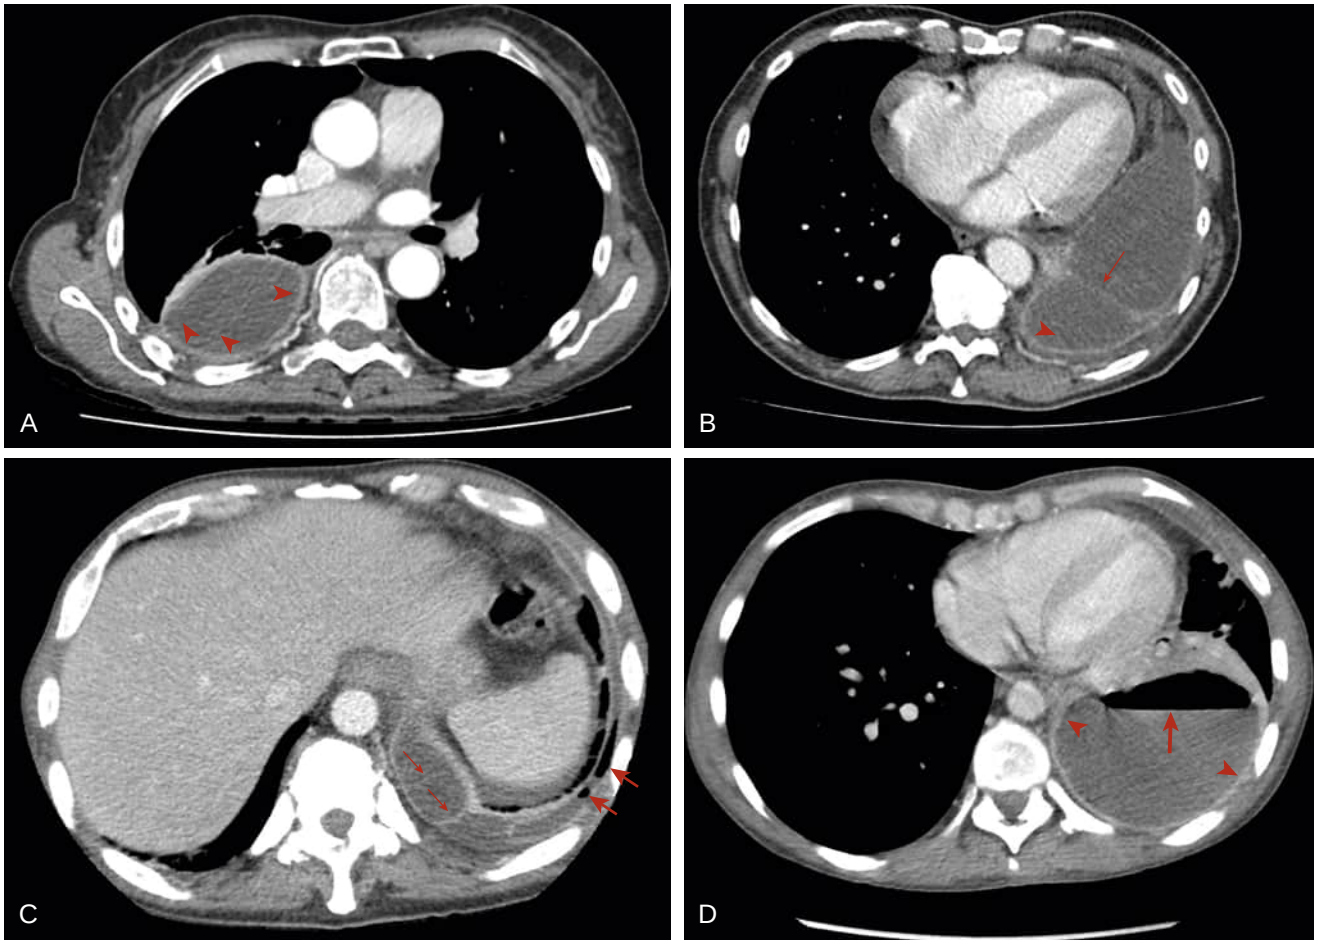
eFIGURE IMAGE GALLERY



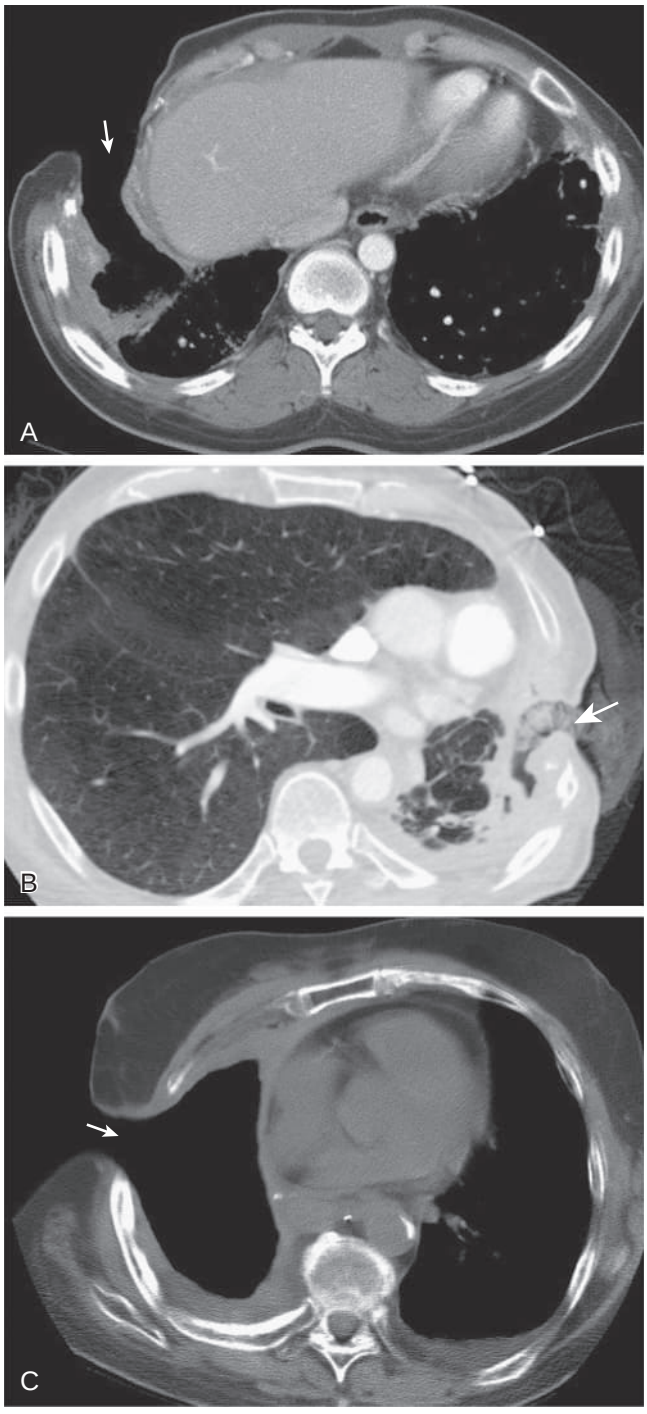
eFigure 109.1 Thoracic ultrasound imaging of pleural infection. (A) A moderately sized effusion is shown, lying cranial to a flattened diaphragm (D) and underlying liver (L). Collapsed and consolidated lung (CL) is seen above the diaphragm. Several septations (S) running through the fluid create multiple loculations. The fluid itself appears echogenic (EF). (B) Large echogenic effusion (EF), with a few thin septations (S) running through it. The diaphragm (D) and spleen (Sp) are imaged caudal to the fluid. (C) *Echogenic fluid* (EF) with multiple *septations* (S) running through it sits above the *diaphragm* (D).



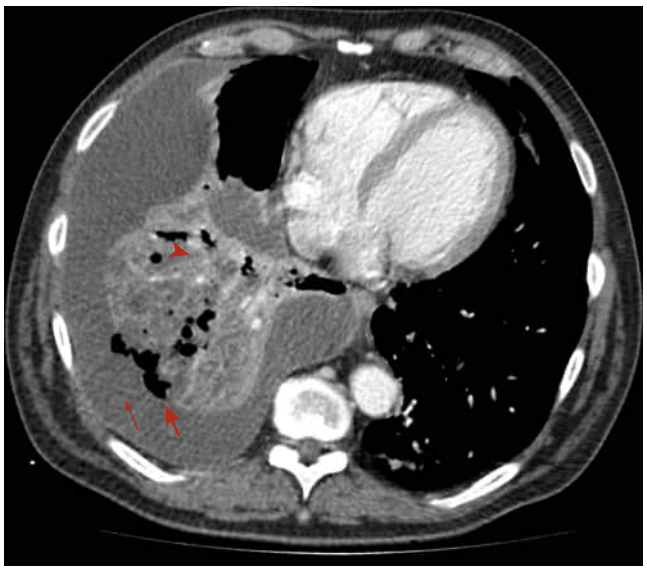
eFigure 109.2 Empyema: chest radiographic and thoracic computed tomography appearance. (A) Frontal chest radiograph shows a left-sided large, homogeneous opacity, without air bronchograms, occupying the left thorax. (B–E) Axial enhanced thoracic computed tomography shows multiloculated left pleural fluid associated with areas of nondependent gas (C, *arrow*) and smooth pleural thickening (E, *arrowheads*). Polymerase chain reaction analysis of material obtained at thoracoscopic débridement showed *Streptococcus anginosus* group bacteria as the causative agent. (Courtesy Michael B. Gotway, MD.)



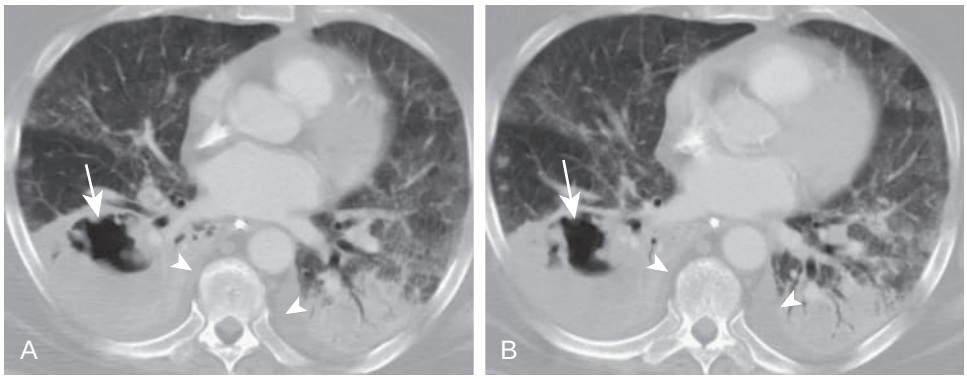
eFigure 109.3 Empyema: contrast chest computed tomography appearance. (A–D) Contrast-enhanced chest computed tomography in four different patients with empyema shows loculated pleural fluid collections with foci of smooth pleural thickening (*arrowheads*). In parts B and C, the collection is loculated, with fine septations (C, *thin arrows*) separating the fluid into pockets. (C–D) Two of the cases show gas-fluid levels (*thick arrows*), both appearing before intervention, a finding suggesting bronchopleural fistula.



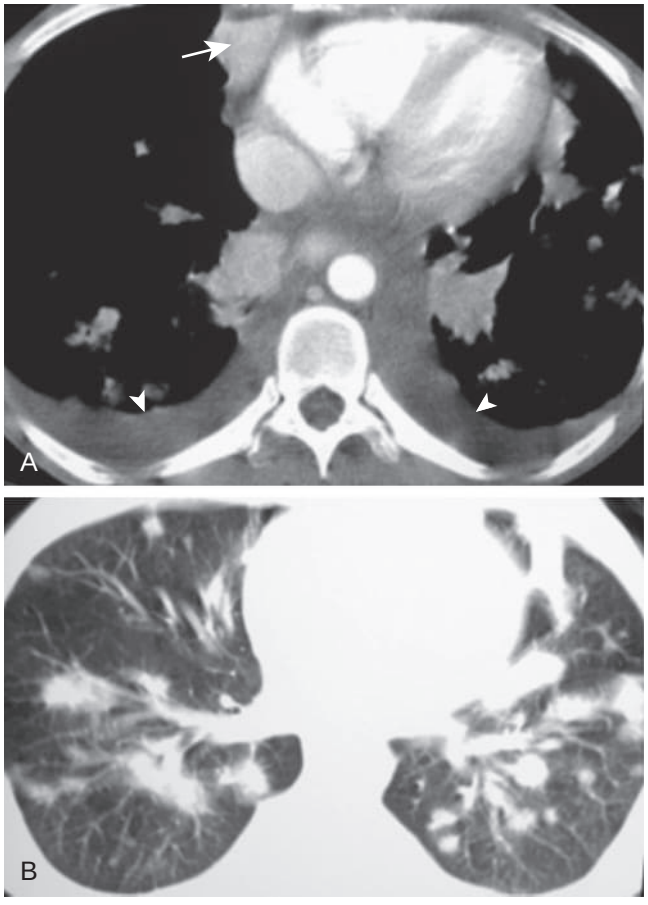
eFigure 109.4 Eloesser flap: chest computed tomography appearance. Axial (A) and (B) contrast and (C) noncontrast chest computed tomography images in three patients who underwent the Eloesser flap procedure, (A) one for chronic empyema, (B) one for treatment of bronchopleural fistula, and (C) the other as part of surgery for mesothelioma. All three images show a clear connection between the thorax and exterior (*arrows*). (C) The patient with mesothelioma shows concentric pleural thickening. (Courtesy Michael B. Gotway, MD.)



eFigure 109.5 Necrotizing pulmonary tuberculosis with associated pleural effusion. On axial chest computed tomography, free gas is visible within the lung (*arrowhead*). This finding represents parenchymal necrosis, with gas seen tracking into the pleural cavity (*thick arrow*), thus demonstrating a bronchopleural fistula. A single septation is seen within the fluid (*thin arrow*).



eFigure 109.6 *Nocardia asteroides* pulmonary infection with pleural effusion. (A–B) Axial enhanced chest computed tomography displayed in lung windows shows bilateral lower lobe consolidation, cavitary on the right (*arrows*). Trace bilateral, nonspecific pleural effusions (*arrowheads*) are present. (Courtesy Michael B. Gotway, MD.)



eFigure 109.7 Pleural effusions in Kaposi sarcoma. (A–B) Axial contrast chest computed tomography displayed in (A) soft tissue and (B) lung windows shows small, symmetrical, bilateral pleural effusions (*arrowheads*). Enhancing right cardiophrenic angle lymphadenopathy (*arrow*) is present. The typical appearance of bilateral, patchy, poorly defined peribronchial nodular opacities is readily appreciated on the lung window images (B). (Courtesy Michael B. Gotway, MD.)

INTRODUCTION

Pneumothorax, or air in the pleural space, is a common clinical problem. A pneumothorax as a result of injury to the chest wall is termed traumatic. If pneumothorax results from an invasive medical procedure (e.g., pacemaker or central venous line insertion), it is referred to as iatrogenic. The term *spontaneous pneumothorax* is reserved for cases arising without preceding trauma or injury. These are typically further subdivided into *primary spontaneous pneumothorax* (PSP), developing in patients with apparently "normal" lungs, and *secondary spontaneous pneumothorax* (SSP), developing in patients with known lung disease. The *British Thoracic Society* (BTS) guidelines suggest that pneumothorax in patients who are older than 50 years or with significant smoking history should be labeled SSP, because there is a high likelihood of pathologic lung changes, even in the presence of a normal *chest radiograph* (CXR).[1]

SPONTANEOUS PNEUMOTHORAX

EPIDEMIOLOGY

The best epidemiologic data for pneumothorax come from large national datasets, of which there have been two recent publications. The largest, covering 50 years of hospital admissions in England, included over 170,000 admissions. This study showed an increase in the incidence of pneumothorax from 1968 to 2016,[2] although the reason for this increase is unknown. In 2016, there were 14.1 pneumothorax admissions per 100,000 people aged 15 years or older. The rate was higher for men (20.8) than for women (7.6 per 100,000),[2] and the study confirmed the classic bimodal age distribution, with a first peak at age 15 to 34 years and an increasing incidence beyond 60 years in both men and women, which had been shown in smaller studies.[3–5] The second large epidemiologic study from France showed similar incidence rates, but the classic bimodal distribution was not seen.[6] The English study for the first time described the admission rates by PSP and SSP on a large scale: 60.8% of patients in 2016 had chronic lung disease and were classified as having SSP.[2]

ETIOLOGY

Historically, patients with spontaneous pneumothorax are subcategorized into PSP and SSP because the outcome and clinical course are very different; consequently, management strategy differs significantly. The mortality and morbidity from patients admitted with SSP is higher than PSP.[5] However, the traditional view that PSP presents in the absence of lung disease is being challenged, and it is likely that these patients do not have completely "normal" lungs.[7,8] This section focuses on the two spontaneous entities, PSP and SSP. Other etiologies such as traumatic, iatrogenic, and catamenial are covered separately.

PRIMARY SPONTANEOUS PNEUMOTHORAX

Ectomorphic Body Shape

The classic body shape for the patients with PSP is "tall and thin." Indeed, PSP is more common in taller patients with low body mass index and in smokers.[9–11] A large-scale study of 5604 cases of pneumothorax in Japan found a significantly lower weight/height ratio in patients with pneumothorax compared to healthy individuals.[10] The risk of recurrence (i.e., another episode of pneumothorax) in PSP patients was higher in taller patients, but only in men. Interestingly, height (in women) and a lower body mass index (in either sex) were not associated with increased risk of recurrence.[9]

Abnormal Lung Parenchyma and Smoking

Although PSP may present in patients without overtly recognized lung pathology, there is evidence that patients with PSP have macroscopic and microscopic structural abnormalities characterized by microscopic evidence of distal airways inflammation, "pleural porosity," and emphysema-like changes. Such emphysema-like changes include subpleural blebs and bullae, commonly seen in

patients with PSP on surgical inspection and on *computed tomography* (CT) scans,[12–18] but also in healthy volunteers (both smokers and nonsmokers).[12,19] Therefore, one cannot assume that these abnormalities are the sole cause of pneumothorax because they are not present in all patients with PSP and may be present in healthy individuals without PSP.

Smoking is a well-known risk factor for pneumothorax.[20,49] Although the exact mechanism is unclear, it has been postulated that small airways inflammation associated with smoking results in weakening of the visceral pleura, or dilation of the distal airways, resulting in increased airway pressure. However, it should be noted that not all smokers get pneumothorax, and there is likely an underlying susceptibility to cigarette smoke that results in the pneumothorax phenotype. Interestingly, risk of recurrence is not consistently increased in smokers compared to nonsmokers.[9,20–22] It is not yet known whether pneumothorax and lung changes are associated with the use of marijuana or e-cigarettes.

Blebs and Bullae. The anatomic lesion known as a bleb was first described in 1947 by Miller, as distinct from a bulla (or bullous emphysema).[23] A bleb is defined as an outpouching (or vesicle) of the visceral pleura caused by air in the interstitium, forming between the lamina elastica interna and externa of the visceral pleura, typically less than 1 cm in diameter (Figs. 110.1 and 110.2). In contrast, a bulla is an airspace measuring greater than 1 cm, which is sharply demarcated by a thin wall (≤1 mm in thickness). In 1967, Reid further subdivided bullae into three types: type I, a small amount of hyperinflated lung tissue that is narrow (pedunculated) and contains no lung parenchyma; type II, a relatively smaller amount of hyperinflated lung tissue that is broad (sessile); and type III, a large amount of hyperinflated lung tissue extending to the pulmonary hilum, with ill-defined margins and minimal parenchyma in each bulla.[24] These areas of disrupted mesothelial cells at the visceral pleura, replaced by an inflammatory fibroelastic layer, along with observed small pores, may contribute to a more general "pleural porosity."

Microscopic Abnormalities. Microscopic abnormalities have been identified in the lungs of PSP patients. In an early pathologic study of 20 young patients with PSP, resected lung parenchyma showed features of chronic distal airway inflammation with lymphocyte and macrophage infiltration alongside fibrotic changes.[25] In another study of 79 patients with PSP, *respiratory bronchiolitis* (RB) was identified on surgical biopsy in 88.6%.[26] Unfortunately, all the patients in this study were smokers, a known cause of RB. Thus, whether RB was a causal step in the development of pneumothorax or simply a marker of smoking status remains unclear. A subsequent study of 126 surgical cases found that RB was present in only 50% of patients.[27] In the same patients, light microscopic assessment demonstrated thickening and fibroelastosis of the pleura. Reid type I bullae were found to have microscopic changes in keeping with that originally described by Miller with respect to blebs, with formation of small air-containing spaces between lamina elastic interna and externa that contains no lung parenchyma (see Fig. 110.1).[24,27] Whether these

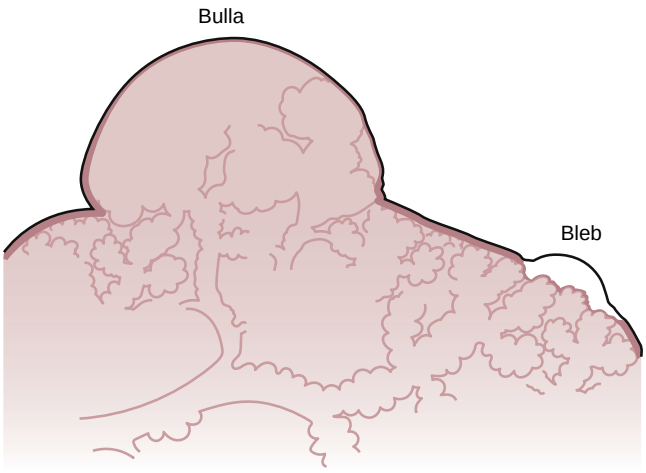

Figure 110.1 Blebs and bullae. The anatomy of emphysematous lung lesions is shown, representing a bleb and a bulla. (From Lyra R de M. Etiology of primary spontaneous pneumothorax. *J Bras Pneumol*. 2016;42[3]:222-226.)

microscopic changes lead to rupture of air into the pleural space and PSP is speculative, the abnormalities found in this study support the hypothesis that the underlying lung in PSP patients is not normal.

Historically, it has been postulated that rupture of blebs or bullae creates direct communication between the alveolar air and the pleural space, thus creating a pneumothorax. This view was contested by the observation that the presence of visible air leaks at thoracoscopy or thoracotomy is highly variable,[28] with many blebs or bullae remaining intact and, in some cases, with no macroscopic lesions at all. The concept of pleural porosity as a possible driver of PSP, rather than bulla or bleb rupture, was elegantly demonstrated in a study by Noppen et al.[19] (see Video 29.11). Twelve patients with PSP were compared to 17 control subjects at thoracoscopy using fluorescein-enhanced autofluorescence. Control subjects were undergoing sympathectomy (for hyperhidrosis) and therefore did not have any lung disease or history of pneumothorax. In both groups, there were areas of parenchymal abnormality, seen as areas of subpleural fluorescence or visible fluorescence leak when inspected under ultraviolet light, at regions of the lung that otherwise appeared normal with inspection under white light. However, high-grade lesions were seen only in PSP patients. Two patients with emphysema-like changes

demonstrated air leak, but the leakage was not directly at the site of the macroscopic blebs or bullae.[19] Thus, areas of porosity appeared to be more closely associated with air leakage than did the blebs and bullae.

Abnormal Elastosis. Areas of porosity may be a consequence of airway inflammation. One theory is that there is an imbalance in the protease-antiprotease systems. *Matrix metalloproteinases* (MMPs) are a group of zinc- and calcium-dependent endopeptidases that can damage basement membrane.[29] MMP-2 and MMP-9, two interstitial collagenases, have been postulated to be pathogenic in other lung diseases,[30] including asthma and COPD.[31] Two Taiwanese groups have examined surgical resection specimens from patients undergoing surgery for PSP and demonstrated overexpression of MMPs.[29,32] In the first study, immunohistochemistry showed overexpression of MMP-2, MMP-7, and MMP-9 in the tissue of PSP patients compared to controls.[29] In the second study, high MMP-2 and MMP-9 expression was found in patients undergoing surgery for recurrence prevention, and higher levels were found in patients presenting with a recurrent pneumothorax compared to those with a first episode.[32] Although these studies present intriguing data on elevated MMP levels in PSP, further prospective studies are required to confirm these findings and determine their clinical applicability in terms of risk stratification of patients or potential treatment options.

Familial Causes

Most episodes of PSP arise sporadically. However, an estimated 10% of patients have a significant family history.[33,34] A number of important inherited conditions predispose to pneumothorax, including Marfan syndrome,[35] *Birt-Hogg-Dubé* (BHD) syndrome,[36] alpha$_1$-antitrypsin deficiency,[37] and homocystinuria.[38] Marfan syndrome is caused by mutations in the *fibrillin 1 (FBN1)* gene; the major manifestations include increased height, disproportionately long limbs and digits, subluxation of the lens of the eye, and dilation of the aortic root.[35] Apical blebs and spontaneous pneumothorax have been described as minor diagnostic criteria for Marfan syndrome.[35] Whether mutations in *FBN1* predispose individuals to PSP in the absence of Marfan syndrome is not clear. Mutations in *FBN1* are not the cause of all autosomal dominant familial spontaneous pneumothorax; an analysis of two pedigrees of patients with a strong family history of spontaneous pneumothorax did not find associated mutations in *FBN1*.[39] It is presumed that the fibrillin mutation causes a weakness in the fibroelastic layer in the visceral pleura, but this has not been proven. BHD syndrome is an autosomal dominant inherited disease caused by mutations in the *folliculin (FLCN)* gene. BHD is characterized by benign skin tumors, diverse types of renal cancer, pulmonary cysts, and spontaneous pneumothorax.[36,40] It is likely that, as our understanding of pathogenesis increases, more genes with a role in pneumothorax will be discovered.

Although familial patterns of inheritance of spontaneous pneumothorax, particularly with autosomal dominance, are uncommon, a strong family history of pneumothorax should prompt further investigation. In this situation, the pneumothorax event may be a precursor to an unrecognized connective tissue disorder (Marfan or Ehlers-Danlos syndrome), skin disease (BHD), or metabolic disorder (homocystinuria) with the need for potential lifelong surveillance for other severe associations (e.g., renal cancer or aortic rupture).

It seems likely that minor mutations in *FBN1* or *FLCN* could predispose to the development of PSP without causing the full clinical spectrum of Marfan or BHD syndrome. This is an area that requires large-scale prospective studies with the collection of genetic and clinical data. Such data, if successful in identifying causative genetic mutation(s), could potentially determine an individual's risk of recurrence.[41,42] Clinicians should be vigilant for PSP being the first manifestation of a systemic disease and should have a low threshold for referral for genetic counseling.[41,42] At present, routine CT scan of the chest and pulmonary function testing are not standard after uncomplicated treatment of a first episode of PSP. However, some clinicians opt for a low-dose CT scan in female patients or males with a strong family history to exclude important familial diagnoses (above) or underlying lung disease such as *lymphangioleiomyomatosis* (LAM).

SECONDARY SPONTANEOUS PNEUMOTHORAX

A host of airway and lung diseases can be complicated by SSP. In the United Kingdom, the most common of these is COPD.[43] The most common cause worldwide remains pulmonary tuberculosis. Other common causes include cystic fibrosis, lung cancer, necrotizing pneumonias, and human immunodeficiency virus–related *Pneumocystis jirovecii* lung infection. However, there are few large-scale epidemiologic studies quantifying the risk of pneumothorax in these chronic diseases. Two rare infiltrative lung diseases are commonly associated with SSP: pulmonary Langerhans cell histiocytosis and LAM, with or without other features of tuberous sclerosis[44] (eFig. 110.1). Indeed, spontaneous pneumothorax in younger women (30 to 40 years old) may be the first manifestation of LAM.[44] Recurrent pneumothorax in women of childbearing age should prompt consideration of catamenial pneumothorax due to thoracic endometriosis.[45,46] The causes of SSP are summarized in Table 110.1.

TENSION PNEUMOTHORAX

Tension pneumothorax is a medical emergency. Tension develops when the leak in the visceral pleura functions as a one-way valve allowing air into the thorax but not allowing escape, thus progressively increasing intrapleural pressure. The increased pressure causes chest discomfort, reduces venous return, and eventually results in hypotension and hemodynamic compromise due to compression of the right ventricle and subsequent reduction in left ventricular end-diastolic filling pressure. These patients require urgent decompression with a cannula placed anteriorly in the second intercostal space in the midclavicular line. The unilaterality of the patient's complaints and signs on examination should be sufficient to identify the pneumothorax; in this setting, treatment should not be delayed for radiologic confirmation.[1] Tension is relatively rare in PSP and usually develops in the context of trauma or in ventilated patients in intensive care units,[48] but it should be noted that the true incidence is unclear.

Table 110.1 Disorders Associated With Spontaneous Pneumothorax

Common	COPD, pulmonary tuberculosis
Uncommon	Cystic fibrosis, lung cancer, *Pneumocystis jirovecii* infection
Rare	**Interstitial lung diseases**: idiopathic pulmonary fibrosis, sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis **Connective tissue diseases**: rheumatoid arthritis, scleroderma, ankylosing spondylitis, Marfan syndrome **Familial conditions:** Birt-Hogg-Dubé syndrome, Ehlers-Danlos syndrome, homocystinuria, catamenial pneumothorax

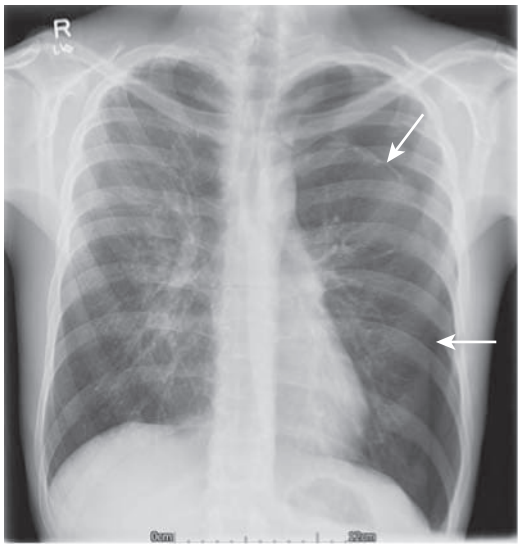

Figure 110.3 Chest radiograph showing left-sided pneumothorax without mediastinal shift. The visceral pleura is clearly visible (*arrows*) with an absence of lung markings distally.

DIAGNOSIS AND MANAGEMENT

Symptoms

Patients usually present with chest pain and/or breathlessness. The cause of chest pain is not clear but may be due to acute inflammation of the parietal pleura[47] or to tearing of small adhesions as the visceral pleura moves away from the parietal surface. Tearing of adhesions would be likely to cause some bleeding (hemopneumothorax), but significant intrapleural bleeding is a rare complication of pneumothorax; on the other hand, the CXR in many patients with pneumothorax demonstrates a basal air-fluid level if this is carefully looked for, perhaps suggesting a small pleural bleed. The physiologic cause of breathlessness is not clear—this may be due to expansion of the chest wall and depression of the diaphragm or an alteration in respiratory mechanics and perception. Such changes have been postulated to contribute to breathlessness in patients with emphysema and in those with pleural effusion.

Clinical Examination

On examination, there is usually ipsilateral increased chest wall size, decreased chest wall expansion with breathing, a hyperresonant percussion note (tympany), and diminished breath sounds. However, signs can be subtle in patients with small pneumothoraces or when the patient has underlying emphysema or cystic lung disease. Deviation of the trachea to the contralateral side on examination, if present, with hemodynamic compromise along with tympany and enlargement of the hemithorax on the affected side would signify tension pneumothorax and the urgent need to intervene (see later). Arterial blood gas measurements are not usually clinically indicated; in a large and acute pneumothorax, these may demonstrate hypoxemia and an increase in the alveolar-arterial oxygen tension difference. However, in most pneumothoraces where the underlying lung is not diseased, very little disturbance to oxygen saturations is seen, possibly because of matched perfusion-ventilation defects as a result of lung collapse (see Chapter 44).

Imaging

In patients with suspected non–tension pneumothoraces, a CXR should be used to confirm the diagnosis: the visceral pleura is clearly visible as a line with an absence of lung markings distally (Fig. 110.3). Often the distinction of the visceral pleural line and other lines, such as skinfolds, can be challenging (Fig. 110.4). A pleural line should have air on both sides, have no lung markings distal to it, and be continuous along the length of the pneumothorax.

In most cases, a standard erect frontal CXR is sufficient to confirm the diagnosis of pneumothorax. Small pneumothoraces can be difficult to ascertain and may be missed on a frontal CXR. In cases where there is a high clinical index of suspicion, lateral CXRs are sometimes useful and can detect pneumothorax in up to an additional 14% of cases.[49] In a supine patient, the intrapleural air of a pneumothorax will move and lie in the anterior region of the pleural space, where it will have a different appearance on CXR. As an example, in a supine patient, a pneumothorax can produce the deep sulcus sign, in which the air collects between the diaphragm and chest wall (Fig. 110.5).

However, with ready access to CT scanning, many physicians opt for a chest CT to avoid any doubt. This is particularly important in situations in which missing a small pneumothorax may have detrimental consequences, such as in patients with extensive lung disease or in those on positive-pressure ventilation.[50] Another indication for CT scan is to differentiate pneumothorax from severe bullous lung disease because an erroneous diagnosis and subsequent chest tube insertion could lead to puncture of the lung, with risk of ongoing leak and bronchopleural fistula (Fig. 110.6).

Midline Shift. Midline shift refers to deviation of the mediastinal structures away from the side of the pneumothorax. Certainly, a tension pneumothorax will show a midline shift (unless the mediastinum is fixed in place). However, midline shift can also be seen in patients without hemodynamic compromise and thus does not equate to tension pneumothorax. If the mediastinum is not fixed in place, the mediastinum can shift in response to a difference in pressure between the two hemithoraces without one side having positive intrapleural pressure indicative of tension physiology.

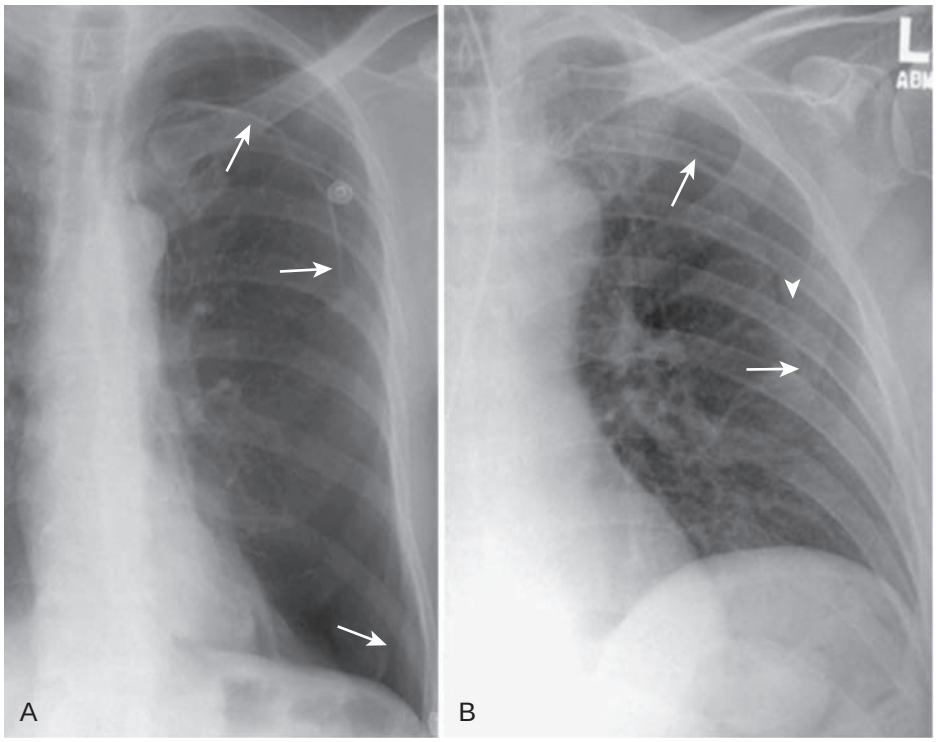

Figure 110.4 Distinguishing a pneumothorax from a skinfold. (A) Chest radiograph of a pneumothorax. The pleural line has lucency on either side, representing air in the pleural space on one side of the line and air in the lung on the other. The line is sharply demarcated and can be traced along its course (*lower arrow*). No blood vessels can be seen beyond the superior (*upper arrow*) and lateral (*middle arrow*) extent of the line. (B) Chest radiograph of a skinfold (*arrows*) that could be mistaken for a pneumothorax. The border is more of an edge, with lucency on only one side. The edge is poorly defined and cannot be followed continuously (*lower arrow*). Blood vessels can be traced beyond the border of the fold (*arrowhead*).

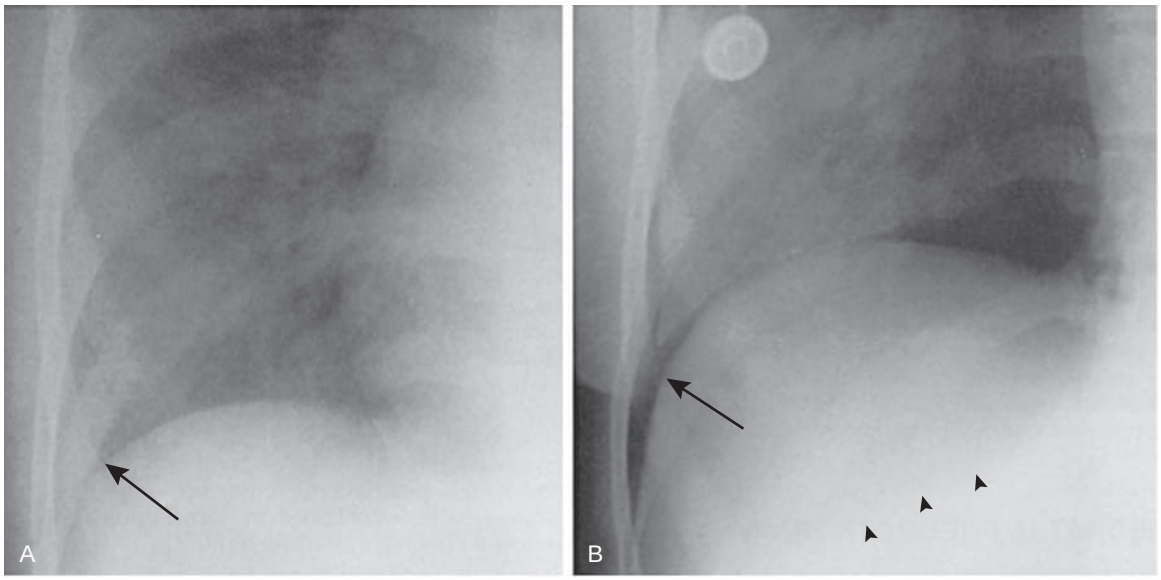

Figure 110.5 Deep sulcus sign of pneumothorax in a supine patient. Detailed views of the right costophrenic angle from successive supine chest radiographs taken before (A) and after (B) the development of a pneumothorax. Both images show diffuse infiltration in the right lower lung field. Note change in costophrenic angles (*arrows*) caused by air in the pleural space between the diaphragm and chest wall: the deep sulcus sign. Air in the anterior pleural space can also be recognized by an air-tissue interface (*arrowheads*).

Use of Ultrasound in Pneumothorax. There is increasing interest in the use of thoracic ultrasound to diagnose pneumothorax (see Chapter 23). The majority of the studies are prospective case series comparing imaging modalities in diagnosing pneumothorax in the context of trauma, iatrogenic (e.g., post–image-guided biopsy), or critical care. The absence of normal-appearing lung on thoracic ultrasound (i.e., the absence of the normal findings of lung sliding and of B lines) can be used to diagnose pneumothorax with very high sensitivity and specificity. There are now *randomized controlled trials* (RCTs) assessing clinical impact or outcome and four

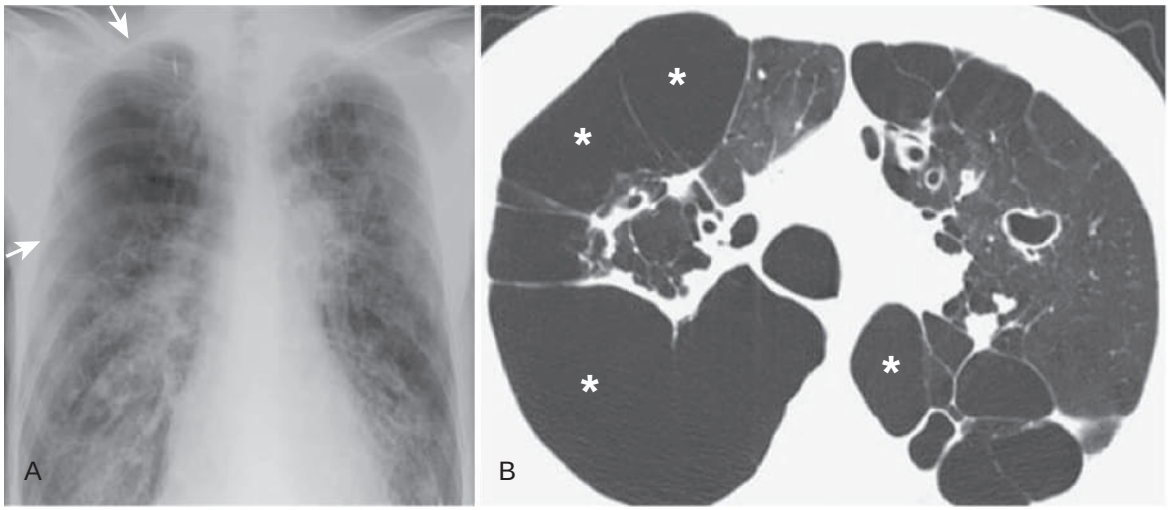

Figure 110.6 Bullae resembling pneumothorax. (A) Frontal chest radiograph of a patient with cystic fibrosis and extensive bullous disease of the right apex that was initially mistaken for a pneumothorax. Note lucent area (*arrows*) within the right upper lung field. (B) Computed tomography scan confirms the presence of bullae (*asterisks*) and excludes pneumothorax.

meta-analyses of these data comparing the accuracy of thoracic ultrasound for pneumothorax compared to CXR.[51–54] Pooled sensitivity for ultrasound was 78–90% with a specificity of greater than 98%. CXR performed more poorly with a pooled sensitivity of 39–52% but a similar specificity. However, the vast majority of these patients were trauma patients lying in a supine position in the emergency department, which naturally reduces the sensitivity of CXR.

It is important to note that there are also false-positives for ultrasound in diagnosing pneumothorax, particularly in patients with underlying lung diseases. This is particularly evident in patients with COPD who may have bullae close to the pleural surface, which can also show an absence of the lung sliding sign and thereby give an appearance similar to pneumothorax.[55]

Thoracic ultrasound can potentially be used to identify pneumothorax post–lung biopsy[56–58] or to determine when pneumothoraces have resolved after chest tube drainage.[59] However, further studies are required before this becomes standard practice. We use thoracic ultrasound in the diagnosis of pneumothorax post–lung biopsy and during pleural procedures but not as a primary diagnostic strategy in most cases, in which a combination of CXR and CT is optimal.

Decisions on Intervention

The first treatment decision is whether intervention is required or not. Clinically stable patients with a small PSP on CXR can be managed conservatively (i.e., observation alone) with close CXR follow-up to ensure resolution. However, there is considerable controversy about the optimal treatment of a minimally symptomatic PSP patient with a large pneumothorax on CXR, and management therefore varies.

Size of Pneumothorax. The size of a pneumothorax is difficult to infer from the two-dimensional CXR image. There are a number of methods of estimating pneumothorax size. One is the Light index, calculated using the ratio of the cube of lung diameter to hemithorax diameter.[37] Using this formula, a pneumothorax with a 2 cm depth at the level of the hilum on CXR has an approximate volume of 50% of the hemithorax. Another method suggested by Rhea et al. uses the average of the interpleural distances measured at the apex, midpoint of the upper half of the lung, and midpoint of the lower half of the lung on an erect CXR.[60] However, international guidelines do not agree on size measurement criteria.[1,7,61] In clinical practice, the most commonly used methods are the two adopted by the BTS and the American College of Chest Physicians, which rely on depth of pneumothorax from the chest wall, possibly because these are relatively simple and therefore applicable in clinical daily practice.

The BTS definition of a large pneumothorax is greater than 2 cm of air between the lung margin and the chest wall measured at the level of the hilum on CXR.[1] The American College of Chest Physicians consensus statement proposes that a large pneumothorax has 3 cm or greater of air measured from the apex to the inner chest wall at the thoracic cupola.[61] The Belgian Society of Pneumology proposed that a large pneumothorax has a visible lung visceral pleural line along the whole length of the lateral chest wall[62] (also referred to by some authors as complete dehiscence). However, it is clear that there is little consensus and potentially limited use in size calculation. A study of 49 cases of pneumothorax compared the classification of pneumothorax size across these three guidelines and found agreement in only 47%[63] of cases. In addition, it is acknowledged that size of the pneumothorax on CXR does not correlate to symptoms. The BTS guidelines include the caveat that "in some patients with a large pneumothorax but minimal symptoms, conservative management may be appropriate."[1] Therefore, the decision to treat or not is largely based upon clinical judgment rather than size; patients with a small pneumothorax but severe symptoms may require intervention, whereas stable patients with a pneumothorax classified as large may be initially managed conservatively with observation only.

In a recently reported randomized trial in moderate to large PSP, conservative management (i.e., no intervention) was compared to standard care (i.e., aspiration and/or chest tube insertion). The conservative group did quite well, and the majority of patients in both arms had resolution of their pneumothorax by 8 weeks.[64] These data add evidence

to the BTS guidance that patients with minimal symptoms can be safely managed conservatively.

In contrast to PSP, in which observation or short-term treatment is encouraged as the first treatment, current guidelines recommend that all patients with SSP should be admitted to the hospital for at least 24 hours and receive supplemental oxygen. Most SSP will require a chest tube.[1] This cautious approach is recommended in SSP because the underlying lung disease is thought to increase the risk of complications (such as respiratory failure) or prolonged ongoing air leak; indeed, there are data suggesting that spontaneous resolution of pneumothorax is far less common in SSP versus PSP.[65,66]

Initial Management Options

Once the decision is made to intervene, the next choice is whether to attempt *needle aspiration* (NA) or to insert a small-bore chest tube. BTS guidelines recommend NA (using a 16- to 18-gauge cannula) of up to 2.5 L of air as initial treatment. If NA is unsuccessful in expanding the lung, chest tube insertion is required.[1] These recommendations are based upon RCTs showing "equivalence" of NA and chest drainage in terms of initial success rates, varying between 59% and 80%.[67–70] However, there were significant differences in the definition of "initial success," and trial design between the studies (eTable 110.1), and none of the studies was designed as a true noninferiority comparison.

In 2007, the first Cochrane review of this topic[71] included only one RCT. This study by Noppen et al. included 60 patients with a first episode of PSP randomized to either NA or chest tube. Initial success rates were not significantly different between the groups: 59.3% after NA and 63.6% after chest tube.[69]

In 2017, Carson-Chahhoud et al. updated the Cochrane review,[72] this time with six RCTs,[67–70] including Parlak,[73] who also recruited patients with traumatic (as well as spontaneous) pneumothoraces. The Cochrane review concluded that immediate success rates were higher in the chest tube group than the NA group.[72] However, there was heterogeneity in the definitions of immediate success. Recurrence rates were no different between the groups. Hospital stay was shorter in the NA group with fewer complications compared to the chest tube group.[72]

Since that review, two more RCTs have been published: Ramouz et al. enrolled patients with PSP and again found similar immediate success rates with NA and chest tube and shorter hospital stay in the NA group.[74] Thelle et al. recruited both PSP and SSP patients and reported NA to be more effective than chest tube drainage for initial treatment success (68.8% vs. 31.8%), although 37.5% of patients required a second aspiration.[75] This was the first study to include significant numbers of patients with SSP and to report the results separately; there was a higher success rate for NA in both PSP and SSP patients. The authors suggest the guidelines should be changed to treat SSP in the same way as PSP (i.e., with NA as initial treatment).[75] However, it should be noted that the chest tube group had a lower success rate (31.8%) than in previous studies; thus, first-line treatment of SSP with NA requires further validation before it can be widely recommended.

Supplemental Oxygen

In patients who are not undergoing intervention to drain the pneumothorax, supplemental oxygen can be prescribed. Evidence from a small study in 1971 suggests that use of 100% oxygen in patients with spontaneous pneumothorax can increase the rate of absorption fourfold compared to air (on the basis of mean reduction in pneumothorax size of 4.8 and 18 cm^2/day, respectively).[76] The rationale is that by reducing the partial pressure of nitrogen in the inspired gas, and thus in pleural capillaries, the rate of nitrogen absorption from the pneumothorax is increased, thereby increasing the rate of resolution of the pneumothorax.

Reexpansion Pulmonary Edema

Unilateral pulmonary edema (*reexpansion pulmonary edema* [RPE]) may develop in certain patients whose lung has been rapidly reinflated after a period of collapse secondary to a pneumothorax or a pleural effusion. This is likely due to mechanical stress on the lung leading to increased permeability of the pulmonary vasculature during rapid reexpansion. The incidence of RPE is likely to be low: retrospective series suggest that the incidence may be as low as 0%[77] or 1%[78] in patients treated for pneumothorax. More recent series report a high incidence of RPE (16%, 27/173), but this was largely asymptomatic because only five patients (3%) required treatment.[79]

Typically, patients with RPE will report cough or chest tightness. In extreme cases, patients can be hypoxemic and hypotensive. Treatment is supportive with supplemental oxygen and diuretics.

Ambulatory Care

With the increasing pressures on health care systems, ambulatory management has been proposed for patients with a number of medical conditions. Given that patients with PSP tend to have little comorbidity, this patient group might represent an ideal cohort for outpatient management to reduce both inconvenience and risk for patients and the economic costs of an inpatient hospital stay. This is not a new concept; a number of studies have demonstrated the feasibility of outpatient management for PSP using a chest tube attached to a one-way (also called a flutter or Heimlich) valve, but this treatment has not been widely adopted. As far back as 1976, a case series of 226 patients with PSP managed by observation or flutter valve concluded that outpatient management was "safe, efficient, and economical."[80] The first randomized trial of 30 PSP patients compared "thoracic vent" to standard chest tube. This study showed no significant difference in complications or reexpansion rates, but 70% of the "vent" patients were managed as outpatients and required fewer analgesics, with patients in the control group (standard chest drain) hospitalized for a median of 8 days.[66] Since then, a number of observational or retrospective studies also describe high rates of success with outpatient management of PSP with one-way valves.[81–85] These data were summarized in a 2013 systematic review[86] in which an overall success rate was reported as 85.8% and successful outpatient management reported in 77.9% with "few complications." However, the evidence was of poor quality with a high risk of bias.[86] As a result, a large multicenter RCT was designed to answer the question of efficacy and safety of ambulatory management.[87] In this trial, ambulatory management (using an ambulatory device containing a one-way valve) was compared to standard care (aspiration with or without chest tube, per BTS

eTable 110.1 Randomized Controlled Trials of Needle Aspiration vs. Chest Tube: Initial Success Rates

Study	Year	*N*	Needle Aspiration Success Rate (%)	Chest Tube Initial Success Rate (%)

guidelines). Ambulatory management significantly reduced hospital stay compared with standard care (median, 0 days [interquartile range, 3 days] vs. 4 days [interquartile range, 8 days]; $P < 0.0001$). Patients who underwent ambulatory treatment had fewer pleural procedures, but serious adverse events were higher due to hospital readmission.[87]

Suction. Suction refers to the application of negative pressure to the intrapleural space via the chest tube. Use of suction is not recommended by the current guidelines.[1] There have been two small RCTs, neither of which showed a significant difference in success rates when comparing suction to standard underwater seal management.[88,89] However, suction is advocated by some physicians in cases of nonresolution of pneumothorax (particularly if the lung has not reinflated). Suction aims to remove air from the pleural space at a rate faster than it can accumulate in the chest, hence, speeding resolution of the pneumothorax; however, it should be noted that this does not treat the underlying visceral pleural defect. However, some authorities state that full lung expansion allows earlier healing of the pneumothorax due to apposition of the visceral and parietal pleura. This hypothesis has not been proven, and recent data argue the opposite.[64] In a recent RCT, those managed conservatively (e.g., without drainage of air) had a lower recurrence of pneumothorax over the next year than those receiving standard management (e.g., with aspiration and/or chest tube drainage),[64] suggesting that slow reexpansion may improve healing.

Although the guidelines do not explicitly recommend suction, they state that a "high volume" (up to 15–20 L/min) "low pressure" suction could be used.[1] The application of suction is not without risk; rapid reinflation of the lung may precipitate RPE and, perhaps more worryingly, the increased airflow through the visceral leak could increase the size of the hole in the visceral pleura. Therefore, the use of suction needs to be considered carefully.

Failure of Medical Management

In most patients with pneumothorax, the visceral pleural injury and therefore the air leak will resolve spontaneously, with drainage intended to prevent symptoms and complications such as tension. Failure of medical management for patients with pneumothorax describes the clinical situation in which the lung has not reinflated with chest drainage and/or there is a prolonged air leak.

A number of treatment options are possible in this situation. However, it is important to understand the rationale behind each treatment before it is used in an unstructured manner.

Prolonged Air Leak. *Prolonged air leak* (PAL) is typically defined as an ongoing leak despite 5 to 7 days of chest tube drainage. There are data to suggest that most PSP patients with PAL will eventually resolve given time. Chee et al. found that 100% of patients with PSP with PAL for greater than 7 days had resolved by 14 days.[65] Therefore, any decision to define failure must be considered as a balance between allowing time for the leak in the visceral pleura to heal (with spontaneous cessation of PAL) and the inconvenience and expense of having a chest tube in place while in the hospital for an extended period.

Current BTS guidelines suggest that drainage should be attempted for at least 3 days, and a thoracic surgical opinion should be sought "early" at 3 to 5 days.[1] Presumably, this recommendation was intended to allow the necessary arrangement for surgical intervention as, in theory, PAL is not confirmed until at least day 5.[1] However, these timings are somewhat arbitrary and not evidence based.

Chest Tube Size. In the presence of a large air leak, some physicians and surgeons may advocate replacing a small-bore tube with a large-bore tube to allow a greater total flow rate of air or using high-volume, low-pressure suction attached to the chest tube. The larger chest tube allows a greater flow rate because turbulent flow is proportional to the fifth power of the radius of the tube, as described by the Fanning equation: $v = \pi^2 r^5 P/fl$ (where v is flow, r is radius, P is pressure, l is length, and f is a friction factor).[89a] The goal is to remove air faster than air is entering, thereby reinflating the lung. This approach would seem rational if there is clear evidence of insufficient drainage of air (e.g., subcutaneous emphysema, increasing pneumothorax size, major bubbling through the water seal, or worsening clinical condition). However, there is no good trial evidence to support the use of larger drains or suction in stable patients with PAL.

Thoracic Surgery. Definitive treatment for failed medical treatment or recurrence prevention is thoracic surgery. It is important to distinguish the two purposes of surgery in this situation. The first is to repair the leaking lung, allowing full lung expansion and removal of the chest drain, which is required only in cases of PAL. The second is recurrence prevention, which is largely an elective operation; if air leak repair is to be performed at surgery, it makes sense to conduct recurrence prevention surgery at the same time.

Surgery is performed by *video-assisted thoracoscopic surgery* (VATS), which has superseded open thoracotomy in most countries as the approach of choice. During surgery, the operator aims to identify and seal any areas of air leakage, resect any visible blebs or bullae on the visceral pleura, and perform a pleurodesis procedure. Pleurodesis is required alongside bleb/bullectomy to achieve lower recurrence rates.[28,90,91] Pleurodesis can be achieved by pleural abrasion, pleurectomy, or chemical pleurodesis (typically by insufflation of talc, called "poudrage"). A study of VATS for PSP recurrence prevention (or for PAL) showed a lower rate of recurrence with talc poudrage (1.8%) compared with subtotal pleurectomy (9.2%) regardless of whether ligation or stapling of bullae was performed.[92] The low recurrence was confirmed in two large case series of VATS with talc poudrage after bleb/bullectomy, which reported recurrence rates of only 1.7%[93] and 1.9%.[94]

Where the option exists, patients with PAL could undergo medical thoracoscopy performed under conscious sedation (rather than under general anesthesia, as in VATS) with talc poudrage. Although this is being performed in Europe, it is not current practice in the United Kingdom or United States. An RCT comparing medical thoracoscopy with talc poudrage to standard chest tube alone showed a reassuringly low recurrence rate of 5% compared to 34% for chest tube drainage.[95] It should be noted that deep conscious sedation or general anesthesia

is required to perform talc poudrage pleurodesis at thoracoscopy in patients with pneumothorax because this procedure can be painful.[96]

Recurrence Prevention After First Pneumothorax. In cases in which a recurrent pneumothorax is likely and would be accompanied by serious clinical consequences, efforts to prevent recurrence are indicated. This can be approached with a surgical, usually VATS, or medical thoracoscopy or with a medical, usually talc, pleurodesis. Also, various additional procedures have been used to stop ongoing air leaks to allow pleurodesis or discharge.

Surgical Pleurodesis. At present, recurrence prevention surgery after a first episode of spontaneous pneumothorax is recommended only in certain circumstances and usually when the patient's occupation would increase risk in the event of a recurrence (e.g., airline pilot or commercial diver). Otherwise, the indications for surgery are recurrence (either ipsilateral or contralateral), synchronous bilateral pneumothorax, or PAL.[1] However, there are advocates of surgical intervention after a first episode of PSP. There have now been two RCTs comparing early VATS to conservative management after a first PSP. The first study randomized 41 patients to either VATS within 24 hours of admission to the hospital or to "conservative" treatment with chest tube drainage.[97] They found no recurrence (0%) in the VATS group but 40.9% in the conservative group. It should be noted that the recurrence rate in the conservative group is significantly higher than expected from other studies in the literature,[2,6] and that this study was small and therefore underpowered. A larger RCT by Olesen et al.[98] of 373 PSP patients showed a significantly lower recurrence rate in those treated with VATS (13%) compared to conservative treatment (34%). The 13% recurrence in the VATS group was unexpectedly high but may be due to the use of abrasion rather than talc as the method of pleurodesis.

The main issue regarding recurrence prevention after the first event is determining which patients would benefit. Around 28–30% of patients will have a recurrence after simple chest tube drainage,[2,6] but 70% will not. It therefore follows that operating on all patients results in approximately 70% having an unnecessary operation. Although VATS or medical thoracoscopy is generally considered a safe procedure, there are still risks of significant morbidity or mortality, especially persistent chest pain.[99] If patients at higher risk could be identified, a more personalized approach could potentially shift the balance of risks and benefits towards early surgery or thoracoscopy.

Risk stratification based on high-resolution CT scan findings was proposed by Ouanes-Besbes et al.[100] Unfortunately, stratification by bullae size or "dystrophic score" has not convincingly identified patients at higher risk of recurrence. As such, the case for early surgery or thoracoscopy for PSP recurrence prevention has yet to be made. The combination of clinical and radiographic findings may provide better information for patients and clinicians on potential risks and benefits of early intervention, although validated data are currently lacking.

Patients Unfit for Surgery. By definition, patients with SSP have demonstrable lung disease. Patients with long-standing lung disease such as COPD and interstitial fibrosis are particularly susceptible to PAL and recurrence. Unfortunately, the respiratory disease renders such patients unfit for surgery due to the high risk of general anesthesia. These patients present a significant management challenge for physicians and may have multiple episodes of pneumothorax with prolonged hospital stays due to the presence of bronchopleural fistulas.[101] Heimlich valves attached to chest tubes offer the option of discharge from the hospital and outpatient follow-up, but this may only be feasible in the most stable patients. Alternatively, a pleurodesis procedure could be performed via the chest tube, via chemical pleurodesis or the instillation of autologous blood (blood patch pleurodesis) in an attempt to reduce or stop the ongoing air leak.

Medical Pleurodesis. Pleurodesis is the application of chemical or mechanical injury to the pleura, inducing inflammation and subsequent adhesion of the pleural layers, to prevent reaccumulation of fluid or air. Medical pleurodesis is the instillation of a chemical irritant to the pleural space. This is commonly performed to prevent the reaccumulation of pleural fluid (usually in the context of malignancy)[102] (see Chapter 114). A number of pleurodesis agents can be used for recurrence prevention in spontaneous pneumothorax, including talc, tetracycline, minocycline, and autologous blood.[103] Graded talc (talc with the smallest particles removed) is the most commonly used and successful agent for pleurodesis.[1,7,8] In the treatment of malignant pleural effusion, the success rates of talc for pleurodesis are high (around 70–80%).[102,104] It should be noted that for pleurodesis of any form to work, there needs to be apposition of the visceral and parietal pleura; therefore pleurodesis has no role in the presence of a pneumothorax with complete separation of the visceral and parietal layers. The minimal amount of apposition required to achieve success with pleurodesis is debated.

In an RCT by Chen et al,[105] pleurodesis was attempted for patients presenting with a first episode of PSP. Minocycline was instilled via chest tube in the intervention arm, compared with standard tube drainage only, and reduced the rate of recurrence at 1 year to 29.2% compared to 49.1% in the control group. However, the recurrence rate in the control arm was much higher than previously reported,[7] and this strategy results in treating a significant number of patients who may never have a recurrence.

A systematic review has compared efficacy of chemical pleurodesis agents in spontaneous pneumothorax via either medical or surgical approaches.[103] In the medical approach (i.e., without surgery on the lung), talc poudrage during medical thoracoscopy had the lowest recurrence rate at 2.5–10%. The recurrence rates following instillation through the chest tube were 13–33% for tetracycline and 34% for talc (as a slurry).[95] On this basis, medical pleurodesis is most commonly conducted using talc and, while recurrence rates are lowest using VATS or medical thoracoscopy, slurry via chest tube remains an option, especially for those not fit enough for surgery.

Blood Patch Pleurodesis. Blood patch pleurodesis involves the instillation of 1 to 2 mL/kg of autologous venous blood into the pleural space via chest tube. Although this is technically not pleurodesis, it can successfully resolve PAL in some cases.[106] It is presumed that the fibrin and clotting factors within the blood aid the repair of the visceral leak

and help resolve the pneumothorax. Case series support the use of this technique using 2 to 4 mL/kg of blood, but definitive data are lacking.

Endobronchial Valves. Another possible treatment option is the use of endobronchial valves, which are increasingly used in COPD treatment to achieve lung volume reduction. These valves, inserted at bronchoscopy, occlude the relevant lung segment corresponding to the site of the air leak, thereby closing the bronchopleural fistula.[107] While there are case reports and small case series suggesting successful treatment, high-quality evidence on their efficacy is lacking, but they remain a useful option in difficult-to-treat patients. Once the leak is controlled and the lung reinflates, a medical pleurodesis can be attempted to reduce recurrence risk.

Total Pleural Covering. The visceral pleura can be covered with an absorbable cellulose mesh via VATS in an attempt to reinforce the visceral pleura and reduce recurrence without creating a pleurodesis. This novel approach has been attempted in selected patients with a high risk of recurrence (e.g., innumerable cysts that preclude resection) and reasons to avoid pleurodesis. Pleurodesis in patients with LAM increases bleeding complications at the time of future lung transplantation and, although pleurodesis is not a contraindication for lung transplantation, alternatives to pleurodesis are desirable. Total pleural covering has been used in both BHD[108] and LAM,[109] where it appears to be a promising approach to reduce recurrence. An ATS treatment guideline advocates further study of this option.[110]

Follow-up. Patients should be counseled about risk of recurrence and recommendations regarding air travel and scuba diving. Patients should be advised to return to the emergency department if they experience similar chest pain or breathlessness.[1] During follow-up, the possibility of underlying lung disease should be considered and investigated.

Lifestyle advice on smoking cessation should be reinforced because continued smoking increases the risk of recurrence.[4,94] Advice on air travel is mandatory (see Chapter 106). An undrained pneumothorax will increase in size as a result of the decreased ambient pressure in the aircraft cabin and potentially cause respiratory compromise; thus, an untreated pneumothorax is an absolute contraindication to air travel. Current guidance recommends waiting for 7 days after full resolution of pneumothorax on CXR before it is considered safe to fly.[111] Patients who have had definitive surgical management with pleurodesis for pneumothorax can fly once they have fully recovered from surgery, but they should be aware that their recurrence risk is still around 1–2%. In patients with SSP who are not fit for surgery, patients should seek safer modes of transportation (road or rail) instead of flying.[111]

Scuba diving (using compressed gas) should be avoided lifelong after pneumothorax unless recurrence prevention surgery with pleurodesis has been conducted[112] (see Chapter 107). There is no evidence to link recurrence with physical exertion, but general advice is that patients can return to work and normal physical activities once symptoms have resolved. Pragmatically, patients should refrain from high-impact physical sports in the short term.

TRAUMATIC PNEUMOTHORAX

The incidence of pneumothorax after blunt trauma depends on the severity of trauma. Data on incidence of pneumothorax are limited but, in some series, the incidence exceeds 35%.[113]

A traumatic pneumothorax can result from either penetrating or nonpenetrating chest trauma (see Figs. 104.4, 104.7, and 104.8 and eFigs. 104.10 and 116.5). In penetrating chest trauma, air can enter the pleural space from the outside via a wound in the chest wall, or from the lung via a break in the visceral pleura. With nonpenetrating trauma, a pneumothorax may develop if the visceral pleura is lacerated secondary to a rib fracture or dislocation. However, in the majority of patients with pneumothorax secondary to nonpenetrating trauma, there are no associated rib fractures. In this circumstance, pneumothorax may result from the sudden chest compression abruptly increasing the alveolar pressure, thereby causing alveolar rupture. Air then enters the interstitial space and dissects toward either the visceral pleura or the mediastinum. A pneumothorax develops when either the visceral or the mediastinal pleura ruptures.

DIAGNOSIS

The diagnosis of pneumothorax is commonly made by CXR or CT. However, patients with significant trauma will commonly be lying in a supine position and may be immobilized. As mentioned earlier, pneumothorax on CXR in the supine position can be easily missed. CT scans, increasingly used in major trauma, will identify many more pneumothoraces, even small ones. A pneumothorax detectable on CT, but not on CXR, is called an occult pneumothorax and accounts for about 40% of traumatic pneumothoraces[114] (see Fig. 104.7).

TREATMENT

There is some controversy about whether treatment is required for traumatic pneumothorax. Most clinicians initiate treatment with chest tube for a large pneumothorax. However, whether to intervene in patients with occult or small pneumothoraces is not clear. In one series of 803 patients, 300 with pneumothoraces less than 1.5 cm were initially managed without chest tubes, and only 33 (10%) subsequently required chest tube insertion.[115] The remaining 504 patients were treated with chest tubes, but 66% had the chest tube removed within 24 hours because the lung reexpanded and air leak ceased.[115] As discussed earlier in regard to PSP and SSP, if the leak persists for more than a few days, consideration should be given to performing thoracoscopic surgery to identify and repair the site of the air leak.[116]

IATROGENIC PNEUMOTHORAX

On the basis of two large series, iatrogenic pneumothoraces are probably more common than PSPs and SSPs combined.[117,118] A leading cause of iatrogenic pneumothorax is transthoracic needle aspiration. Historically, the incidence

of iatrogenic pneumothorax postaspiration was as high as 25%, although this has reduced since the introduction of ultrasound for all pleural procedures.[119] Another leading cause of iatrogenic pneumothorax is CT-guided transthoracic lung biopsy. This procedure is more likely to result in a pneumothorax if the patient has COPD, if the lesion is deep within the lung, or if larger needles are used. In a meta-analysis, the pneumothorax rate was 25.3% for core lung biopsy and 18.8% for fine-needle aspiration.[120]

Other common causes of iatrogenic pneumothorax (with approximate incidences) are subclavian vessel puncture (e.g., during cardiac pacemaker insertion; 22%), pleural biopsy (8%), mechanical ventilation (7%), and transbronchial lung biopsy (6%).[1] Iatrogenic pneumothorax also frequently complicates cardiopulmonary resuscitation. Radiofrequency ablation is increasingly used to treat lung tumors but carries a high incidence of pneumothorax (≈30%).[121,122] A series of 137 radiofrequency ablation procedures found 27 symptomatic pneumothoraces requiring chest tube drainage.[123] In another series, the risk for pneumothorax was associated with the number of tumors ablated, electrode positions, and the electrode trajectory through aerated lung.[122]

DIAGNOSIS

The diagnosis should be suspected in any patient who becomes more dyspneic or whose condition deteriorates after an intervention procedure. Importantly, the pneumothorax can present late and therefore may not be evident for 24 hours or longer after the procedure.[124] The diagnosis needs confirmation by ultrasound or radiographic imaging. In patients with extensive pulmonary opacities, there may be little evidence of lung collapse; the air in the pleural space may instead be indicated by the deep sulcus sign (Figs. 110.5 and 104.8).

Iatrogenic pneumothorax should be suspected in any patient treated by mechanical ventilation whose clinical condition suddenly deteriorates. A sensitive indicator of the development of a pneumothorax in such patients is increased peak and plateau pressures if the patient is on a volume-cycled ventilator or a decreased tidal volume if the patient is on a pressure-cycled ventilator.

TREATMENT

The treatment of iatrogenic pneumothorax differs from that of spontaneous pneumothorax in that preventing recurrence is not an issue. If the patient has minimal or no symptoms and the pneumothorax is small, the patient can be observed. However, in cases of symptomatic patients or larger pneumothoraces, practice varies significantly.[125] Simple needle aspiration can be attempted, but many patients require chest tube insertion. More recently, two studies have postulated an "early discharge strategy" in which patients with significant pneumothoraces are managed as outpatients with small-bore chest tubes attached to Heimlich valves.[126,127]

The management of patients with an iatrogenic pneumothorax secondary to positive-pressure mechanical ventilation should include urgent tube thoracostomy to reduce the risk of tension pneumothorax. If the patient continues to receive mechanical ventilation, the chest tube should be left in place for at least 48 hours after the air leak stops. Two studies have demonstrated that high-frequency ventilation does not consistently improve gas exchange or decrease air leak through the fistula.[128,129]

CATAMENIAL PNEUMOTHORAX

A catamenial pneumothorax is a pneumothorax that develops in conjunction with menstruation. It is probably underdiagnosed and underreported.[130] With catamenial pneumothorax, respiratory symptoms usually develop within 24 to 48 hours of the onset of menstruation.[131] Most pneumothoraces are right-sided, but left-sided and bilateral pneumothoraces have been reported. Catamenial pneumothoraces tend to be recurrent; patients typically have five pneumothoraces before the diagnosis is recognized.[131]

Case series report an incidence of catamenial pneumothorax in 3–6%[45] of pneumothoraces in young women, but the rate may be as high as 30–40%[46] in patients requiring surgery for recurrence or ongoing air leak.

PATHOGENESIS

The pathogenesis of catamenial pneumothorax is unclear. When the syndrome was initially described,[132] it was hypothesized that air gained access to the peritoneal cavity during menstruation and then entered the pleural cavity through a diaphragmatic defect. In a subsequent review of 28 patients who had undergone thoracoscopy, endometriosis (primarily diaphragmatic) was present in 18 and diaphragmatic perforations or nodules were present in 21.[133] It has been suggested that diaphragmatic endometriosis tissue undergoes cyclical necrosis, leading to a diaphragmatic defect.[134] These authors concluded that diaphragmatic abnormalities play a fundamental role in the pathogenesis of catamenial pneumothorax.[133,134] Alternatively, endometriosis of the visceral pleura could lead to alveolar pleural air leaks during menstruation.

TREATMENT

Any woman who has a spontaneous pneumothorax within the first 48 hours of her menstrual period should be suspected of having a catamenial pneumothorax. The treatment of catamenial pneumothorax is aimed at treating endometriosis, known or suspected, by suppressing the ectopic endometrium. This can be attempted by suppression of ovulation with oral contraceptives or by suppression of gonadotropins with danazol or gonadotropin-releasing hormone to produce a medical oophorectomy. Alternative treatments include thoracoscopy with stapling of blebs, closure of diaphragmatic defects, and parietal abrasion or pleurectomy, or pleurodesis.[130] One study reported significantly reduced recurrence by combining surgical treatment with hormonal therapy over a 4-year follow-up period.[135]

Key Points

- Patients with pneumothorax present with chest pain, perhaps due to inflammation of the pleura or pleural tethering, and dyspnea, potentially caused by expansion of the chest wall.
- Mediastinal shift on imaging indicates a difference in pleural pressures on the right and left sides without necessarily indicating tension. Tension pneumothorax signifies positive intrapleural pressure that completely collapses the lung, reduces venous return causing hemodynamic compromise, and requires emergency decompression.
- Pneumothorax in a young woman should raise the possibility of catamenial pneumothorax or lymphangioleiomyomatosis.
- In *primary spontaneous pneumothorax* (PSP) a conservative approach with no drainage may also be an option for patients with mild or moderate symptoms who can be followed as outpatients. Those with severe symptoms should be managed initially by needle aspiration followed by chest tube insertion in those who do not respond to treatment.
- Secondary spontaneous pneumothorax should be treated initially with chest tube drainage; consideration should then be directed to prevent recurrence, usually with talc pleurodesis.
- Patients with PSP are now recognized to have abnormal underlying lung, with inflammation and emphysema-like changes (blebs, bullae, and pleural porosity) that represent areas of abnormal tissue beneath the visceral pleura.
- PSP may be the first manifestation of a systemic disease (e.g., Birt-Hogg-Dubé syndrome or Marfan syndrome) that may require further investigation for associated abnormalities.
- All patients require advice on flying, scuba diving, and smoking cessation.

KEY POINTS

INTRODUCTION

Chylothorax, first described by Bartolet in 1633,[1] is defined as the presence of chyle in the pleural space. Chylothorax is uncommon, with an incidence rate less than 2.5% in a single-center retrospective study containing 876 consecutive thoracenteses.[2] Chylous effusions are often underrecognized or misdiagnosed as empyema, causing a delay in management. Finding the underlying cause is important. A multidisciplinary therapeutic approach is often necessary to control its recurrence.

OVERVIEW OF THE LYMPHATIC SYSTEM AND DRAINAGE OF THE THORACIC DUCT

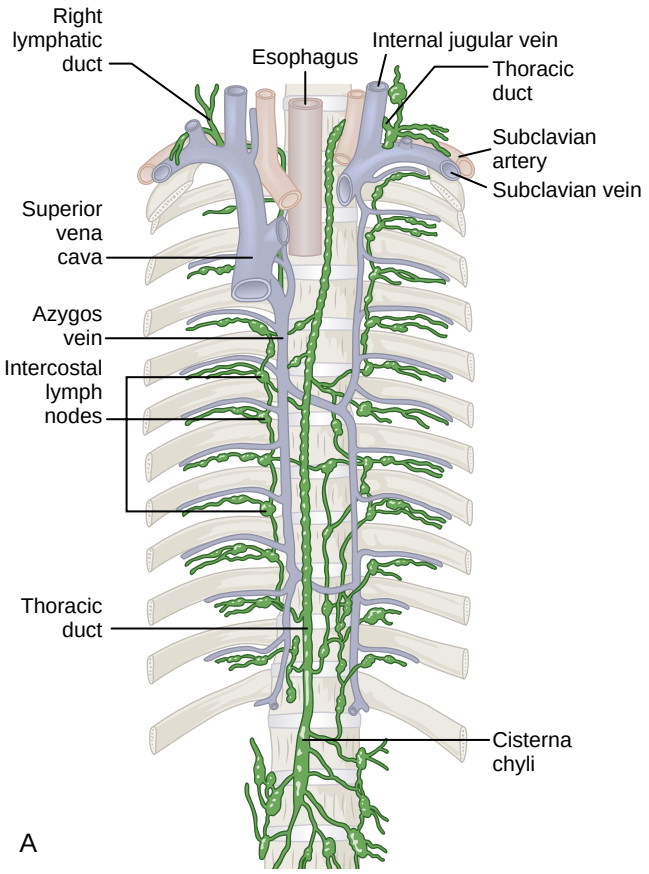
ANATOMY

The thoracic duct originates at the cisterna chyli, a dilated sac at the anterior aspect of the bodies of the first and second lumbar vertebrae receiving the chyle from the intestines, and passes through the aortic hiatus of the diaphragm on the anterior surface of the vertebral body between the aorta and the azygos vein into the posterior mediastinum. The thoracic duct then ascends extrapleurally along the right side of the anterior surface of the vertebral column. At the level between the bodies of the fourth to sixth thoracic vertebrae, the duct crosses to the left side of the vertebral column and continues cranially to enter the superior mediastinum along the left border of the esophagus. Here it passes behind the aortic arch and then runs posterior to the initial segment of the left subclavian artery (Fig. 111.1A–B). The thoracic duct may ascend as multiple channels[3–5] or as a plexiform structure[3,5–7] instead of as a single duct. Once the thoracic duct passes the thoracic inlet, it arches above the clavicle and descends anterior to the first part of the left subclavian artery. The thoracic duct may terminate into the venous system either as a single channel or as multiple channels[5,7–10]; in a small proportion of cases, the thoracic duct may terminate on the right side (6%).[7] From a systematic review summarizing studies in the past century, the thoracic duct most commonly enters the venous system at the internal jugular vein (46%), contrary to the traditional belief, then at the junction of the internal jugular and subclavian veins, the jugulovenous angle (32%), and lastly at the subclavian vein (18%).[7] The duct itself has several valves at the lymphovenous junction that prevent the reflux of blood into the duct.[7,11] The above classical description of the thoracic duct pathway is only present in about 50–65% of the population,[3,12] and various anatomic variations exist.[7]

COMPONENTS OF CHYLE

Chyle, the fluid drained in the thoracic duct, consists of lymph and emulsified fats from the intestine. Most dietary lipids are transported via the lymphatics,[13] and 75% of the body's lymph is drained by the thoracic duct.[7] Chylomicrons are formed in the intestine and are then transported to the cisterna chyli and thoracic duct. On the other hand, the majority of absorbed *medium-chain triglycerides* (MCTs) are systemically absorbed and transported in the portal vein to the liver,[14] and less than 1% is transported via the thoracic duct.[15]

Chyle is alkaline in nature[16–18] and conventionally said to be bacteriostatic,[19] though this has not been formally assessed. Chyle is also not believed to be an irritant and is



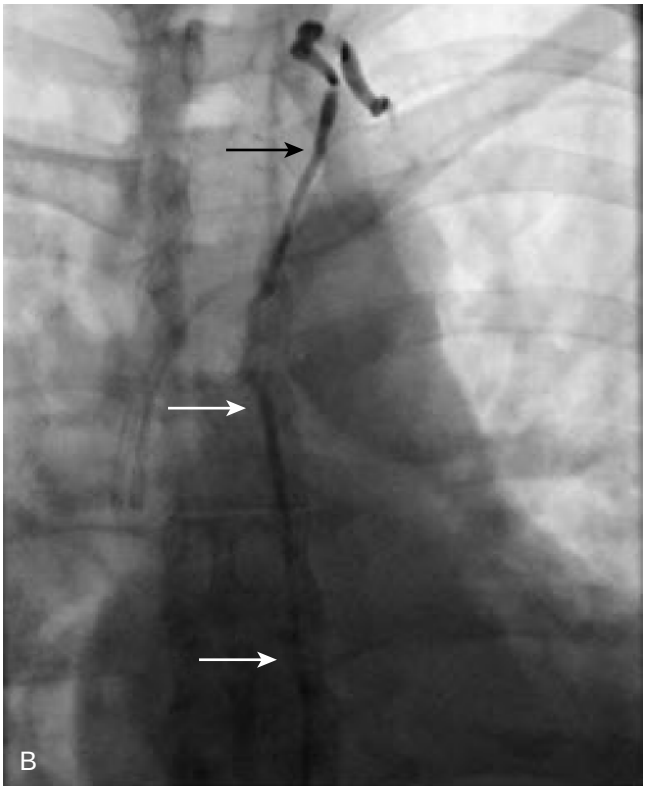


Figure 111.1 Normal anatomy of the thoracic duct. (A) The thoracic and right lymphatic ducts. (B) Normal thoracic duct (*arrows*) in a patient undergoing lymphangiography, who developed chylous effusion postesophagectomy. No leak was detected on imaging. The chylothorax resolved after lipiodol lymphangiography, octreotide treatment, and implementation of a fat-free diet. (A, Modified from Strandring S, ed. *Gray's Anatomy*. 40th ed. London: Elsevier; 2008.)

unlikely to induce pleural thickening. It contains abundant immunoglobulins, white blood cells (mostly T lymphocytes),[17,20] protein (20 to 40 g/dL),[17,18,21] and electrolytes (similar in content to serum).[17,18]

FLOW OF CHYLE

The thoracic duct normally conveys 1500 to 2500 mL of chyle daily[16,17,22]; ingestion of fat can increase its flow by as much as tenfold for several hours.[16,23] Ingestion of water (but not protein or carbohydrate),[24,25] physical activity, and increases in interstitial fluid pressure can also increase the lymph flow.[17] In contrast, the flow rate can drop to 14 mL/hour if the patient is immobile, starved, receiving continuous nasogastric suction, or when the pressure of the lymphovenous system is raised.[17] Numerous substances, such as octreotide and somatostatin, can slow the flow of collecting lymphatics and the thoracic duct.[25,26]

ETIOLOGY AND CLINICAL MANIFESTATIONS OF CHYLOTHORAX

ETIOLOGY OF CHYLOTHORAX

Chylothorax can form whenever there is disruption of the integrity of the lymphatic wall along the thoracic duct and its tributaries (Table 111.1).

Chylothorax can result from traumatic and nontraumatic causes; their relative frequencies vary among series. In a summary of five separate series from the 1960s and 1980s totaling 143 patients, more than half of chylothoraces were caused by tumors, especially lymphoma, followed by trauma.[1,27–31] In a single tertiary institute series of 203 patients containing adult and pediatric patients, trauma/surgery were the most common (50%) causes compared to nontraumatic causes (44%).[32] No recent large reports exist on the contemporary epidemiology of chylothorax.

Traumatic Chylothorax

Traumatic chylothorax is now more likely to be caused by iatrogenic injury (especially postoperative) than by physical injury.[32,33] The anatomic variation and the multiple collateral channels make the thoracic duct vulnerable to injury from surgical procedures involving the esophagus,[34,35] cardiovascular system,[36,37] lungs,[38–40] spinal cord,[41–44] neck,[45] and upper abdomen.[46] Esophagectomy in adults and congenital heart surgery in the pediatric group are commonly associated with postoperative chylothorax,[32,47] with an incidence of 0.2–4.0%[34,35,48,49] and 0.9–6.6%,[36,50–57] respectively. Squamous cell carcinoma, low body mass index, preoperative chemoradiotherapy, and high intraoperative fluid balance are risk factors for postesophagectomy chylothorax.[58] Chylothorax can also present after pulmonary resection, with an incidence rate of 1.4–4.0%,[39,40,59] and bilateral chylothoraces may develop following bilateral neck dissection.[60] Chylothorax may also develop following surgical repair of congenital diaphragmatic hernia in neonates (incidence

Table 111.1 Common Causes of Chylothorax

Type	Cause	Examples
Traumatic	Iatrogenic	Surgical procedures along the thoracic duct (e.g., esophagectomy, lung resection, CHD repair, neck or thyroid surgery, spinal surgery) Vascular intervention (e.g., SVC or SCV cannulation, pacemaker implantation) Thoracic irradiation
	Non-iatrogenic	Penetrating injury Blunt injury Spine fracture or hyperextension, rib fracture
Nontraumatic	Malignancy	Lymphatic obstruction or infiltration (e.g., lymphoma, metastatic lymphadenopathy, lung cancer) SVC obstruction
	Increased venous pressure	CHF, cardiomyopathy, restrictive pericarditis, SVC or SCV thrombosis
	Lymphatic obstruction	Retrosternal goiter, TB, sarcoidosis, fibrosing mediastinitis, post-thoracic irradiation
	Lymphatic disorders	LAM; Gorham, Down, Noonan, and yellow nail syndromes
	Transdiaphragmatic movement of fluid	Chylous ascites

CHD, congenital heart disease; CHF, congestive heart failure; LAM, lymphangioleiomyomatosis; SCV, subclavian vein; SVC, superior vena cava; TB, tuberculosis.
Data from Skouras V, Kalomenidis I. Chylothorax: diagnostic approach. *Curr Opin Pulm Med*. 2010;16(4):387–393.

4.6%), especially if patch repair or extracorporeal membrane oxygenation is employed.[61,62] Surgical procedures that involve the posterior mediastinum (e.g., esophageal surgery) and mobilization of the left subclavian artery are particularly prone to postoperative chylothorax. Thrombosis of the *superior vena cava* (SVC) or subclavian vein after catheterization[63–69] may lead to chylothorax due to increased venous pressure and obstruction of chyle flow. Direct injury to the thoracic duct by needle puncture may also cause chylothorax.

Although penetrating injury may precipitate chylothorax[70] by direct thoracic duct injury,[71] blunt chest injury,[70,72,73] especially when associated with hyperextension, dislocation or fractures of the spine, or posterior ribs,[32,74–77] can also sever the thoracic duct. Vigorous coughing,[78] vomiting,[79] excessive stretching while yawning[80] (especially after a fatty meal[81]), and childbirth[82] have been associated with the development of chylothorax.

Nontraumatic Chylothorax

Malignancy is the most common nontraumatic cause of chylothorax.[32,83] Lymphoma and metastatic carcinomas can result in lymphadenopathy or metastatic deposits in the mediastinal region obstructing or infiltrating the thoracic duct with a resultant chyle leak.[84–87] SVC obstruction due to malignancy can also lead to chylothorax.[88]

Benign causes of chylothorax can include various congenital and acquired disorders. *Lymphangioleiomyomatosis* (LAM); lymphatic dysplasia syndromes,[89,90] including yellow nail[91] and Gorham syndromes[92–94]; Down syndrome; Noonan syndrome[89,95–100]; and syndromes due to other chromosomal aberrations[99,101] are associated with lymphatic maldevelopment and chylothoraces. Other acquired benign diseases can impede chyle flow by physical obstruction via lymphadenopathy (e.g., tuberculosis[102] and sarcoidosis[103]) or development of a retrosternal goiter.[104] Although uncommon, conditions that raise venous pressure into which the thoracic duct drains (e.g., mediastinal radiotherapy,[32,105,106] amyloidosis with restrictive cardiomyopathy,[107,108] and heart failure)[32,109,110] can potentially cause chylothoraces. Chylothorax can present in patients with liver cirrhosis due to various mechanisms.[111–114] Numerous other rare causes not covered account for the remaining small percentage of all chylothoraces.[16] In about 5–10% of cases, no identifiable cause can be found.[32]

Specific syndromes and conditions related to chylothorax are discussed at ExpertConsult.com.

CLINICAL MANIFESTATIONS

Chylothorax may present in a patient with symptoms related to a pleural effusion or incidentally during the workup of another disease (especially lymphoma).[33] Breathlessness is the most common symptom with large effusions. Chest pain and fever are uncommon, presumably because of the nonirritative nature of chyle.[16] The classic milky appearance of the pleural fluid (often described as looking like a vanilla or strawberry milkshake) should alert the clinician to the possibility of chylothorax; however, not all chylothoraces are milky in appearance. It is important to remember that a clear effusion can also be a chylothorax.

The laterality of effusion depends on the etiology and site of chyle leak. Defects of the thoracic duct between T4 and T6 levels may produce bilateral chylothorax, whereas lesions below and above this point may lead to right and left chylothoraces, respectively.[84] The rapidity of clinical decompensation depends on the rate of fluid leakage and duration of chyle loss.[33,84] Symptoms may be noted within 1 or 2 days after major thoracic duct damage but may be delayed by 2 to 7 days in case of minor injury.[84] Chyloma, a collection of chyle generally formed in the mediastinum, may produce symptoms due to pressure on vital structures before it ruptures into the pleural space as a chylothorax.[33,77,149–154] For persistent pleural effusions of undetermined cause, chylothorax should be considered in the differential diagnosis.[29]

Specific Syndromes/Conditions Related to Chylothorax

Lymphangioleiomyomatosis. LAM is a multisystem disease of women characterized by proliferation of abnormal smooth muscle–like LAM cells leading to cystic lung destruction and extrapulmonary disease (e.g., renal angiomyolipomas).[115,116] The obstruction of lymphatic vessels and lymph nodes in the mediastinum by infiltration of LAM cells is believed to be the reason for chyle leak.[117,118] The incidence of chylothorax in LAM ranges from 0–48%, with a rate of 21% in the largest registry containing 230 patients.[118–121] Chylothorax is considered one of the characteristic clinical features of LAM in the latest practice guideline[122] and may occasionally be the initial presentation.[119,121] From observations, chylothorax arises more commonly in sporadic LAM than in tuberous sclerosis complex–associated types of LAM.[119,123] Dyspnea and cough are common symptoms.[124] Most chylothoraces are unilateral (76%) and right sided (63.2%).[124] The size of the chylothorax does not correlate with the extent of lung involvement,[125] but most are large enough to require intervention.[118] Typical clusters of HMB45-positive LAM cells can also be found in the chylous pleural fluid.[126–130] (See Chapter 97.)

Hepatic Cirrhosis. Chylothorax and chyloascites can present in patients with liver cirrhosis. High portal venous pressure can increase thoracic duct lymph flow and pressure,[111] eventually leading to rupture of dilated serosal lymphatic vessels and the creation of chylothoraces.[112] Flow of chylous ascites across defects in the hemidiaphragm into the pleural cavity can give rise to chylothorax, which is usually right-sided.[113,114] In a retrospective cohort involving 1038 cirrhotic patients, 49 (4.7%) and 3 (0.3%) patients had hepatic hydrothorax and chylothorax, respectively.[111] Although uncommon, coexisting chylothorax should be considered in cirrhotic patients with recurrent pleural effusion.

Fetal and Neonatal Chylothorax. Fetal chylothorax, sometimes termed primary fetal pleural effusion or congenital chylothorax, is rare with an incidence of 0.005–0.03% of newborns.[131–134] Although rare, chylothorax is the most common cause of neonatal pleural effusion.[135–137] It is usually idiopathic[47] but can be associated with nonimmune hydrops fetalis (3.2–66.7%),[133,138] congenital malformations,[132,139] lymphatic disorders, congenital syndromes, and genetic mutations.[140–145]

Fetal chylothorax usually presents as bilateral pleural effusions on prenatal ultrasound screening and as respiratory distress after delivery.[132–134] Chylothorax can cause respiratory depression within the first week, particularly in the first 24 hours after birth.[146,147] The presence of lymphocytic (>80%) effusion in neonates without alternative cause found is highly suggestive of chylothorax.[95,148]

Prolonged drainage of chyle, especially in postoperative chylothorax, may lead to multiple complications, including hypolipidemia,[155] hypovolemia,[132,156] electrolyte imbalance,[156,157] metabolic acidosis,[1,44] depletion of trace elements,[158] venous thrombosis,[159–161] and immunodeficiency from ongoing loss of T and B cell lymphocytes.[50,84,131,163–167] Drugs (digoxin,[168] cyclosporin A,[169,170] and possibly amiodarone[171,172]) normally carried in the chyle may leak into the pleural space, causing subtherapeutic plasma levels. The incidence and clinical significance of most of these complications have not been extensively studied in a prospective way.[162]

DIAGNOSIS

Chylothorax should be suspected for any pleural effusion in a compatible clinical context or for any drainage of milky fluid.

FLUID APPEARANCE

The milky fluid appearance should not be expected in all chylothoraces; in fact, this classic appearance presents in only 44% of cases[148,173] (Fig. 111.2A). The turbidity depends on the ingested fat contents, and chyle leak may not look milky if the patient is fasting.[174] A chylothorax may have a serous appearance when caused by diseases that cause transudative effusions.[2,173,175,176] A bloody appearance may point towards trauma or LAM as the underlying cause.[150,173,124,125] A change to a milky appearance after the resumption of diet from a fasting state (or consumption of high-fat diet)[75,177] or a bluish-green discoloration after ingestion of a fatty meal mixed with methylene blue may establish the diagnosis of chylothorax. However, the latter method may not be helpful in posttraumatic chylothorax because discoloration of pleural fluid can also be observed in patients with esophageal perforation.[84]

BIOCHEMICAL ANALYSIS

Confirmation of the presence of chylomicrons in pleural fluid by lipoprotein electrophoresis is the gold standard test to define chylothorax.[33] However, lipoprotein electrophoresis is not widely available,[84,178] and Sudan III staining to detect the presence of oil is not sufficiently specific.[33,73,84] Instead, pleural fluid *triglyceride* (TG) levels greater than 110 mg/dL (>1.24 mmol/L) are virtually diagnostic of chylothorax, while pleural fluid TG levels less than 50 mg/dL (<0.56 mmol/L) can rule out chylothorax in 95% of cases.[29] High TG levels may be misleading in two circumstances. In patients with hypertriglyceridemia, high TG values in pleural fluid may not indicate chylothorax; in these patients, using fluid/serum TG ratio greater than 1 as another diagnostic test for chylothorax may avoid this false-positive pitfall.[114,179] High TG level can also be seen in pseudochylothorax; thus, a simultaneous cholesterol measurement is also suggested.[180] Low TG levels in chylothorax may be found during fasting, a malnourished state, or the presence of a second pathology contributing to the effusion.[33,114,148,173] In situations in which chylothorax is suspected but the TG level is low or in the borderline range (50 to 110 mg/dL), one can measure chylomicrons[29,33,173,178] or monitor for a change in the fluid color and recheck the fluid TG level after administration of a high-fat enteral meal.[148,162]

The chylous fluid is usually exudative based on the protein criterion of Light's criteria,[2,181] but the lactate dehydrogenase level is often low. An elevated lactate dehydrogenase level in chylothorax should raise concerns of coexisting inflammatory or lymphomatous conditions driving pleural fluid production.[2,114,173] Some (14%) chylothoraces are transudative[173] and are usually due to concurrent conditions known to produce transudates,[114] especially cirrhosis and nephrotic syndrome.[107] Chylothorax is typically lymphocytic if the effusion is due simply to leakage from the thoracic duct.[2] Alternative, or concurrent, causes should be considered if the fluid is neutrophilic. Pleural biopsy or thoracoscopy is usually not indicated in the workup of patients with a chylothorax because the pathology primarily involves the thoracic duct, not the pleura.

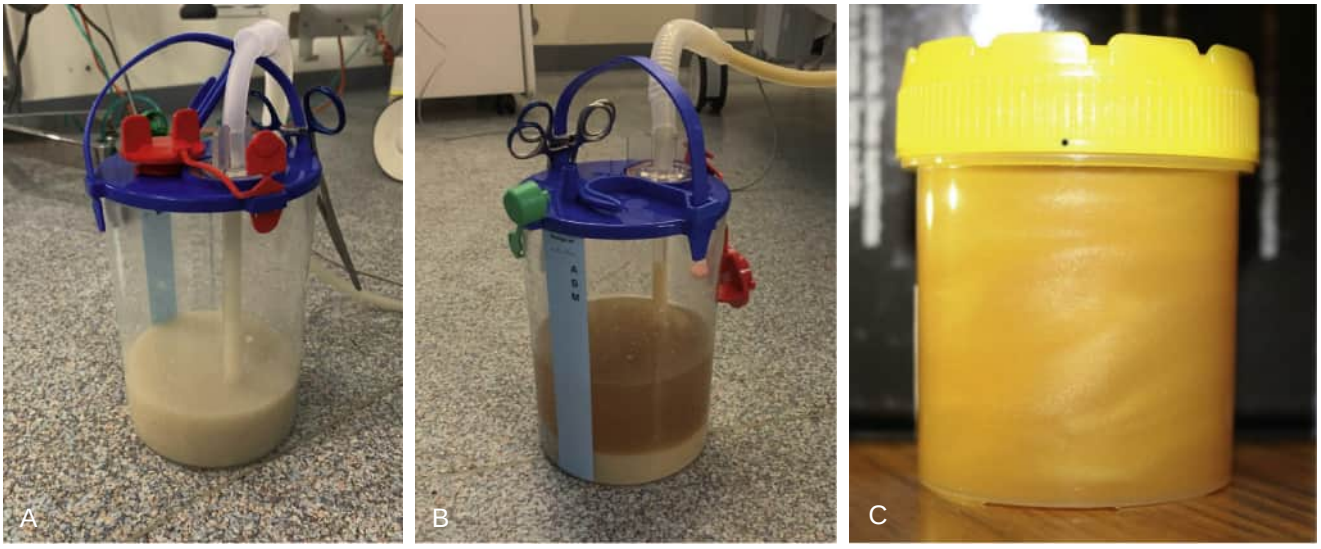

Figure 111.2 Milky-appearing pleural fluid collections. (A) Chylothorax. This pleural fluid was drained from a patient with chylothorax due to lymphoma, showing a homogeneously milky appearance. If this fluid were allowed to sit overnight, there would be no evident change in appearance. (B) Empyema. Pleural fluid drained from a patient with empyema allowed to sit overnight, showing a relatively clear supernatant with a sedimented bottom layer of cells and debris. (C) Pseudochylothorax. Pleural fluid collected after drainage of a pseudochylothorax, showing an opaque appearance with a satin-like sheen.

Two other causes of turbid pleural fluid, empyema and pseudochylothorax, must be considered and differentiated from chylothorax. In empyema, the milky appearance is caused by suspended leukocytes and debris, which will sediment upon centrifugation, leaving a clearer supernatant (Fig. 111.2B). In chyle and pseudochyle, the milky appearances are caused by TG or cholesterol (or lecithin-globulin complexes), respectively, and the supernatant will remain cloudy after centrifugation. Rarely, leakage of *total parenteral nutrition* (TPN) from a central line into the pleural space can present as a milky pleural effusion that also will not clear on centrifugation.[182–184]

IMAGING

Ultrasound is sensitive for the detection of pleural fluid but cannot identify effusions as chylous.[185] Cross-sectional imaging, including *computed tomography* (CT) and magnetic resonance imaging, may sometimes indicate the cause of chylothorax.[33,175] CT can sometimes show low-density collections consistent with the presence of fat (Video 111.1). Magnetic resonance imaging can help identify the thoracic duct,[186] and chyle often appears with high signal on T2-weighted imaging.[194]

To identify the site of chyle leak, lymphatic imaging such as lymphangiography or ^{99}Tc lymphoscintigraphy can be used.[187–190] In conventional lymphangiography, particulate substances are injected into the web spaces of the foot to opacify draining lymphatics, which can then be injected with oil-based contrast (Lipiodol). Direct inguinal lymph node injection is a more efficient technique that involves ultrasound-guided Lipiodol injection into the sinus of an inguinal node (eFig. 111.1). Following either injection technique, serial fluoroscopic imaging is performed to track the contrast to the cisterna chyli and thoracic duct. When opacified, the thoracic duct can be accessed with a needle, then threaded with a wire and microcatheter. Contrast is injected into the microcatheter within the thoracic duct, revealing the site of the chyle leak.[189] Noncontrast CT following lymphangiography may identify the site of chyle leak in up to 75% of cases.[190] Lymphangiography may have additional therapeutic value as described later.[182] Lymphoscintigraphy requires an intradermal injection of a radioactive tracer, Tc-99m-labeled albumin, followed by imaging with a gamma camera.[187,188] Focal abnormal uptake of radiotracer can reveal the site of the leak. Combination with targeted single-photon emission CT can help define the specific anatomic site.[191,192]

Novel magnetic resonance techniques also provide potential noninvasive investigation.[188] High-resolution T2-weighted imaging can delineate the thoracic duct due to its high contrast.[193] Dynamic contrast magnetic resonance lymphangiography is a new technique that involves bilateral ultrasound-guided punctures of the inguinal nodes and intranodal injection of gadolinium-based contrast.[188] Dynamic imaging and high-resolution magnetic resonance angiography sequences obtained in this manner can provide detailed anatomy of the lymphatics and the lymph flow within and, in some cases, identify the site of chyle leak.[188,194]

TREATMENT

GENERAL APPROACHES

The management of chylothorax may vary among patients and is partly governed by the etiology, availability of therapeutic options, physicians' preference, overall condition of the patient, anatomy of the thoracic duct, and other clinical factors such as the rate of chyle leak. The lack of high-quality evidence explains the lack of formal structured treatment recommendations.[16,162] A combination of treatment modalities is often used[174] (Table 111.2).

DRAIN THE PLEURAL FLUID

The level of breathlessness varies and in part relates to the size of the chylothorax. With large chylothoraces, pleural fluid drainage for symptom relief is often necessary. Every attempt should be made to avoid prolonged continuous drainage, which can result in chyle loss and resulting malnutrition and immunosuppression.

In refractory cases, a pleuroperitoneal shunt can relieve symptoms, minimize chyle loss,[195] and reduce the need for TPN.[196] The presence of ascites is a relative contraindication for pleuroperitoneal shunt placement.[197] Drain patency should be checked regularly because the shunt is easily clotted due to the high quantity of fibrinogen in the chyle.[150]

Indwelling pleural catheters (IPCs) in refractory chylothoraces have been reported in several retrospective series.[198–200] Although there have been concerns of chronic nutritional loss through the intermittent drainage via the IPC, there is no evidence to support this suspicion.[201] Instead, the use of IPCs may negate the need and risks of repeated pleural interventions.[200] Caution must still be exercised, and IPC should only be considered in selected cases given the paucity of prospective and randomized clinical data.

REDUCE THE FLOW OF CHYLE AND CLOSE THE DEFECT

Reducing or stopping chyle flow in the thoracic duct can promote healing of the defect.

Table 111.2 Management of a Chylothorax

Drain the pleural fluid to improve respiratory symptoms ▪ Thoracentesis and tube thoracostomy (short term only) ▪ Pleuroperitoneal shunt ▪ Indwelling pleural catheter
Reduce the flow of chyle and close the defect ▪ Dietary management: fasting ± TPN, low-fat or fat-free diet with MCT supplementation ▪ Drugs: octreotide, somatostatin, etilefrine, midodrine ▪ Minimally invasive treatments: lymphangiography, TD embolization, TD disruption ▪ Surgery: TD ligation
Replace chyle components and nutrients
Treat the underlying disease
Obliterate the pleural space: pleurodesis

MCT, medium-chain triglyceride; TD, thoracic duct; TPN, total parenteral nutrition.

Dietary Management

There is no high-quality evidence or formal guidelines on the optimum method of dietary management.[174,203] Enteral nutrition with high-fat content can increase lymph flow and should be avoided. A low-fat or fat-free (<5 kcal per serving with MCT supplementation) diet may be tried to reduce the flow of chyle[16,17,174,204,205] (eFig. 111.2).

For patients with short-term self-limiting causes of chyle leak (e.g., postsurgery or trauma), a short period of fasting with TPN may significantly minimize chyle flow and enhance healing. When TPN was given to patients with postoperative chylothorax (including patients after esophagectomy) who were only allowed to take clear oral fluid, 67% of thoracic lymph leaks resolved.[206]

The latest systematic review analyzing 31 retrospective case series found that 72% of chylothoraces successfully resolved without surgical intervention. TPN has a slightly lower success rate compared with the low-fat/fat-free diet, but no statistically significant difference in the rate of resolution of chyle leak.[174] If effective, the low-fat/fat-free diet should be continued for at least four weeks after control of chylothorax before returning the patient to a normal diet.[51]

Drugs

Somatostatin and its analogue octreotide can slow chyle flow.[207] The mechanism is unclear, but a reduction of gastrointestinal motility, blood flow, and secretion[208–215] may contribute.[207,212,216] The drugs are commonly used as an adjunct to dietary management in congenital and postoperative chylothorax, but the evidence is largely limited to pediatric reports.[207,216–218] Both agents are considered safe with few side effects (e.g. flushing, nausea, diarrhea).[207,208,216,219,220] Octreotide is usually the treatment of choice because of its longer half-life, greater potency, and ability to be delivered subcutaneously (or intravenously).[207] However, there is no practice recommendation for either agent at the moment.[221] Variable dosage and titration regimens have been reported,[207,216,218,221–225] and 5 to 6 days of treatment may be required to observe an effect.[216,226]

Etilefrine (a sympathomimetic agent)[17,227–231] and midodrine (an α-1 adrenoreceptor agonist)[232] can induce vasoconstriction of the lymphatic system and reduce chyle flow, especially in refractory postoperative and idiopathic chylothoraces.[233–235] Midodrine is more readily available and may be a better option than etilefrine. However, the efficacy of these agents needs further verification.

Conservative measures (e.g., dietary management and pharmaceutical interventions) should be attempted but have a variable (20–80%) success rate in slowing down chyle flow in traumatic chylothorax. A high rate of chyle leak (e.g., output >500 to 1000 mL/day) predicts failure of these interventions.[17,49,217,236,237]

Minimally Invasive Treatments: Lymphangiography, Embolization, and Disruption

There are multiple minimally invasive treatments for high-output chylothorax, including lymphangiography, thoracic duct embolization, and thoracic duct disruption.[33,189,238–244] These have much lower rates of morbidity and mortality than surgery.[189]

Lymphangiography with direct injection of Lipiodol into the inguinal lymph node has been shown to be useful not only in imaging, but also in treating high-output chylothorax.[189,238,239] The therapeutic effect may be due to a sclerosing or other direct action of the Lipiodol. A meta-analysis from Kim et al. demonstrated a clinical success rate of 56.6% (despite a high technical success rate of 94.2%).[242] Although the clinical efficacy is relatively low, watchful waiting after lymphangiography can be considered before proceeding to more invasive treatments, especially if the chylothorax has a low output (<500 mL/day).[242,245]

Thoracic duct embolization (TDE) is an image-guided procedure designed to occlude the thoracic duct. After the cisterna chyli is opacified with Lipiodol, it is percutaneously accessed with a wire, and a microcatheter is inserted over the wire to the thoracic duct. Contrast is injected through the microcatheter to demonstrate the chyle leak. Embolic agents include coils, alcohol, glue (histoacryl), or a combination of these (Fig. 111.3).[190,244] In patients with a hypoplastic or absent cisterna chyli, the thoracic duct can be accessed either through a transabdominal approach similar to a cisterna chyli puncture or a retrograde catheterization following a puncture of the left subclavian vein.[189] The technical success of TDE, reported at 63.1%, is limited by the difficulty in cannulating the cisterna chyli or thoracic duct.[242] However, if technically possible, TDE has a high success rate of 79.4%.[242]

Thoracic duct disruption is considered when the thoracic duct cannot be catheterized. The thoracic duct is disrupted by numerous passes of a needle through it or the cisterna chyli within the upper abdomen, limiting the flow of lymphatics up to the site of the leak.[243] The explanation for the effect of the needle disruption is unknown but is speculated to involve healing after the needle injury. The clinical success rate of thoracic duct disruption is 60.8%.[242]

The overall complication rate for interventional procedures is low at around 0–2%.[191] There is no reported associated mortality. Rare complications include infection, pulmonary artery embolization with Lipiodol, and chylous ascites.[189,244]

Surgery: Thoracic Duct Ligation

Thoracic duct ligation (TDL) is a surgical approach that should be the last resort to stop the chyle leak if TDE or thoracic duct disruption is unavailable or fails. It can lower the mortality[35,246,247] and complication rates[148] in traumatic chylothorax. Although the benefit of TDL may be maximized if it can be done early, conservative treatments should be initiated first before proceeding to surgery.[84,156,162,247,248] Indications for early surgical referral have been proposed[249] but have not been prospectively validated.[16] In a systemic review, patients with greater peak 24-hour drainage rates were more likely to undergo surgical intervention.[174] The decision to proceed to TDL must balance considerations of nutritional status, disease prognosis, and expected success rate of conservative treatment.[16,250]

Accurate localization of the thoracic duct and its leakage site is essential to avoid extensive dissection and exacerbation of chyle leak during TDL.[33] Preoperatively, radiologic localization should be performed.[251–253] Intraoperatively, localization can be enhanced by enteral

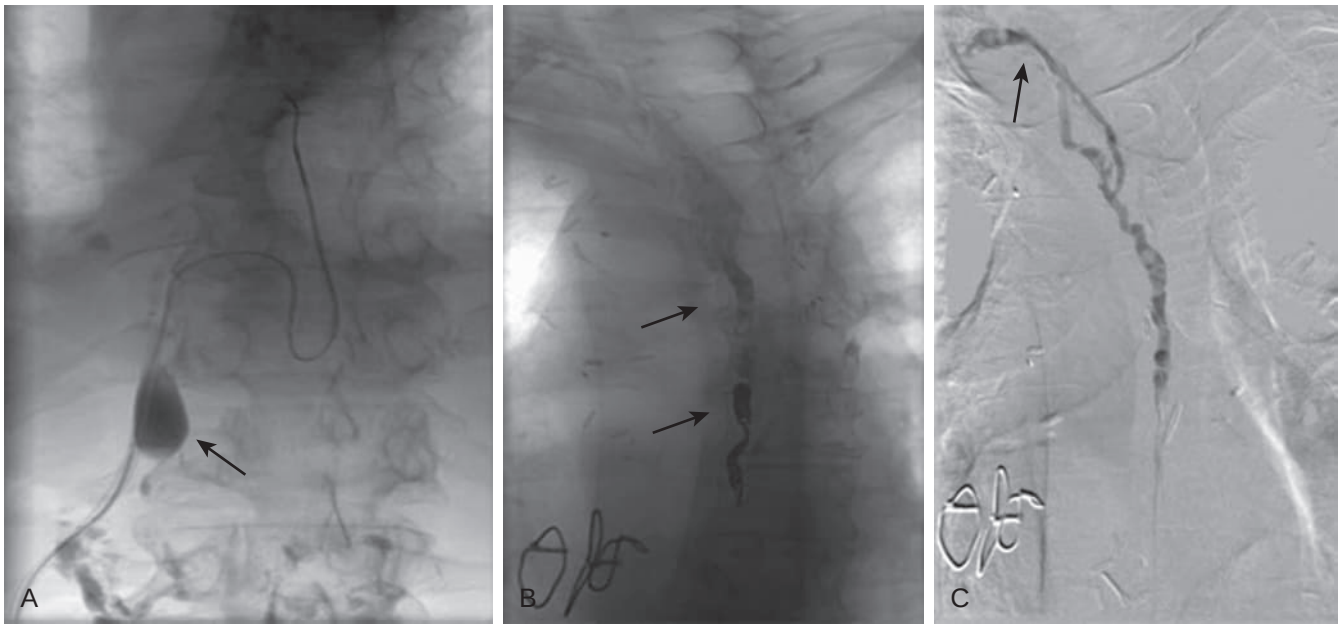

Figure 111.3 Thoracic duct embolization. (A) A microcatheter has been placed directly into the cisterna chyli (*arrow*) by a percutaneous route. (B) Coils and glue (*arrows*) are placed in the *thoracic duct* (TD) to occlude the TD inferior to the site of the leak. (C) TD leak in the thoracic inlet with pooling and extravasation of contrast (*arrow*). The terminal TD entering the subclavian vein is not seen above the leak.

feeding of approximately 50 to 60 mL of cream to stimulate the flow of chyle.[33,75,254] The duct is ligated above and below the site of the leak. If the duct cannot be identified,[84,255,256] mass ligation of all tissue between aorta, spine, esophagus, and pericardium above the diaphragmatic hiatus can be performed.[84] It halts the flow from any unidentified accessory ducts and offers a 90% success rate in resolving a chylothorax.[150,257–259] Lymph flow may be temporarily obstructed proximal to the ligated site until new collateral channels are formed that carry the chyle around the ligated site of the leak, which may require 2 to 3 weeks.[156,260]

REPLACE CHYLE COMPONENTS AND NUTRIENTS

Complications may arise after prolonged drainage of chylothorax and loss of chyle components.[17] No high-quality evidence exists to recommend replacement of other chyle components (including immunoglobulins, anticoagulation factors, and albumin).[162,261,262] Supplementation with MCTs is necessary to replace the essential fatty acids when adopting the no-fat diet. Octanoic acid may be the preferable MCT substrate.[15] However, long-term use of pure MCTs may result in linoleic acid deficiency, reduction in vitamin E status, and adverse gastrointestinal symptoms.[14,263] Input from an experienced dietitian is desirable.[15,264] The reinfusion of chyle back into the systemic circulation is not supported by evidence, has risks of anaphylaxis,[265] and is technically difficult.[266,267]

TREAT THE UNDERLYING DISEASE

Successful control of the underlying etiology of the chylothorax is the ideal management for chylous effusions. The likelihood of success depends on individual disease.[268–272]

Mediastinal Lymphadenopathy (Especially Lymphoma) and Obstructive Mediastinal Structures

Removal of obstructive lesions along the thoracic duct may help to restore the chyle flow. Chylothorax can resolve after oncologic treatment for malignant mediastinal or SVC lesions,[87,88,268,271] excision of retrosternal goiter,[104] corticosteroids for sarcoidosis,[273] or anticoagulation and thrombolysis for SVC thrombosis.[68,274,275]

Lymphangioleiomyomatosis

The mammalian target of rapamycin inhibitors, sirolimus and everolimus, are now standard therapies for LAM.[117,124,125,276–278] A systematic review found that sirolimus is effective in all LAM patients with chylothorax, with complete and partial resolution in 87% and 13% of patients, respectively,[124] although the resolution may take a few months.[276,279] Treatment can significantly reduce the need for therapeutic pleural drainage.[276]

Pleurodesis is the second most commonly used treatment option for LAM-related chylothorax, with a favorable outcome in 56.8%.[124] Lung transplantation in LAM is not contraindicated after pleurodesis, though the complication rate (especially for bleeding) is higher. Hence the decision to perform pleurodesis should be undertaken together with a transplant surgeon.[281]

Hepatic Cirrhosis

Correction of portal hypertension in cirrhosis may decrease thoracic duct flow[282–284] and reduce chyle leak. Both surgical portosystemic shunt[285,286] and transjugular intrahepatic portosystemic shunt[287–290] can decrease the portosystemic pressure gradient, reduce hepatic and gastrointestinal lymph flow, and promote healing of the thoracic duct. Pleurodesis is

often unsuccessful in chylothorax due to the rapid fluid reaccumulation, especially in cirrhosis-related cases.[291]

OBLITERATE THE PLEURAL SPACE

The pleural space can be obliterated through a pleurodesis procedure to prevent accumulation of chylothorax. It is useful when conservative treatment fails and TDL is not feasible.[292] The success rate of thoracoscopic talc pleurodesis was reported to be 100% in patients with lymphoma-related chylothorax who were refractory to chemotherapy and radiotherapy.[293] Different pleurodesis agents have been studied, with talc more commonly used in adults,[294,295] fibrin glue in postoperative patients,[256,296–298] and OK-432 in the fetal/pediatric group.[299–303] Surgical techniques may also be considered in cases of complicated chylothorax and may include pleural decortication with pleurodesis.[84,255]

A brief discussion of the prevention of chylothorax during thoracic and neck surgery and on long-term outcomes is available at ExpertConsult.com.

PSEUDOCHYLOTHORAX

Pseudochylothorax, also known as cholesterol pleurisy or chyliform effusion, is defined as the presence of cholesterol crystals in the pleural space. *Tuberculosis* (TB) (including those cases treated with artificial pneumothorax) and *rheumatoid arthritis* (RA) underlie most cases of pseudochylothoraces.[319,320] Other reported associations include paragonimiasis,[321,322] echinococcosis,[323] hydatidosis,[324] malignancy,[320] and coronary artery bypass surgery.[325] Previous successful treatment for TB does not preclude the development of pseudochylothorax.[320]

PATHOPHYSIOLOGY

Although pseudochylothorax was first reported over a century ago, its precise pathogenesis remains unknown. A majority of patients have a gradual onset of their effusion over several years. The pleura is thickened and sometimes calcified.[85,326,327] A minority of patients (≈20%) have a recent onset effusion without pleural thickening.[319,328,329] It is often hypothesized that the cholesterol crystals are formed due to the degeneration of cellular lipid membranes in long-standing pleural fluid and become trapped in the poorly vascularized and fibrotic pleural space.[85] However, this belief has been challenged in patients without pleural thickening.[319,329]

CLINICAL MANIFESTATION

Pseudochylothorax may develop in patients with long-standing pleural effusions. Pleural thickening is a prominent feature in TB-related, but not in RA-related, pseudochylothorax.[319] Breathlessness is common but may not be noticed in up to one-third of patients, presumably because of its gradual onset.[326,330]

The pleural fluid from a pseudochylothorax is milky (sometimes turbid, cloudy, or with a "motor-oil" appearance) with a satin-like sheen due to the high levels of cholesterol or lecithin-globulin complexes[16] and cholesterol crystals[326] (Fig. 111.2C). Complications are uncommon but may include infection (reactivation of TB, fungal), fistula formation (bronchopleural, pleurocutaneous), poor lung function, and poor quality of life.[85]

DIAGNOSIS

Thoracentesis is needed to establish the diagnosis. The demonstration of cholesterol crystals with a typical rhomboid appearance in the pleural fluid is considered confirmatory, although its absence does not exclude pseudochylothorax. Alternatively, a high fluid cholesterol level greater than 200 mg/dL may serve as a cutoff to diagnose pseudochylothorax, but it may miss 25% of cases.[319] Instead, a cholesterol/TG ratio greater than 1 has a higher sensitivity of up to 97.4% and helps to differentiate from chylothorax.[319] The cholesterol level usually decreases after serial aspiration of the pleural fluid[326]; therefore it should be tested on the first pleural fluid sample. Pleural fluid TG levels can be elevated in pseudochylothorax, which mimics chylothorax. Adding 1 to 2 mL of ethyl ether will clear the milky appearance seen in pseudochylothorax, which can differentiate this condition from chylothorax.[331] The fluid TP and lactate dehydrogenase levels are usually elevated, with a predominance of lymphocytes.[319] However, the fluid cell count may not be reliable due to interference with the counting by the presence of cholesterol crystals.[332] Pleural thickening may be observed on imaging or thoracoscopy,[85] though this is not a universal observation.[319,329]

In patients with a secured diagnosis of pseudochylothorax, it is crucial to look for underlying TB and RA if these conditions are not already established. The yield of TB culture from pleural fluid and biopsy may be low.[85,319,320] The pleural fluid adenosine deaminase level can be misleading in pseudochylothorax and should not be used to guide diagnosis or therapy.[320,328,333] Fibrosis and chronic inflammatory changes are common findings in biopsy samples, which only give limited additional evidence, especially in those with intensely thickened pleura.[319,334] Pseudochylothorax may precede the clinical manifestation of arthralgia symptoms in patients with RA.[335]

TREATMENT

There is no high-quality evidence on treatment of pseudochylothorax. The underlying disease should be treated, and TB should always be considered. Anti-TB therapy is recommended for patients with a positive stain or culture for TB and those with enlarging effusions of suspected tuberculous origin. Pleural fluid drainage should only be considered if the effusion is large enough to cause respiratory symptoms or if there is evidence of infective complications, because recurrence is frequent and there is the risk of fistula formation.[320,326] The lung is often nonexpandable (trapped) from grossly thickened pleura.[330] Surgical decortication has been attempted in selected cases,[320,334,336] with an overall success rate of 86.7% according to a systematic review[280] (see also Chapter 112).

Acknowledgment

We thank Charles Handley, MD, for his assistance in chylothorax imaging and thoracic duct embolization.

PREVENTION OF CHYLOTHORAX DURING SURGERY

Efforts should be taken to prevent thoracic duct injury during thoracic and neck surgery. However, this can be technically challenging due to the unpredictable route of the thoracic duct, extensive tributaries, and difficult identification.[304,305] Preoperative manipulation to highlight the thoracic duct (as described in the section on TDL) can be considered during surgery.[17,84,148,306]

Whether the thoracic duct should be ligated prophylactically during esophagectomy to prevent postoperative chylothorax is a matter of debate.[35,307–310] Compared with preservation of the thoracic duct, prophylactic TDL lowered the incidence of chylothorax (0.3% vs. 2.1% in a randomized trial)[308] without a significant difference in postoperative complications.[311] However, a subsequent retrospective analysis revealed that prophylactic TDL had shorter median survival times and did not reduce the incidence of chylothorax.[310] The access of the surgical site for esophagectomy may play a role, although there is no strong evidence favoring a transhiatal[35] or transthoracic approach.[34] Administration of low-fat tube feeding following esophagectomy was associated with a lower incidence of chylothorax.[312]

PROGNOSIS

The long-term outcome depends on the etiology, rate of chyle leak, and treatment used. Patients with malignant chylothoraces secondary to solid malignancy had a shorter life expectancy than those caused by lymphoma.[271] Postesophagectomy chylothorax has a worse prognosis than other postoperative chylothoraces, with more respiratory complications, longer hospital stay, higher reintervention rate, lower response rate to TPN, and higher mortality (0–50%).[35,48,49,154,206,307,313–315] Chylothorax complicating congenital heart surgery was associated with significantly longer ventilator dependence,[161] higher incidence of central venous thrombosis,[161] longer ICU stay,[53] longer hospital stay,[53] and more early postoperative complications.[53] Its mortality rate ranges from 0–23%,[36,50–53,55,161,219,316–318] but it is not consistently increased when compared with those without chylothorax.[53,161]

Key Points

- Due to the long route of the thoracic duct and its extensive tributaries, leakage of chyle and resultant chylothoraces can result from any disruption (especially trauma, iatrogenic causes, and malignancy) of the lymphatic wall along the duct and its tributaries.
- Breathlessness is the most common presenting symptom. Prolonged drainage of chylothorax can result in nutritional deficiency, electrolyte disturbance, and lymphocyte depletion.
- The appearances of pleural fluid from chylothorax and pseudochylothorax are similar. Chylothorax is defined as the presence of chyle in the pleural space, which can be confirmed by a high triglyceride level or presence of chylomicrons in the pleural fluid. Pseudochylothorax is defined as the presence of cholesterol crystals in the pleural space.
- A computed tomographic scan of the thorax may identify the underlying etiology, and lymphangiography or lymphangioscintigraphy may help locate the site of chyle leak.
- The flow of chyle through the thoracic duct can be slowed or stopped by different treatments, including dietary, pharmacologic, embolization or disruption of the thoracic duct, or surgical ligation. However, the lack of high-quality evidence precludes formal structured treatment recommendations. A combination of treatment modalities is commonly needed, and the choice is often based on the etiology, availability of therapeutic options, and other patient factors.
- The mammalian target of rapamycin inhibitors sirolimus or everolimus are effective in treating lymphangioleiomyomatosis-related chylothorax, while thoracic duct embolization is an emerging modality for chylothorax with known leakage sites along the thoracic duct.
- Pseudochylothorax is most often associated with tuberculosis and rheumatoid arthritis.

112 PLEURAL FIBROSIS AND UNEXPANDABLE LUNG

AMELIA O. CLIVE, MBBS, PHD • RAHUL BHATNAGAR, MBCHB, PHD

INTRODUCTION
DIAGNOSIS OF PLEURAL FIBROSIS AND OF UNEXPANDABLE LUNG
GENERAL MANAGEMENT PRINCIPLES
CAUSES OF PLEURAL FIBROSIS
Asbestos-Related Pleural Fibrosis
Rheumatologic Diseases
Malignancy
Uremia
Tuberculosis
Immunoglobulin G4–Related Disease
Amyloid
Medications and Iatrogenic Causes
Pleuroparenchymal Fibroelastosis
Pleural Infection
Post–Coronary Artery Bypass Graft Surgery
Hemothorax
KEY POINTS

INTRODUCTION

Any insult or injury to the pleural membranes can result in inflammation (pleuritis) and subsequent fibrosis. In some cases the extent or location of this fibrosis may be deemed pathologic, with a range of clinical sequelae possible. Pleuritis may be caused by benign or malignant processes within the pleural cavity and variably causes symptoms and/or pleural effusion.

The anatomic location of the pleural fibrosis has important clinical and potentially medicolegal implications. For example, localized parietal pleural fibrosis, in the form of asbestos-related pleural plaques, is not thought to cause sufficient physiologic impairment to result in respiratory symptoms but may alert the patient to significant asbestos exposure.[1] However, if a fibrotic, thickened "rind" develops in the visceral pleural membrane, this can result in reactive infolding of the underlying lung (known as folded lung, rounded atelectasis, or Blesovsky syndrome) and a restrictive defect, which may lead to symptoms of breathlessness.

The mechanisms by which the pleural membrane becomes fibrotic are not well understood, although imbalances of fibrin turnover are likely to be crucial.[2] Release of tissue factor during an acute insult stimulates the conversion of fibrinogen to fibrin and thereby matrix formation. The imbalance between the profibrotic pathways (matrix formation and *tissue factor pathway inhibitor* [TFPI] production), and the fibrinolysis pathways is the likely driver of pleural fibrosis. Several cytokines have been implicated in these processes, including vascular endothelial growth factor, transforming growth factor-β, and basic fibroblast growth factor.[3]

Inconsistent use of the terminology relating to pleural fibrosis and its clinical sequelae can lead to confusion. *Unexpandable lung* or *nonexpandable lung* refers to an irreducible pleural space, caused by either a restrictive visceral pleural rind, which impairs expansion of the underlying lung, endobronchial obstruction, or prolonged atelectasis.[4] *Trapped lung* and *lung entrapment* are both causes of unexpandable lung but are intended to describe different pathophysiologic processes. Trapped lung refers to fixed, established fibrosis encasing and restricting the lung, whereas lung entrapment refers to the restriction seen with active pleural inflammation or malignancy that may be reversible. It has been proposed that these two entities may be differentiated using pleural manometry during a therapeutic pleural aspiration, although this has not been confirmed.[4] The importance of this distinction is in ensuring that the cause of any potentially reversible, ongoing inflammation in the context of lung entrapment is promptly treated. Finally, the term *fibrothorax* refers to fibrotic fusion of the visceral and parietal pleural layers resulting in complete obliteration of the pleural cavity. This is usually the result of prolonged or extreme inflammation and can cause volume loss of the hemithorax, a restrictive pulmonary defect and, depending on its extent, refractory dyspnea. A summary of terminology is provided in Table 112.1.

We would suggest that these three terms are simply different potential disease courses of the inflammation and scarring within the pleural cavity after an insult or injury. It is not understood, for example, why some patients will get an unexpandable lung and why others develop a fused pleural cavity (fibrothorax). One can speculate that the different outcome may relate to whether a pleural effusion was part of the initial insult.

DIAGNOSIS OF PLEURAL FIBROSIS AND OF UNEXPANDABLE LUNG

Pleural fibrosis is usually initially identified radiologically. Chest radiography may reveal features, such as calcified pleural plaques or costophrenic angle blunting and, in more pronounced disease, peripheral thickening or loss of hemithorax volume (Fig. 112.1). Thoracic ultrasound may be used to identify pleural thickening, with this made easier if there is an adjacent pleural effusion to provide greater visual contrast. Cross-sectional modalities, however, are normally used to diagnose and monitor pleural fibrosis

Table 112.1 Nomenclature Associated With Pleural Fibrosis and Unexpandable Lung

	Definition
Pleuritis	Inflammation of the pleural membrane(s); often associated with the typically sharp pain of pleurisy
Pleural fibrosis	The deposition of fibrotic material within the pleural membranes, likely as a result of previous inflammation
Unexpandable lung/ nonexpandable lung	The lack of apposition of visceral and parietal pleura at the end of a therapeutic pleural drainage procedure
Trapped lung	Unexpandable lung due to a fibrous, visceral pleural peel as a result of a resolved inflammatory insult
Lung entrapment	Unexpandable lung due to an active pleural process (e.g., malignancy or inflammation)
Fibrothorax	Fibrosis and fusion of the visceral and parietal pleura

Modified from Huggins JT, Maldonado F, Chopra A, et al. Unexpandable lung from pleural disease. *Respirology*. 2018;23:160–167.

because they are usually able to provide an estimate of overall disease burden and can allow precise measurements where necessary, facilitating more effective monitoring. *Computed tomography* (CT) imaging, preferably with contrast enhancement timed for pleural enhancement, is most commonly used. Aside from the research setting or rarer specific circumstances, such as in some cases of suspected malignancy, there is a limited role for magnetic resonance imaging and *positron emission tomography* (PET) in the diagnosis of pleural fibrosis. Pleural biopsy may be obtained by image guidance or by thoracoscopy and may be useful when there is an increased index of suspicion for underlying malignancy or active infection.

Establishing a diagnosis of pleural fibrosis is aided by identifying an underlying cause. Finding a likely cause for pleural fibrosis may be relatively straightforward, depending upon the clinical presentation and knowledge of the patient's background. However, if there is ongoing diagnostic uncertainty, a thorough, systematic approach is advised (Table 112.2). If a cause for fibrosis does not become apparent, there should be careful follow-up to ensure progression does not take place, particularly for those with previous asbestos exposure who are at risk of malignant

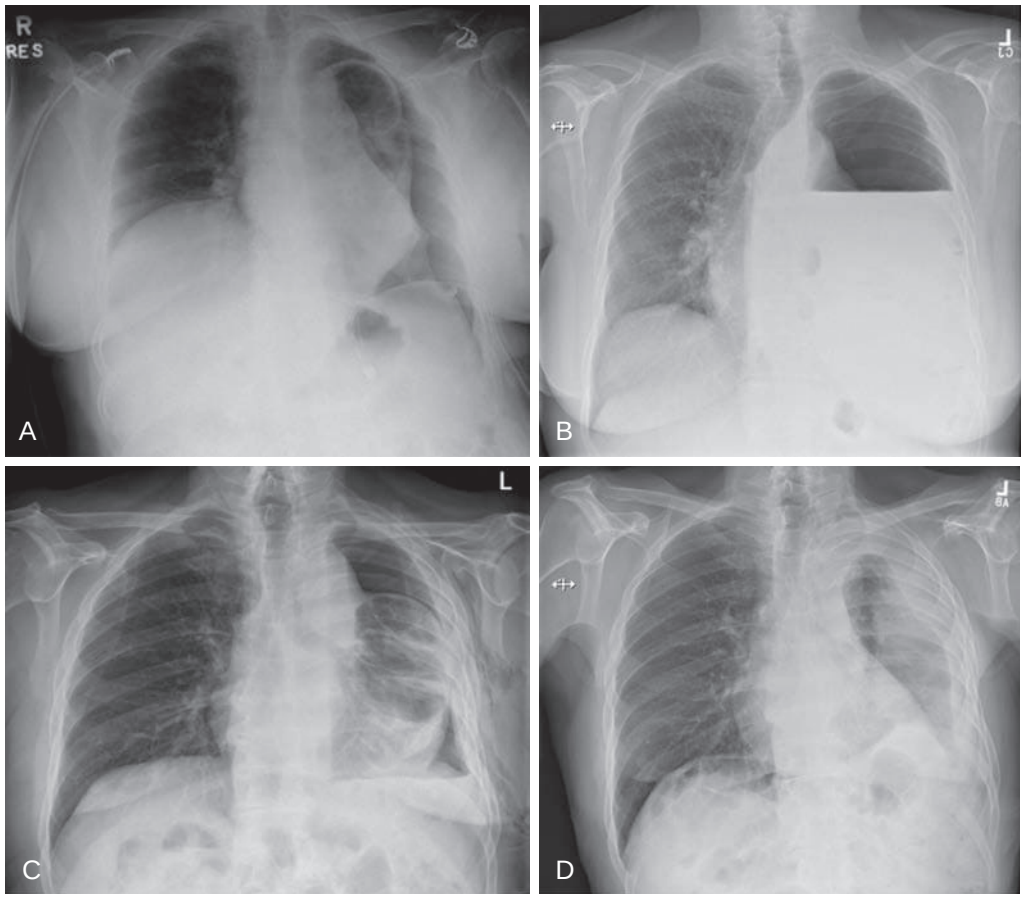

Fig. 112.1 Chest radiographic appearance of unexpanded lung following intervention. (A) Frontal chest radiography in a patient with malignant pleural mesothelioma after thoracoscopy shows left-sided pneumothorax despite the presence of a thoracostomy tube, consistent with unexpanded lung. Note presence of visceral pleural thickening. (B) Frontal chest radiography 1 week after thoracoscopy shows a large left hydropneumothorax. (C) Frontal chest radiography in a patient with chronic left pleural space infection shows an unexpanded left lung associated with left-sided hydropneumothorax with visceral pleural thickening. (D) Three months after (C), substantial left-sided pleural thickening associated with left thoracic volume loss is noted, although the sepsis had resolved and the patient had only minimal breathlessness.

Table 112.2 The Approach to Diagnosis of Pleural Thickening

History and physical examination	Previous chest trauma Previous or current infective symptoms Risk assessment for TB: previous history, TB contact, travel history Rheumatic symptoms Weight loss, systemic symptoms Full asbestos exposure history Previous pneumothoraces: may be seen in PPFE History of previous pleurodesis Drug history: specifically bromocriptine, cabergoline, pergolide, and methysergide; β-blockers; and tyrosine kinase inhibitors (imatinib and dasatinib)
Pleural fluid analysis (if fluid present)	Review biochemistry, cytology, cultures, TB culture Consider special tests: ADA: increased in TB pleuritis and IgG4 Flow cytometry: if effusion lymphoma considered. Evaluate symptomatic benefit from therapeutic pleural aspiration: to help inform future effusion management strategy Consider post-aspiration CXR or pleural manometry to look for unexpandable lung
Imaging	Ultrasound: may help evaluate effusion and define chest wall invasion in suspected malignancy CT: interval CT follow-up may be required in undiagnosed cases for at least 2 years, particularly if previous asbestos exposure PET: if suspected malignancy; may be helpful in suspected IgG4-related disease MRI: may be useful in certain cases (e.g., to identify if chest wall invasion in suspected malignant pleural thickening)
Pleural biopsy	Obtain biopsy and consider special stains for amyloid, IgG4 Evaluate for specific disease patterns: PPFE, IgG4-related disease Send for standard culture and TB culture
Additional tests	Full autoimmune profile: including ANA, complement, anti-CCP antibodies, rheumatoid factor, ANCA Ferritin: elevated in adult-onset Still disease Myeloma screen: if considering amyloid Serum IgG4 levels

ADA, adenosine deaminase; ANA, antinuclear antibodies; ANCA, antineutrophil cytoplasmic antibody; CCP, cyclic citrullinated peptide; CT, computed tomography; CXR, chest radiograph; IgG4, immunoglobulin G4; MRI, magnetic resonance imaging; PET, positron emission tomography; PPFE, pleuroparenchymal fibroelastosis; TB, tuberculosis.

mesothelioma, which may have nonspecific CT and fluid cytology features in the early stages.[5]

In patients with a symptomatic pleural effusion, identification of unexpandable lung may help with the selection of the most appropriate treatment strategy for that individual. Specifically, the lack of pleural apposition caused by substantial unexpandable lung will result in talc pleurodesis being ineffective and, therefore, if long-term control of an effusion is needed, an indwelling pleural catheter may be a better treatment option for these patients. In certain patients, pleural intervention may not be necessary, particularly in those with unexpandable lung resulting from a confirmed pathology and in those without symptoms of breathlessness. However, we would almost always advocate an initial trial of therapeutic thoracentesis for patients with suspected unexpandable lung, to ensure that fluid removal confers symptomatic benefits before a more definitive intervention is considered.

During a thoracentesis, patients with unexpandable lung may experience symptoms of pain, cough, or central chest tightness, and the operator may notice increased resistance to drainage. In this circumstance, discomfort may improve if air is introduced into the pleural cavity, either by the operator through active entrainment of air back through the aspiration device (a therapeutic pneumothorax)[6] or after the formation of a pneumothorax ex vacuo, which may arise due to high transpulmonary pressures, either causing a small parenchymal-pleural fistula or pulling air alongside the catheter into the pleural space.[4] Postdrainage chest radiography in the context of unexpandable lung may thus reveal a pneumothorax or hydropneumothorax, with no specific treatment for this required. Indeed, the risk of additional pain or injury to the lung may be increased by attempting to inflate the lung further.

Noninvasive detection of unexpandable lung may also be possible using thoracic ultrasound. In a small study of patients with large pleural effusions, motion-mode (M-mode) ultrasound was used to image the atelectatic lung. With the requisite knowledge and skill, the operator could recognize that movement of the collapsed lung in response to the cardiac impulse was significantly reduced in those with unexpandable lung compared to those without, typified by reductions in total lung movement and the degree of measured deformation.[8]

The presence of unexpandable lung can also be established using pleural manometry during thoracentesis. This is a well-described technique that allows measurement of pleural pressure during thoracentesis, using either a water manometer (sometimes damped to reduce the effect of respiratory motion) or a digital equivalent within the drainage circuit.[7] Although continuous measurement has been described experimentally,[8] the acquisition of readings usually requires the interruption of drainage every 100 to 200 mL, which contributes to the practical challenge of implementing pleural manometry for the majority of centers. Newer electronic devices, with measurement components

integrated into the thoracentesis catheter and linked to a real-time graphic display, are currently being tested and may make manometry more accessible in the future.[9]

Measured pleural pressure values can be used to calculate pleural elastance (the change in pleural pressure divided by volume removed), which is usually displayed in the form of elastance curves (Fig. 112.2). These are then grossly characterized as monophasic or biphasic and described further by the steepness of the elastance curve(s). The presence of unexpandable lung is inferred by a steeper curve (higher elastance values) because resistance to lung expansion is manifested in rapidly decreasing pleural pressure as volumes are withdrawn. Monophasic curves are seen when the whole lung expands (or fails to expand) to drainage in a relatively uniform fashion, whereas biphasic curves may be seen when isolated regions or lobes of the lung have varying degrees of restriction.[4,10]

Despite pleural pressure measurement being technically feasible and able to identify unexpandable lung, its role in routine management remains uncertain.[11] A multicenter, randomized controlled trial involving 128 patients allocated participants with pleural effusions to undergo either thoracentesis guided by symptoms alone or thoracentesis guided by symptoms in addition to predetermined pleural manometry criteria.[12] The study showed no difference in chest discomfort between treatment groups, confirming retrospective data that also contradicted the previously held belief that knowledge of real-time pleural pressures could reduce the likelihood of complications during or after thoracentesis.[13–15] In those with malignant pleural effusion, early pleural manometry and favorable elastance values have been correlated with pleurodesis success, although only in relatively small studies.[16] Despite these data, clinical management pathways for malignant pleural effusion that incorporate early detection of unexpandable lung are not the norm due to the practical limitations mentioned earlier. However, ongoing randomized trials may change this, with investigators exploring whether first-line indwelling pleural catheter treatment for those with suspected unexpandable lung on initial thoracentesis is worthwhile.[9,17]

GENERAL MANAGEMENT PRINCIPLES

The management of pleural fibrosis and resultant unexpandable lung depends on the underlying cause; specific etiologies are discussed in more detail later (Table 112.3). If there is an ongoing inflammatory process within the pleural cavity, such as infection or an active rheumatologic condition, targeting this with disease-specific measures may help prevent progression of pleural fibrosis. Recognition, removal, and future avoidance of drugs that may contribute to pleural fibrosis are also important.

Thereafter, managing symptomatic effusions with repeated pleural drainage may be indicated, and indwelling pleural catheters may have a role in some patients, especially those with malignant infiltration of the pleural membranes. Continued drainage is only indicated if the effusion is determined to be causing or contributing to the patient's symptoms. As mentioned, often the effusion merely collects in the pleural space when the lung cannot reinflate to fill

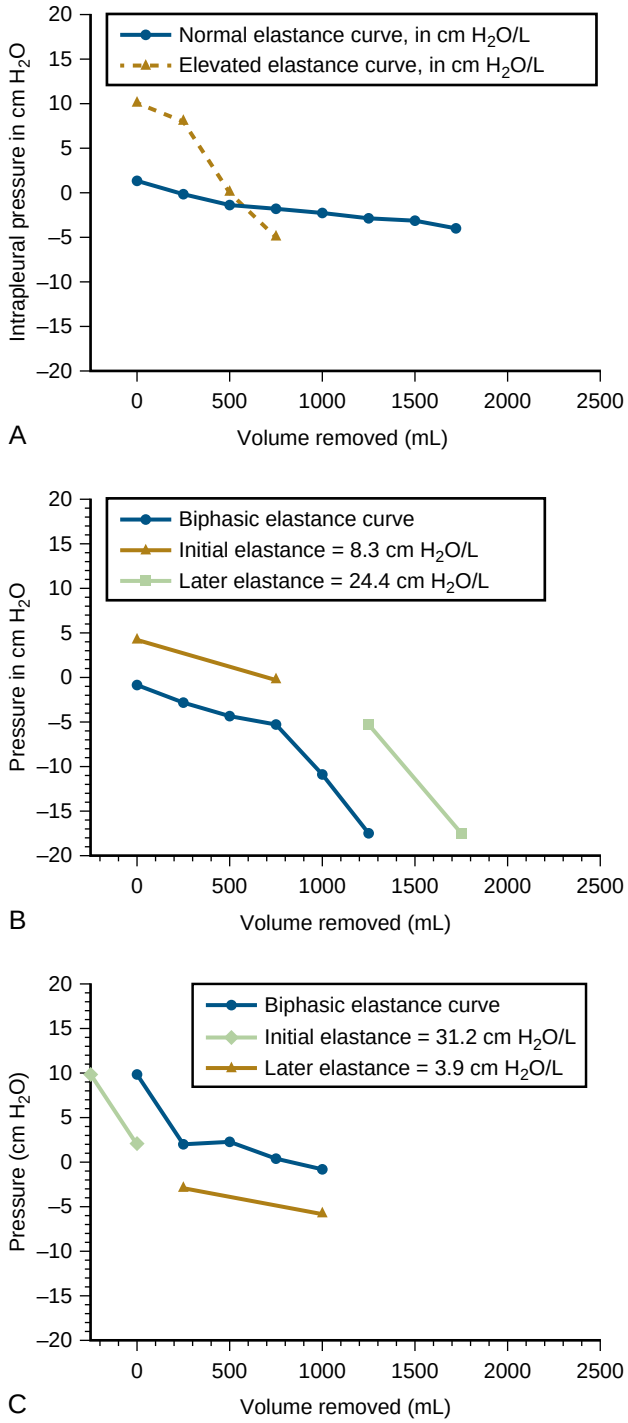

Fig. 112.2 Pressure/volume curves in patients receiving pleural manometry. (A) Monophasic pressure/volume curves of uniform slope. These curves are from two different patients, one with normal elastance and the other with abnormal elastance. (B) Biphasic pressure/volume curve with a distinct inflection point after 1000 mL of volume removed. Note the two distinct portions of the curve, with lines drawn to demonstrate the different slopes. Patients with biphasic curves usually have a normal elastance followed by a high elastance. (C) Biphasic pressure/volume curve with a distinct inflection point after 250 mL removed. Note the initial steep portion of the curve, followed by a more flat curve, with normal elastance. Curves with an initial steep portion followed by a more shallow section can sometimes be seen in patients with large hydrothoraces. The initial steep portion is likely due to lung stiffness from the hydrothorax that is relieved with drainage. (From Heidecker J, Huggins JT, Sahn SA, Doelken P. Pathophysiology of pneumothorax following ultrasound-guided thoracentesis. *Chest.* 2006;130:1173–1184.)

Table 112.3 Causes of Pleural Thickening

Cause	Specific Conditions	Specific Investigations	Management Considerations
Asbestos related	Pleural plaques	Consider CT to exclude other asbestos-related diseases	
	Diffuse pleural thickening		Follow-up for up to 2 yr to ensure no evolving features to suggest mesothelioma
	Mesothelioma	Pleural biopsy	For current therapy of mesothelioma, see Chapter 114
Rheumatologic	Rheumatoid arthritis SLE Sjögren Systemic sclerosis Dermatomyositis Granulomatosis with polyangiitis Ankylosing spondylitis Periodic fever syndromes Adult-onset Still disease	Autoimmune screen (ANA, ANCA, rheumatoid factor, complement, anti-CCP antibodies)	Proactively manage underlying condition to minimize risk of unexpandable lung (e.g., with suitable immunosuppression)
	IgG4-related disease	Serum IgG4 levels Biopsy pleural thickening Consider PET	
Malignancy	Primary (mesothelioma) or secondary	Pleural fluid/biopsy to confirm diagnosis	If coexisting effusion, perform therapeutic pleural aspiration to assess symptom benefit and evaluate for unexpandable lung
Infection	Bacterial pleural infection	Pleural fluid aspiration Consider pleural biopsy to increase microbiologic yield	Get control of sepsis through effusion drainage, antibiotics, and surgery/fibrinolytics if required Residual pleural thickening will usually resolve within 6 mo
	Tuberculosis	Pleural biopsy Pleural fluid TB culture ADA	Treat TB according to usual protocols Steroids unlikely to be beneficial
Iatrogenic	Drug causes	Bromocriptine Cabergoline Pergolide Methysergide β-Blockers Tyrosine kinase inhibitors (imatinib and dasatinib)	Stop causative agent
	Previous pleurodesis Post-CABG effusion After thoracic radiotherapy		No specific treatment required
Traumatic	After hemothorax		
Miscellaneous	Amyloid PPFE	Congo red stain of pleural tissue	
	Uremia		May require initiation or alteration of renal replacement therapy

ADA, adenosine deaminase; ANA, antinuclear antibodies; ANCA, antineutrophil cytoplasmic antibody; CABG, coronary artery bypass graft; CCP, cyclic citrullinated peptide; CT, computed tomography; IgG4, immunoglobulin G4; PET, positron emission tomography; PPFE, pleuroparenchymal fibroelastosis; SLE, systemic lupus erythematosus; TB, tuberculosis.

the space; in this setting, no drainage is needed. In all patients with unexpandable lung, the use of repeated drainage techniques must be considered carefully. Whereas some patients will gain symptomatic benefit from each drainage, and may even have their lung fully or partially reexpand over time, others will experience significant or limiting pain or cough on each occasion and, in such cases, it may be more suitable to manage dyspnea pharmacologically or conservatively. However, drainage may be the optimal approach. In a recent study of 145 patients with symptomatic pleural effusions, relief of dyspnea after drainage was documented in 73%; importantly, symptomatic improvement did not depend on whether or not the lung reexpanded.[17a] Thus, one must not neglect the potential benefit of drainage even when the lung cannot expand.

Surgical decortication is also a recognized treatment option but is very rarely required. The role for surgery depends on the underlying disease process. In general, there is a dearth of evidence regarding best practice in all disease areas relating to pleural fibrosis and unexpandable lung, and future studies looking at long-term function and symptom outcomes are warranted.

CAUSES OF PLEURAL FIBROSIS

A broad range of benign and malignant conditions can result in pleural fibrosis (see Table 112.3).

ASBESTOS-RELATED PLEURAL FIBROSIS

Occupational asbestos exposure is known to cause pleural thickening. Pleural plaques are well demarcated, raised, nontapering areas of parietal pleural fibrosis or calcification. However, due to their discrete position on the parietal pleura, they do not impair respiratory motion or function and usually are asymptomatic, unless they conglomerate and are extensive. In a recent study evaluating the lung function of miners, who were exposed to asbestos-contaminated vermiculite, the presence of pleural plaques did not significantly accelerate the decline in lung function.[18]

Diffuse pleural thickening (DPT) is another potential consequence of previous asbestos exposure and develops in 4–5% of asbestos-exposed individuals.[19] About 40% of cases are preceded by an episode of benign asbestos pleural effusion.[20] Likely as a result of significant mechanical impairment of lung expansion by thickening of the visceral pleura, DPT is associated with a restrictive defect and usually symptoms of breathlessness. On imaging, an adjacent area of folded lung (also called rounded atelectasis) may be seen (see eFig. 101.13). Recent observational data suggest that forced vital capacity is substantially reduced if the costophrenic angle is obliterated by DPT compared to control subjects or those without costophrenic angle involvement, but the most marked lung restriction is seen in those with bilateral DPT.[21] DPT must be carefully monitored to ensure that an underlying diagnosis of mesothelioma is not missed. DPT is usually slowly progressive. Surgical intervention is not usually beneficial, and management is supportive.

RHEUMATOLOGIC DISEASES

A number of inflammatory conditions cause pleuritis and, if pleural inflammation is persistent, may lead to pleural fibrosis. If pleuritis from rheumatologic disease is suspected, it is worthwhile looking for evidence of a serositis elsewhere (e.g., pericardial disease or a contralateral effusion). Often the initial inflammatory insult is associated with pain, a pleural effusion, and diffuse smooth pleural thickening and, over time, if the pleural inflammation persists, a fibrotic pleural peel can develop, preventing underlying lung expansion.

Pleural involvement is a well-established complication in rheumatoid arthritis; the extent of resultant pleural fibrosis can range from small, fibrous plaques to extensive fibrosis. Proactively targeting the underlying inflammatory condition with systemic steroids or other immunosuppressive agents and managing an associated symptomatic effusion is the mainstay of management. The aim of treatment is to reverse the inflammatory element and prevent the development of pleural fibrosis. Fibrothorax has also been reported in systemic lupus erythematosus.[22] Other collagen diseases, such as Sjögren, systemic sclerosis, dermatomyositis, granulomatosis with polyangiitis, ankylosing spondylitis, periodic fever syndromes, and adult-onset Still disease can also result in inflammatory pleural effusions that, if left untreated, can lead to pleural thickening.[23]

MALIGNANCY (See Chapter 114)

Malignant infiltration of the pleura can result in thickened, restrictive pleural fibrosis. The pleura can either be affected by a primary malignancy (mesothelioma) (see Figs. 114.3 and 114.5) or metastasis from elsewhere. This is often associated with a malignant pleural effusion, although many patients with malignant involvement of the pleura have isolated pleural thickening with no pleural effusion. If there is sufficient visceral pleural involvement, unexpandable lung may become evident after drainage. Unexpandable lung can be quite common in mesothelioma, affecting 33% of patients in one observational cohort.[24]

In the context of a malignant pleural effusion, if the lung fully reexpands and visceral and parietal pleural apposition is obtained, and the patient has symptomatic benefit from the removal of the effusion, attempting a pleurodesis is a reasonable approach. With pleurodesis, one attempts to obliterate the pleural cavity and prevent future pleural fluid reaccumulation. However, if the lung is not able to expand, pleurodesis is not indicated. Although guidelines would suggest pleurodesis can be attempted with as little as 50% pleural apposition,[25] placement of an indwelling pleural catheter, followed by repeated drainage for symptomatic benefit, is likely to be a more effective solution in this setting. As mentioned, although an isolated IPC drainage may not lead to full lung reinflation, the restoration of diaphragmatic motion and return of the chest wall to a more normal position can result in symptomatic relief for patients, albeit not universally.[26] In the presence of unexpandable lung, IPC drainage often needs to be undertaken cautiously and stopped if pain or significant cough arises. At present, there does not appear to be a role for decortication in malignant lung entrapment, although a feasibility study evaluating the role of pleurectomy decortication compared to IPCs in mesothelioma is ongoing.[27]

UREMIA

Pleural thickening and inflammatory changes were first described in the context of chronic renal disease as far back as the early 1800s.[28] Later, as uremic pneumonitis became increasingly recognized as a distinct entity, so did associated pleuritis, with the latter identified in up to 20% of cases of a 107-patient series of those with pneumonitis.[29] Literature and evidence regarding uremic pleuritis specifically, however, remains relatively sparse; in a report from 1970, uremia was recognized as the primary cause of pleural exudate in less than 1% of cases.[30] In those small series, which describe the causes of exudates specifically in patients with renal disease, approximately one-quarter are attributed to uremia.[31,32] The precise mechanism for uremic pleuritis is unclear but is assumed to result from accumulated toxins that would otherwise be excreted by normal kidneys. Despite this, pleuritis has been described in patients who are otherwise well managed on hemodialysis.[33] Overall, effusions are found in only 10% of kidney failure patients, and their presence is often attributed to other coexisting etiologies, for example, congestive cardiac

failure, nephrotic syndrome, or infection, particularly in the immunocompromised.[34]

Treatment strategies for uremic pleuritis vary. Management of symptomatic effusions is important, and successful use of empirical corticosteroids has been described.[35] Some authors consider the presence of uremic pleuritis, much like pericarditis, to be an indication for initiating dialysis[36] or for increasing the frequency or intensity of dialysis; however, pleuritis is not mentioned at all in certain high-profile guidelines.[37] As with other chronic pleural inflammatory conditions, the development of a restrictive fibrous peel has been described after uremia.[38] For those few patients in whom there is sufficient restriction, and in whom an operation is appropriate, surgical decortication has been reported to be effective,[33,39] although it is rarely performed.

TUBERCULOSIS

TB pleuritis, due to a delayed (type IV) hypersensitivity reaction within the pleural cavity, is thought to be triggered by release of TB antigens into the pleural space from rupture of an area of subpleural pulmonary disease. Fulminant empyema due to TB pleural infection is much rarer. After TB pleuritis, a subgroup of patients may be left with residual pleural thickening and adhesions, which have the potential to impair respiratory function. In a Spanish study of 81 patients treated for TB pleuritis, 10% had spirometric evidence of a restrictive ventilatory defect after a median follow-up for 23 months.[40] Pleural thickening may be more common after TB empyema (see Fig. 20.35).

Some data suggest that early pleural fluid drainage to empty the pleural cavity as completely as possible may minimize symptoms of breathlessness and limitation in lung function at 12 months.[41] A Cochrane review has evaluated the role of oral corticosteroids in TB pleuritis and found that their use may improve chest radiographic appearances of residual pleural changes. However, there appeared to be no difference in terms of long-term respiratory impairment, and steroids were found to be associated with a higher incidence of adverse events.[42]

IMMUNOGLOBULIN G4–RELATED DISEASE

This systemic, fibroinflammatory condition was described only relatively recently.[43] Given the paucity of clinical data on IgG4-related disease–associated pleural thickening, which is limited to a handful of case reports in the literature, the natural history, prognosis, and functional outcomes are not yet well established.

The condition is characterized by tissue infiltration with lymphoplasmacytic IgG4-positive plasma cells, storiform (e.g., whorled, cartwheel pattern) fibrosis, and obliterative phlebitis (Fig. 112.3). It can affect almost any organ system, and pulmonary involvement can manifest as hilar or mediastinal lymphadenopathy, lung nodules, airways disease, interstitial lung disease, or pleural involvement.[44] In the pleura, IgG4-related disease most commonly causes a pleural effusion, although isolated pleural thickening has been reported.[45,46]

The diagnosis requires a biopsy demonstrating the characteristic features, although a recent study suggests that high levels of IgG4-positive cells in a pleural fluid cell block may help support the diagnosis.[45] Serum IgG4 and pleural fluid adenosine deaminase levels may also be elevated, although these are neither sensitive nor specific.[44,47] Because patients appear to be at an increased risk of cancer, a clinical suspicion of IgG4-related pleural disease should prompt further imaging to exclude other disease sites and exclude occult malignancy.[44] IgG4-related disease is often avid on PET imaging, although there are reports of IgG4-related pleural disease without abnormal PET scans.[48] Typically, the condition is responsive to oral steroid treatment although, in resistant or relapsing cases, other immunosuppressive agents, such as rituximab, may be needed.[48]

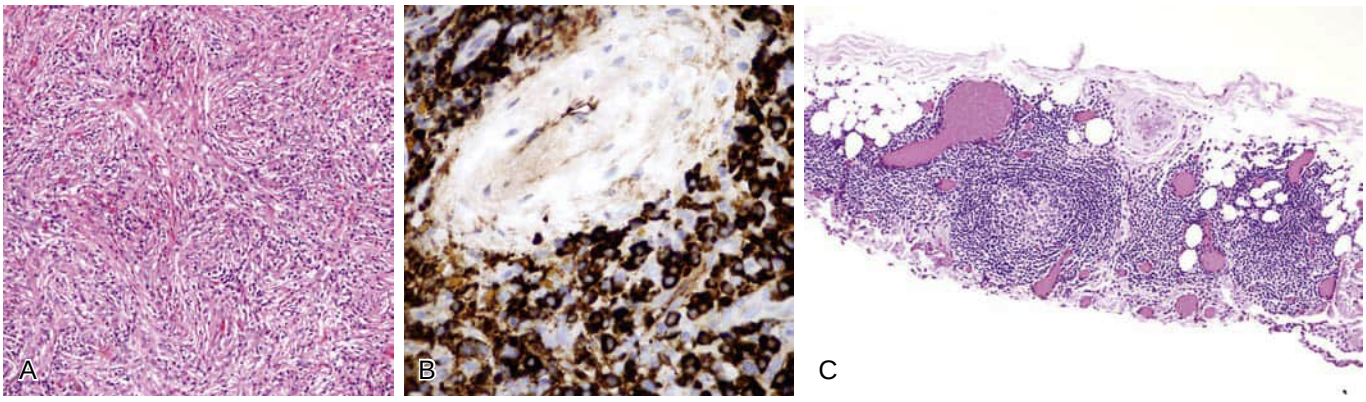

Fig. 112.3 Pathologic findings of *immunoglobulin* (Ig)G4-related disease. (A) IgG4-related disease fibrosis with a storiform or loose-swirling pattern. This image is of the disease affecting the lung in a 52-year-old man. (B) IgG immunohistochemical staining for IgG4 shows numerous plasma cells with a strong cytoplasmic positivity in IgG4+ sclerosing lung disease. There should be >50 IgG4+ plasma cells per 10 high-power field, with an IgG4/IgG ratio of >40%. (C) In IgG4-related pleural disease, the pleura is surfaced by a dense lymphoplasmacytic infiltrate that includes germinal centers. The other characteristics of IgG4-related disease are not evident in this case. However, the clinical features were strongly suggestive of IgG4-related disease as was the IgG4 immunostain. (A, From Lindberg MR. *Diagnostic Pathology: Soft Tissue Tumors*, ed 3. Philadelphia: Elsevier; 2019. B, From Suster S, Moran CA. *Diagnostic Pathology: Thoracic,* ed 2. Philadelphia: Elsevier; 2017. C, From Deshpande V, Khosroshahi A. Diagnostic guidelines for IgG4-related disease with a focus on histopathological criteria. *Diagn Histopathol.* 2013;19:119–127.)

AMYLOID

Pleural amyloid is a rare phenomenon, found in just 1–2% of patients with systemic amyloid, and may manifest as masslike pleural thickening mimicking malignancy.[49] Pleural biopsies are diagnostic but may require specific staining using Congo red to identify the amyloid proteins.

MEDICATIONS AND IATROGENIC CAUSES

A variety of drugs have been implicated in the formation of pleural fibrosis, including amiodarone, ergot alkaloids (such as bromocriptine, cabergoline, pergolide, and methysergide), β-blockers, and tyrosine kinase inhibitors (imatinib and dasatinib).[50,51] Once pleural fibrosis is identified, it is important these drugs be stopped and avoided in the future. Primarily in the malignant setting, agents such as talc, doxycycline, or iodopovidone are often introduced into the pleural space, with the express intention of creating pleural inflammation and a lasting pleural fibrosis. Previous pleurodesis may become apparent as calcification on CT or localized avidity on PET[52] but is not known to result in functional or spirometric impairment.

Previous radiation therapy to the thoracic cavity can result in pleural thickening. In one study, pleural thickening was evident on CT in 70% (19 of 27) of patients 12 months after chemoradiotherapy for stage II non–small cell lung cancer.[53]

PLEUROPARENCHYMAL FIBROELASTOSIS (See Chapter 90)

Pleuroparenchymal fibroelastosis (PPFE) is a rare, upper zone–predominant fibrotic lung condition associated with visceral pleural thickening (Fig. 112.4 and Figs. 90.12 and 90.13). Some patients may present with recurrent pneumothoraces. PPFE has specific histopathologic features of collagenous visceral pleural fibrosis, subpleural elastosis, and intra-alveolar collagenous fibrosis. It may be idiopathic, drug induced (e.g., bleomycin and cyclophosphamide),[54,55] or associated with other conditions, including stem-cell or lung transplantation or connective tissue diseases. The rate of progression can vary, with some experiencing an indolent course and others having more rapidly progressive and often fatal disease. Steroids or immunosuppression are rarely effective in slowing disease progression, and occasionally lung transplant is required.[56]

PLEURAL INFECTION

Infection in the pleural space creates the ideal acute inflammatory environment for the development of pleural thickening. In rare cases, this can lead to the development of a restrictive pleural rind.[57] Most often, the pleural thickening post-empyema resolves[61] and, even if it persists, it may not have a significant impact on pulmonary function.[66]

The mainstays of pleural infection treatment are antibiotics and drainage. In those patients who have already developed septation or loculation, intrapleural therapy is increasingly common, particularly in those who are not surgical candidates. This typically takes the form of combination fibrinolytic and deoxyribonuclease, with single-agent treatment proven to be either ineffective in comparison to placebo or potentially harmful[59,60] (see Chapter 109). In the majority of cases, however, it appears that any pleural thickening associated with pleural infection resolves over 3 to 6 months with basic antibiotic and drainage therapy.[61,66]

When sepsis due to pleural infection is not responding to medical therapy, thoracic surgery remains an option. There are also numerous reports of surgery being used specifically to manage chronic or established (stage III) disease in both adults and children.[62–64] The nature of the procedure chosen is often reliant upon the stage at presentation, with débridement of the pleural space typically sufficient in early disease but decortication, which may require a thoracotomy approach, preferred by some when a thick pleural peel has become established because it is believed to improve lung function and chest expansion.[65] In one retrospective study of patients after VATS, the degree of visceral pleural thickening was associated with the duration of postoperative chest tube drainage and hospitalization time.[67] In another retrospective study comparing VATS and thoracotomy, those undergoing VATS débridement had the shortest postoperative length of hospital stay (6 days vs. 15 days in the open decortication group). On long-term follow-up, 42% of patients included in the study reported residual symptoms, and 46% were found to have some degree of respiratory impairment.[57] Regardless of approach, surgical intervention for late-stage

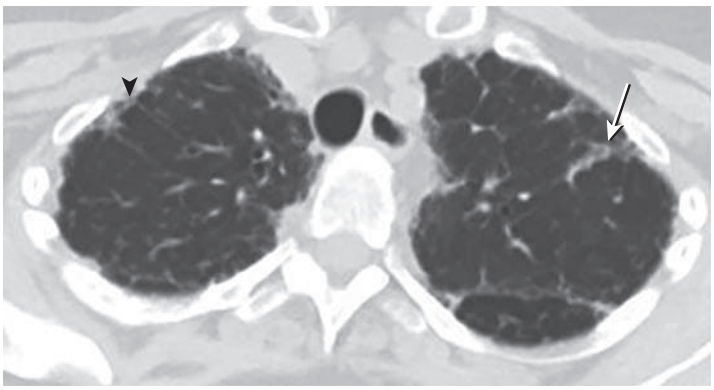

Fig. 112.4 Pleuroparenchymal fibroelastosis. Axial high-resolution chest computed tomography image shows patchy areas of subpleural linear and reticular (*arrowheads*) abnormalities, some of which are bandlike, extending from the pleural surface centrally (*arrow*). (Courtesy Michael B. Gotway, MD.)

pleural infection carries a significant risk of early mortality and morbidity, with these reported as up to 3% and 25%, respectively.[57,68]

Despite reports of favorable surgical results, there has been no comparison of surgical and nonsurgical outcomes. Given that pleural thickening after empyema generally resolves spontaneously[61,66] surgery should only be considered in those rare individuals who have symptomatic pleural thickening that persists or progresses at least 6 months after the empyema.

POST–CORONARY ARTERY BYPASS GRAFT SURGERY

Pleural effusions have been described in as many as 89% of patients post–*coronary artery bypass graft* (CABG).[69] Whereas many of these are seen early in the postoperative period as a direct result of surgical trauma, a small proportion (0.4%–9.7%)[70–75] develop into chronic exudates, often despite repeated thoracentesis or tube drainage, and are described as "late" or "persistent" if present for more than 2 to 6 months.[76] A further subgroup may go on to develop unexpandable lung, although it is not clear why this happens or what the risk factors are.[69] No clear association between the operative approach for the CABG and the development of a late effusion has been found.[72,74]

A small case series described histologic appearances of post-CABG effusions requiring thoracic surgical intervention and found that the development of established fibrosis was time dependent and was preceded by initially raised and then diminishing levels of B cell lymphocyte–predominant inflammation over periods of many months, although the trigger and role for the lymphocytes remained unclear. Collagen deposition over the longer term was not wholly attributable to fibroblast activity; the authors speculated that mesothelial cells may also have a role in the formation of pleural rind in this context.[69]

Data regarding the optimal approach for those with established post-CABG pleural fibrosis are limited, with most data drawn from retrospective, single-center, and noncomparative studies that do not differentiate between those with true unexpandable lung and chronic but simple inflammatory changes. Nonetheless, the use of VATS or thoracotomy to facilitate decortication for those found to have fibrous pleural peel is well described and, according to a systematic review of 10 studies (none of them randomized), appears to be safe and efficacious. The authors of this study suggest, although acknowledging the lack of quality data, that early surgical intervention in preference to thoracentesis or drainage may be the best approach to established post-CABG effusions.[77]

HEMOTHORAX (See Chapter 113)

Hemothorax can arise spontaneously or as a result of thoracic trauma, rib fracture, or surgery. Small and uncomplicated cases may resolve with conservative management, but drainage is frequently required for more substantial or infected collections (or hemopneumothoraces) to relieve symptoms and prevent complications. Long-term pleural sequelae from hemothorax may include the development of unexpandable lung and pulmonary restriction.[2] This is rare, however, being described in less than 1% of cases of hemothorax,[78] meaning data specific to the treatment and long-term outcomes of patients with visceral fibrosis originating from hemothorax are scarce.

Reports from a number of settings seem to support the use of early surgical intervention, usually VATS débridement, for the management of complex retained hemothoraces with a view to preventing unexpandable lung.[79,80] There are also limited data reporting the successful use of intrapleural urokinase in patients with residual hemothorax post–lung surgery.[81] In the posttraumatic population, however, a retrospective comparative series of streptokinase versus VATS débridement found that those treated by surgical débridement appeared to have more complete radiographic improvement and a shorter postoperative stay.[82]

Key Points

- Pleural inflammation, thickening, and fibrosis can be caused by a wide range of conditions.
- The diagnosis of pleural fibrosis is heavily reliant on identifying potential cause(s) from the history and on cross-sectional imaging.
- Most cases of pleural thickening will resolve spontaneously or in response to treatment of the underlying cause.
- Visceral pleural fibrosis can cause unexpandable lung.
- Unexpandable lung may be challenging to manage; however, if patients have symptomatic improvement from effusion drainage, they may be benefit from repeated pleural drainage or an indwelling pleural catheter. In the presence of unexpandable lung, drainage may offer symptomatic improvement by improving chest wall or diaphragmatic mechanics.
- Pleural thickening after empyema usually resolves within months after successful treatment of the empyema. Therefore, surgical decortication of post-empyema pleural thickening is rarely necessary and should be considered only if symptomatic pleural thickening persists for more than 6 months post-empyema.

113 HEMOTHORAX

JOSEPH FRIEDBERG, MD • SHELBY J. STEWART, MD

INTRODUCTION
DIAGNOSIS
ETIOLOGY
Traumatic Hemothorax
Nontraumatic Hemothorax
Iatrogenic Hemothorax
MANAGEMENT
Complications of Hemothorax
Surgical Intervention
KEY POINTS

INTRODUCTION

Hemothorax is defined as the accumulation of blood within the pleural space; it is recognized when the hematocrit of the pleural fluid is greater than 50% of the hematocrit of the patient's peripheral blood. Due to the significant color change of pleural fluid with very small amounts of blood, it is imperative to confirm the diagnosis by fluid analysis. The etiology of hemothorax is varied but can be broadly classified as traumatic, nontraumatic, and iatrogenic.

DIAGNOSIS

The detection of hemothorax is largely based on a high degree of suspicion, physical examination, and thoracic imaging. A hemothorax should be suspected in any patient with chest trauma, whether penetrating or blunt, a recent invasive thoracic procedure, or an undiagnosed pleural effusion in a hypotensive patient. Examination of the patient with hemothorax may reveal signs consistent with any pleural effusion, such as asymmetric chest expansion, diminished breath sounds, and dullness to percussion. The sensitivity of the exam findings increases with the size of the effusion.

The chest radiograph is often the initial imaging modality of choice to identify a pleural effusion when hemothorax is suspected. Lateral decubitus, anteroposterior, and upright lateral views may accurately display the presence of pleural fluid. Supine films may fail to display a large volume of pleural fluid, where it can appear only as a slight and uniform haziness. A carefully performed lateral decubitus chest radiograph is the most sensitive plain radiograph and can reportedly detect as little as 10 mL.[1] After trauma, a pneumothorax can accompany a hemothorax. In a series of patients enrolled with blunt trauma, 2.4% (207/8661) had hemothorax, and 1.3% had both hemothorax and pneumothorax.[2] In a separate series of patients with hemothorax after penetrating trauma, 83% (307/373) had pneumothorax.[3]

The sensitivity of the more commonly performed anteroposterior upright chest radiograph is significantly less than that of other views and typically requires blunting of the costophrenic angle with approximately 200 mL of fluid in the chest.[4] Other findings include blunting of the cardiophrenic angle and mediastinal shift away from the effusion. The hemidiaphragm is generally obscured with a pleural effusion of 500 to 650 mL.[4] Lateral films can identify a smaller amount of fluid because the costophrenic angles are deepest posteriorly.

Blackmore and colleagues devised a prediction model for visual estimation of pleural fluid volume in 1996[5]; this model was verified and updated by Mammarappallil et al. in 2015.[4] Frontal and lateral radiographic images were given a score of 1 to 3 based on the presence of a meniscus below the hemidiaphragm, at the hemidiaphragm, and above the hemidiaphragm, respectively (eFig. 113.1). These levels were validated by *computed tomography* (CT) imaging; on a frontal chest radiograph, a score of 1 indicated a mean volume of approximately 100 mL, a score of 2 indicated approximately 250 mL, and a score of 3 indicated approximately 650 mL or more.

Ultrasound is increasingly used due to its portability, diagnostic speed, and reliability in patients who are immobile or difficult to transport. The sensitivity of ultrasound in the diagnosis of pleural effusion is reported to be 67–100% with a specificity of 99% or higher.[6] The ability to predict the volume of pleural fluid may be achieved with a greater than 80% accuracy when correlated to aspirated volume using a simple calculation from measurements obtained during ultrasound imaging.[7] In a systemic review and meta-analysis of 19 studies, ultrasound was found to be accurate for the diagnosis of pleural effusion assumed to be hemothorax and for pneumothorax in trauma patients seen in the emergency department.[8] Ultrasound may have particular value in monitoring the size of a known hemothorax, aiding in deciding whether to continue to observe or to intervene.[9]

CT is a highly sensitive diagnostic modality and offers the benefit of identifying additional injuries or relevant diagnostic findings for the patient. CT is considered the gold standard for identifying hemothorax size as well as related injuries to the thorax or vessels. It is important to note that hemothorax may present in a delayed fashion in up to 20% of patients with thoracic injury, most commonly in patients with blunt trauma and in those with one or more rib fractures; thus repeat imaging of patients with thoracic injury is advised within 24 to 36 hours (Fig. 113.1).[10–13]

CT attenuation values have been used in an attempt to distinguish hemothorax from nonhemorrhagic pleural effusion. In images obtained *without* intravenous contrast, Hounsfield units 15.9 or greater (or the ratio of Hounsfield

units in pleural fluid to aortic blood of 0.56 or greater) predicted the presence of hemothorax with significant accuracy.[14] The presence of a "hematocrit effect" (i.e., the linear separation of cellular and liquid components of blood creating a plasma-blood interface) suggests the presence of unclotted blood products, indicating either coagulopathy or active hemorrhage within the pleural space (Fig. 113.2 and eFig. 113.2).[15]

Identification of a small to moderate pleural effusion concerning for hemothorax requires thoracentesis and pleural fluid analysis. A pleural fluid hematocrit greater than 50% of the peripheral blood is diagnostic for hemothorax. Alternatively, if a pleural hematocrit is not available, the pleural fluid hematocrit can be roughly estimated by dividing the pleural fluid red blood cell count by 100,000. (For example, a pleural fluid red blood cell count of 2 million/μL would be equivalent roughly to a hematocrit of 20%.[16])

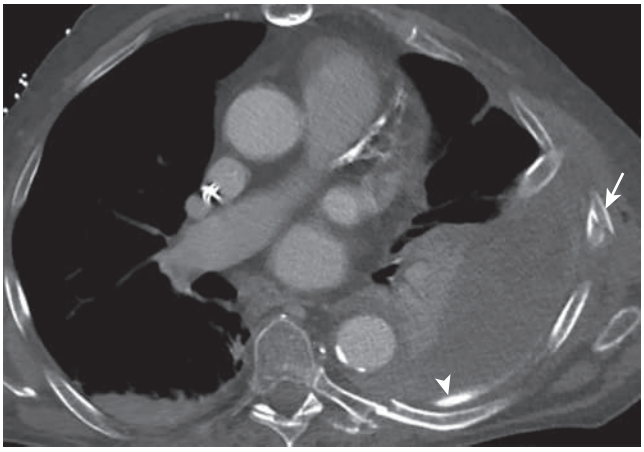

Figure 113.1 Delayed hemothorax following thoracic trauma. Ten days after a fall, an 86-year-old man on anticoagulation developed acute hypotension with a drop in his hemoglobin. Computed tomography scan showed a large left hemothorax, acute rib fractures (*arrow*), as well as active contrast extravasation (*arrowhead*) consistent with active hemorrhage. The patient was emergently referred for transcatheter intercostal artery embolization with selective intercostal artery angiography confirming intercostal artery injury with active hemorrhage. (Courtesy Michael B. Gotway, MD.)

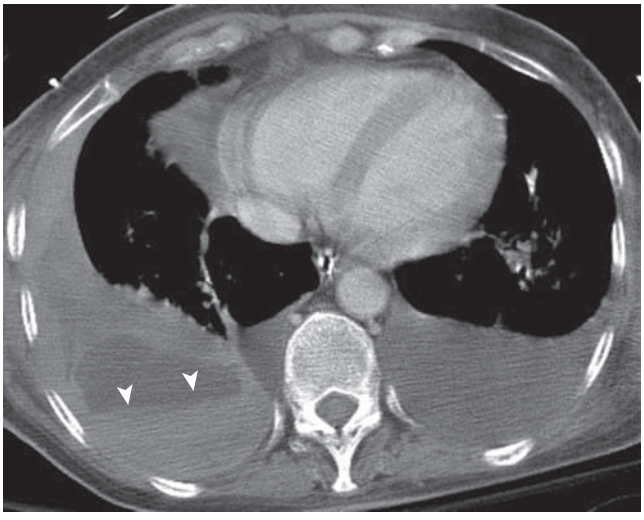

Figure 113.2 Hematocrit effect seen in hemothorax. Axial enhanced chest computed tomography in a patient with hemothorax showing the "hematocrit effect." Note the presence of a fluid-fluid level (*arrowheads*). (Courtesy Michael B. Gotway, MD.)

ETIOLOGY

The etiology of hemothorax may be largely categorized into three types: traumatic, nontraumatic, and iatrogenic.

TRAUMATIC HEMOTHORAX

Trauma is the most common cause of hemothorax, with nearly 300,000 cases in the United States each year.[17] Blunt force injury to the intercostal vessels, lung, diaphragm, great vessels, or mediastinal structures may be caused by motor vehicle collisions or falls. Penetrating injury, such as a gunshot or stab wound, often leads to clinically significant hemothorax. Rib fractures may be associated with hemothorax in patients with thoracic trauma. Lin et al. identified a positive correlation between the incidence of hemothorax and number of rib fractures; patients with more than five rib fractures were found to have a 48% or greater likelihood of concomitant hemothorax.[18] Hemothorax may lead to significant hemodynamic instability due to hypovolemia and thus should be considered in all patients with thoracic trauma, particularly if they are unstable.

NONTRAUMATIC HEMOTHORAX

Spontaneous pneumothorax is the most common cause of nontraumatic or spontaneous hemothorax. Hemothorax develops in 2–7% of spontaneous pneumothorax cases, most commonly from torn adhesions between the visceral and parietal pleura when the lung collapses, or from rupture of a vascularized bullae.[19]

A second etiology of nontraumatic hemothorax is vascular pathology leading to vascular rupture. Hemothorax, usually on the left side, can complicate descending aortic rupture resulting from aortic dissection of the aorta.[20] The aorta can also rarely rupture without trauma, aneurysm, or dissection. Rupture of pulmonary arteriovenous malformation, often associated with hereditary hemorrhagic telangiectasia, is another known cause of hemothorax due to vascular pathology.[21-23]

Neoplasms such as schwannoma, soft tissue tumors, and pleural metastases are rare causes of hemothorax. Resection of hemorrhagic schwannoma has resulted in a favorable outcome in documented cases.[24,25] Conversely, hemothorax can arise with neurofibromatosis type 1 and pleural metastasis and is associated with high mortality.[24-27]

Intrathoracic ectopic endometrial implants may lead to hemothorax in young women and has been documented in 14% of women with thoracic endometriosis syndrome.[28,29] Hemothorax in the setting of endometriosis, although rare, is often right sided and reflects a large pleural endometrial burden.[30,31]

IATROGENIC HEMOTHORAX

Iatrogenic causes of hemothorax have been documented following thoracic surgical procedures, thoracentesis, pleural biopsies, lung biopsies, vascular catheterization, anticoagulation, and cardiopulmonary resuscitation (Fig. 113.3; see also eFig. 21.5).

The incidence of hemothorax following thoracentesis is typically low, with a reported overall risk of 0.01%.[32] The addition of ultrasound guidance allows for identification of

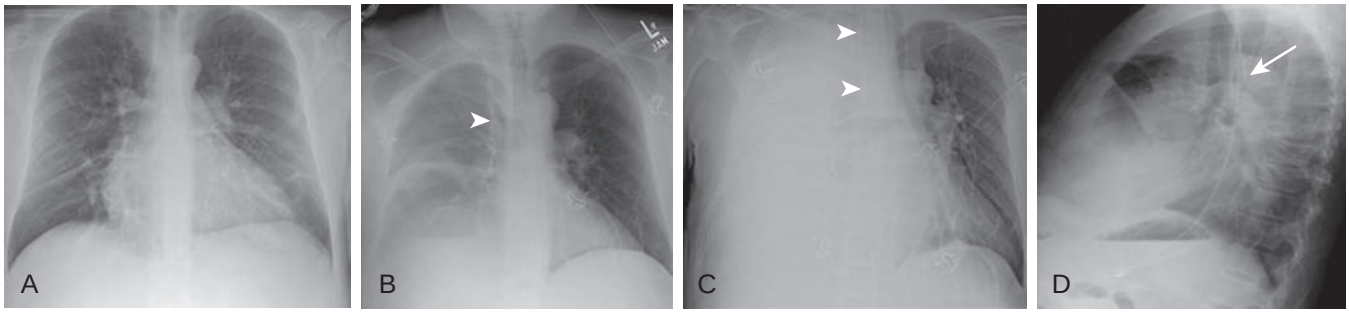

Figure 113.3 Hemothorax following central venous catheter insertion. (A) Frontal chest radiograph obtained several hours prior to right internal jugular central venous catheter insertion. (B) Frontal chest radiograph obtained immediately following right internal jugular central venous catheter insertion later the same day, 14 hours after A, shows new right pleural effusion. The catheter (*arrowhead*) projects over the expected location of the superior vena cava. Frontal (C) and lateral (D) chest radiography performed 6 hours after B shows complete opacification of the entire right hemithorax with contralateral mediastinal shift, consistent with a large pleural effusion. The lateral chest radiograph (D) shows that the catheter (*arrow*) has an abnormal posterior course, clearly posterior to the trachea, and incompatible with superior vena cava placement.

the superior border of the rib and avoidance of the inferior rib border where the intercostal vessels are located and at risk for disruption. A vascular ultrasound probe with color flow may allow for improved identification and avoidance of vascular thoracic structures.[33]

Although there are no randomized trials reviewing bleeding complications associated with thoracentesis and coagulopathy, current data suggest that there is no association between laboratory values of coagulopathy, administration of anticoagulative therapy, and risk of bleeding complication. Historically, correction of *international normalized ratio* (INR) greater than 2.0 and platelets for counts less than 50,000/μL were encouraged prior to thoracentesis due to presumed increased bleeding risk. Ault et al., in a prospective study over 12 years of thoracenteses, found no significant correlation between postprocedural bleeding and INR, partial thromboplastin time, and platelet count values.[34] Hibbert et al. completed a prospective cohort analysis of patients with INR greater than 1.6 and/or platelet values of less than 50,000 μL. The patients were placed into two groups, those whose coagulopathy was corrected prior to thoracentesis and those whose procedures were completed without correction. Hibbert et al. identified a total of two hemothoraces requiring evacuation out of 303 thoracenteses performed. Both hemothoraces were in the group of patients receiving correction of coagulopathy.[35] A third study reviewing thoracentesis or the placement of small-bore chest tubes in patients on clopidogrel reported 1 of 25 (4%) patients with hemothorax whereas no patients in the non-clopidogrel group had the same complication.[36] Clinical judgment and procedural experience is used to determine the need for corrective blood products or coagulopathy reversal agents. In elective procedures and extreme coagulopathy such as platelet counts 20,000/μL or less, INR 5 or greater, or use of multiple antithrombic medications, consideration of reversal agents is recommended. Conversely, in patients where the risk of holding or correcting anticoagulation is high, such as in the setting of recent deep vein thrombosis/pulmonary embolism, stroke, or cardiac intervention, one may consider proceeding without administration of reversal agents. In these higher-risk settings, the use of ultrasound guidance and an experienced operator are required.

The incidence of hemopneumothorax following central venous catheter placement is reported as 1.3–1.5% with no significant difference in the subclavian versus internal jugular approach.[37] Currently, ultrasound guidance is the standard of care for placement of a central venous catheter. Inadvertent puncture of the subclavian artery and development of hemothorax are significantly reduced using ultrasound guidance.[38]

MANAGEMENT

The first line of treatment for hemothorax is pleural drainage. Most commonly, this is performed with tube thoracostomy. The *Eastern Association for the Surgery of Trauma* (EAST) practice management guidelines recommend drainage of all hemothoraces irrespective of presumed volume.[17] However, risks associated with tube thoracostomy placement are documented at 22% and include empyema, pneumonia, residual hemothorax, and chest tube malposition with need for a second chest tube.[39,40] Due to these risks, there have been challenges to these guidelines to determine the minimal volume requiring pleural drainage. Updated EAST guidelines from 2020 have suggested that clinical judgement and the effect on pulmonary function may be considered in the decision to drain small hemothoraces.[40a]

The classic model of expectant management was described by Stein et al., who determined the "Stein line," or height at which a meniscus is visible on upright chest radiograph and likely represents an effusion volume of 200 to 300 mL. Stein determined that those patients with pleural fluid volumes below 300 mL could be managed without pleural drainage.[41] This view was further supported in 2018 by Demetri et al. in a retrospective review of 340 patients with traumatic hemothorax. A hemothorax greater than 300 mL, concurrent pneumothorax, and advanced patient age were predictors for failed observation, requiring placement of a tube thoracostomy or intervention after 24 or more hours of observation.[42] Several additional studies suggest that successful expectant management may be achieved in patients with 300 mL or less with close observation and repeat imaging.[9,43-45] To date, there is no universally accepted approach to patients with hemothorax. In patients who are expectantly managed, it is recommended that trends in hematocrit, changes in the physical exam, and review of subsequent axial or upright anteroposterior imaging over 24 hours direct the decision to proceed with more invasive procedures.

In patients for whom tube thoracostomy is indicated, historically, a large-bore (32-French or greater) tube was recommended. More recent studies suggest that smaller-bore percutaneous thoracostomy tubes result in equivalent pleural drainage and complication rates. In a prospective study by Bauman et al., patients requiring chest drainage were reviewed and evaluated for volume of drainage, complications, and failure rate. The study determined that the use of 14-French pigtail catheters were not inferior to larger bore (32- to 40-French) chest tubes.[46] Several additional studies in trauma patients with hemothorax have returned similar findings.[47-49] Kulvatunyou et al. compared patients with large-bore chest tubes and patients with 14-French catheters placed both emergently at day 0 and delayed up to 10 days with a mean placement date of 2.3 days. The patients with 14-French catheters were found to have equivalent drainage.[50] Traditional thoracic surgical dogma is that a chest tube should be placed at the base of the lung for optimal drainage of a hemothorax. In a 2015 study in the *Journal of Trauma*, the authors determined whether the positioning of a "directed" chest tube led to improved drainage of acute hemothorax. Tube location was confirmed by CT imaging. The findings in the 291 patients reviewed suggest that, in patients with acute hemothorax, inserting a tube in any location, preferably in the "triangle of safety," as shown in Figure 113.4, with the application of suction should provide equivalent drainage of hemothorax.[51]

In patients with significant comorbidity or those deemed poor surgical candidates, transcatheter arterial embolization of the intercostal artery may be considered in patients with intercostal artery hemorrhage identified on imaging or due to high suspicion. Following embolization, 90% of patients require surgical intervention ranging from chest tube placement to video-assisted thoracic surgery/thoracotomy for evacuation of hemorrhage.[52] Patients with severe anemia or chronic liver failure, or those requiring embolization of two or more arteries, are at increased risk of technical failure and rebleeding.[52] Although embolization is often safe and reliable, complications can be serious; spinal cord ischemia resulting from inadvertent displacement of embolic material into the artery supplying the spinal cord (the artery of Adamkiewicz or the anterior segmental medullary artery) and hemoptysis due to collateral vessel rupture have been documented.[53]

Figure 113.4 Triangle of safety. The triangle of safety is bordered by the pectoralis major muscle anteriorly, the latissimus dorsi muscle posteriorly, and the fourth to fifth intercostal space distally.

The need for surgical intervention in patients with hemothorax is based largely on experience acquired during the Vietnam War.[54] Expert opinion has led to the recommendation for surgical intervention in patients with acute blood loss of 1500 mL or more upon chest tube placement or 500 mL of retained hemothorax on chest radiograph following tube thoracostomy.[54] This scrutiny also led to the suggestion that patients with persistent drainage of 250 mL or more over 3 to 4 hours undergo surgical intervention. Karmy-Jones et al. corroborated this observation in a retrospective multicenter review. The risk for death was 3.2 times greater if chest tube drainage exceeded 1500 mL prior to thoracotomy than with chest tube drainage of 500 mL or less.[55]

Retained hemothorax, seen in up to 35% of patients managed with tube thoracostomy, may progress to empyema (see below).[56] Although surgery is the most common strategy for those with retained hemothorax, observation alone has been reported to be successful in selected patients such as those with fluid collections estimated as less than 300 mL on CT, the elderly, those without rib fractures, and those whose chest tubes were initially placed for management of pneumothorax.[43,56] Due to the increasing use of lytic therapy for the management of empyema, this therapy has been proposed as an alternative to surgery for patients with retained hemothorax.[57] A meta-analysis published in 2019 suggests that up to 87% of patients with retained hemothorax avoided surgical intervention with the use of lytic therapy. Additionally, less than 7% of patients who were given tissue plasminogen activator experienced a bleeding complication.[58] Despite these positive findings, current literature recommends the use of lytic therapy only in patients who cannot tolerate surgery due to their inability to tolerate single-lung ventilation or to the presence of comorbidities precluding surgery as a safe option.[17] This view has been supported by the 2020 EAST practice guidelines.[40a]

As a general rule, in the majority of patients with recent hemothorax, the hemothorax can be evacuated effectively with minimally invasive surgical approaches. Patients who present with hemodynamic instability or with more mature or chronic hemothoraces are more likely to require a thoracotomy.[17]

COMPLICATIONS OF HEMOTHORAX

Documented complications in patients with hemothorax include empyema and pneumonia. Fibrothorax, although often considered a complication, has not been confirmed to be a complication of hemothorax.

Empyema, as previously mentioned, can be a complication of retained hemothorax. A prospective observational multicenter study of 328 patients with retained hemothorax found an incidence of empyema of 26%.[56] Empyema was associated with higher volumes of hemothorax retention (>300 mL) and was more common in patients who required bilateral chest tube placement following traumatic injury. In this cohort of posttraumatic patients, independent risk factors for the development of empyema included longer duration of tube thoracostomy, longer intensive care unit length of stay, rib fractures, presence of pulmonary contusion, and need for exploratory laparotomy.[56] However, in another study of trauma patients with hemothorax, the incidence of empyema was lower (4.9%), with a similar incidence in those with retained hemothorax and

those with completely drained hemothorax. The authors suggest that incidence of empyema in their study was not related to retained hemothorax, but to other factors such as shock, pleural contamination, pneumonia, and duration of chest tube drainage.[59] In another study of 102 patients with hemothorax, 9% developed empyema; however, the incidence of empyema was higher in those with retained hemothorax (33%) than in those without (2%).[60] These studies suggest that all patients with hemothorax require close observation to ensure that the development of empyema is quickly identified and managed.

Pneumonia has been documented in 20% of patients with retained hemothorax in trauma patients. Development of pneumonia following hemothorax is associated with age greater than 55 years, blunt trauma, and the presence of pneumothorax requiring tube thoracostomy placement. Additionally, the development of pneumonia was found to be associated with patients who were not dosed with empiric antibiotics at the time of chest tube insertion.[61] Conversely, a 2004 prospective multicenter study comparing cefazolin dosed for 24 hours and cefazolin dosed for the duration of tube placement versus placebo failed to identify a significant decrease in the incidence of empyema or pneumonia.[61a] Currently, there is no official recommendation for or against the use of antibiotics to reduce the incidence of empyema or pneumonia in chest tube placement.[62] Further studies are currently reviewing the use of antibiotics in the setting of chest tube placement.

Fibrothorax or "trapped" lung has historically been a concern for delayed management of retained hemothorax; however, the association between retained uncomplicated hemothorax and development of fibrothorax has not been established. Findings suggest that retained hemothorax is not an independent risk factor for development of clinically relevant fibrothorax. Rather, fibrothorax is more likely due to the presence of poor or delayed empyema management.[60,63] Aggressive identification and management of empyema with appropriate drainage versus decortication if required is recommended (see Chapter 112).

SURGICAL INTERVENTION

Either video-assisted thoracoscopic surgery or open thoracotomy is an appropriate surgical approach to hemothorax. Video-assisted thoracoscopic surgery should only be considered in hemodynamically stable patients. In hemodynamically unstable patients, thoracotomy is preferred. The operation is performed in lateral decubitus position in both video-assisted thoracoscopic surgery and thoracotomy. If a thoracotomy is required, typically a posterolateral approach is used, and the chest is approached through the fourth or fifth interspace. The surgeon may choose to alter the interspace or even the type of incision, depending upon where the preponderance of clot burden appears to be on the preoperative chest CT or the presence of additional injuries. Video-assisted thoracoscopic surgery is usually performed with three ports—an anterior, utility, and camera port—but has been used with one port.[64] Regardless of the approach, the operation is accomplished using suction and generous irrigation with sterile water or saline to remove free blood and loose clot. Mechanical removal is typically required for more mature clot, and a decortication with sharp dissection may be required for empyema or fibrothorax. The pleural space is inspected for a bleeding source that, if identified, may be controlled with a variety of techniques, including electrocautery, suture ligation, mechanical stapling, lung resection, and/or application of hemostatic agents. The goals of the operation are to remove all the blood from the chest, control any identified bleeding source, and achieve maximal lung reexpansion; for optimal postoperative care, the goals of surgery are to provide adequate chest tube drainage to maintain lung expansion and to identify/evacuate any subsequent bleeding. The typical number of chest tubes placed ranges from one to three depending upon the operative findings, the procedure performed, and the surgeon's judgment/experience.

Key Points

- Hemothorax is an accumulation of blood within the pleural space.
- Hematocrit of the pleural fluid is greater than 50% of the hematocrit of the patient's peripheral blood in hemothorax.
- Hemothorax can be traumatic (blunt or penetrating), nontraumatic, or iatrogenic.
- Computed tomography scan is the gold standard in the detection of hemothorax. Ultrasonography and chest radiography may also diagnose and monitor hemothorax.
- The first line of treatment for hemothorax is pleural drainage.
- Small-bore (14-French) tube thoracostomy is not inferior to large-bore (32- to 40-French) drainage catheters.
- Expectant management may be achieved in patients with a small hemothorax, of 300 mL or less, with close observation and repeat imaging.
- Arterial embolization can be considered in patients with active intercostal artery bleeding who are considered poor candidates for surgery.
- Surgical intervention may be required when there is (1) acute blood loss of 1500 mL, (2) retained hemothorax of 500 mL or greater on chest radiograph following tube thoracostomy, or (3) persistent drainage of 250 mL or more over 3 to 4 hours.

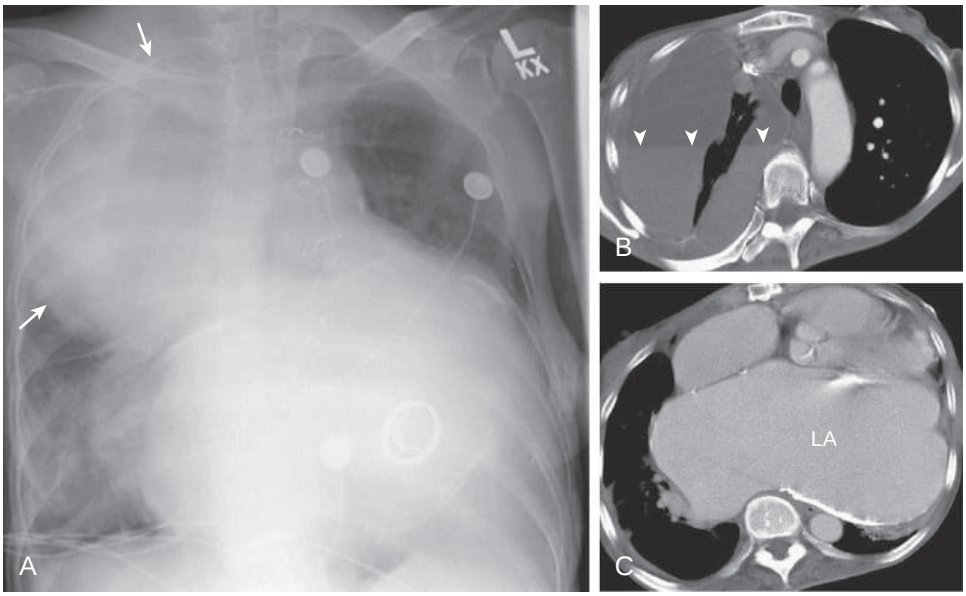
	Normal	Blunting below Hemidiaphragm	Blunting at Hemidiaphragm	Obscuring of Hemidiaphragm
Score	0	1	2	3
Mean Volume		100 mL	250 mL	650 mL

eFigure 113.1 Prediction model for visual estimation of pleural fluid on the frontal upright chest radiograph. A score of 0 corresponds to a normal image. A score of 1 indicates a blunted costophrenic angle and the presence of a meniscus below the hemidiaphragm. A score of 2 indicates a blunted costophrenic angle and meniscus identified at the level of the hemidiaphragm. A score of 3 indicates that the hemidiaphragm is completely obscured. The scores 1, 2, and 3 are given a volume of up to 100 mL, 250 mL, and 650 mL, respectively.



eFigure 113.2 Iatrogenic hemothorax following thoracentesis showing the "hematocrit effect." (A) Frontal chest radiography in a patient with rheumatic heart disease treated with anticoagulation shows a large, homogeneous opacity in the superior right thorax (*arrows*) that developed following thoracentesis for right pleural effusion. Note prosthetic mitral valve. (B–C) Axial enhanced thoracic computed tomography shows a hematocrit level (i.e., blood-fluid level [*arrowheads*]; the dependent high attenuation is due to the heavier blood elements settling dependently). Note enlarged left atrium (LA) with wall calcification. (Courtesy Michael B. Gotway, MD.)

KEY POINTS

INTRODUCTION

Malignant pleural effusion (MPE) is the second most common cause of exudative pleural effusion, after infection.[1] In most cases, MPE represents spread of metastatic cancer, and the treatment goal is palliation, not cure. Survival is generally poor, with a median of 4 months, although significant individual variations exist.[2] In the United States, there are approximately 126,000 hospital admissions for MPE annually, with a mean length of stay of 6.3 days.[3] Thirty-day readmission rates are almost 40%,[4] which is significantly higher than for acute myocardial infarction and congestive heart failure. Hospitalization costs for MPE amounted to $1.37 billion in the United States alone in 2014.[3]

Malignant mesothelioma is the most common primary pleural cancer and affects approximately 15,000 persons per year worldwide. Its global incidence is growing, especially in developing regions.[1] Mesothelioma is universally fatal with a median survival of 12 months.[5] Less common tumors such as solitary fibrous tumor of the pleura, primary effusion lymphoma, and pyothorax-associated lymphoma are also discussed.

METASTATIC PLEURAL DISEASE

TYPES OF TUMOR

Most primary cancers can spread to the pleura, the most common being lung, breast, gastrointestinal, and genitourinary cancers, as well as lymphomas (Table 114.1). Pleural effusion is the most common presentation of pleural malignancies. Most cases are exudative.[6] Transudative malignant effusions are now a recognized phenomenon as a result of concurrent causes of transudative fluid formation (especially cardiac failure in the elderly). In occasional cases of MPE, the primary tumor is never identified, although this is becoming less common with advances in diagnostic pathology.[7]

The patterns of metastatic spread are different between primary and secondary malignant pleural cancers. Malignant mesotheliomas generally originate on the parietal pleura and spread to the visceral pleura, whereas metastases from lung or other cancers usually involve the visceral pleura before spreading to the parietal pleura.[6,8] Most MPEs from bronchogenic carcinoma arise from the ipsilateral side of the primary tumor.[8]

CLINICAL FEATURES

Breathlessness, and sometimes cough, are the most common symptoms of an MPE (see also Chapter 108). These symptoms are nonspecific and often multifactorial. Removal of the fluid may be the only means to determine if, and how much of, the breathlessness and cough are attributable to the MPE. In a series of 150 patients undergoing pleural fluid drainage (median, 1.6 L), 27% did not find relief of breathlessness after fluid evacuation.[9] Clinicians should search for other pleural (tumor encasement of the lung), pulmonary (e.g., pulmonary emboli, pneumonia, tumor obstruction of airways), or systemic (e.g., anemia) causes for the symptoms.[10]

Chest pain can often be described as a dull ache and may indicate involvement of the chest wall and/or parietal pleura. Systemic symptoms associated with cancer (e.g., weight loss and malaise) should not be overlooked.

MALIGNANT PLEURAL EFFUSIONS

Malignant pleural disease can exist without pleural effusion (Video 114.1). In autopsy studies of patients with malignancy, pleural malignancy was found *without* an effusion in 40%[8] to 45%[6] of cases. Malignant cells can reach the

pleural space without effusion and lavage of the pleural space before resection of lung cancer in those without effusion can have positive cytologic results in as many as 5.3% in a study of 1200 patients undergoing surgery.[11] Positive cytologic results on pleural lavage indicate poorer prognosis and may be incorporated into future modifications of lung cancer staging systems. The development of an MPE may depend on the ability of the tumor cells themselves to secrete bioactive mediators or their ability to initiate inflammatory, angiogenic, or fibrinolytic processes in the normal tissues.[12]

Lung cancer is the most common cause of MPEs[13] (see Table 114.1) and, together with breast cancer, accounts for more than half of all MPEs. Of the histologic types of bronchogenic cancers, adenocarcinomas are most frequently associated with MPEs, but effusions may be seen with all types.[14] In patients who had surgical resection of lung cancer, presence of visceral pleural invasion beyond the elastic layer is now a recognized adverse prognostic factor.[15,16] Standardized grading for visceral pleural invasion (from PL0 to PL3) has been incorporated into the International Association for the Study of Lung Cancer tumor-node-metastasis staging scheme.[17,18]

Breast cancer is the second most common cause of MPEs.[13,19] Effusion often develops within a few years of the initial diagnosis but can present much later, even after 20 years. The effusion is usually ipsilateral to the site of the original tumor (50%) but can also be contralateral (40%) or bilateral (10%).[20]

Lymphoma is the third most common cause in most series[13] but is possibly the most common cause in young adults.[19] Pleural effusions are common in both non-Hodgkin (eFigs. 114.1 and 114.2A) and Hodgkin lymphoma.[21] In patients with non-Hodgkin lymphoma, approximately 16% will develop malignant effusions, and most will have the effusion at the time of initial diagnosis in association with evidence of disease elsewhere.[22] Chylothorax is common with non-Hodgkin lymphoma; in one analysis of 88 patients with chylothorax, 12.5% were due to lymphoma, all non-Hodgkin lymphoma.[23] In Hodgkin lymphoma, effusions may be caused by hilar or mediastinal lymph node involvement as well as pleural involvement.[21] In one study of 110 patients presenting with Hodgkin lymphoma, effusions were present in 26 (24%); these were equally unilateral or bilateral. The presence of effusion was more common in those with higher-stage cancer, extranodal involvement, and bulky mediastinal disease.[24]

Malignancies produce pleural fluid accumulation often both by increasing the entry of fluid into the pleural cavity and decreasing its exit (Table 114.2) (see Chapter 14). Pleural fluid formation can be increased by several mechanisms: (1) increased permeability of the pleural vessels by direct invasion of tumor cells, inflammatory and vasoactive cytokines (e.g., *vascular endothelial growth factor* [VEGF]), or injury (e.g., radiation induced); (2) increased permeability of *pulmonary* vessels by infection, pulmonary embolism, or pulmonary infarct, with movement of liquid from lung to pleural space; (3) increased hydrostatic forces due

Table 114.1 Primary Tumors Responsible for Malignant Pleural Effusion

Primary Tumor Site	Total (%)
Lung	37.5
Breast	16.8
Lymphoma	11.5
Gastrointestinal	6.9
Genitourinary	9.4
Other*	7.3
Unknown	10.7

A compilation of data from five different reports with a total of 2040 patients.

Table 114.2 Physiologic Mechanisms (Neoplastic and Paraneoplastic*) by Which Malignancy May Cause Pleural Effusions

Means of Increasing Liquid	Mechanism	Site/Source	Examples
Increased entry	Increased vascular permeability	Pleural vessels	Invasion by tumor Cytokines (e.g., VEGF) Injury (e.g., radiation)
		Pulmonary vessels	Infection (e.g., postobstructive pneumonitis) Cytokines/injury
	Increased vascular hydrostatic gradient	Pleural vessels	Decreased pleural pressure (e.g., atelectasis) Increased venous pressure (e.g., SVC syndrome) Decreased plasma osmotic pressure (e.g., hypoproteinemia)
	Nonvascular entry	Thoracic duct	Chylothorax
Decreased exit	Increased resistance to lymphatic flow	Pleural lymphatics Lymph nodes	Infiltration of parietal pleura Infiltration of mediastinal lymph nodes
	Increased gradient opposing lymphatic flow		Decreased pleural pressure (e.g., atelectasis) Increased venous pressure (e.g., SVC syndrome)

Both an increase in entry and a decrease in exit are likely required to produce a stable pleural effusion.
*Refers to mechanisms taking place outside the pleural space.
SVC, superior vena cava; VEGF, vascular endothelial growth factor.
Modified from Broaddus VC. Physiology: fluid and solute exchange in normal physiological states. In Light R, Lee Y, eds. *Textbook of Pleural Diseases*. 2nd ed. London: Hodder Arnold; 2008:43–48.

to venous obstruction or hypoproteinemia; and (4) entry of other sources of fluid (e.g., chyle) from a disrupted thoracic duct. Exit of fluid from the pleural space can decrease by mechanisms that reduce lymphatic drainage: (1) infiltration of parietal pleural lymphatics or mediastinal lymph nodes, (2) lowered pleural pressure due to atelectasis from bronchial obstruction, or (3) elevated central venous pressure, as from superior vena cava syndrome. Often multiple factors combine to form a pleural effusion in association with malignancy.[25]

Pleural malignancy may come to light when the advent of another nonmalignant condition, such as heart failure or pneumonia, precipitates the appearance of a symptomatic pleural effusion. In these cases, malignancy may contribute to, but not be the sole cause of, the effusion.[25] The combination of different processes may explain how malignancy can be associated with transudative effusions, for example, if malignancy interferes with lymphatic clearance and a separate transudative process increases entry of fluid into the pleural space.[26] In the same way, malignancy may lead to bilateral effusions; in a prospective study of bilateral effusions, malignancy was found to be a common contributing cause along with other processes.[27]

Understanding the mechanisms of effusion formation could lead to new therapeutic approaches, especially to counteract the vascular hyperpermeability. In several animal studies, bioactive molecules involved in angiogenesis and permeability, such as VEGF and monocyte chemotactic protein-1,[28–30] have been identified that may play key roles in accumulation of effusions in malignancy.[12] However, there remains no convincing evidence of clinical benefits of therapy targeted to VEGF (e.g., bevacizumab or cediranib) to control MPE to date.[31,32]

PLEURAL FLUID ANALYSIS

The majority of MPEs are exudates. The higher protein and lactate dehydrogenase values are caused by increased vascular permeability and inflammatory changes. Interestingly, at least 5% of MPEs are transudates.[33] The primary etiology of fluid formation, in most of these cases, is a transudative cause (e.g., congestive heart failure, superior vena cava syndrome, volume overload) in which malignancy has a secondary, contributing role.[33]

The fluid usually is lymphocyte predominant. Although eosinophils may be present, they are not helpful in diagnosis. In a study of 460 effusions, 20% of the eosinophilic effusions were found to be malignant, as were 20% of noneosinophilic effusions.[34] Eosinophilia is most likely a result of prior entry of air or blood into the pleural space. Malignant disease is the most common cause of bloody effusions.[35] However, about half of malignant effusions are not bloody in appearance (pleural fluid red blood cell counts < 10,000 cells/μL).[35]

MPEs are often metabolically active with low pleural fluid pH and glucose concentrations.[36] Some studies have reported a shorter survival with MPEs of a low pleural pH or glucose,[37,38] presumably a reflection of larger pleural tumor burden as well as a lower likelihood of pleurodesis success; however, these associations were not shown in other studies.[37–41] Neither pleural fluid pH nor the glucose level should therefore be relied on for selecting patients for pleurodesis.

Pleural fluid amylase concentration is elevated in 10% of MPEs.[42] However, the origin of the amylase is from a salivary rather than a pancreatic source.[43] In one series of consecutive effusions, a very high amylase concentration in MPE (>600 IU/L) was a poor prognostic factor.[42] Hyaluronan is known to be present in higher concentrations in mesothelioma pleural effusions[44,45] but is not considered to have sufficient diagnostic accuracy as a standalone test. Its supplementary role to fluid cytology[46] and other biomarkers such as mesothelin[44,45] is a subject of research.

RADIOGRAPHIC EVALUATION

The size of MPEs varies from small to complete "whiteout" of the hemithorax. In one retrospective series of 766 patients, malignancy was found as the cause of 55% of large (opacifying two-thirds of the hemithorax) and massive (opacifying the entire hemothorax; see eFigs. 114.1A and 114.2A) effusions[47]; the other causes were pleural empyema and tuberculous effusions. Interestingly, cytologic examination was no more likely to be positive in these large/massive effusions than in smaller ones (63% yield from large effusions, 53% from small).[47]

If the effusion is large, the mediastinum is expected to shift contralaterally in an uncomplicated situation (see eFig. 114.2A). If the mediastinum stays midline, one can suspect either significant ipsilateral lung collapse offsetting pressure from the presence of the effusion, or a fixed mediastinum that cannot shift in response to a pressure differential. If the mediastinum is shifted toward the side of the effusion, the pressure is most likely lower on the side of the effusion than on the other side (Video 114.2); in that case, a central bronchial obstruction or significant lung infiltration by tumor (see eFig. 114.2B) should be suspected, and the lung is unlikely to expand fully with fluid drainage.

Pleural ultrasound is useful to detect the presence of pleural fluid, guide thoracentesis, and allow assessment of the parietal and diaphragmatic pleura (see Video 23.16) and can help direct biopsy. Findings of pleural thickening greater than 1 cm, pleural nodularity, and diaphragmatic thickening greater than 7 mm are highly suggestive of malignant disease.[48]

Computed tomography (CT) is part of routine workup of MPE. Features that have been found to be helpful in distinguishing malignant from benign pleural disease are circumferential pleural thickening, nodular pleural thickening, parietal pleural thickening greater than 1 cm, and mediastinal pleural involvement[49] (Fig. 114.1 and eFig. 114.3). The specificities of these findings were 100%, 94%, 94%, and 88%, respectively, and the sensitivities were 41%, 51%, 36%, and 56%, respectively. In a CT study of 211 consecutive patients with effusions, the most specific findings for malignancy were pleural nodules and nodular thickening.[50] Pleural thickening alone was not as specific and could be seen in many benign conditions. When present, pleural nodules were highly specific, but they were evident only in 17% of MPEs. Half of the patients with malignant effusions had no pleural abnormalities detected on CT, possibly due to the relative lack of difference in attenuation between the pleural thickening, nodules, and adjacent pleural fluid. Interestingly, the presence of air in the pleural cavity—because of nonexpandable lung or genuine

air leak—can outline fine pleural abnormalities (especially nodules) on CT.[51]

CT may also reveal the site of the primary cancer (e.g., pulmonary or breast lesions) and/or other metastatic sites. These features would favor a malignant cause for the effusion (Video 114.3).[50] Even minimal pleural effusions may represent malignant involvement; in patients with lung cancer, a minimal (<10 mm thick) effusion on CT has been shown to be a poor prognostic factor; these minimal effusions were thought to indicate early malignant involvement of the pleural space or of the mediastinal lymph nodes.[52] When performing a CT for the workup of a pleural effusion, a pleural phase enhancement contrast scan may help to uncover subtle pleural abnormalities.[53]

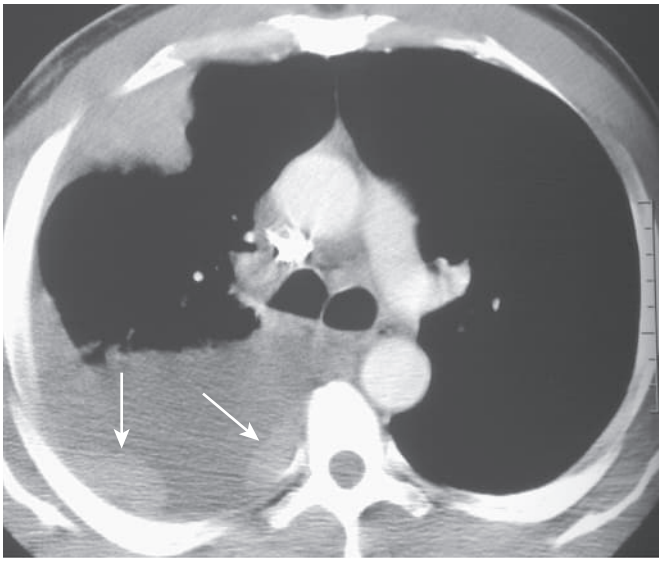

Figure 114.1 Metastatic adenocarcinoma. Axial contrast-enhanced chest computed tomography shows right pleural effusion associated with enhancing nodular masses (*arrows*) emanating from the parietal pleura, later shown to be metastatic adenocarcinoma. (Courtesy Michael B. Gotway, MD.)

Magnetic resonance imaging is not advocated for routine evaluation of MPEs. However, its excellent soft tissue contrast may be useful for a detailed evaluation of tumor invasion, especially of the chest wall and pleura as well as in the apices of the hemithoraces.[54]

Positron emission tomography (PET) with *^{18}F-fluorodeoxyglucose* (^{18}FDG), used appropriately, can add valuable information to the workup of potential MPEs in several ways. In cases of significant pleural thickening, absence of ^{18}FDG uptake favors a benign etiology and may help to avoid pleural biopsies. ^{18}FDG-avidity can be due to malignancy but can also represent active pleural inflammation of a benign nature. For example, ^{18}FDG-avidity can persist (probably indefinitely) after talc pleurodesis[55] (Fig. 114.2). In patients with diffuse pleural thickening (or abnormalities) suitable for image-guided pleural biopsy, a preceding PET scan may help in the selection of biopsy sites. PET may also reveal extrapleural sites (e.g., regional lymphadenopathy) more accessible than the pleura for a biopsy to provide a diagnosis. PET with novel tracers other than ^{18}FDG may offer information other than inflammation (e.g., cell proliferation with ^{18}F-thymidine) and is an area of active research.[56,57]

DIAGNOSIS

Cytologic examination is reportedly diagnostic in approximately 60% of patients,[58] but the diagnostic yield varies with the type of tumor, extent of tumor involvement of the pleura, and the expertise of the cytologist. Cytologic results are more likely to be positive in adenocarcinoma than in squamous cell lung cancer, for example, perhaps because adenocarcinoma is more often located peripherally and has a greater tendency to invade the pleural space.[35] Interestingly, cytologic yield does not vary greatly with the size of the effusion, as mentioned.[47] Generally speaking, repeating thoracentesis does not increase the yield of cytology for malignancy unless the first sample was inadequately processed or was very small in volume.

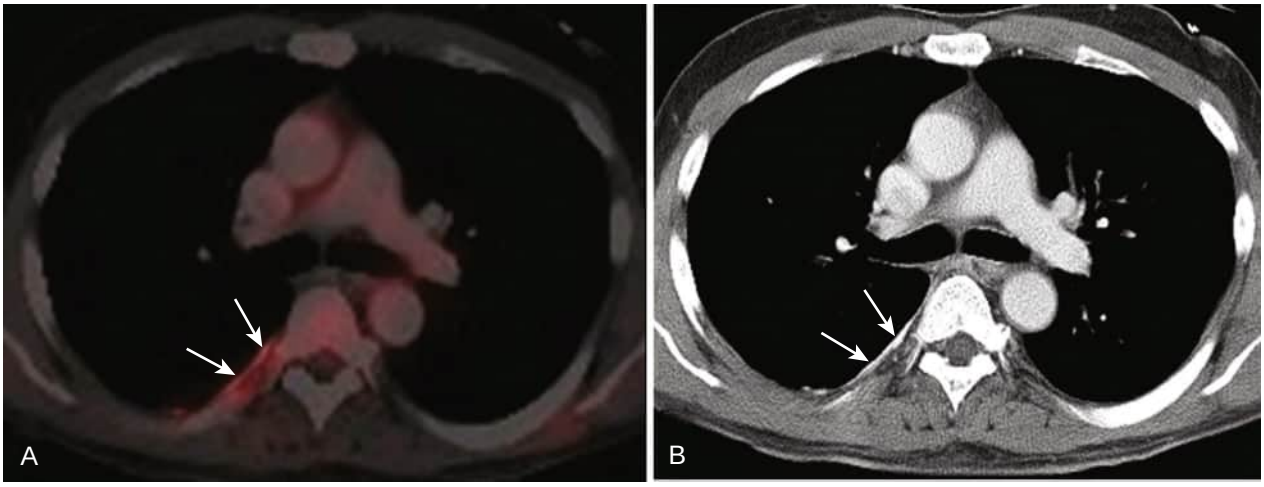

Figure 114.2 Increased *positron emission tomography* (PET) activity at site of talc pleurodesis. (A) A PET/*computed tomography* (CT) scan obtained in a patient with a prior talc pleurodesis for recurrent pneumothorax shows increased pleural uptake (*arrows*). (B) The axial chest CT image confirms that the area of increased PET uptake corresponds to an area of high attenuation (*arrows*) characteristic of talc deposits. (Courtesy Michael B. Gotway, MD.)

Immunohistochemical staining of cell blocks can be quite useful for diagnosis. Certain markers, such as thyroid transcription factor 1, have a high specificity for a primary lung tumor, whereas GATA3 may be useful for breast cancer.[59]

Molecular studies can be carried out using cytologic specimens, including sequencing for mutations of epidermal growth factor receptor[60]; with highly sensitive sequencing (e.g., next-generation sequencing),[61] such markers may be detected even when cytologic examination reveals a low percentage or even no malignant cells.[62] Pleural fluid supernatant and cells can both be tested to increase the yield.[63,64]

Biopsy may be necessary when cytologic examination is negative or indeterminate. In the past, closed (or "blind") pleural biopsy was performed as a next step in cases where cytologic results were negative. However, the patchy involvement of the parietal pleura by malignancy appears to make closed pleural biopsy a hit-or-miss technique and, not surprisingly, image-directed biopsies have been shown to be more accurate. In one randomized study comparing CT-guided biopsy with closed pleural biopsy using an Abrams needle, CT-guided biopsy was significantly more sensitive (87% vs. 47%) with a better negative predictive value (80% vs. 44%).[65] Thoracoscopy is a well-tolerated procedure that permits excellent visualization of the entire pleural surface (see Chapter 29). Directed biopsies of suspicious areas lead to a correct identification of metastatic pleural disease in nearly 100% of cases.[66] This technique has additional advantages, including the ability to provide large biopsy specimens for immunohistochemical and genetic analysis for molecular markers (e.g., epidermal growth factor receptor), if needed, to provide information about the gross appearance of tumor, to provide information for staging, to lyse adhesions, and to drain the pleural space for talc pleurodesis. It is worth remembering that an initial approach to the diagnosis of metastatic disease may be by fine-needle aspirates of abnormal lymph nodes in the supraclavicular or cervical regions or in the mediastinum, which can obviate the need for more invasive procedures.

Biomarkers in pleural fluid have the potential to assist the cytologic diagnosis. Unfortunately, biomarkers have had indeterminate sensitivity and specificity, leading to overlap between malignant and nonmalignant conditions. One approach has been to combine tumor markers to improve diagnostic yield, although malignancy can also be predicted by using clinical characteristics (time of symptoms >1 month, absence of fever, serosanguineous fluid, and chest CT findings of malignancy).[67] For mesothelioma, detecting the molecule mesothelin, a product of mesothelial cells, may have diagnostic utility in certain circumstances (see "Mesothelioma" section later).[68–70] However, pleural fluid mesothelin levels are elevated in some patients with malignant effusions other than mesothelioma, whereas the mesothelin level is not elevated in benign effusions (provided the patient has no renal impairment). A high mesothelin level is therefore strongly suggestive of the presence of pleural malignancy and requires further workup.[70]

Two new diagnostic markers have significantly improved the diagnosis of mesothelioma from cytologic and histologic specimens and have been included in diagnostic guidelines.[71] Loss of *BRCA-1 associated protein* (BAP)-1 by immunostaining and homozygous loss of the cyclin-dependent kinase inhibitor 2A gene by fluorescent in situ hybridization in cells of mesothelial lineage are now recognized as diagnostic of mesothelioma.[72] (See "Mesothelioma" section later for details.)

The future of diagnosis may include genetic analysis, either for features of malignancy (DNA methylation, mutations, microsatellite, telomerase, aneuploidy) or in the genetic expression fingerprint (microarray) characteristic of tumors.[73,74] High-throughput sequencing technology enables rapid sequencing of either the whole genome or the small percentage of the genome coding for expressed genes (i.e., the exome). Cell-free DNA, captured either in pleural fluid supernatant or blood, has shown significant promise in helping diagnose certain cancers and in capturing driver mutations in lung cancer patients.[75]

THERAPY AND PALLIATION

The therapeutic and palliative approach to MPEs is guided by many factors (Table 114.3). First, the clinician should determine whether the effusion is causing either dyspnea or cough, symptoms that can be due to the volume of the effusion and its effect on lung and cardiac function. Often that may be evident from the parallel worsening of symptoms and progressive increase of effusion on imaging. In patients with multiple causes of breathlessness (such as severe cardiac dysfunction, extensive parenchymal lung disease, or significant pulmonary emboli), it is useful to establish the extent of symptom relief of fluid removal (e.g., by therapeutic thoracentesis) before embarking on any invasive "definitive" procedures for long-term fluid control. In the PLEASE (Pleural Effusion And Symptom Evaluation) study,[9] 27% of the 145 patients who underwent fluid drainage (median, 1.6 L) did not have significant improvement

Table 114.3 Options for Control of Symptomatic Malignant Effusions

Option	Patient Eligibility and Considerations
Chemotherapy, targeted therapy	Responsive tumor
Therapeutic thoracentesis	Slowly recurring effusion Used for patients with very short life expectancy
Pleurodesis	
Via chest tube	Lung able to reinflate
Via thoracoscopy	Can free up lung tacked down by adhesions, obtain biopsies Thoracoscopy must be available
Indwelling pleural catheter	Can be used as first line and coupled with talc pleurodesis if suitable Good outpatient situation Good for trapped lung
Pleuroperitoneal shunt	Patient able to operate pump Good for trapped lung Good for chylothorax (provided there is no concurrent ascites)
Pleurectomy	
Via thoracoscopy	When other less-invasive options have failed
Via thoracotomy	Good patient status and life expectancy

in breathlessness. In these patients, effort should focus on treating other reversible causes of breathlessness and, if that fails, management should be directed towards symptom control measures (e.g., oxygen supplementation, opiates, use of fans) rather than further pleural fluid drainage procedures.

In patients with a symptomatic MPE, several approaches of varying invasiveness are available to help control the effusion. Because most patients with MPE have limited life expectancy, the overall goal is to provide the greatest symptom relief using options that are least invasive and require the fewest days in hospital. Management issues have also been addressed in clinical guidelines from the American Thoracic Society/Society of Thoracic Surgeons/Society of Thoracic Radiology and a statement from the European Respiratory Society/European Association of Cardiothoracic Surgeons.[76,77]

If the underlying malignancy may respond significantly to systemic therapy (e.g., lymphoma, lung cancer with targetable mutations), it would be reasonable to use simple pleural fluid drainage to provide temporary relief to allow time for initiation of systemic treatment. However, these therapies often eventually fail over time, and the fluid recurs. At that point, more definitive control of the MPE is recommended. Radiation therapy is not useful for MPE management because tumor involvement of the underlying pleura is generally extensive. Irradiation of the entire parietal, pleural, and diaphragmatic pleura is not practical.

Repeated thoracentesis may be used for the occasional patient whose fluid reaccumulates slowly or who has a short life expectancy. Most MPEs recur rapidly and, to avoid frequent drainages, "definitive" treatment is preferred. This refers to approaches with an intent to provide long-term control of fluid-related symptoms without requiring repeated invasive drainage procedures. In broad terms, definitive treatment for MPEs at present generally refers to pleurodesis or placement of an *indwelling pleural catheter* (IPC), or both.

Pleurodesis involves iatrogenic obliteration of the pleural cavity to prevent fluid accumulation. It requires induction of pleural fibrosis that results in symphysis of the parietal and visceral pleural surfaces, usually either by mechanical means (e.g., pleural abrasion or pleurectomy) or via intrapleural administration of a sclerosant. Pleurodesis is only feasible if the underlying lung expands sufficiently and comes in contact with the parietal pleura. No data exist on how much of the lung needs to be expanded to provide a meaningful pleurodesis. Nonexpandable (trapped) lung most commonly results from malignant visceral pleural involvement prohibiting full expansion (see also Chapter 112). Occasionally central airway obstruction can cause nonexpandable lung. In the former case, surgical decortication (resection of the visceral pleural peel) can theoretically be attempted to "free" the trapped lung. Limited quality data exist, however, to support decortication for malignancy, which is known to carry risks of injuring the lung and creating (often prolonged) air leak.[78] In a randomized trial for mesothelioma, 6% of patients who received pleurectomy/decortication experienced prolonged (>10 days) air leak postoperatively.[78]

Pleural manometry has been recommended as a means of predicting nonexpandable (trapped) lung to guide choice of management for patients with MPE. However, recent studies have failed to confirm a clinical role of pleural manometry. First, manometry did not accurately predict nonexpandable lung when compared with postdrainage chest radiographs in 70 MPE patients.[79] In another study, manometry also failed to predict subsequent nonexpandable lung in patients undergoing IPC insertion.[80] Furthermore, in a two-center randomized study, monitoring pleural pressures with manometry also had no benefits in preventing cough and breathlessness during thoracentesis.[81] At present, there is no justification to perform manometry routinely during pleural procedures.[82]

Talc is the most effective pleurodesing agent in animal studies and in clinical head-on comparison studies with other agents, including tetracycline and bleomycin.[83,84] Nonetheless, there is significant variability in the practice of pleurodesis, as shown in a survey of pulmonologists in five countries.[85] Other agents include tetracycline derivatives (e.g., doxycycline and minocycline), bleomycin, iodopovidone, silver nitrate, OK-432, and *Staphylococcus* endotoxin C.[84] Agents such as nitrogen mustard and *Corynebacterium parvum* are seldom used.

Talc can be delivered to the pleural space by instillation as a slurry through a chest tube or by insufflation as a powder (poudrage) during thoracoscopy. Talc slurry has been compared with talc poudrage (via surgical thoracoscopy) in three randomized trials[86–88] and in a fourth trial against talc poudrage during medical thoracoscopy (pleuroscopy).[89] No advantage was found with thoracoscopic talc poudrage in any of these studies, which is perhaps not surprising. One of the proposed advantages of poudrage is the ability to distribute talc powder more evenly over the pleural surfaces. However, talc most likely works by inducing an acute pleural inflammatory response rather than by serving as a "glue." Hence, direct spread of talc over the entire pleural membrane appears not to be essential.

Talc slurry can be given via small or large chest tubes, with or without rotation of the patient. A multicenter randomized trial[90] showed a slightly lower pleurodesis failure rate at 3 months using larger (24 French vs. 16 French) chest tubes (24% vs. 30%, respectively), but the former was associated with more pain at most of the time points captured. Small studies have found no benefit from rotation of patients as determined by instillation of radiolabeled talc and by outcome.[91]

Success rates of talc pleurodesis vary significantly in the reported literature. However, recent large multicenter trials have consistently shown a success rate of around 70%.[86,89,90,92] It should be noted that failure of pleurodesis appears to increase over time, although long survivors were few in the studies.[86]

Talc pleurodesis can be painful and, in a small percentage of patients, can lead to pulmonary edema and acute respiratory failure.[1] Evidence suggests that the smaller talc particles (<10 μm) can exit the pleural space and distribute systemically; in a randomized study, pleurodesis with graded talc (with most particles <10 μm removed) was associated with fewer complications than a mixed talc that included small particles.[93]

IPC has been accepted by the latest MPE guidelines as an effective alternative to talc pleurodesis and can also lead to a symphysis and removal of catheters in many patients. The

catheter is inserted under local anesthesia, and the patient or caregiver drains the effusion at home. Several randomized trials have found that IPCs provide symptom relief as effectively as talc slurry pleurodesis[92,94] and improve patients' quality of life.[95]

An added benefit of this outpatient approach is a reduction in hospitalization time, a particularly attractive feature for patients with advanced cancer. The Australasian Malignant Pleural Effusion-1 randomized trial found that MPE patients treated with IPC spent an average of 3.6 fewer days in the hospital in their remaining life compared with those who received talc slurry pleurodesis.[92] The Therapeutic Intervention for Malignant Effusion-2 randomized controlled trial compared IPC against talc slurry pleurodesis in 106 patients with MPEs.[94] Patients spent significantly fewer days in the initial hospital stay because insertion of an IPC generally is a same-day procedure. A similar benefit was found in a randomized trial of IPC versus doxycycline pleurodesis.[96]

Both the Australasian Malignant Pleural Effusion-1 and Therapeutic Intervention for Malignant Effusion-2 studies found that use of IPC significantly reduced the need for further pleural drainage procedures. More patients in the talc group underwent further pleural procedures (22% vs. 6%).[94] However, in both studies, the IPC group experienced more adverse events over time. IPC-related pleural (and superficial) infections and symptomatic loculations are complications seen in 4–12%[97] and approximately 10%[98] of patients, respectively. IPC-related pleural infection is a concern for clinicians, but studies have consistently demonstrated very low morbidity (≈0.3%)[97] from the infections, which can be treated with systemic antibiotics and intrapleural fibrinolytic/deoxyribonuclease therapy. Interestingly, pleurodesis commonly develops postinfection and often allows catheter removal. Symptomatic loculations respond well to intrapleural fibrinolytic treatment.[98] Other less common IPC-related complications have been described elsewhere.[99]

An exciting development is the combined use of IPC and talc slurry pleurodesis. In a randomized trial of talc slurry (vs. placebo) instillation via IPC in 154 patients with MPE, Bhatnagar et al.[100] showed that outpatient administration of talc via IPC was feasible (with only one case of significant catheter blockage) and significantly promoted the likelihood of successful pleurodesis and catheter removal. Combining the benefits of IPC and talc offers the best of both worlds to patients. Similar approaches combining IPC and talc therapy are being evaluated in the OPTIMUM and Australasian Malignant Pleural Effusion-3 trials compared to conventional chest tube talc pleurodesis or video-assisted thoracic surgery pleurodesis, respectively.

At present, IPC is the guideline-recommended option for patients with nonexpandable lung (estimated to be one-third of all MPE patients) and for those who failed talc or video-assisted thoracic surgery pleurodesis. Using IPC as the first approach negates the need for determining before the procedure if the patient's lung will expand; if the underlying lung expands, talc slurry via IPC would be appropriate; if not, IPC for long-term ambulatory drainage is appropriate.

It is important to recognize that all the above options have limitations and, in the setting of patient palliation, patient preference must be taken into consideration in guiding treatment choice.[94]

Pleuroperitoneal shunting is another alternative for palliation when the lung cannot reexpand or pleurodesis is unsuccessful, but it is no longer commonly used, especially with the easy availability of IPCs.

Pleurectomy via thoracotomy can achieve a pleural symphysis. However, with the advent of effective alternatives such as pleurodesis and IPCs, pleurectomy cannot be recommended.

PROGNOSIS

The overall prognosis is poor for most patients with MPEs. When used to predict survival for any individual patient, pleural fluid pH or glucose level is not sufficiently robust.[2] Performance status remains one of the strongest predictors. In a prospective trial of 85 consecutive patients with MPEs referred for thoracoscopic pleurodesis, those with a Karnofsky score above 70 had a median survival of 13.2 months, whereas those with a score below 30 had a median survival of 1.1 months.[40]

The first validated prognostic score in MPE was derived in 2014 from a study of data from 789 MPE patients from the United Kingdom, the Netherlands, and Australia in which 14 variables were analyzed (Table 114.4). The LENT

Table 114.4 The LENT Score to Predict Survival in Patients with MPE

	Variable	Score
L	**LDH level in pleural fluid (IU/L)**	
	<1500	0
	>1500	1
E	**ECOG performance score**	
	0	0
	1	1
	2	2
	3–4	3
N	**Neutrophil/lymphocyte ratio**	
	<9	0
	>9	1
T	**Tumor type**	
	Lowest-risk tumor types:	0
	Mesothelioma	
	Hematologic malignancy	
	Moderate risk tumor types:	1
	Breast cancer	
	Gynecological cancer	
	Renal cell carcinoma	
	Highest risk tumor types:	2
	Lung cancer	
	Other tumor types	
Risk Categories		**Total Score**
Low		0–1
Moderate		2–4
High		5–7

Using this score, survival can be estimated. In this study, those with an MPE and a low risk score had a median survival of 319 days, whereas those with a high-risk score had a median survival of 44 days.[101]

ECOG, Eastern Cooperative Oncology Group; LDH, lactate dehydrogenase; MPE, malignant pleural effusion.

From Clive AO, Kahan BC, Hooper CE, et al. Predicting survival in malignant pleural effusion: development and validation of the LENT prognostic score. *Thorax*. 2014;69(12):1098–1104.

(lactate dehydrogenase, *Eastern Cooperative Oncology Group* [ECOG] performance status, blood neutrophil/lymphocyte ratio, and tumor type) scoring system classifies patients as low-, moderate- and high-risk groups and predicts survival with significantly better accuracy than ECOG performance status alone.[101] Based on data from 203 patients in one cohort, the low-risk group lived a median duration of 319 days (interquartile range, 228–549 days; $n = 43$), the moderate-risk lived 130 days (47–467 days; $n = 129$), and the high-risk group lived 44 days (22–77 days; $n = 31$), respectively. In the high-risk group, only 65% (20 of 31) of patients survived 1 month from diagnosis, and just 3% (1 of 31) survived 6 months.

In the tumor-node-metastasis classification of lung cancer, pleural malignancy (malignant effusions or pleural nodular malignancy) is considered along with contralateral lung nodules as intrathoracic metastatic disease (M1a). Intrathoracic metastatic disease (M1a) is classified separately from extrathoracic metastatic disease (M1b) because of a somewhat better prognosis.[102]

MESOTHELIOMA

INCIDENCE AND ETIOLOGY

Malignant mesothelioma is a universally fatal malignancy originating from serosal surfaces lined by mesothelial cells. Mesothelioma typically affects the pleural cavity (in more than 90% cases), although primary disease of the peritoneum, pericardium, and tunica vaginalis can also happen.

The majority of mesotheliomas develop as a result of prior asbestos exposure. Asbestos is a heat-resistant, fibrous silicate mineral that was heavily used for insulation in industry as well as domestic constructions, especially in Europe and Australia, where use of asbestos has since been banned. However, asbestos is still actively mined in countries such as Russia, China, Brazil, and Kazakhstan. Global consumption of asbestos continues to increase because of its low cost and excellent fire retardant/insulation properties.

Asbestos can be divided into the amphibole and serpentine groups. Amphibole asbestos—the most common ones being crocidolite (blue asbestos) and amosite (brown asbestos)—are long, thin, sharp fibers that are difficult to degrade once inhaled. In experimental animals, they are up to 100 times more likely to induce mesothelioma than the more frequently used serpentine group, which mainly consists of chrysotile (white asbestos).

Patients with mesothelioma can be classified by their source of asbestos exposure.[103] The first wave consisted of workers directly involved in handling raw asbestos material during its mining, milling, and transportation. The second wave describes those exposed in their work with asbestos-containing materials. Because asbestos has been included in many manufactured goods, exposed workers include building and construction workers and tradespersons such as plumbers, boilermakers, electrical installers, shipbuilders, and dockyard workers. The third wave, or those exposed in their environment, affects a much wider part of society because people are environmentally exposed in their workplaces and homes, especially when asbestos products used in buildings have aged and loose fibers are released into the atmosphere. Householders renovating their asbestos-containing houses are typical subjects in this group.

Erionite, a nonasbestos crystalline fibrous form of the mineral zeolite, shares physical similarities with asbestos fibers. Erionite is a recognized cause of mesothelioma in regions where it is present in the environment, such as Cappadocia in central Turkey. Carbon nanotubes[104,105] are even finer than crocidolite fibers and share their resistance to degradation. In animal experiments, they can cause significant mesothelial changes mimicking the early stages of mesothelioma development.

Inhalation of these fibers induces a cascade of biological events that can contribute to the pathogenesis of mesothelioma: direct mesothelial damage, generation of toxic oxygen radicals, disorganization of cell-signaling pathways, and dormancy of tumor suppressor genes including *BAP1*, cyclin-dependent kinase inhibitor 2A, (or p16), and neurofibromin 2.[106,107]

Thorium dioxide, a radiocontrast agent used between the 1930s and 1950s, had been associated with mesothelioma. Exposure to simian virus 40 (e.g., via contaminated polio vaccines in the 1950s) and contact with human-made vitreous fibers (rock/slag wool and fiberglass) have been postulated, but largely dismissed,[108–113] as potential causes of mesothelioma. Cigarette smoking has no role in the development of mesothelioma.

Although asbestos exposure causes most mesotheliomas, only a small fraction of asbestos-exposed subjects develops the disease. Genetic predisposition may play a role. Patients with germline *BAP1* mutation are predisposed to a range of uncommon cancers (*BAP1* tumor predisposition syndrome),[114] including mesothelioma, uveal and cutaneous melanoma, and renal cancers. Germline mutations in *BAP1* are present in an estimated 1–2% of Europeans[115]; hence, work is ongoing to search for other complex genetic-environmental interactions. Clinicians should consider genetic testing for *BAP1* in mesothelioma patients presenting with a family history of the disease or multiple malignancies (particularly of the skin, eyes, and kidneys) and in those who are young and/or without significant asbestos exposure. It should be noted that not all carriers of germline *BAP1* mutations will develop tumors.[116]

DEMOGRAPHICS

The incidence of mesothelioma is highest in the United Kingdom, Australia, and the Netherlands, reflecting previous asbestos mining and/or its heavy use. The incidence of mesothelioma in the United States has remained stable[117] at around 2500 cases per year.[118] Similarly, the incidence in Australia has been stable but has not decreased[106] as initially predicted. The World Health Organization has raised significant concerns about rapidly rising incidences of mesothelioma in developing countries where use of asbestos is poorly regulated.

The risk of mesothelioma increases with time after first exposure to asbestos. Owing to reduction of occupational asbestos use since the 1960s, mathematical models predict a reduction in the incidence of mesothelioma in the people younger than 74 years, but a rise in those older

than 75 years[119] (who were already exposed), in part due to longer life expectancy in the general population. This was observed recently by Kerger et al.[117] and Soeberg et al.[120] using data from the United States and Australia, respectively. These older patients are likely to have more comorbidities, which will influence individuals' diagnostic and treatment options.

CLINICAL FEATURES

Mesothelioma often presents 20 to 40 years following the first asbestos exposure; hence, the average age of diagnosis is in the mid-70s.[121] Men and women are equally vulnerable; however, more than 80% of patients are male, reflecting demographics of workers in at-risk occupations.

Most patients present with a pleural effusion, and some with pleural thickening or mass. Breathlessness (especially on exertion), cough, chest pain, and constitutional symptoms (fever, fatigue, weight loss, and night sweats)[122] are common. Contraction of the ipsilateral hemithorax or palpable tumor extension into the chest wall can be seen in patients presenting at an advanced stage. Laboratory findings are nonspecific. Anemia, thrombocytosis, and raised inflammatory markers have been associated with poorer prognosis.

Soluble mesothelin-related protein, or mesothelin, is a Food and Drug Administration–approved biomarker for mesothelioma.[68] This glycoprotein is expressed on the surface of mesothelial cells and overexpressed in mesothelioma (and some other cancers, especially ovarian). Mesothelin can be measured in pleural fluid and/or serum.[70] Because it is renally excreted, mesothelin can be elevated with renal impairment, leading to falsely positive results. An elevated mesothelin level strongly suggests malignant pleural disease, especially mesothelioma. A negative mesothelin test does not exclude mesothelioma. Mesothelin has a potential role in monitoring for disease progression and/or treatment response.[123]

Other biomarkers, including serum osteopontin and fibulin-3, do not improve diagnostic accuracy sufficiently to warrant their clinical use.[124]

SUBTYPES

Histologic subtypes of mesothelioma have clear prognostic significance. Mesothelioma can be of epithelioid (approximately 60% of cases) or sarcomatoid (20%), including desmoplastic, subtypes. The remaining 20% are mixed (biphasic)[125] if they consist of at least 10% of both subtypes. Studies of surgically excised lung showed that the more areas of pleura sampled, the more likely a mixed subtype will be found.[126,127] Studies have consistently shown that epithelioid mesothelioma has the best prognosis, sarcomatoid the worst, with biphasic mesotheliomas in between.[128,129]

DIAGNOSIS

Securing a diagnosis of mesothelioma relies on a multifaceted approach. Recent guidelines emphasized the importance of multidisciplinary discussion involving pulmonologists, radiologists, pathologists, palliative care physicians, clinical nurse specialists, and administration staff.[130–132]

RADIOGRAPHIC EVALUATION

Pleural effusion, with the associated imaging features, is the most common presentation. CT features of mesothelioma are akin to those of malignant pleural disease, as described previously. No distinguishing features reliably differentiate mesothelioma from other pleural malignancies or between epithelioid and sarcomatoid subtypes of mesothelioma.[133] Asbestos-related pathologies such as pleural plaques may be seen (eFig. 114.4; Video 114.4), but their absence does not exclude mesothelioma.

As mesothelioma progresses, tumor can encase the lung and contract the hemithorax, causing ipsilateral mediastinal shift (Fig. 114.3). Pleural nodularity and chest wall invasion often develop (eFigs. 114.5 and 114.6; Video 114.5). Lymphatic involvement may be seen on CT (eFig. 114.7). Contralateral pleural, pericardial, or transdiaphragmatic spread can be seen late.

Needle tract metastases are common with mesothelioma. Studies have shown that the larger the pleural puncture sites (e.g., thoracotomy or thoracoscopy), the higher the risks of tract metastases.[134] Hence, clinicians should always try to minimize the number of procedures in patients with mesothelioma and, when appropriate, choose the least invasive interventions.

The revised, modified Response Evaluation Criteria in Solid Tumors[135] is commonly used in research to monitor treatment response using CT scans but is not useful in routine clinical management.

Magnetic resonance imaging does not offer routine diagnostic advantage but, in selected cases, can help define tumor invasion into the chest wall, mediastinum, and diaphragm[136–139] (Fig. 114.4, eFig. 114.8).

The role of ^{18}FDG-PET in mesothelioma has not been fully defined.[140] Mesothelioma is generally FDG avid provided that the pleural abnormality is of sufficient thickness (Fig. 114.5; eFigs. 114.5 and 114.9; see also Fig. 25.6). PET avidity, however, cannot differentiate malignant

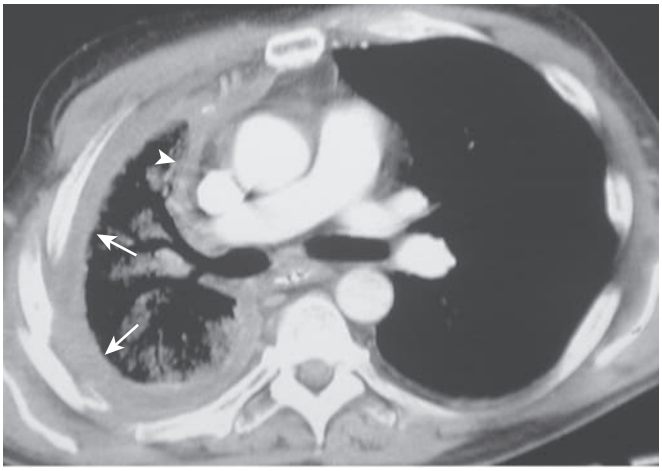

Figure 114.3 Mesothelioma. Axial chest computed tomography scan shows diffuse right pleural thickening (*arrows*) associated with marked volume loss in the right thorax. Note the presence of mediastinal pleural involvement (*arrowhead*). (Courtesy Michael B. Gotway, MD.)

from inflammatory pleuritis or separate mesothelioma from metastatic pleural diseases. PET can guide percutaneous pleural biopsy, especially in patients with concurrent benign pleural thickening. Total glycolytic volume can help in monitoring disease response and may have prognostic value.[141]

PATHOLOGIC FEATURES

Because most mesothelioma patients present with a pleural effusion or pleural thickening/mass, the same diagnostic approaches as described for MPE apply. The pathologic diagnosis of mesothelioma critically depends on the experience of the pathologist. Referral to specialist pathologists for expert or further opinion, especially in cases of high suspicion, can potentially save unnecessary invasive procedures.

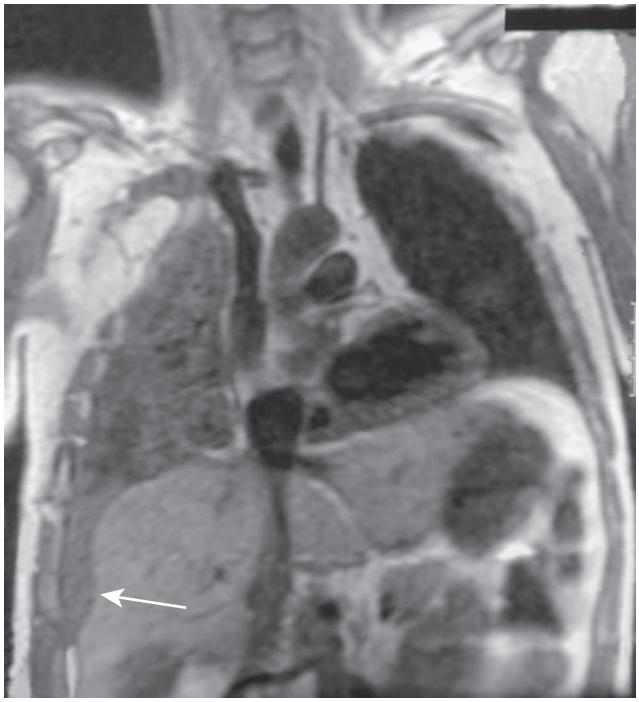

Figure 114.4 Mesothelioma. Magnetic resonance imaging of the same patient as in Fig. 114.3 with malignant mesothelioma showing invasion across the diaphragm by tumor (*arrow*). (Courtesy Michael B. Gotway, MD.)

The diagnosis is challenging because mesothelioma cells may be morphologically similar to metastatic carcinomas. In most cases, they can be distinguished by immunohistochemical panels; confirmation of mesothelial lineage of malignant cells will define mesothelioma.

Another challenging aspect is separating normal or reactive mesothelial cells from malignant mesothelioma cells. This explains the low diagnostic yield of pleural fluid cytology in many centers and the conventional need for tissue biopsies to establish invasion of the abnormal cells (of mesothelial lineage) into deeper structures as evidence of malignancy. In specialist centers, however, cytologic diagnosis of mesothelioma can be achieved with high accuracy. A large single-center study with such expertise found that definitive cytologic diagnosis was made in 377 out of 517 cases of mesothelioma, resulting in an "absolute" sensitivity of 73%, compared with subsequent histologic or postmortem confirmation, and with no false-positive diagnoses of malignancy. Latest guidelines from the International Academy of Cytology, the Papanicolaou Society of Cytopathology,[71,125,142] and the International Mesothelioma Interest Group all advocate diagnosis of epithelioid-containing mesothelioma on cytopathologic grounds. Recent advances in molecular markers have made this more feasible for nonspecialist pathologists. Demonstration of loss of *BAP1* expression by immunohistochemical panels (present in more than 60% of mesothelioma cases) and/or confirmation by fluorescent in situ hybridization of homozygous deletion of the cyclin-dependent kinase inhibitor 2A (*p16INK4a*) gene in abnormal cells of mesothelial lineage confirms mesothelioma. Detection of these mutations in combination may identify up to 85% of mesothelioma cases.[72,143] It is anticipated

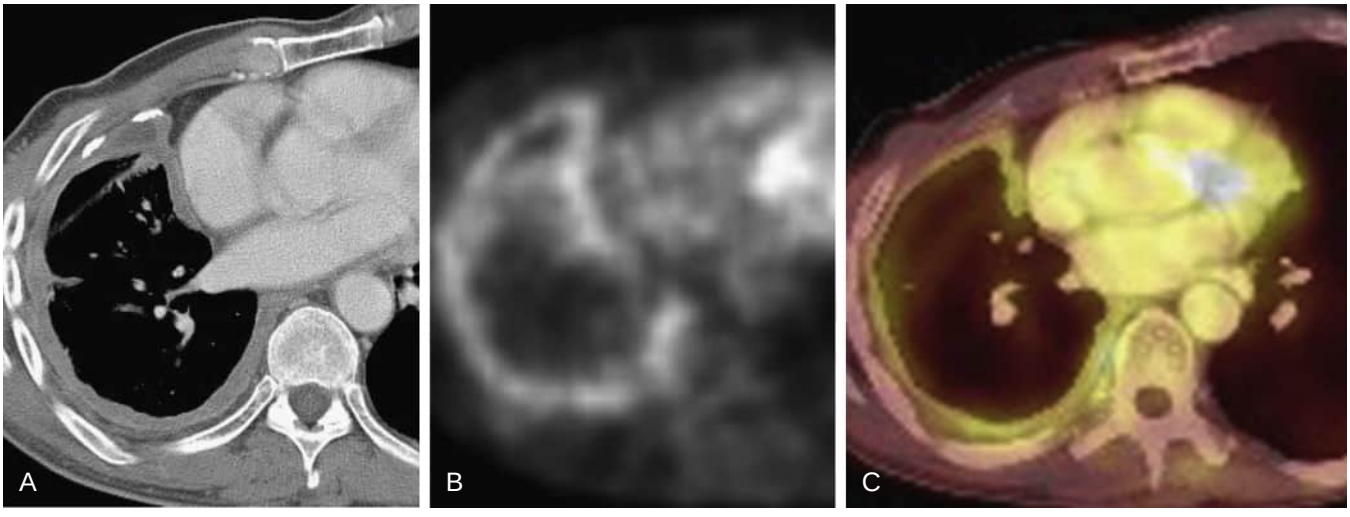

Figure 114.5 Malignant pleural mesothelioma: *positron emission tomography* (PET)/*computed tomography* (CT) appearance. (A) Axial enhanced chest CT shows extensive, nearly circumferential right pleural thickening associated with volume loss affecting the right thorax. (B) PET and (C) fused PET/CT images show extensive metabolic activity within the tumor, correlating with the location of the pleural thickening seen at CT. (Courtesy Michael B. Gotway, MD.)

that the need for tissue biopsy to confirm mesothelioma will decrease over time.

STAGING

Most of the staging systems are based on suitability for surgery. There are no clear benefits of performing additional procedures purely for the purpose of staging because it generally does not influence management. The inaugural staging system was proposed in the 1970s.[144] The tumor-node-metastasis–based system was originally introduced by the International Mesothelioma Interest Group. International Association for the Study of Lung Cancer and International Mesothelioma Interest Group committees introduced the currently adopted eighth iteration of the tumor-node-metastasis–based system.[145,146]

PROGNOSIS

Reported median survival rates of mesothelioma range between 9 and 18 months from the time of diagnosis, and fewer than 5% of patients survive more than 5 years.[117] Rare cases of long-term survivors have been reported.

Individual survival varies significantly and is difficult to predict. Performance status and histologic subtype[147,148] (sarcomatoid being worse) are the most consistent prognosticators. In the Surveillance, Epidemiology, and End Results database, median survival of patients who underwent surgery (i.e., fitter patients) with sarcomatoid mesothelioma was 4 months compared to 19 and 12 months with epithelioid or biphasic disease, respectively ($P = 0.01$).[149]

Other poor prognostic predictors include advanced age, male gender, serologic markers of systemic inflammation, including anemia, thrombocytosis, leukocytosis, elevated C-reactive protein or lactate dehydrogenase levels, and an increased neutrophil/lymphocyte ratio.[150–152]

Imaging modalities may also carry prognostic implication with increased disease burden, advanced stage, and increased total glycolytic volume on ^{18}FDG-PET/CT imaging, portending a poor outcome.[150,153]

Various scoring systems have been suggested, yet no reliable, universally applicable tool is useful for routine clinical practice.[147,154–156] Brims et al. derived, from classification and regression tree modeling, a scoring system that incorporates most of the known factors (e.g., histologic subtype, performance status, hemoglobin and albumin levels, and weight loss) to stratify patients into categories of different median survival[128] (Fig. 114.6). In this scoring system, the strongest predictive variable was weight loss. Group 1 had the best outcome (median survival, 34.0 months), and group 4 had the worst (median survival, 7.4 months).

APPROACH TO THERAPY

There is no cure for mesothelioma; symptom palliation, maintenance of quality of life, minimization of invasive procedures, and hospitalization are important. Significant controversies exist, and various guidelines advocate differing management approaches. It is advisable that clinicians adhere to best available evidence in determining therapy. Unproven treatment should be tested in clinical trial settings.

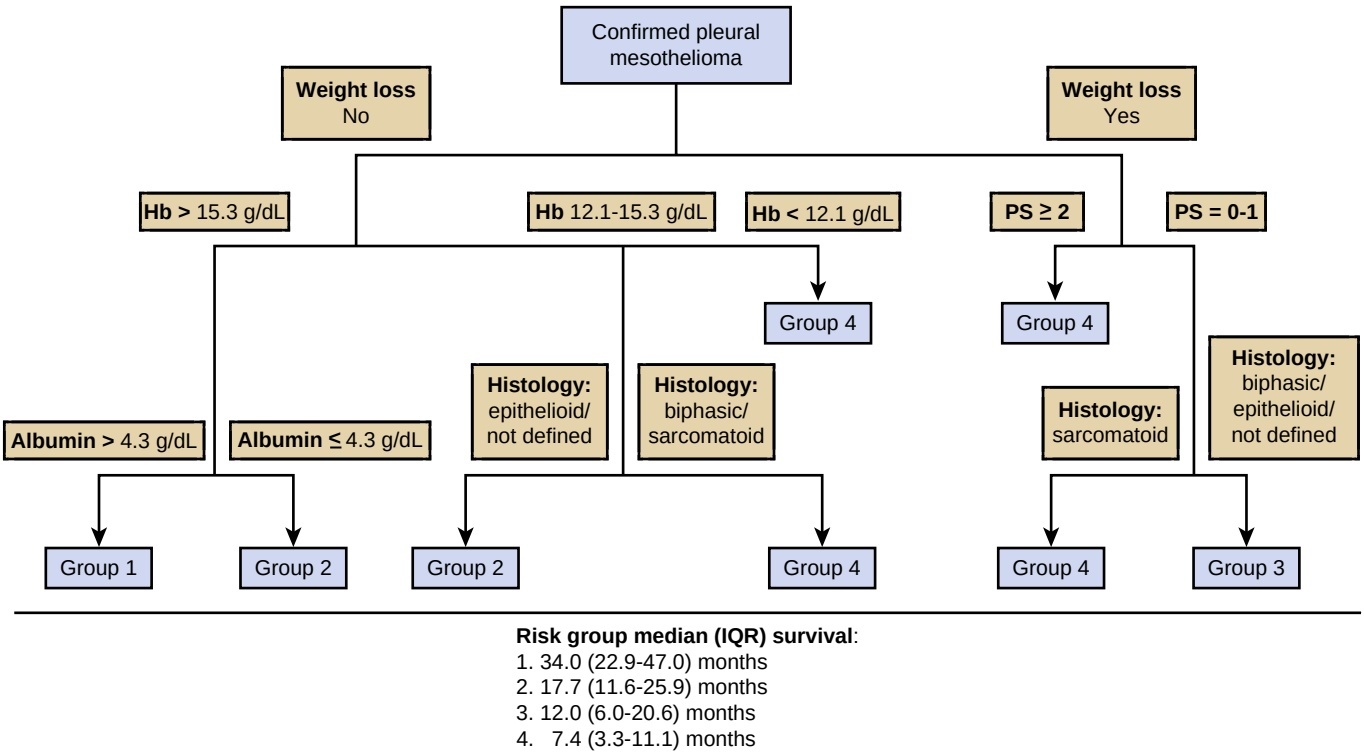

Figure 114.6 A predictive model of survival in mesothelioma patients based on simple, commonly obtained parameters. In this model, the strongest predictive variable was weight loss, defined as any weight loss deemed significant by the caring physician. Median survivals range from 34.0 months to 7.4 months. Hb, hemoglobin; IQR, interquartile range; PS, Eastern Collaborative Oncology Group performance status. (From Brims FJ, Meniawy TM, Duffus I, et al. A novel clinical prediction model for prognosis in malignant pleural mesothelioma using decision tree analysis. *J Thorac Oncol*. 2016;11[4]:573–582.)

Surgical Therapy

There is no proven role for radical surgical resection of mesothelioma, although it is still practiced in many centers. Mesotheliomas are usually multifocal tumors that spread along the pleural surfaces and invade the deeper tissues, making complete surgical eradication impossible. In postmortem series, distant tumor metastases (often silent clinically) are common[157] and may explain why local surgical clearance of mesothelioma failed to affect survival, and distant "relapse" is common even after *extrapleural pneumonectomy* (EPP).[158]

EPP is one of the most aggressive thoracic surgeries in its attempt to provide complete resection of pleural mesothelioma. It removes the lung with its visceral pleura, the hemidiaphragm, pericardium, and parietal pleura. This aggressive procedure has very high postoperative mortality (at least 5%) and major morbidity (25%). The Mesothelioma and Radical Surgery trial[159] randomized 50 mesothelioma patients to EPP or no surgery. EPP was harmful and *shortened* median survival by 5 months (14.4 vs. 19.5 months), with a hazard ratio of 2.75 compared with no surgery, even after adjusting for histology, staging, age, and sex. EPP should no longer be recommended to patients.

Extended pleurectomy/decortication aims to debulk the tumor by removing the same structures as EPP but sparing the lung. The Meso-VATs trial[78] randomized 175 mesothelioma patients to debulking parietal pleurectomy performed under video-assisted thoracic surgery or to only talc pleurodesis. Surgery conferred no survival benefit at 12 months (52% vs. 57% of talc group) but was associated with more complications, especially prolonged air leak.

Neither the most (EPP) nor the least (video-assisted thoracic parietal pleurectomy) aggressive form of surgical resection confers survival benefits in mesothelioma. The more aggressive the procedure, the more complications and the more detrimental it is to clinical outcomes.[160]

Combining surgery with other treatments (e.g., radiotherapy and/or chemotherapy, hyperthermic treatment, photodynamic therapy) has not been subjected to prospective randomized trials.

Chemotherapy

Only three randomized trials on treatments for mesothelioma have shown survival benefits (albeit small). Combination of cisplatin and multitargeted antifolate drugs have been shown in two randomized trials (one using pemetrexed[161] and one raltitrexed[162]) to improve median survival (12.1 months with pemetrexed/cisplatin vs. 9.3 months with cisplatin alone). Addition of folic acid and vitamin B_{12} reduces toxicity.

The Mesothelioma Avastin Cisplatin Pemetrexed Study (n = 448) evaluated platinum/pemetrexed therapy[163,164] with or without bevacizumab, a monoclonal antibody inhibitor of VEGF. Addition of bevacizumab improved median overall survival from 16.1 to 18.8 months but induced more adverse effects.

No second-line therapies have shown benefits in randomized trials. Various targeted therapies, such as antiangiogenic tyrosine kinase inhibitors directed against receptors of VEGF or platelet-derived growth factor, have demonstrated no convincing advantage over routine clinical care.[165–170]

Immunotherapy

Immunotherapy for mesothelioma is an area of intense research with many ongoing clinical trials[171] examining various *immune checkpoint inhibitors* (ICIs) singly or in combination with other ICIs or with chemotherapy. Promising results in pilot nonrandomized studies are accumulating. However, the first published randomized trial (DETERMINE study)[172] found no survival benefits in those treated with tremelimumab, a cytotoxic T lymphocyte–associated antigen-4 monoclonal antibody (n = 382), and those who received placebo (n = 189). Interest has since shifted to the use of anti–programmed death ligand 1 therapy, in patients with and without programmed death ligand 1 expression. Again, promising data in small, nonrandomized or noncontrolled studies (e.g., INITIATE[173] and MAPS2[174] trial) have attracted strong interest but, until phase III studies are available, the benefit of immunotherapy will remain contentious. Clinicians should encourage interested patients to enroll in clinical trials.

Alternative immunotherapy agents (e.g., antimesothelin strategies, dendritic cell-harvested immunotherapy, and vaccine against Wilms tumor 1) are under investigation. Gene (immunogene) therapy is another approach under investigation.[175]

Radiation Therapy

Although mesothelioma is radiosensitive, therapeutic doses of radiation for mesothelioma result in significant pneumotoxicity and damage to adjacent organs. Use of radiotherapy as neoadjuvant or adjuvant treatment in conjunction with surgery has not yet been shown to be beneficial. Intensity-modulated conformal radiotherapy is being studied,[176] but definitive evidence supporting its use is still lacking. However, radiation for symptom palliation, such as for chest wall metastases for pain control, remains useful.

The role of prophylactic radiotherapy at pleural puncture sites to prevent tract metastasis has been refuted by two multicenter randomized trials.[177,178] Both found a small and statistically nonsignificant reduction of incidence of tract metastasis: 3.2% versus 5.3% from Bayman et al. (n = 375)[177,178] and 9% versus 16% by the SMART study group (n = 203).[177,178] Prophylactic radiotherapy should not be routinely applied. Irradiation of symptomatic IPC tract metastases is safe and does not require prior catheter removal.[179]

Palliative Therapy

As an incurable malignancy, the key goals of care for mesothelioma are symptom palliation, improvement in quality of life, and minimization of hospitalization. A multidisciplinary approach incorporating physical aspects as well as nutritional, psychological, and social needs is advisable. Early referral to a palliative care service, however, has not shown benefits in a randomized trial,[180] implying that these care needs can be adequately delivered by pulmonologists/oncologists in most cases.

Management strategies for MPE associated with mesothelioma generally follow those outlined earlier in this chapter.[181] In an unselected review of 390 mesothelioma patients, 42.3% underwent pleurodesis, surgically (n = 78) or by bedside instillation of sclerosants (n = 87). As in other MPE studies, surgical pleurodesis showed no advantages

over bedside pleurodesis in efficacy (32% vs. 31% failures requiring further drainage; $P = 0.98$). No clinical, biochemical, or radiographic parameters tested adequately predict pleurodesis outcome.

Pain is common and generally can be controlled with analgesia, especially opioids. Radiotherapy to pain site (if localized) should be considered early. With severe diffuse pain refractory to conventional measures, nerve blocks or percutaneous or intrathecal drug delivery may be required. Cervical cordotomy has been evaluated in small studies as effective but requires procedural expertise.[182]

Mesothelioma patients often have unique psychosocial needs.[183,184] Anger and frustration towards being exposed to an avoidable occupational source is common. Patients with occupational asbestos exposure should be referred for possible compensation.[184a] It should also be noted that compensation claims can be protracted and induce stress. Old literature describing mesothelioma patients dying from drowning due to a growing effusion, suffocation, and untreatable pain often create additional anxiety for patients and caregivers.

SCREENING AND CHEMOPREVENTION

At present, no uniformly agreed upon screening test for mesothelioma exists, and its role, given the poor overall prognosis and lack of curative treatment, remains debatable. Previous studies of high-risk populations have assessed use of low-dose CT imaging, serum, and exhaled biomarkers (i.e., mesothelin, osteopontin, and volatile organic compounds); none demonstrated sufficient sensitivity as a screening tool for early-stage disease.[68,185–189]

Chemoprevention efforts in asbestos-exposed populations have not shown efficacy.[190]

SOLITARY FIBROUS TUMOR OF THE PLEURA

Solitary fibrous tumors are mesenchymal tumors that can arise not only in the pleura but throughout the body, including the mediastinum.[191] The term *solitary fibrous tumor of the pleura* (SFTP) is now used in preference to earlier terms such as *benign mesothelioma* or *localized mesothelioma* for several reasons: to distinguish it clearly from malignant mesothelioma, to acknowledge that it may contain malignancy within it, to appreciate there is no relationship with asbestos contact, and also to recognize that its cellular origin is more likely from pluripotential fibroblasts than from mesothelial cells.[192,193] These tumors are rarer than mesotheliomas, accounting for 8% of all benign pathologic processes of the chest and 10% of all pleural neoplasms.[194]

CLINICAL FEATURES

More than half of patients are asymptomatic, and the tumor is found incidentally on radiographic examination.[195] If symptoms do arise, chest pain, breathlessness, and cough are most common, usually related to the local mass effect of the tumor.[192,196] Paraneoplastic syndromes can develop. Hypertrophic pulmonary osteoarthropathy has been described in 14%[196] to 19%[192] of patients and usually resolves a few months following tumor resection.[192] Hypoglycemia, from tumor release of insulin-like growth factor-2 (Doege-Potter syndrome), has been described in 4%[192] and 14%[196] of patients[197] and resolves after surgical resection. Corticosteroids, which act to suppress insulin-like growth factor-2 production, have been successful in controlling the hypoglycemia.[198]

RADIOLOGIC FEATURES

Chest radiography usually reveals a solitary, clearly defined, circumscribed lesion (eFig. 114.10; see also eFigs. 80.7 to 80.9 and 80.11), which rarely occupies the entire hemithorax (see eFig. 80.10). Smaller masses result in an obtuse angle with the chest wall, whereas larger or lobulated lesions form an acute angle; rarely they appear to arise intra-parenchymally due to the latter characteristic[199] (see eFig. 80.7). Pleural effusion is rare, but calcification may be seen regardless of the tumor's neoplastic potential.

CT or magnetic resonance imaging scans characteristically reveal a smooth, well-defined, rounded mass with no invasion of adjacent structures (Fig. 114.7). Heterogeneous areas of enhancement pathologically correlating with areas of cystic necrosis and hemorrhage may be seen in larger tumors (see eFigs. 80.8 and 80.10). Magnetic resonance imaging demonstrates a low signal on T1- and T2-weighted images and may better define mediastinal and diaphragmatic involvement (see eFigs 80.8C–D).[200]

PET may be helpful to differentiate benign solitary fibrous tumor of the pleura from malignant disease (see eFig. 80.11C).[201]

PATHOLOGIC FEATURES

Macroscopically, most solitary fibrous tumors arise from the visceral pleura.[196] They appear as a smooth, rounded or lobulated, firm mass surrounded by a translucent vascular membrane. Malignant tumors are often larger (e.g., >10 cm in diameter). On cut section, the tumor has a fibrous, gray, whorled appearance with occasional calcification, hemorrhage, and/or central necrosis.

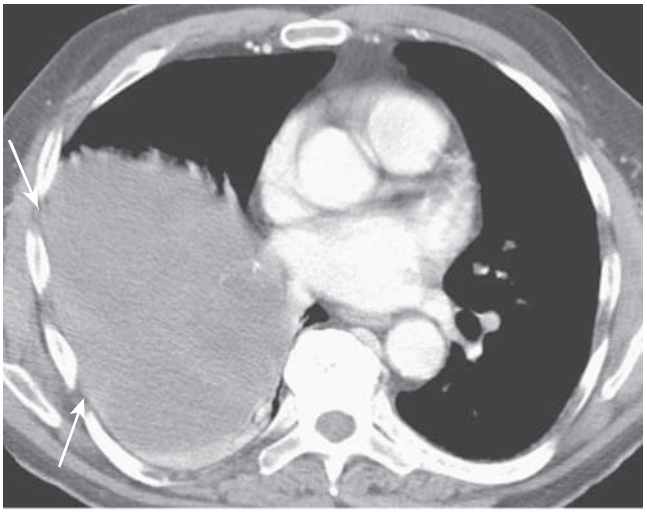

Figure 114.7 Solitary fibrous tumor of the pleura. Axial computed tomography image shows a large, somewhat heterogeneous mass in the right lower chest with extensive chest wall contact (*arrows*). (Courtesy Michael B. Gotway, MD.)

Histologically bland, elongated spindle cells are arranged haphazardly in a storiform or patternless pattern, interspersed with varying amounts of fibrohyaline tissue. Malignant transformation often exhibits increased cellularity, increased mitotic activity, nuclear pleomorphism, and prominent areas of necrosis or hemorrhage. On immunohistochemical staining, SFTPs can be distinguished from sarcomatoid mesothelioma by positive staining for STAT6[202]; nuclear staining is present in more than 98% of SFTPs but is negative in mesothelioma.[202,203] Additionally, SFTPs are generally negative for cytokeratin staining, although focal expression may be present.[125,204] Sarcomatoid mesotheliomas are generally positive, at least focally, for the broad-spectrum antikeratin 1 and 3 and pancytokeratins.[71,125,205]

Solitary fibrous tumors can be distinguished from several other uncommon tumors (e.g., synovial sarcoma and histiocytoma) by their staining for vimentin,[206] a marker of mesenchymal cells, CD34 (a hematopoietic progenitor cell antigen), and Bcl-2 protein; these tumors typically are negative for thyroid transcription factor-1 and keratin.[196,207]

STAGING

Staging of SFTP depends on the tumor size and origin together with its histologic malignant potential. Designation of stage allows prognostication and estimation of the risk of recurrence[208] (eTable 114.1).

Surgery is advised in most cases, allowing both a diagnostic excision biopsy and definitive treatment. Complete resection is curative in approximately 90% of cases. It is often performed via thoracotomy or video-assisted thoracic surgery, with a tumor margin of more than 1 cm recommended. Tumor recurrence may present more than a decade following initial resection; therefore, surveillance is advised. The risk of recurrence is much greater in patients with stage III or IV disease, which shows malignant histology and either sessile or metastatic morphology.[208,209] Occasionally malignant changes are documented in the recurrent tumor despite a benign primary lesion (see eFig. 80.13).[192,210]

The prognosis of benign solitary fibrous tumors is generally good, with near 100% 5-year survival rates. Patients with malignant transformation, however, have poorer outlook, with 0% 5-year survival reported for stage IV disease.

Treatment of recurrent tumors is resection. Approaches targeting VEGF and angiogenesis pathways are being evaluated.[191,210a]

PRIMARY PLEURAL LYMPHOMA

Two distinct forms of primary lymphoma affect the pleura: primary effusion lymphoma and pyothorax-associated lymphoma.

Primary effusion lymphoma is a type of high-grade B-cell lymphoma that develops along serosal surfaces (i.e., the pleura, peritoneum, or pericardium). Human herpesvirus-8/Kaposi sarcoma herpes virus infection is always present, and its identification is required for the diagnosis of primary effusion lymphoma[211]; approximately 50% of patients display Epstein-Barr virus coinfection.[212] The majority of body cavity–based primary effusion lymphomas arise in patients with *human immunodeficiency virus* (HIV), although it has been described in HIV-negative patients, usually elderly persons of Eastern European/Mediterranean descent, in an epidemiologic pattern similar to that of HIV-negative, classic Kaposi sarcoma.

Primary effusion lymphoma mirrors mesothelioma radiologically, and histologic differentiation is essential (Fig 114.8). Pleural fluid is exudative and lymphocyte dominant. Cytologically, the lymphocytes typically stain negatively for B and T cell antigens,[213] yet flow cytometry can reveal clonality sufficient to secure the diagnosis. Occasionally, pleural biopsy is required. Identification of human herpesvirus-8 can be performed by extracting DNA from involved tissues followed by Southern blot analysis, by in situ hybridization of slides from paraffin-embedded samples, and by in situ reverse transcriptase polymerase chain reaction of cytologic smears or cell blocks.[214]

Prognosis is poor, with survival reported between 6 and 9 months.[213] Treatment with chemotherapy and, if HIV positive, antiretroviral agents may help with management of the pleural effusion.[215]

Pyothorax-associated lymphoma is a human herpesvirus-8–negative high-grade non-Hodgkin B cell lymphoma strongly associated with Epstein-Barr virus[216] (in up to 70% of tumors in the largest series).[217] Typically, pyothorax-associated lymphoma develops in patients who had a pyothorax as a complication of artificial pneumothorax used for the treatment of pleuropulmonary tuberculosis, often more than 2 decades before.[218] It is more commonly reported in Japan than in the Western world, where few cases are described.[219] Chest radiograph or CT scan images reveal a localized pleural mass in an area of chronic pleural abnormality; intense FDG avidity is seen on PET/CT.[220,221]

There are no large series evaluating specific treatments for this disease. Various treatments have been studied, including surgical excision, chemotherapy, or radiotherapy,[217,222] with limited success. Overall prognosis is poor with a 5-year survival of 22%.[217]

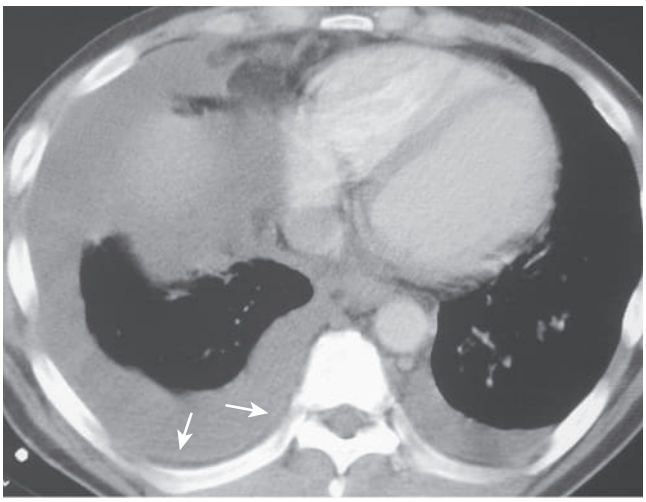

Figure 114.8 Primary effusion lymphoma. On axial computed tomography, the malignancy is manifest in bilateral effusions. *Arrows* indicate a minimally thickened parietal pleura, without nodularity. (Courtesy Michael B. Gotway, MD.)

eTable 114.1 Staging of Solitary Fibrous Tumor of the Pleura

Stage	Histology	Morphology
0	Benign	Pedunculated
I	Benign	Sessile or inverted*
II	Malignant	Pedunculated
III	Malignant	Sessile or inverted
IV	Malignant	Metastatic, synchronous

*Inverted tumors can grow inside the lung parenchyma without actual invasion, as seen in <3% of cases.

Modified from de Perrot M, Fischer S, Brundler MA, et al. Solitary fibrous tumors of the pleura. *Ann Thorac Surg*. 2002;74(1):285-293.

IMMUNE CHECKPOINT INHIBITOR–RELATED PLEURAL EFFUSION

The rapidly growing use of ICIs, such as pembrolizumab, nivolumab, and atezolizumab, has led to the recognition of many new immune-related adverse events,[223] including development of pleural effusion that requires differentiation from pleural spread of the primary cancer. Pleural fluid of ICI pleuritis is typically a cytologically negative lymphocyte-rich exudate. If patients are symptomatic, the ICI should be withheld and pleural drainage undertaken. Corticosteroids can be considered in appropriate cases.

Key Points

- Malignant effusions are most commonly due to lung cancer, followed by breast cancer and lymphoma. The incidence of mesothelioma varies among countries.
- Malignant effusions, especially those from adenocarcinomas, can often be diagnosed by cytologic examination of the pleural fluid. If cytologic results are negative, biopsy of the pleural tissue using image-guidance modalities or thoracoscopy should be considered to help establish a diagnosis. Cell-free DNA from pleural fluid supernatant or blood can help detect driver mutations in malignant pleural effusion from lung cancer patients with epidermal growth factor receptor mutations.
- In the eighth edition of tumor-node-metastasis staging for lung cancer, pleural malignancy with or without effusion is now classified as a metastatic lesion (M1a, intrathoracic metastasis).
- In most patients with a symptomatic malignant pleural effusion, palliation of symptoms is the key management goal. Therapeutic thoracentesis, talc pleurodesis, and indwelling pleural catheter drainage are established options. The choice depends on the life expectancy of the patient and whether the lung can reexpand.
- Indwelling pleural catheters are now accepted as an alternative to talc pleurodesis for first-line definitive management of malignant pleural effusions. The catheter has been shown in randomized trials to improve symptoms and quality of life while reducing days spent in the hospital. It can be combined with talc slurry to increase the likelihood of pleurodesis and catheter removal.
- Malignant pleural mesothelioma should be considered in any patient with an exudative effusion, especially if there is a history of exposure to asbestos, chest pain, and a rind-like nodular thickening of the pleura.
- Recent randomized studies have changed management practice for mesothelioma. Chemotherapy with cisplatin, pemetrexed, and bevacizumab can improve survival. All randomized trials to date have found no benefits of surgical resection for malignant pleural mesothelioma. Routine use of prophylactic radiotherapy is not recommended.
- Solitary fibrous tumors of the pleura are mesenchymal tumors that can involve the visceral pleura. Most are benign and can be successfully resected.
- Primary effusion lymphoma and pyothorax-associated lymphoma arise in the pleural cavity, often presenting *without* and *with* a mass, respectively. Primary effusion lymphoma is associated with systemic immunosuppression from human immunodeficiency virus and is caused by human herpesvirus-8; pyothorax-associated lymphoma is associated with long-standing pleural inflammation and is associated with Epstein-Barr virus.

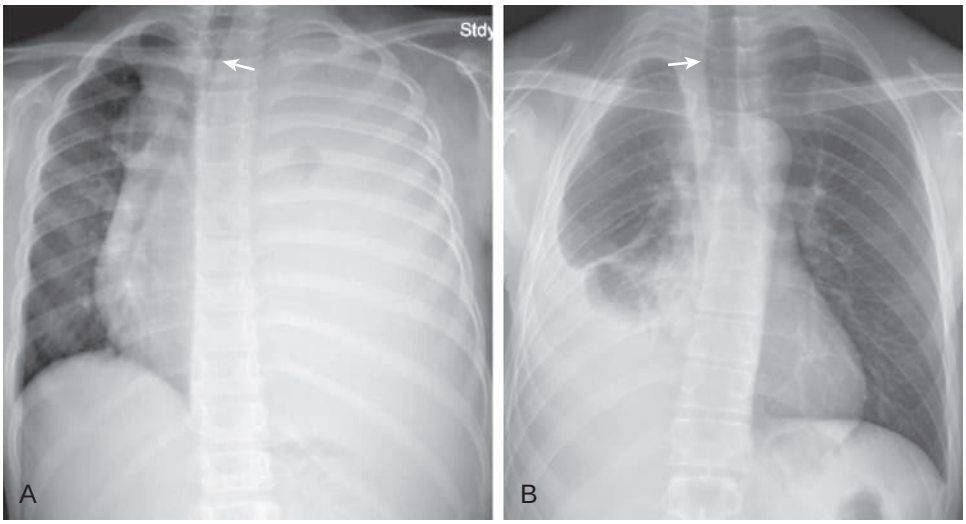
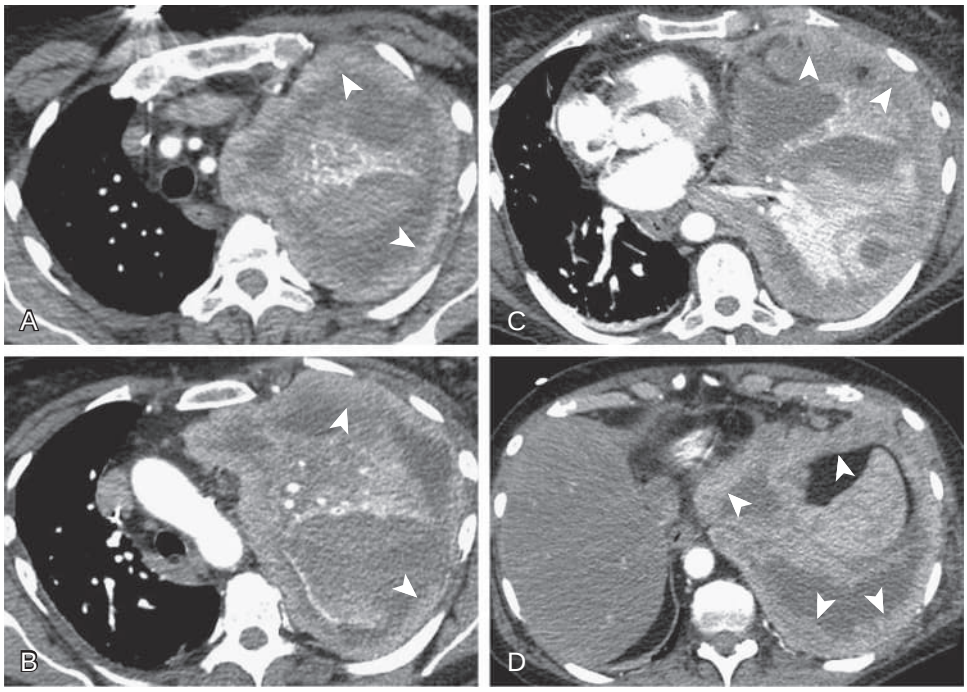
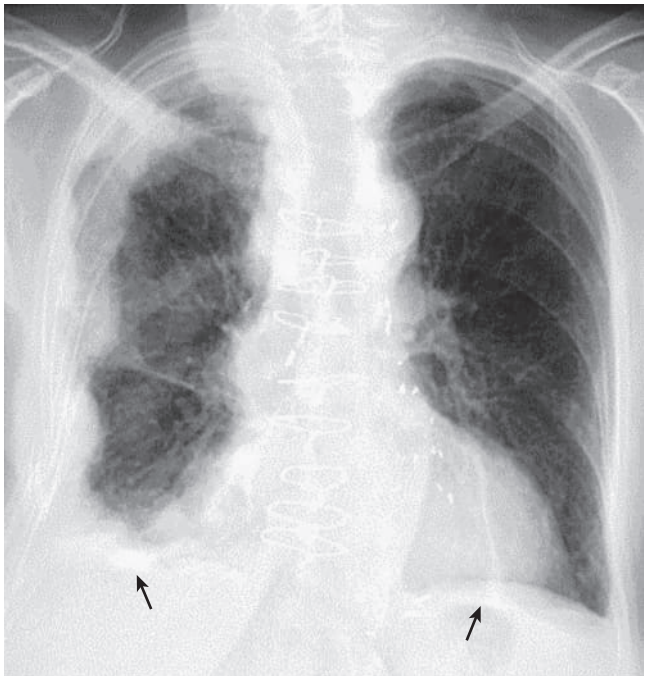
eFigure 114.1 Pleural effusion due to non-Hodgkin lymphoma. (A) Frontal chest radiograph shows complete opacification of the right hemithorax due to a massive right pleural effusion. (B–E) Axial enhanced chest computed tomography shows a large right pleural effusion associated with prominent multifocal pleural thickening (*arrows*). (Courtesy Michael B. Gotway, MD.)



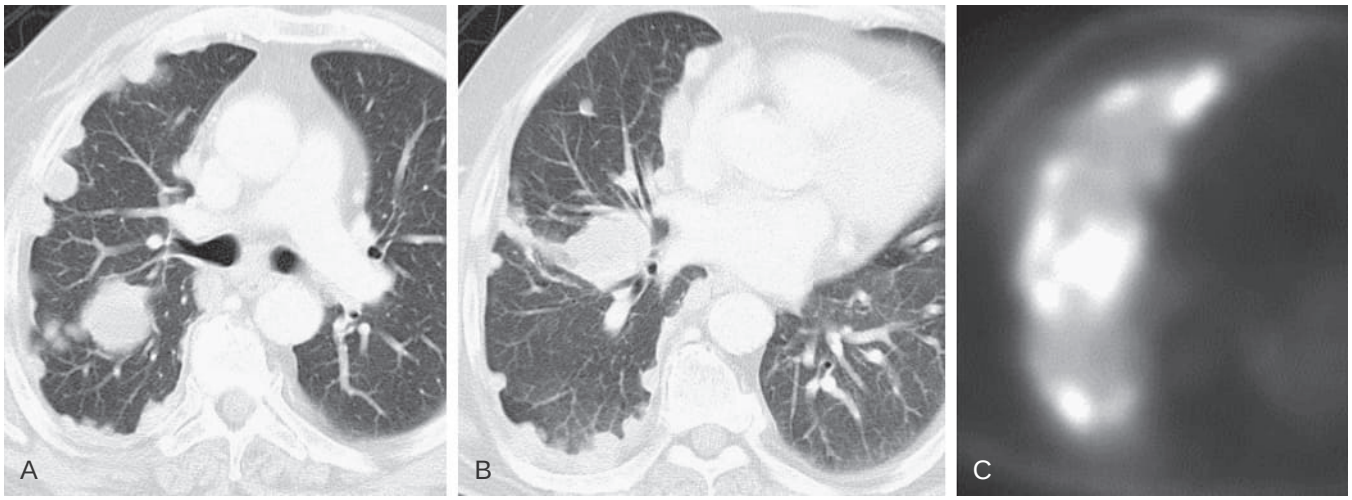
eFigure 114.2 Pleural effusion effect on mediastinal position. (A) Frontal chest radiograph in a patient with a large left effusion due to non-Hodgkin lymphoma shows *contralateral* shift of the cardiomediastinal structures; note rightward displacement of trachea (*arrow*). (B) Frontal chest radiograph in a patient with a moderate right pleural effusion shows slight *ipsilateral* shift of the cardiomediastinal structures; note slight rightward displacement of trachea (*arrow*). The right pleural effusion in this patient was due to metastatic mucinous adenocarcinoma with extensive infiltration of lung. (Courtesy Michael B. Gotway, MD.)



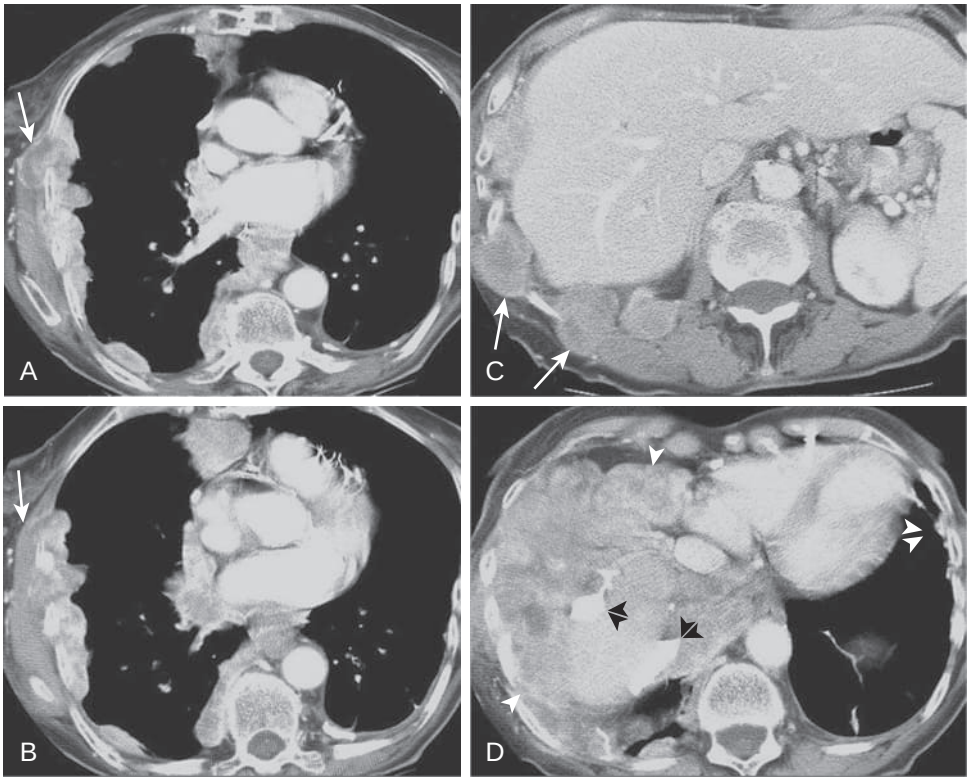
eFigure 114.3 Chest computed tomography appearance of malignant pleural disease. (A–D) Axial enhanced chest computed tomography shows extensive, nodular, circumferential pleural thickening (*arrowheads*) due to metastatic bronchogenic malignancy. (Courtesy Michael B. Gotway, MD.)



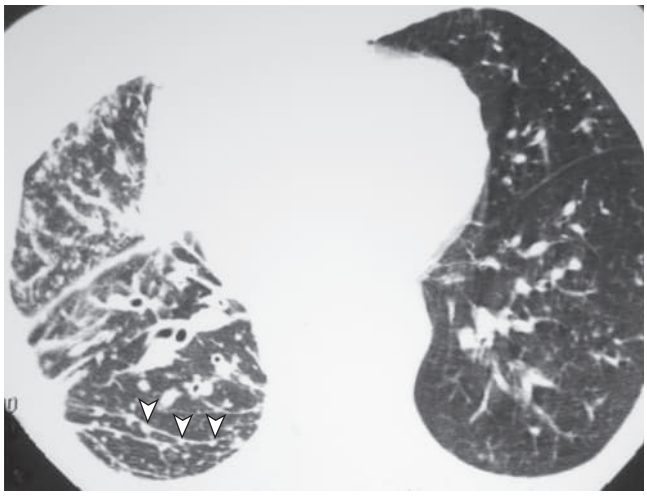
eFigure 114.4 Malignant pleural mesothelioma complicating asbestos-related pleural disease. Frontal chest radiograph shows extensive nodular pleural thickening affecting the right pleura associated with mild volume loss affecting the right lung. Calcified diaphragmatic pleural plaques (*arrows*), reflecting asbestos-related pleural disease, are present. (See chest computed tomography for this patient in eFig. 114.6.) (Courtesy Michael B. Gotway, MD.)



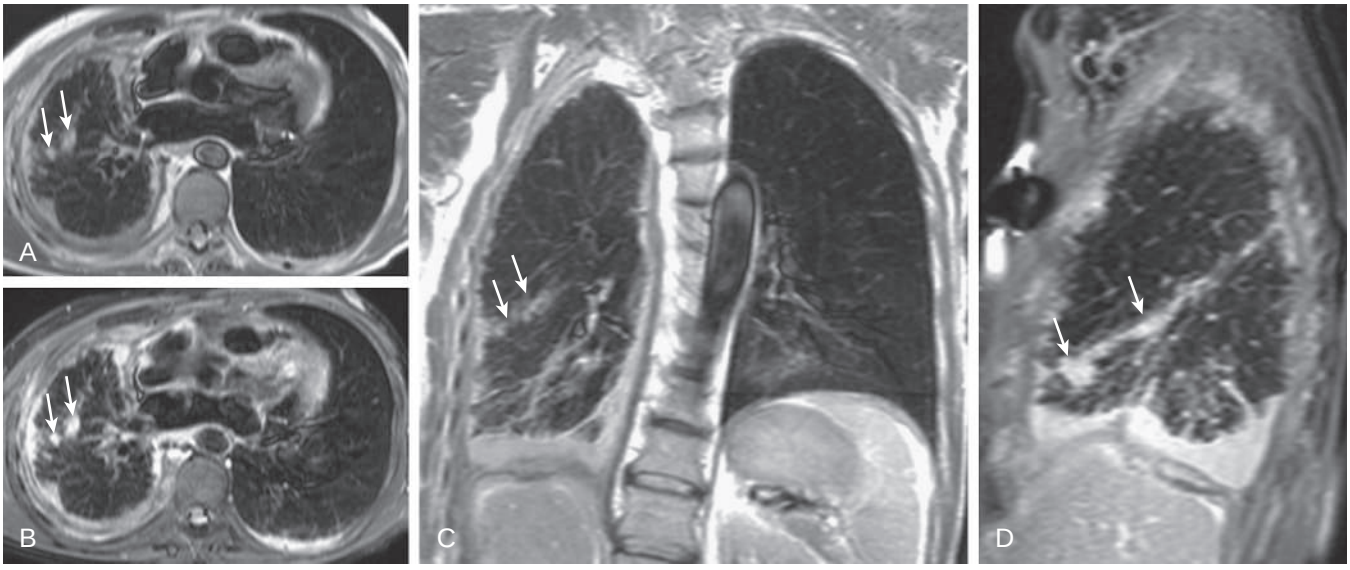
eFigure 114.5 Malignant pleural mesothelioma: pleural nodules. (A–B) Axial chest computed tomography displayed in lung windows shows large nodules nearly circumferentially involving the right pleura. (C) Axial positron emission tomography image shows extensive metabolic activity within the nodules. (Courtesy Michael B. Gotway, MD.)



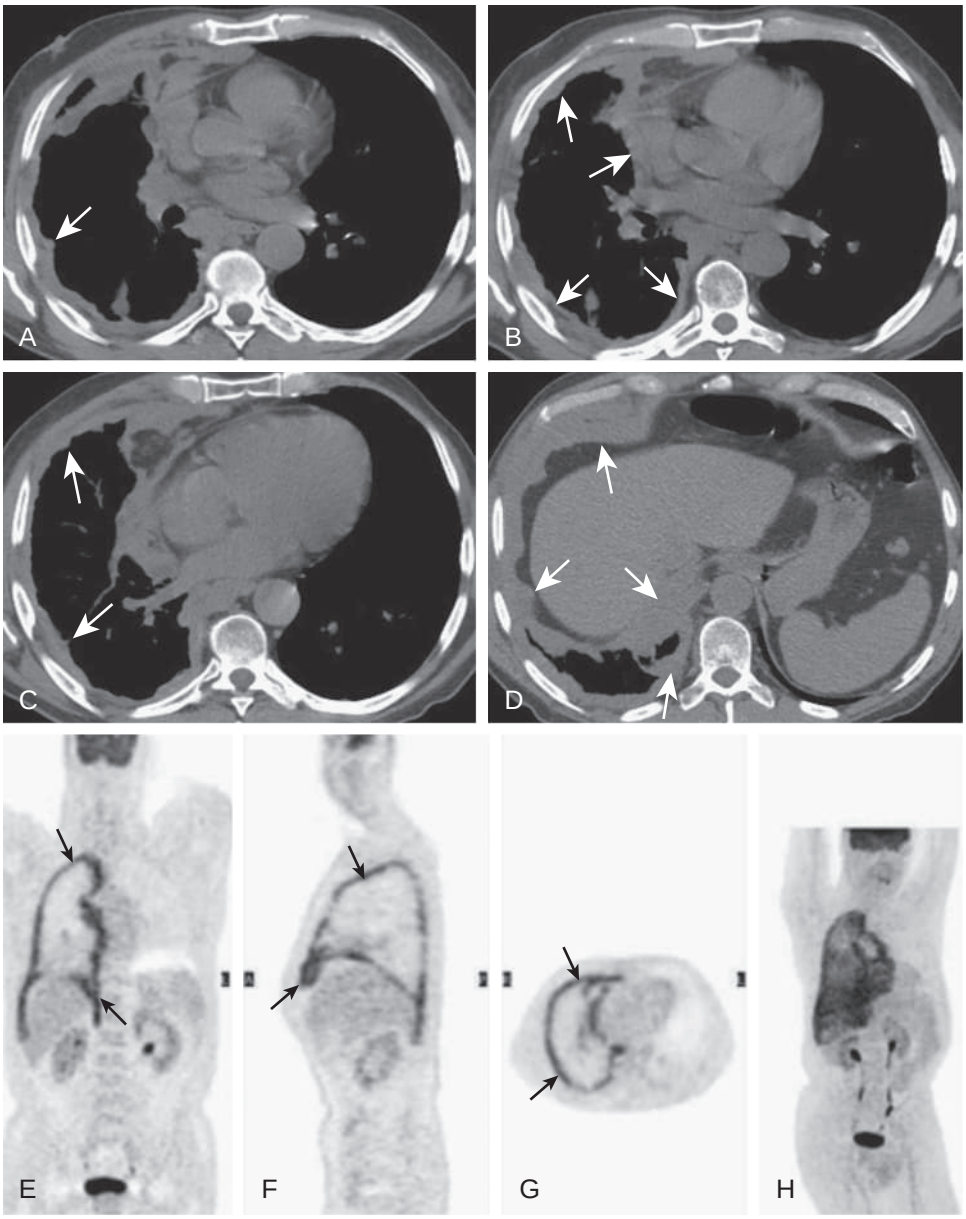
eFigure 114.6 Malignant pleural mesothelioma: chest wall and diaphragm invasion. (A–D) Axial enhanced chest computed tomography shows extensive, nodular right pleural thickening with extension of the pleural disease into the adjacent chest wall (*arrows*). Extensive nodular soft tissue thickening involving the basal pleura and right hemidiaphragm (*arrowheads*) is present, and partially calcified pleural plaques (*double arrowheads*), representing asbestos-related pleural disease, are seen bilaterally. (Courtesy Michael B. Gotway, MD.)



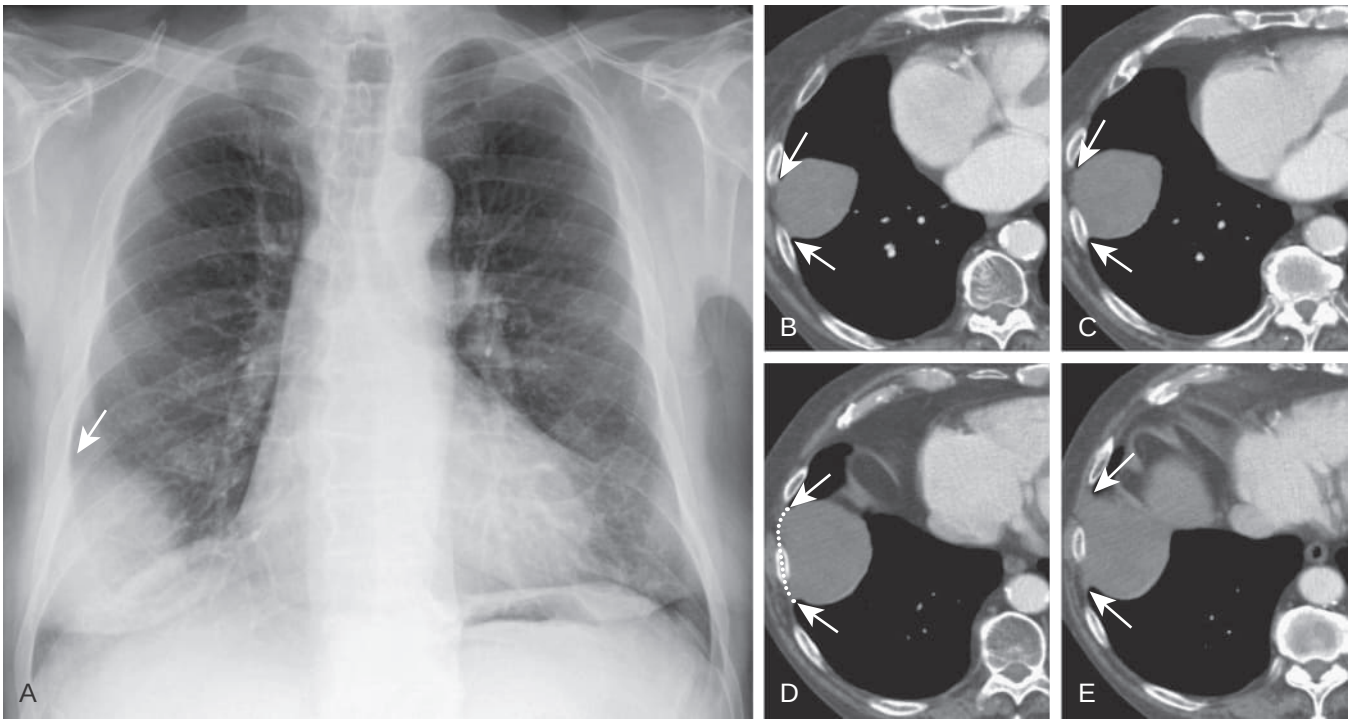
eFigure 114.7 Malignant pleural mesothelioma: lymphatic metastases. Axial chest computed tomography displayed in lung windows shows volume loss affecting the right thorax associated with extensive interstitial thickening. Clear nodular interlobular septal thickening (*arrowheads*) is present. (Courtesy Michael B. Gotway, MD.)



eFigure 114.8 Malignant pleural mesothelioma: magnetic resonance imaging appearance. (A–B) Axial T1-weighted imaging before (A) and following (B) intravenous contrast administration shows enhancing circumferential right pleural thickening with clear nodularity involving the right major fissure (*arrows*). Coronal unenhanced (C) and sagittal fat saturation enhanced (D) T1-weighted images show extensive pleural thickening and enhancement with a nodular appearance involving the right major fissure (*arrows*). (Courtesy Michael B. Gotway, MD.)



eFigure 114.9 Malignant pleural mesothelioma: chest computed tomography and *positron emission tomography* (PET)/computed tomography appearance. (A–D) Axial unenhanced chest computed tomography shows extensive, circumferential, nodular pleural thickening (*arrows*) associated with mild right thoracic volume loss. (E–H) Coronal (E and H), sagittal (F), and axial (G) PET images show intense metabolic activity circumferentially involving the right pleura (*arrows*), correlating with the chest computed tomography findings. (Courtesy Michael B. Gotway, MD.)



eFigure 114.10 Solitary fibrous tumor of the pleura creating acute angles with the chest wall. (A) Frontal chest radiograph shows a focal, circumscribed right peripheral chest mass creating an acute angle (*arrow*) at its cranial point of contact with the chest wall. (B–E) Axial enhanced chest computed tomography shows a circumscribed, homogeneous mass abutting the right inferior chest wall, creating acute angles (*arrows*) with the chest wall, raising the possibility of a location within the subpleural lung rather than the chest wall. The long length of contact of the lesion with the chest wall (*dotted lines*, D) favors a chest wall origin. Tissue sampling showed fibrous tumor of the pleura. (Courtesy Michael B. Gotway, MD.)

INTRODUCTION

The mediastinum is the region in the chest between the pleural cavities that contains the heart and other thoracic viscera. The mediastinum should be considered a unique body region due to the diversity and importance of the structures it contains and the multiplicity of disease processes that can affect it. Mass lesions that arise in the mediastinum represent a heterogenous group of benign and malignant processes that defy easy categorization. The nonspecific clinical manifestations of most of these disorders and the relative inaccessibility for tissue sampling result in considerable challenges to the clinician evaluating mediastinal disease. This chapter describes the normal anatomy and contents of the mediastinum, the clinical manifestations produced by mediastinal disease, and the means available for diagnostic investigation. It then reviews the features of specific mediastinal lesions by compartment and outlines an overall clinical approach to the evaluation of mediastinal disease. Discussion of pathology is focused on lesions that arise primarily in the mediastinum; lung cancer is discussed briefly as it pertains to findings in the mediastinum and is covered more fully in other chapters (see Chapter 76). Mediastinal inflammatory and infectious conditions that cause lymphadenopathy and mass-like lesions are also discussed in Chapter 116.

NORMAL ANATOMY OF THE MEDIASTINUM

The anatomy of the mediastinum has been traditionally divided into anterior, middle, and posterior compartments.[1] This three-compartment model is consistent with embryonic development of the region and with the characteristic distribution of individual clinical disorders. The three-compartment model was developed using margins of a lateral radiograph, but the International Thymic Malignancy Interest Group more recently advocated utilizing a similar three-compartment division scheme based on axial *computed tomography* (CT) images: defining prevascular (anterior), visceral (middle), and paravertebral (posterior) compartments.[3] The compartments correspond to the traditional radiographic definition,[2] with added precision with respect to boundary structures.[3] The anatomic relationships of the mediastinal viscera and tissue planes are best appreciated in the axial and sagittal planes on tomographic images (Fig. 115.1).[3] All the mediastinal compartments are defined superiorly by the thoracic inlet and inferiorly by the diaphragm.

The anterior or prevascular compartment consists of everything anterior to the pericardium; its boundaries are

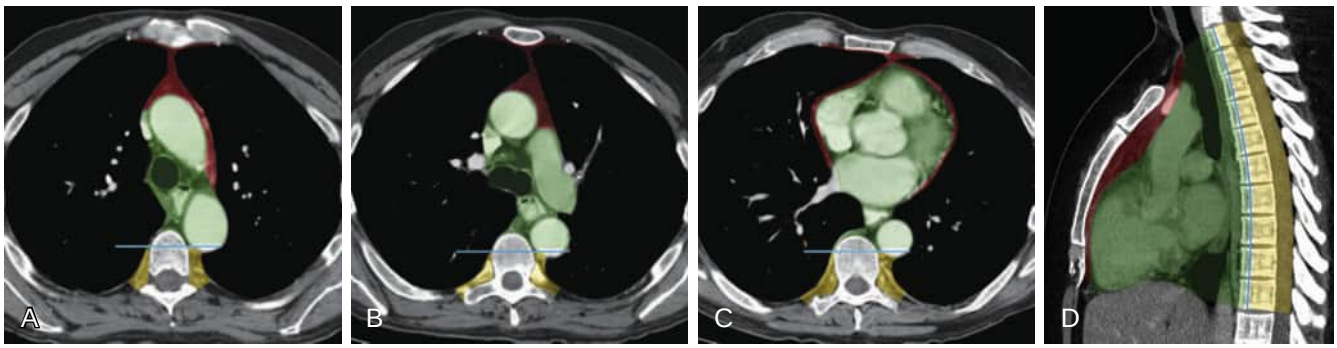

Figure 115.1 Mediastinal compartments by contrast-enhanced chest computed tomography. Red denotes the anterior/prevascular compartment; green, middle/visceral compartment; yellow, posterior/paravertebral component. (A) Axial image slightly below the aortic arch. (B) Axial image at the level of the left pulmonary artery. (C) Axial image at the level of the left atrium. (D) Sagittal image denoting the components. (From Carter BW, Tomiyama N, Bhora FY, et al. A modern definition of mediastinal compartments. *J Thorac Oncol.* 2014;9[9]:S97–S101.)

the sternum, the first rib, and an imaginary curved line following the anterior heart border and brachiocephalic vessels from the thoracic inlet to the diaphragm. Within the anterior compartment lie the thymus gland, any substernal extensions of the thyroid and parathyroid glands, and lymphatic tissue.

The middle or visceral compartment extends from the anterior aspect of the pericardium to a posterior margin on CT developed by creating a vertical line connecting a point on each thoracic vertebral body at 1 cm posterior to its anterior margin. It contains the heart, the pericardium, the aortic arch and its major branches, the innominate veins and *superior vena cava* (SVC), the pulmonary arteries and hila, the trachea, and several groups of lymph nodes. The esophagus, descending aorta, azygos and hemiazygos veins, paravertebral lymph nodes, and thoracic duct are now considered within this compartment. In addition, the phrenic and upper vagus nerves course through the middle mediastinal compartment.

The posterior or paravertebral compartment occupies the space posterior to the boundaries of the middle compartment defined above, with posterolateral boundaries created by a vertical line at the posterior margin of the chest wall at the lateral margin of the transverse processes of the thoracic spine.[3] The lower portions of the vagus nerve and sympathetic chains lie within the posterior mediastinum.

CLINICAL PRESENTATIONS OF MEDIASTINAL DISEASE

There are three broad reasons mediastinal disease comes to the attention of clinicians: (1) the mediastinum is being assessed in the setting of lung cancer or other metastatic malignancies (particularly tumors originating in the head and neck, the esophagus, the genitourinary tract, the breasts, and the skin); (2) an asymptomatic mass in the mediastinum is detected incidentally; or (3) there are systemic symptoms that point to the mediastinum as a site of disease. The majority of mediastinal masses are discovered incidentally—at least half of all mediastinal masses are asymptomatic and detected by chest radiography performed for unrelated reasons. About 80% of such asymptomatic masses are benign, whereas more than half of those that produce symptoms are malignant.[4–6]

Symptoms in patients with mediastinal mass lesions are nonspecific and are usually caused by compression or invasion of adjacent intrathoracic structures.[4,5] Chest pain, from traction on mediastinal tissues, tissue invasion, or bone erosion, is common. Cough may be due to extrinsic compression of the trachea or bronchi, erosion into the airway, and sometimes postobstructive pneumonia. Hemoptysis, hoarseness, or stridor also may be part of the clinical presentation. Invasion or inflammation of the pleural surface may produce a pleural effusion and cause pain and dyspnea. Compression or direct invasion of the esophagus may lead to dysphagia or odynophagia. Rarely, anterior mediastinal tumors can cause pericarditis or pericardial tamponade, and masses in the middle mediastinum can produce right ventricular outflow obstruction and right heart failure.

The SVC is especially vulnerable to extrinsic compression and obstruction because it is thin-walled and has low intravascular pressure; thus any encroachment, such as tumors in the middle mediastinum, can result in the SVC syndrome.[7] This is characterized by dilation of collateral veins in the upper portion of the thorax and neck, edema and plethora of the face, neck, and upper torso. Neurologic symptoms such as headache, disturbance of consciousness, and visual distortion may be present. Numerous benign causes of SVC syndrome are described,[8] but bronchogenic carcinoma (Video 115.1 and eFig. 115.1) and lymphoma (Video 115.2 and eFig. 115.2) are now the most common etiologies.[9,10] The compression or invasion of nerves may result in hoarseness from involvement of the recurrent laryngeal nerve, Horner syndrome from involvement of sympathetic ganglia, dyspnea from involvement of the phrenic nerve causing diaphragmatic paralysis, tachycardia from involvement of the vagus nerve, and clinical manifestations of spinal cord compression. In addition, primary mediastinal tumors are associated with a wide array of distinctive systemic syndromes, which provide clues to the etiology of the tumor.[4,5,11–13] For example, thymomas are classically associated with myasthenia gravis (Video 115.3 and eFig. 115.4).

Table 115.1 Characteristic Chest Computed Tomography Findings in Mediastinal Disease

Feature	Likely Etiology
Bulky mass on initial presentation	Anterior: lymphoma, germ cell tumor, thymic neoplasm, metastatic disease Posterior: neurogenic tumor
Fat density	Mediastinal lipomatosis or lipoma, liposarcoma, thymolipoma, teratoma
Calcification in mass	In rim of mass: cystic thymoma or thyroid adenoma, aneurysm (including saphenous vein bypass grafts), silicosis ("eggshell" calcification), teratoma In center of mass: goiter, teratoma, thymic neoplasm, treated lymphoma, sarcoidosis, mediastinal granuloma
Teeth or bone	Teratoma
Phleboliths	Hemangioma
Air-fluid level in mass	Esophageal disease, abscess, diaphragmatic hernia, developmental cyst, cystic teratoma (rare)
Mass with associated parenchymal opacity	Granulomatous inflammation/infection Metastatic bronchogenic carcinoma Lymphoma with direct extension into lung Esophageal abnormality with aspiration pneumonitis Bronchial compression by primary mediastinal mass
Mass with associated pleural effusion	Metastatic disease with pleural involvement Granulomatous inflammation of lymph nodes Thymic neoplasms (with "drop" metastases)
Superior vena cava obstruction	Recent onset: Bronchogenic carcinoma, lymphoma, catheter-associated thrombosis, extrinsic compression Long-standing: fibrosing mediastinitis
Erosion or destruction of bone	Metastatic disease, discitis/osteomyelitis, arterial aneurysm, tumors of peripheral nerves or sympathetic ganglia, meningocele
Spine or rib deformity	Enteric cyst, neurofibromatosis
Intensely enhancing lesions	Thyroid disorders, vascular abnormalities, metastases (renal cell carcinoma, thyroid carcinoma, melanoma, cholangiocarcinoma), Kaposi sarcoma, paraganglioma, angiofollicular lymphoid hyperplasia (Castleman disease), hemangioma

IMAGING THE MEDIASTINUM

The mediastinum is relatively inaccessible for examination or exploration; thus imaging studies play an important role in the initial evaluation of mediastinal disease. These include conventional radiographic studies, CT, *magnetic resonance imaging* (MRI), transthoracic and endoscopic ultrasonography, *positron emission tomography* (PET), and other radionuclide studies.

CONVENTIONAL RADIOGRAPHIC TECHNIQUES

Most mediastinal abnormalities are first detected by standard posteroanterior and lateral chest radiographs, and certain mass lesions have characteristic findings (Table 115.1). These findings give clues to the possible origin of a mediastinal mass, but further imaging evaluation is usually required. Although largely supplanted by CT, other studies may be useful in specific circumstances. For example, barium esophagram can demonstrate extrinsic compression, esophageal diverticulum, tumor invasion, or fistula formation.[4] Angiography can identify vascular compression or invasion, can define the vascular supply of tumors, and can sample blood for hormonal localization of certain tumors. Myelography may help delineate intraspinal extension of posterior mediastinal tumors and differentiate neurogenic neoplasms from meningoceles.

COMPUTED TOMOGRAPHY

CT imaging is the mainstay of radiographic evaluation of the mediastinum because this modality can firmly determine the anatomic location, morphology, and tissue density of a mass. The axial plane of CT is well suited for assessment of mediastinal structures, most of which are oriented perpendicularly to this plane. Administration of intravenous contrast helps delineate vascular structures as they relate to a mass and to other mediastinal structures. Easily identified CT patterns include the high density of calcified tissue and contrast-enhanced blood vessels, and the characteristic low density of fat (Fig. 115.2).[14] Normal anatomic variations and fluid-filled cysts can be confidently distinguished from bulky solid masses, which may be irregularly bordered and possess necrotic areas. Additionally, the site of origin of mediastinal masses can often be identified.[15] Characteristic CT findings in a variety of mediastinal disorders have been described (see Table 115.1). For example, the specificity of the CT appearance of teratomas (Video 115.4, eFigs. 115.9 and 115.10), thymolipomas (Video 115.5 and eFig. 115.11), and omental fat herniation (Video 115.6 and eFig. 115.12) is nearly 100%, but the overall accuracy of CT for predicting the diagnosis of all mediastinal masses is less than 50%.[14]

Lymph nodes are readily identifiable on CT scan and can be categorized by size and morphology. Mediastinal lymph nodes greater than 1 cm in diameter in the short axis are considered to be abnormally enlarged and are suspicious

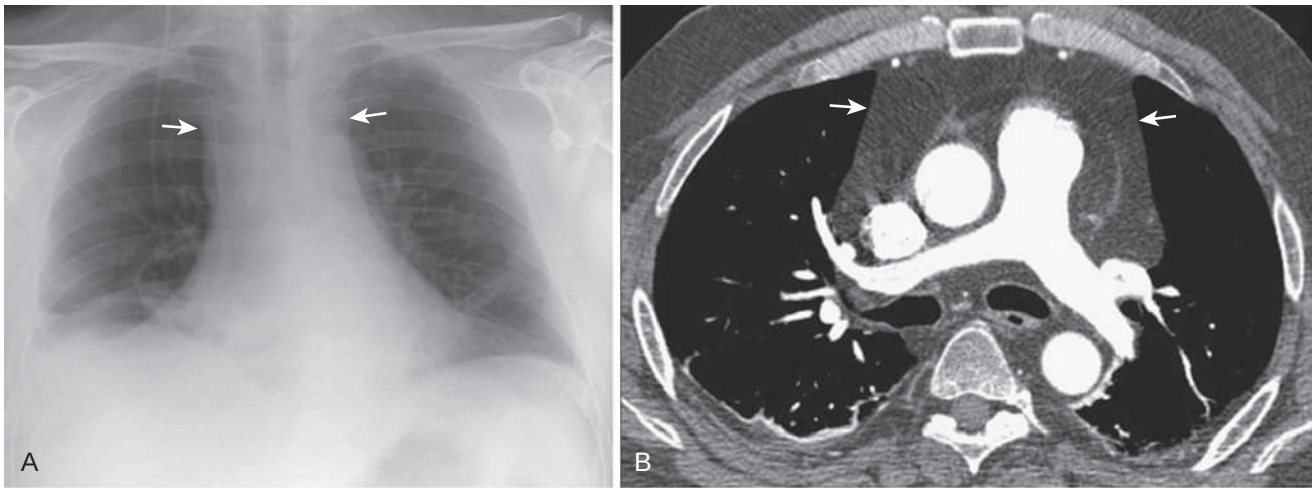

Figure 115.2 Mediastinal lipomatosis. Chest radiograph (A) showing diffuse mediastinal widening *(arrows)* and chest computed tomography scan (B) showing extensive fat deposition *(arrows)* in the anterior mediastinum in a patient with mediastinal lipomatosis.

for malignancy in the proper clinical context. Mediastinal lymph nodes greater than 2 cm in diameter are virtually always abnormal; however, CT cannot reliably distinguish between benign and malignant disease.[16] Nonetheless, CT remains the initial imaging procedure of choice for the evaluation of the mediastinum in patients with a suspected primary mediastinal mass[11–13] or with suspected lung cancer.[17] CT can precisely defines the mediastinal anatomy and guides subsequent invasive diagnostic and staging procedures or can confirm a clinical suspicion of extensive mediastinal involvement or visceral organ invasion that precludes curative resection.

MAGNETIC RESONANCE IMAGING

Although CT is often the initial modality used in diagnosing mediastinal abnormalities, MRI exhibits superior soft tissue resolution. This is advantageous in assessing the precise localization of tumors, extension and tissue boundaries, and relationship with other anatomic structures.[18–22] The respiratory and cardiac variation that has typically been a significant limitation can be overcome through pneumatic belt compression of the chest, breath-hold sequences, or continuous image acquisition synchronized with diaphragmatic movement.[18] Blood vessels are identifiable without the need for contrast enhancement (Fig. 115.3) (Video 115.7A–B); thus MRI can provide an alternative to patients who cannot be given iodinated contrast material required by CT. Ionizing radiation exposure is also eliminated.[23] Although much less frequently used than CT in evaluating mediastinal lesions, MRI is used most frequently for the evaluation of cystic and indeterminate mediastinal masses. MRI has utility in evaluating neurogenic tumors, and it may also be useful in evaluating thymoma and distinguishing it from congenital cyst or thymic carcinoma.[24] MRI can be helpful for defining anatomy before surgical resection of superior sulcus tumors or those invading the mediastinum, chest wall, or diaphragm (eFig. 115.15 and Video 115.8).[17,25]

There have been efforts to use MRI to distinguish benign from malignant masses. In a study of 53 mediastinal lesions, diffusion-weighted MRI distinguished between malignant and benign mediastinal lesions based on apparent diffusion coefficient levels with a sensitivity of 95% and specificity of 87%,[20] with evidence of lower apparent diffusion coefficient values indicating a slower diffusion of water molecules in the malignant lesions. The use of MRI to establish malignancy or benignity requires further study. However, lesions that have features of benignity can sometimes be followed with serial imaging.[26]

ULTRASONOGRAPHY

Ultrasonography can confirm the cystic nature of mediastinal masses, but it cannot readily distinguish between benign and malignant cystic lesions. Both transthoracic and endoscopic ultrasound probes are useful in the evaluation of mediastinal disease in the context of guiding endoscopic biopsy procedures, discussed later.[27]

NUCLEAR IMAGING

Nuclear imaging studies rely on the localization of markers based on specific metabolic or immunologic properties of the target tissue to provide a functional image of a lesion. The spatial resolution of radionuclide scans is relatively poor, but the overall diagnostic accuracy may be high if a sufficiently specific probe is available. Nuclear studies offer the potential to identify a primary malignancy and identify distant metastases with a single scan of the entire body.

PET is a widely used nuclear imaging technique that relies on high-energy photon-emitting probes, such as ^{18}*F-fluorodeoxyglucose* (FDG), which are chemically trapped within metabolically active neoplastic cells. The result is a high signal-to-background ratio and excellent spatial resolution for a functional image of a tumor. Use of combined and coregistered PET and CT images has allowed for more accurate anatomic localization of the lesions in question.[16,28]

PET is useful in the evaluation of mediastinal involvement of thoracic malignancies, and its role in lung cancer staging is discussed in Chapter 25. Although PET is indicated for staging lung cancer, granulomatous, inflammatory, infectious conditions or brown fat can also lead to

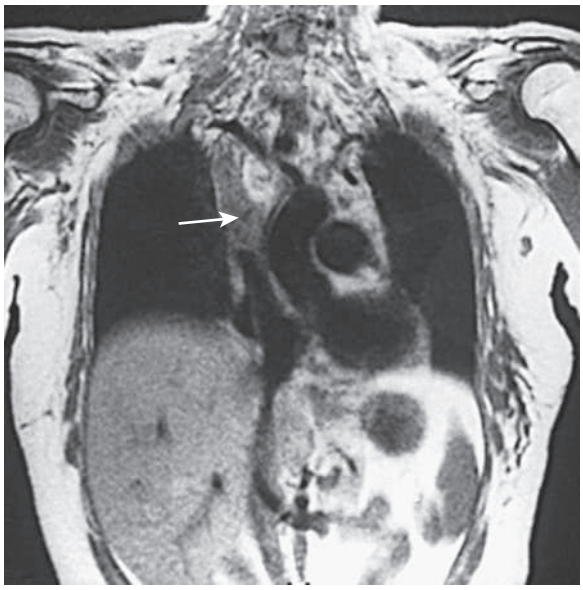

Figure 115.3 Magnetic resonance imaging of superior vena cava syndrome. A 52-year-old woman with multiple myeloma experienced symptoms of superior vena cava obstruction following placement of an indwelling central venous catheter in preparation for bone marrow transplantation. Vertically oriented structures are clearly discernible, and black flow void is present within the heart and great vessels. The superior vena cava is completely obstructed by thrombus *(arrow)*.

elevated FDG uptake in mediastinal lymph nodes; thus tissue confirmation is usually required.[29]

The utility of PET for the evaluation of primary mediastinal lesions is not as well established as it is for lymph node metastases. FDG-PET may differentiate between thymoma and thymic carcinoma,[30] but has low sensitivity in differentiating between nonaggressive and aggressive subtypes of thymoma,[24] and is not used routinely for staging of thymoma. However, PET is considered standard of care in the pretreatment workup and follow-up of mediastinal lymphoma (see "Lymphoma" later). FDG-PET also plays a role in detecting residual postchemotherapy malignant germ cell tumors, specifically seminomas, of the mediastinum. There is little role for PET in evaluating neurogenic tumors.[31]

Several other imaging techniques are utilized for specific conditions. Radioiodine scanning is used for the detection of ectopic thyroid tissue and a positive result is pathognomonic for that condition[4]; I-meta-iodobenzylguanidine scintigraphy is used for detection of neuroblastic tumors and may be used with MRI to improve the prediction for unfavorable histology.[32] ^{99m}Technetium sestamibi scanning is used for primary hyperparathyroidism.[33]

TECHNIQUES FOR OBTAINING MEDIASTINAL TISSUE

In many cases of a mediastinal mass with a confident presumptive clinical diagnosis, a patient may proceed with definitive surgical resection, precluding the need for a diagnostic biopsy (see "General Approach to a Mediastinal Mass" later). When pathologic confirmation is required to make decisions about medical treatment, as in the case of lymphoma or metastatic adenopathy, tissue biopsy can be obtained by image-guided and surgical approaches.

IMAGE-GUIDED BIOPSY

Endobronchial and Endoscopic Ultrasound-Guided Aspiration

Endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) of mediastinal tumors adjacent to the airways is a less invasive option than surgical tissue sampling and is commonly used in the setting of lung cancer staging (see Chapter 27). TBNA with a 19- or 22-gauge needle is performed under real-time ultrasonographic guidance via a curvilinear probe on the end of a bronchoscope (Videos 115.9A–B). The ability to visualize the area of interest as well as adjacent vascular structures has vastly improved diagnostic yields over blind bronchoscopic TBNA.[34–39] Upper and lower paratracheal, subcarinal, and hilar lymph nodes are readily accessible by EBUS-TBNA, as is any mediastinal or hilar lesion immediately adjacent to a large airway. EBUS-TBNA has the advantage over mediastinoscopy in accessing the posterior subcarinal lymph nodes as well as hilar nodes or masses, in addition to being an ambulatory procedure with lower associated health care costs.[40]

Beyond its role in lung cancer, EBUS-TBNA is useful in the evaluation of isolated mediastinal adenopathy due to other conditions. The diagnostic yield of EBUS-TBNA for the diagnosis of sarcoidosis manifesting as mediastinal and hilar adenopathy is superior to blind TBNA, with a sensitivity of 83% and specificity of 100%.[41] In a prospective trial of 77 patients with isolated mediastinal adenopathy, a specific diagnosis of sarcoidosis, tuberculosis, lymphoma, or other malignancy was made in 87%, thus obviating the need for a more invasive surgical mediastinoscopy.[42] EBUS-TBNA can be useful in providing a definitive diagnosis of primary or recurrent lymphoma; however, its role in the initial diagnosis of mediastinal lymphoproliferative disorders is likely inferior to surgical biopsy because the amount of tissue provided may not be adequate for histologic subtyping, which is of particular importance in identifying Hodgkin lymphoma.[42–44]

Endoscopic ultrasound (EUS)–guided sampling is similar and relies on the placement of biopsy needles through the working channel of a gastroscope.[45] It is particularly useful for assessing the posterior subcarinal nodes in selected cases and can be used alone or in conjunction with EBUS-TBNA in lung cancer staging.

Transthoracic Needle Aspiration and Biopsy

Transthoracic needle aspiration and biopsy of mediastinal masses, usually in the anterior compartment, can be performed percutaneously using ultrasound or, more often, CT guidance[46] (Fig. 115.4; see also Chapter 21). Transthoracic needle aspiration of the mediastinum has acceptable morbidity and yields comparable to those from percutaneous biopsy of pulmonary lesions. As with TBNA, serious bleeding is seldom encountered,[41] and accurate diagnosis of a wide variety of lesions has been reported.

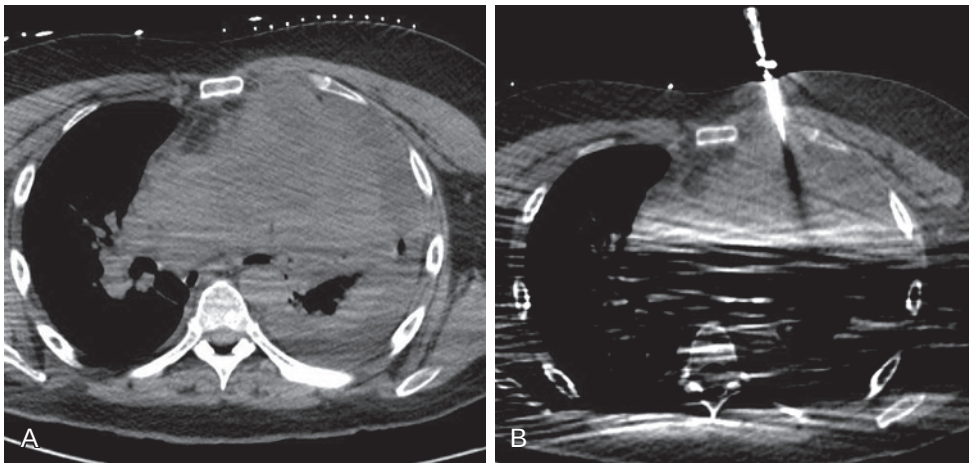

Figure 115.4 Bulky anterior mediastinal mass with CT-guided needle aspiration. (A) A 45-year-old man presenting with hoarseness was found to have a 12 × 10 × 11 cm anterior mediastinal mass. On this noncontrast computed tomography (CT) image, there is central necrosis and mass effect with concurrent left pleural effusion. (B) CT-guided needle aspiration of the mass. The needle is lateral to the sternum. The final diagnosis was primary mediastinal B cell lymphoma.

SURGICAL BIOPSY

Mediastinoscopy

Cervical mediastinoscopy provides direct access to the paratracheal and subcarinal lymph nodes, whereas an *anterior mediastinotomy* (Chamberlain procedure) provides access to the lymph nodes in the aortopulmonary window. Although more invasive than a percutaneous or endobronchial approach, mediastinoscopy has the advantage of providing the entire lymph node for histologic examination, rather than the cellular aspirates or small tissue fragments produced by needle biopsy techniques. Mediastinoscopy is most frequently used in the staging of bronchogenic carcinoma,[47] but has utility in evaluating mediastinal adenopathy or mass lesions of other etiologies. Either frozen section or imprint cytology methods can provide rapid, accurate results and facilitate immediate decisions about the feasibility of curative resection.[48,49]

From the perspective of the surgeon performing a mediastinoscopy, mediastinal anatomy is considered according to whether structures lie anterior, posterior, or immediately to the right or left of the trachea.[50] Mediastinoscopy is feasible for tumors adjacent to the airways, but is not a good option for anterior mediastinal or posterior mediastinal masses. Mediastinoscopy is performed using general anesthesia and is typically an outpatient procedure.[51] Mediastinoscopy is safe and well tolerated. Complications are rare, and include pneumothorax, hemorrhage, recurrent laryngeal nerve or phrenic nerve paralysis, injury to the trachea, esophageal perforation, thoracic duct laceration, air embolism, and mediastinitis.

Video-Assisted Thoracoscopic Surgery

Biopsies of mediastinal lymph nodes or mediastinal masses can also be performed by *video-assisted thoracoscopic surgery* (VATS). VATS provides access to any intrathoracic structure and hence, unlike mediastinoscopy, allows sampling from any tissue in the anterior, middle, or posterior mediastinum. VATS can also be a tool for the evaluation of pleural and lung abnormalities in the management of mediastinal diseases. Mediastinal lymph nodes can be sampled to aid in the staging of malignancies such as esophageal carcinoma and for the diagnosis and resection of primary mediastinal tumors and cysts.[52–54] VATS requires general anesthesia, the ability to tolerate single-lung ventilation, chest tube placement at the conclusion of the procedure, and typically a limited inpatient stay.

MEDIASTINAL MASS

CLASSIFICATION

Mediastinal masses are considered primary, that is, arising solely from structures within the mediastinum, or secondary, usually as metastatic disease from intrathoracic or extrathoracic malignancy. In the most practical classification of primary mediastinal masses, lesions characteristically found in the anterior, middle, or posterior compartments are grouped together (Table 115.2). Nonetheless, it is important to recognize that masses will not necessarily respect anatomic borders and may have extended from another area in the mediastinum.

In a series of 400 consecutive patients with a primary mediastinal lesion,[55] 25% had a primary benign cystic lesion and 42% had a malignant lesion. The anterior compartment was the most common compartment for a lesion, which was more likely to be malignant, followed by the posterior and then middle compartments. Only one-third of lesions are malignant, and the likelihood of malignancy depends on the location, age of the patient, and presence or absence of symptoms.[56,57]

INCIDENCE

The true incidence of primary mediastinal masses is difficult to ascertain. In a study of more than 9000 patients in a lung cancer CT screening trial, the prevalence of an incidentally detected mediastinal mass was 0.77%; among 11,000 follow-up scans, only one additional incident mediastinal mass was detected.[58] Historically, thymomas and developmental cysts were the most common masses found in adults,

Table 115.2 Disorders Presenting as a Mass in the Mediastinum

Anterior/Prevascular Mediastinum	Middle/Visceral Mediastinum	Posterior/Paravertebral Mediastinum
Thymic neoplasms	Lymphadenopathy	Neurogenic tumors
Germ cell tumors	Reactive and granulomatous inflammation	Meningocele
Teratoma	Metastasis	Diaphragmatic hernia (Bochdalek)
Seminoma	Angiofollicular lymphoid hyperplasia (Castleman disease)	Extramedullary hematopoiesis
Nonseminomatous germ cell tumors	Lymphoma	Lymphadenopathy
Embryonal cell carcinoma	Developmental cysts	Lesions arising from posterior spine
Choriocarcinoma	Pericardial cyst	Metastases
Lymphoma	Foregut duplication cysts	Discitis/osteomyelitis
Hodgkin lymphoma	Bronchogenic cyst	Thoracic duct cyst
Non-Hodgkin lymphoma	Enteric cyst	
Thyroid neoplasms/goiter	Others	
Parathyroid neoplasms	Vascular enlargements (i.e., descending aortic aneurysm)	
Mesenchymal tumors	Diaphragmatic hernia (hiatal)	
Lipoma	Esophageal lesions	
Fibroma	Carcinoma	
Lymphangioma	Diverticula	
Hemangioma	Varices	
Mesothelioma		
Sarcoma		
Diaphragmatic hernia (Morgagni)		
NUT midline carcinoma		
Lymphadenopathy		
Vascular lesions		

NUT, nuclear protein in testis.

followed by neurogenic tumors and lymphoma, based on the collection by Silverman and Sabiston of nearly 2400 cases.[4] More recent series suggest a similar pattern,[6,59] although Cohen and associates have observed both a rising incidence of mediastinal masses in general and an increasing proportion of lymphoma and malignant neurogenic tumors over the course of their 45-year survey.[6] Neurogenic tumors, thymomas, and developmental cysts account for about 60% of all mediastinal masses. Lymphomas and germ cell tumors such as teratoma and seminoma account for about 25%, and a large number of other lesions, both benign and malignant, constitute the remaining 15%.[6]

SPECIFIC MEDIASTINAL TUMORS AND CYSTS

LESIONS OF THE ANTERIOR MEDIASTINUM

Thymic Neoplasms

Thymoma is the most common neoplasm arising in the anterior mediastinum.[4,5,15,60] It remains a rare tumor, with an overall incidence of 0.13 per 100,000 person-years in the United States.[61] The peak incidence of thymoma is between the ages of 40 and 60 years and is higher in Asians and African Americans, with equal gender predilection.

Although most thymomas are not biologically aggressive, about one-third of thymomas have already invaded their capsules when discovered. Certain histologic subtypes, as outlined in the World Health Organization classification, are biologically more aggressive.[62] Advanced disease involves extension into local structures, transdiaphragmatic extension into the abdomen, or pericardial involvement, but lymphogenous and hematogenous metastases are rare.[57] Clinical staging historically relied upon the Masaoka or the Masaoka-Koga systems, which are based on the degree of tumor invasion into adjacent structures.[57] The International Thymic Malignancy Interest Group and the International Association for the Study of Lung Cancer have established a tumor-node-metastasis–based classification system based on a multinational cohort of more than 10,000 cases of thymic malignancy, with the T-status largely reflective of invasion. This clinical staging system is poised to become the gold standard.[63]

The majority of patients with thymoma are asymptomatic, although one-third of patients will present with nonspecific chest pain, cough, or dyspnea due to local tumor effects.[64] From 40–70% have at least laboratory evidence of one or more of the two dozen systemic "parathymic" syndromes that have been recognized.[4] Thymomas are associated with numerous systemic syndromes, most of which appear to be autoimmune in origin.[4,5,12] The most familiar of these is myasthenia gravis, reported in 10–50% of patients with thymoma,[4] and thought to be due to autoantibodies to the postsynaptic acetylcholine receptor.[65,66] Other associated syndromes include pure red blood cell aplasia, myocarditis, and hypogammaglobulinemia. Patients with thymoma also have an increased incidence of collagen vascular disease, Whipple disease, and malignancy elsewhere in the body.

On chest radiography, thymomas appear as an ovoid, smooth or lobulated unilateral mass near the junction of the heart and great vessels (Fig. 115.5).[67] Compared

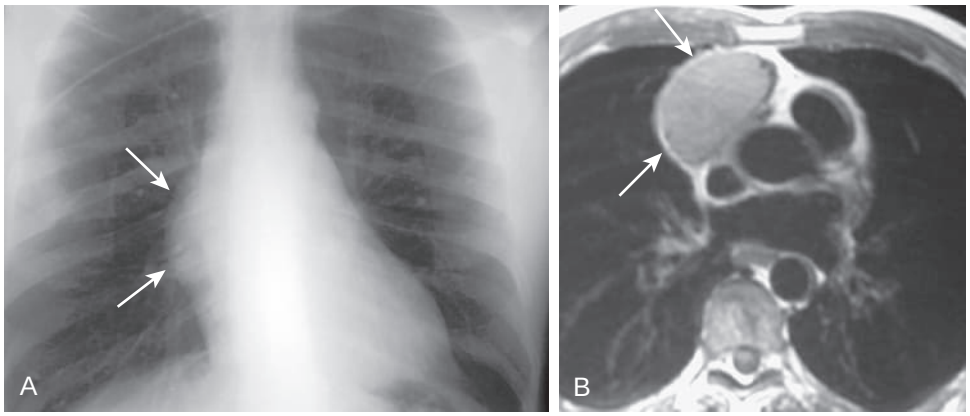

Figure 115.5 Thymoma. (A) Frontal chest radiograph shows a smoothly marginated mass along the right side of the mediastinum *(arrows)*. (B) Axial magnetic resonance T1-weighted image through the base of the heart shows that the mass *(arrows)* is slightly hyperintense compared with the skeletal muscle and resides within the anterior mediastinum. Note the smooth, well-defined margins of the mass, consistent with an encapsulated thymoma. (Courtesy Michael B. Gotway, MD.)

with thymic hyperplasia, which is typically symmetrical, thymoma usually distorts the gland's normal shape asymmetrically and extends to one side.[68] On CT scan, most thymomas present as a solid 5- to 10-cm anterior mediastinal mass outlined by fat; up to one-third of thymomas contain cystic, necrotic, or hemorrhagic areas that enhance heterogeneously. Contrast CT is necessary for the staging of thymoma, specifically for discerning vascular involvement. MRI can help distinguish benign cysts from a cystic thymoma or thymic carcinoma. Due to their relatively indolent nature, most thymomas have low FDG uptake, which limits the utility of PET imaging to discriminate a benign from a malignant thymic mass.[24,57]

The mainstay of therapy for thymomas is surgical resection, which provides the best chance for an optimal prognosis.[57] For advanced stage disease, adjuvant radiotherapy is typically provided, and preoperative or adjuvant chemotherapy is considered on an individual basis.[5,60,69–71]

Patients whose tumors are fully encapsulated with no evidence of invasion can expect postoperative survival equal to that of the general population. Invasive tumors have a poorer prognosis, with 50–77% 5-year and 30–55% 10-year survival.[72] Thymoma recurs after resection in nearly one-third of patients.[72] The largest retrospective survey of thymic tumors from the European Society of Thoracic Surgeons database showed that higher Masaoka stage (with evidence of invasion), incomplete resection, and nonthymoma histology (e.g., thymic carcinomas and neuroendocrine thymic tumors) were factors in recurrence and worse survival.[73]

Thymic carcinoma is an aggressive epithelial malignancy that invades locally and frequently metastasizes.[74,75] This rare cancer develops predominantly in middle-aged men, who present with symptoms of cough, dyspnea, and chest pain as well as nonspecific systemic symptoms.[57] On imaging, thymic carcinomas are heterogenous masses with areas of necrosis and calcifications. They are highly FDG-avid on PET scan.[24,30] The prognosis, which depends on the histologic grade and the anatomic stage, is generally poor. Surgical resection is the treatment of choice, if possible, though recurrence is common. Chemotherapy and radiation therapy are advocated for unresectable disease, and are often used as adjuvant therapy for resectable disease.[73]

Carcinoid tumors occasionally arise in the thymus.[76,77] They may cause Cushing syndrome and be associated with multiple endocrine adenomatosis. Locally invasive carcinoids may be difficult to resect completely, but characteristically have an indolent clinical course.[4] Interestingly, the thymus is also a common site for mediastinal Hodgkin lymphoma, and normal thymic tissue may enlarge following chemotherapy for lymphoma (a process termed *thymic rebound*) (eFig. 115.25), mimicking recurrence of the primary disease.[78] Other thymic mass lesions include benign conditions such as thymic hyperplasia (eFig. 115.26), thymic cysts, and thymolipoma (Video 115.5 and eFig. 115.11).[79]

Germ Cell Tumors

Approximately 10–12% of primary mediastinal masses are derived from multipotent germ cells that migrated abnormally during early embryonic development.[4,5,80,81] These extragonadal *germ cell tumors* (GCT) are classified into three groups: teratoma, seminoma, and nonseminomatous GCT.[81]

Benign teratomas, the most common GCT, are by definition comprised of tissues foreign to the area in which they arise. Ectodermal derivatives predominate, but structures originating in all three primary germ cell layers may be found. *Dermoid cyst* refers to a lesion that contains only the epidermis and its derivatives. Teratomas arise most often in young adults but have been reported in all age groups; men and women are affected with equal frequency. Most patients with teratomas have symptoms caused by the tumor.[4,82] Usual symptoms are pain, cough, and dyspnea. Rarely, teratomas can rupture into the bronchial tree, pleural space, or pericardium.[83] If the tumor erodes into a bronchus, the patient may have hemoptysis or even expectorate differentiated tissue such as hair (trichoptysis) or sebaceous material.[82] On chest radiographs, teratomas

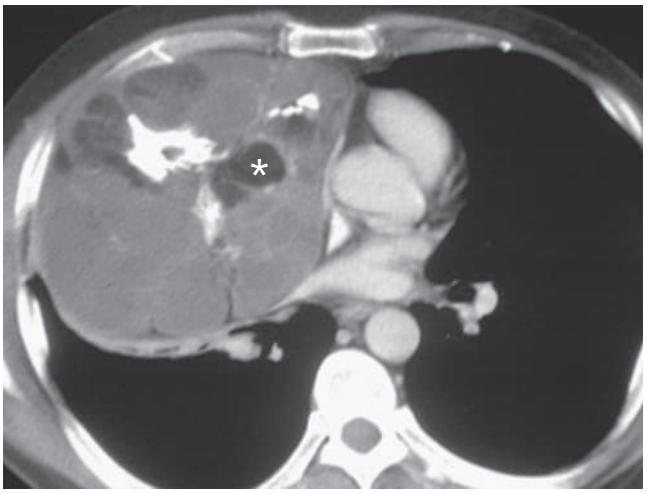

Figure 115.6 Teratoma. Axial computed tomography image through the base of the heart shows a large right-sided anterior mediastinal mass with heterogeneous attenuation. Elements of calcium, soft tissue, and fat *(asterisk)* are present. The presence of fat within an anterior mediastinal mass is most consistent with teratoma. (Courtesy Michael B. Gotway, MD.)

appear smooth, rounded, and circumscribed if they are cystic. Solid lesions can appear lobulated and asymmetric. On CT scans (Video 115.4 and eFig. 115.10), soft tissue, fat, and calcification (and occasionally fully formed teeth and bone) can be identified, rendering this one of few mediastinal tumors that can be diagnosed confidently before surgery[14] (Fig. 115.6). All teratomas should be resected due to malignant potential and effects of impingement on adjacent vital structures. In malignant teratoma, adjuvant combination chemotherapy may result in improved survival.[84]

Malignant primary mediastinal GCT include seminomas and nonseminomatous GCT and affect men in the third and fourth decades of life. These lesions nearly always cause symptoms[5] and appear as a large anterior mediastinal mass on chest imaging (Video 115.10 and eFig. 115.29). Most patients seek medical attention because of chest pain, dyspnea, cough, hoarseness, or dysphagia.

Seminomas are aggressive malignant tumors that extend locally and metastasize distantly, usually to skeletal structures. They may secrete human chorionic gonadotropin, but not alpha-fetoprotein. Factors associated with a poor prognosis include age greater than 35 years; SVC obstruction; supraclavicular, cervical, or hilar adenopathy; and fever.[85,86] Seminomas are extremely radiosensitive and may respond dramatically to chemotherapy, even in cases with dissemination.[81,87] With aggressive cisplatin-based regimens, long-term survival for all mediastinal seminomas is approximately 80%.[81,88]

Nonseminomas include embryonal cell carcinoma and choriocarcinoma.[4,5,85] These malignancies carry a poorer prognosis relative to seminomas and cancers arising from the gonads or other extragonadal sites.[81,89,90] Embryonal cell carcinoma is also called endodermal sinus or yolk sac tumor (Video 115.11 and eFig. 115.30). These highly aggressive tumors often secrete human chorionic gonadotropin and alpha-fetoprotein. In contrast to gonadal GCT, mediastinal GCT have been associated with Klinefelter syndrome[91] and hematologic malignancy.[92] Most patients present with disseminated disease.[5] Cisplatin-based treatment regimens have markedly improved the outcome, with more than 50% of patients achieving long-term survival.[81,92] Long-term survival may also be possible in those who undergo a complete surgical resection following chemotherapy.[93] High-dose chemotherapy followed by autologous hematopoietic cell transplantation is now standard therapy for relapsed metastatic disease.[94–96]

Lymphoma

Lymphoma is distinguished from other mediastinal lesions in that management is primarily medical, not surgical. In most series, lymphomas represent between 10% and 20% of mediastinal masses in both adults and children[4–6,59] and are the most common anterior and middle mediastinal masses in children.[97] The categorization of lymphoid malignancies now encompasses nearly 90 distinct entities based on molecular, histologic, and clinical features.[98] For practical purposes, lymphomas may be classified as *non-Hodgkin lymphoma* (NHL) or *Hodgkin lymphoma* (HL). NHL arises most commonly in older adults, whereas HL has a bimodal distribution, arising in adolescents and young adults as well as in those older than 50. Given that lymphoma can involve any organ of the body, there is a broad range of symptoms. Classically, lymphomas present with painless adenopathy (which can include mediastinal adenopathy) accompanied by constitutional symptoms such as fever, weight loss, and fatigue.

The lymphomas that arise specifically in the mediastinum present similarly but have distinct histologic features. Both *primary mediastinal B cell lymphoma* (PMBCL), a rare subset of NHL, and classic nodular sclerosing HL arise from thymic B cell precursors.[99] A B cell lymphoma that exhibits histologic features of both PMBCL and HL is considered a *mediastinal gray zone lymphoma*.[100] These entities affect adolescents and young adults and are more common in females.[101] These lymphomas present as a bulky anterior mediastinal mass involving the thymus (see Fig. 115.4), sometimes with hemorrhage or necrosis on chest CT. Presenting symptoms include dyspnea, cough, and dysphagia due to compression of the trachea; compression of the great vessels may result in pleural and pericardial effusions. For PMBCL, extrathoracic disease, such as supraclavicular adenopathy or lung metastases, is rare on initial presentation but is often a feature of relapsed or refractory disease. SVC syndrome is a common presentation of PMBCL, but less so for HL (Video 115.2 and eFig. 115.2), which can involve the hilar nodes and lung parenchyma.[102] HL is characterized by the Hodgkin/Reed Sternberg cell in a nodular growth pattern with a specific immunophenotype of $CD30^+$, $CD45^-$, and $CD15^+$ in 85% of cases. PMBCL is histologically characterized by an infiltrate of large cells in a diffuse pattern with an immunophenotype of a mature B lymphocyte expressing CD20 but not CD15.

The prognosis of lymphoma in general has improved strikingly in the past two decades with improvements in disease staging, chemoradiotherapy regimens, and a greater understanding of the underlying biology allowing for targeted therapies. HL is curable in approximately 75% of patients, although late toxicities of conventional treatment contribute significantly to late mortality. Despite similarities, it is important to distinguish HL from PMBCL or other

NHL in order to guide therapy; thus tissue biopsy is indicated. The current standard of treatment for early-stage, bulky mediastinal HL is combined modality therapy, consisting of ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) and radiation. Optimal therapy for nonbulky mediastinal HL is controversial; clinical trials suggest no difference in overall survival but an increase in risk for disease progression with chemotherapy alone.[103,104] The benefits of radiation therapy must be balanced with the risk for serious late complications, including pulmonary fibrosis, cardiovascular disease, and secondary malignancies such as breast and lung cancer.[100]

As with other B cell lymphomas, the standard regimen for PMBCL includes R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone)–based regimens, followed by radiation. In spite of high response rates, this standard approach including radiation confers serious long-term toxicities. More recently the regimen of DA-EPOCH-R (dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin, rituximab) has gained traction as standard front-line therapy, given high event-free survival rates of greater than 85–93% without the need for up-front radiation.[105–107] PET scan, which is often used to restage aggressive lymphomas, appears to have a high negative predictive value and may be useful in determining when to omit radiotherapy after primary chemotherapy.[108,109]

For advanced-stage refractory or relapsed disease (HL, PMBCL, as well as other subtypes of NHL), hematopoietic cell transplantation remains an option. Given that HL and PMBCL tumors have up-regulated immune checkpoint pathways that evade antitumor immune surveillance, the novel immune checkpoint inhibitors, including pembrolizumab, a programmed death-1 blocking antibody, appear to have utility as salvage treatment.[110-112] Genetically modified chimeric antigen receptor T cells targeting CD19 receptors on B cell malignancies is promising cellular-based immunotherapy for refractory B cell lymphomas, including PMBCL.[113]

Thyroid Lesions

In surgical series, ectopic thyroid glands account for fewer than 10% of mediastinal masses but, in clinical practice, they probably represent a higher proportion (see Chapter 128). Thyroid tissue within the mediastinum is of two distinct origins: from the thyroid or from embryonal tissue. Most commonly, a cervical goiter extends substernally into the anterior mediastinum,[114] whereas primary intrathoracic goiter, presumably originating from an embryonic nest of heterotopic thyroid tissue, is rare. Most such goiters are in the anterior mediastinum, but they may arise in the middle or posterior mediastinum as well.[4,5] Intrathoracic goiter presents predominantly in middle-aged or older women. Although it is usually asymptomatic, goiter may cause hoarseness, cough, or swelling of the face and arms. Intrathoracic thyroid tissue is easily recognized by radioactive iodine scanning,[115] as long as the scan is completed before intravenous iodinated contrast injection, which may block iodine uptake for weeks. It may be suspected on the basis of high radiodensity on CT scans, particularly after iodinated contrast injection.[116,117] Treatment is surgical resection.

Parathyroid Lesions

Mediastinal parathyroid tissue accounts for up to 10% of cases of hyperparathyroidism, and the mediastinum is the most common site for ectopic parathyroid adenomas in surgically resistant hyperparathyroidism.[118] Half of ectopic parathyroid adenomas lie in the anterior mediastinum, usually near the thymus (eFig. 115.5). Parathyroid cysts may enlarge sufficiently to appear as a mass on the chest radiograph and to produce symptoms but, in many cases, ectopic tissue may be difficult to locate.[119] Evaluation of the lesion is typically conducted using CT angiography, ultrasound, MRI, and the sensitive 99m-technetium sestamibi scanning.[120] Selective arteriography and venous sampling for parathyroid hormone levels have largely been supplanted by sestamibi radionuclide scanning.[120,121] Parathyroid adenomas are cured by complete resection, and VATS is increasingly utilized.[52] Parathyroid carcinoma may be functional, resulting in varying degrees of hyperparathyroidism, but it is also locally invasive and may metastasize.[122] Cure is possible with aggressive surgical management.[123]

Mesenchymal Tumors

Included in this group of unusual mediastinal masses are lipomas, fibromas, mesotheliomas, and lymphangiomas (see Table 115.2).[4] They arise from connective tissue, fat, smooth muscle, striated muscle, blood vessels, or lymphatic channels and can be found in any region of the mediastinum. Histologically and clinically, they are not substantially different from their counterparts elsewhere in the body. The presence of symptoms usually indicates that the lesion is malignant.[4,15]

Lipoma is the most common mesenchymal tumor of the mediastinum and is most often located in the anterior mediastinum. It may be encapsulated or unencapsulated, appearing as a smooth and rounded lesion with well-defined margins. The characteristic low density of lipomas on CT images (Fig. 115.7) permits a confident diagnosis unless there is associated heterogeneity, invasion of surrounding tissues, or poor demarcation of the mass's perimeter, in which case malignancy (liposarcoma or lipoblastoma) or teratoma must be excluded.[15] Considerably more common than lipoma is mediastinal lipomatosis, or generalized overabundance of histologically normal unencapsulated fat (see Fig. 115.2).[124] Mediastinal lipomatosis appears on the conventional radiograph as a smooth widening or bulging of normal mediastinal contours, and its low homogeneous CT density confirms the diagnosis.[15]

Sarcomas involving the mediastinum are rare but, if present, are likely to be due to nerve sheath sarcoma, spindle cell sarcoma, leiomyosarcoma, or liposarcoma.[125] Prior radiation therapy appears to be a predisposing factor in some cases.[126] Primary mediastinal sarcoma is a rare entity that affects adults; it can present with distant metastases[127] and tends to have an aggressive course.

NUT Carcinoma

Numerous rare neoplasms of the mediastinum have been described in larger case series of mediastinal tumors as well as in isolated case reports.[5,128] In the 1990s, cases of young patients with a highly aggressive squamous cell carcinoma presenting in the mediastinum and other midline

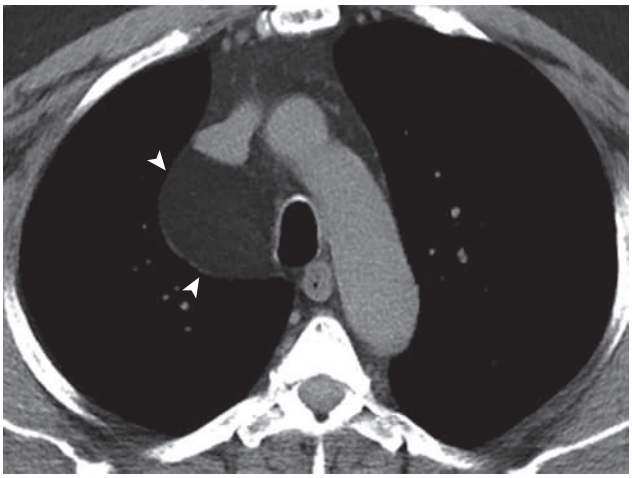

Figure 115.7 *Computed tomography* (CT) of mediastinal lipoma. Axial enhanced chest CT shows a circumscribed, rounded, right paratracheal fat density lesion *(arrows)* typical of lipoma. Note that there is no internal soft tissue or complexity and that the attenuation of the lesion exactly matches that of subcutaneous fat. (Courtesy Michael B. Gotway, MD)

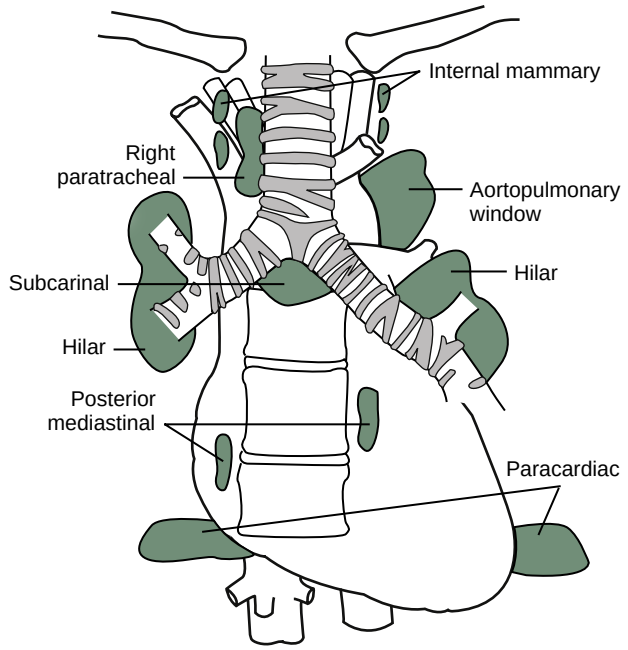

Figure 115.8 Simplified schematic diagram depicting mediastinal lymph node groups. (Modified from McLoud TC, Meyer JE. Mediastinal metastases. *Radiol Clin North Am.* 1982;20:453–468.)

structures were reported; these tumors were found to have t(15;19) translocations, resulting in a *BRD4-NUT* (nuclear protein in testis) fusion oncogene.[129,121] Since these original descriptions, NUT carcinomas have been described outside the thorax. They can present as large masses with local mass effects and distant metastases. Cure is rare.

LESIONS OF THE MIDDLE MEDIASTINUM

Enlargement of Lymph Nodes

Numerous classifications exist for the mediastinal lymph nodes, and this is often most relevant in tumor-node-metastasis staging for non–small cell lung cancer.[130] Figure 115.8 presents a simplified grouping of the main mediastinal nodes that corresponds to findings on chest radiography and CT scans.[131] Most authors consider 1-cm diameter at the short axis to be the upper limit of normal.[16]

Evaluating the mediastinum in the context of staging lung cancer is discussed elsewhere in the textbook (see Chapters 27 and 76). Mediastinal lymph node enlargement is most often due to lymphoma,[132] metastatic cancer,[131] granulomatous inflammation, such as that caused by sarcoidosis, or infection. Infection should be considered when the adenopathy is associated with a pulmonary opacity. Tuberculosis is a notable cause of mediastinal adenopathy that can mimic sarcoidosis or malignancy and should be suspected in a host with known tuberculosis risk factors.[133] Fungal infections that cause granulomas, particularly histoplasmosis, may present with mediastinal and hilar adenopathy in the absence of a pulmonary opacity.[134]

Numerous less-common causes of mediastinal adenopathy are described, including angiofollicular lymphoid hyperplasia (Castleman disease). Mediastinal adenopathy is common in HIV-infected patients and is usually caused by infection, although adenopathy may also be caused by lymphoma, Kaposi sarcoma, and other noninfectious processes.[135]

Ongoing inflammation from prior exposure to histoplasma or tuberculous components can lead to aggregation of caseous lymph nodes into a mass-like lesion called *mediastinal granuloma* (see Fig. 116.6). These can exhibit characteristic calcifications and can drain via fistulization into other organs such as the esophagus (Fig. 116.7). They can compress adjacent tissues but do not invade them. Mediastinal granuloma is not treated with antibiotics but can be drained via VATS if symptomatic. For a full discussion of this entity and related entities such as fibrosing mediastinitis and mediastinal adenitis, see Chapter 116.

Developmental Cysts

Developmental cysts of various sorts comprise 10–20% of all mediastinal masses.[4,136] Most can be identified as bronchogenic, enteric, or pericardial.[4] Bronchogenic and enteric cysts are often referred to as *foregut duplication cysts* because of their origin from aberrant portions of the ventral and dorsal foregut, respectively.

Bronchogenic cysts are found near large airways, often just posterior to the carina (Fig. 115.9), although they may be attached to the esophagus or even lie inside the pericardial space.[4] The cyst wall often contains cartilage and respiratory epithelium. Most are discovered incidentally and cause no symptoms. However, bronchogenic cysts may communicate with the tracheobronchial tree and become infected[137]; enlarge sufficiently to cause local effects including airway obstruction,[138] pulmonary artery compression,[139] or hemodynamic collapse[140]; or rupture.[141]

Enteric cysts are similar in location and appearance to bronchogenic cysts but have digestive tract epithelium. They are relatively uncommon in adults but are the most common cysts found in infants and children, in whom they may be associated with spinal extension and malformations

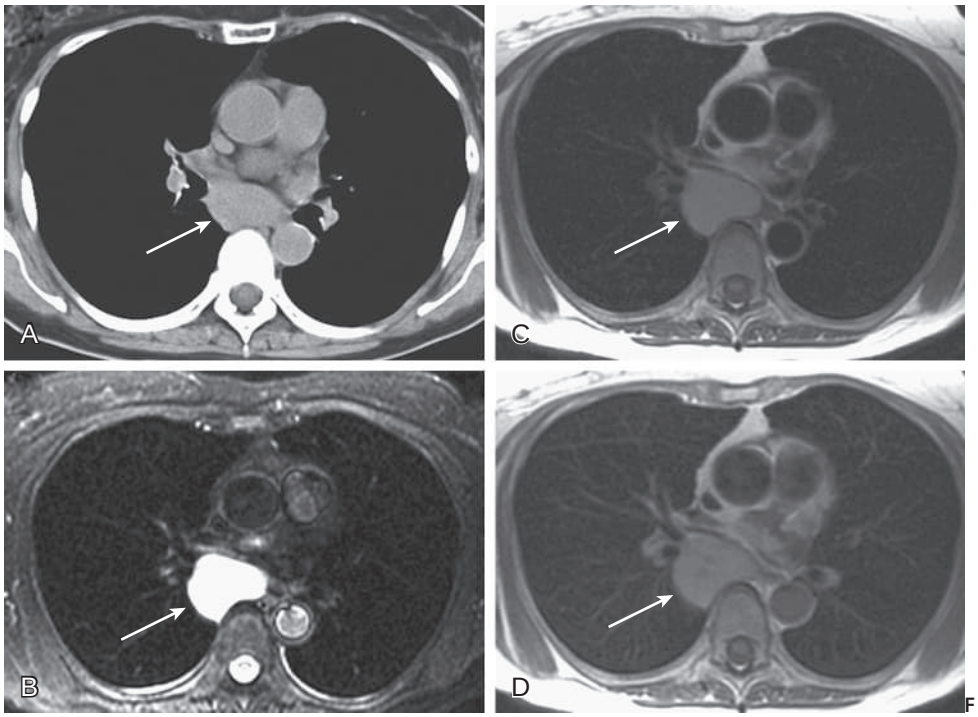

Figure 115.9 Bronchogenic cyst. Axial unenhanced chest computed tomography (A) shows a mildly hyperattenuating structure *(arrow)* in the subcarinal space. Axial triple inversion-recovery magnetic resonance imaging (B) and axial unenhanced double inversion-recovery (DIR) image (C) show the same lesion *(arrows).* Note the very high signal on the fluid-sensitive triple inversion-recovery image (B), consistent with fluid, and the mildly increased signal on the unenhanced DIR image (C), consistent with proteinaceous or hemorrhagic fluid; the latter mechanism also accounts for the hyperattenuating appearance on computed tomography. Enhanced DIR magnetic resonance imaging (D) shows no enhancement of the lesion *(arrow)* following intravenous gadolinium administration, typical of a foregut duplication cyst. (Courtesy Michael B. Gotway, MD.)

of the vertebral column (called *neurenteric cysts*). Enteric cysts can occasionally be multiple and associated with duplications of other portions of the gastrointestinal tract.

Pericardial cysts account for about one-third of cystic masses in adults but are much less common in children. They lie against the pericardium, diaphragm, or anterior chest wall in the right cardiophrenic angle. Rarely, pericardial cysts may communicate with the pericardial space. Although typically harmless, pericardial cysts may enlarge enough to cause right ventricular outflow obstruction,[142] or they may rupture and hemorrhage to cause pericardial tamponade[143] or sudden cardiac death.[144]

These developmental cysts are usually identified by CT (see Fig. 115.9A) or ultrasonography, and the diagnosis may be confirmed by aspiration cytology. MRI is valuable for confirming the cystic nature of these lesions (see Fig. 115.9B–D). Pericardial cysts can be monitored with serial imaging and need not be resected unless they cause symptoms. Bronchogenic cysts can also be followed conservatively if asymptomatic[145]; however, most authorities favor resection for purposes of diagnosis and to reduce the potential for complications.[137,141] Alternatives to thoracotomy include therapeutic aspiration[146,147] and thoracoscopic or mediastinoscopic excision.[53,148,149]

LESIONS OF THE POSTERIOR MEDIASTINUM

Neurogenic Tumors

The vast majority of tumors in the posterior mediastinum represent neoplasms arising from neural tissues,[4,5] historically accounting for about 20% of adult cases and twice that proportion in children. Neurogenic tumors appear radiographically as a unilateral paravertebral mass.[4,150,151] Clinical manifestations include chest pain from nerve or bone erosion, dyspnea secondary to tracheal compression, and neurologic deficits resulting from spinal cord compression by intraspinal tumor extension. In addition, many neurogenic tumors are hormonally active. MRI is usually indicated when there is suspicion for a neurogenic lesion. Although most neurogenic tumors are benign, surgical resection is indicated to alleviate local symptoms from mass effects of the tumor. Neurogenic tumors are classified by site of origin: nerves and their sheaths, sympathetic ganglia, or paraganglionic tissue (Table 115.3).

Arising from nerves and their sheaths, neurofibromas are the most common tumor of this group. They are incompletely encapsulated and may grow quite large, producing symptoms by compression of nerves or other structures. Mediastinal neurofibroma may be one manifestation of neurofibromatosis. As with these tumors found elsewhere in the body, neurofibromas may eventually transform into malignant neurosarcoma in 10–15% of patients.[5]

Arising from the neural sheath itself, schwannoma (neurilemoma) (Videos 115.12A–B and eFig. 115.43) is most often seen in the third to fifth decades of life. Schwannoma usually causes no symptoms and appears as a well-circumscribed, homogeneous density on chest radiography (Fig. 115.10A).[4,5] Schwannomas are always completely encapsulated and do not invade surrounding tissues, although they may extend into intervertebral foramina (Fig.

115.10B–C). Malignant tumors of nerve sheath origin are also known as malignant neurofibroma, malignant schwannoma, or neurogenic fibrosarcoma. These tumors behave aggressively, with both local invasion and distant metastasis. Half arise in patients with neurofibromatosis.[13] Treatment requires wide excision and usually adjuvant radiation.[13]

Arising from sympathetic ganglia, tumors generally affect children and display a spectrum of neoplastic behavior. Ganglioneuromas are benign and cause symptoms merely by mass effect. Ganglioneuroblastomas are malignant, have intermediate behavior, and can invade locally but are less likely to metastasize.[5] Neuroblastoma rapidly displaces and invades adjacent structures and may be widely metastatic at the time of presentation.[152,153] These tumors often elaborate endocrine peptides and catecholamines that cause diarrhea, fever, anorexia, and weight loss.[4] The propensity to produce catecholamines is used to advantage by promoting tumor uptake of the catecholamine precursor ^{123}I- or ^{131}I-meta-iodobenzylguanidine scintigraphy for purposes of diagnosis, identification of distant tumor metastases, and treatment.[154,155] Treatment of neuroblastoma involves using escalating multimodality therapy strategies based on the risk for disease progression.[156]

Arising from paraganglionic or chemoreceptor tissue, neoplasms include pheochromocytomas, which are found rarely in the mediastinum and are indistinguishable clinically and histologically from their counterparts in the abdomen, and paragangliomas (chemodectomas).

Table 115.3 Neurogenic Tumors of the Mediastinum

NEOPLASMS ARISING FROM PERIPHERAL NERVES
Neurofibroma
Schwannoma (neurilemoma)
Neurosarcoma
NEOPLASMS ARISING FROM SYMPATHETIC GANGLIA
Ganglioneuroma
Ganglioneuroblastoma
Neuroblastoma
NEOPLASMS ARISING FROM PARAGANGLIONIC TISSUE
Paraganglioma (pheochromocytoma-like)
Paraganglioma (chemodectoma)

Paragangliomas may secrete catecholamines just as do pheochromocytomas and thus may also be detected and perhaps treated with I-meta-iodobenzylguanidine.[157] They appear benign under the microscope and seldom metastasize but spread locally in an aggressive fashion and thus have high morbidity and mortality rates.[4]

MISCELLANEOUS MEDIASTINAL MASSES

Benign Lesions

Pancreatic pseudocysts may extend into the mediastinum, usually through the aortic or esophageal hiatus,[5,158,159] and have been reported in all three mediastinal compartments. Hydatid cysts also arise rarely in the mediastinum.[5] The posterior mediastinum is occasionally the site of a thoracic duct cyst.[4,59] Also, extramedullary hematopoiesis (Video 115.13 and eFigs. 115.44 and 115.45) in patients with chronic hemolytic anemia or myelofibrosis may appear as a mediastinal mass, often in a posterior location. Meningoceles, outgrowths of the spinal meninges that protrude along the course of a spinal nerve, can produce posterior mediastinal masses.

Vascular Masses and Enlargements

Although not technically masses, a variety of vascular lesions must be considered in the differential diagnosis of a mediastinal mass seen on the chest radiograph.[5,60] These include poststenotic aortic dilation, aneurysms (Video 115.14 and eFig. 115.46) or tortuosity of the aorta and great vessels, aortic coarctation, innominate vein and SVC aneurysm, persistent left vena cava, azygos (Video 115.15 and eFig. 115.48) and hemiazygos vein enlargement, anomalous pulmonary venous return, pulmonary venous varix, and varices associated with portal hypertension (eFig. 115.49).[160,161] Idiopathic dilation of the pulmonary trunk and pulmonary arterial hypertension of any cause may appear as a mediastinal mass, and traumatic aortic transection or more subtle vascular injuries may result in mediastinal hematoma.

Angiography has been the traditional means of diagnosing mediastinal masses of vascular origin, but now CT imaging with intravenous contrast provides a more convenient diagnosis.[162,163] MRI may permit definitive diagnosis without radiation or contrast exposure.

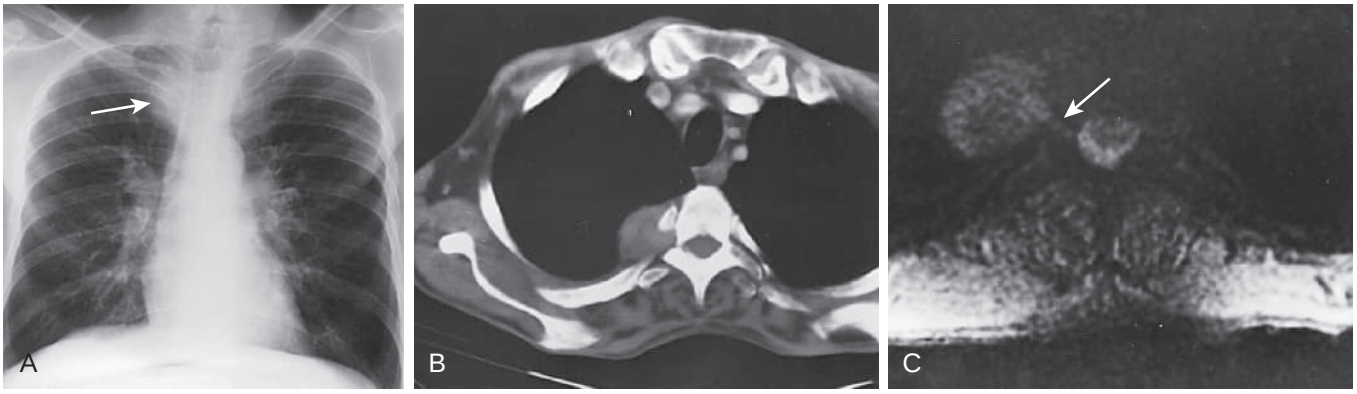

Figure 115.10 Series of imaging studies of a 64-year-old asymptomatic man with a surgically proved schwannoma (neurilemoma). (A) Frontal chest radiograph showing an incidental finding of a discrete mass behind the right clavicular head *(arrow)*. (B) Axial chest computed tomography showing homogeneous, well-circumscribed appearance and posterior location adjacent to the vertebral column. (C) Magnetic resonance image showing extension of the tumor into the intervertebral foramen *(arrow)*.

Diaphragmatic Hernia

Omental fat (Video 115.16 and eFig. 115.50; also Video 115.6 and eFig. 115.12) or other abdominal contents may protrude through the diaphragm via several potential routes, producing mediastinal mass lesions in any compartment.[15] A hernia through the foramen of Morgagni (eFig. 115.50) produces a cardiophrenic angle mass, usually on the right side in the anterior mediastinum. Bochdalek hernia (eFig. 115.51), in the posterior mediastinum, generally appears on the left side, presumably because the liver prevents herniation on the right. Herniation of fat around the esophagus is believed to precede hiatal hernia formation; either may appear as a mediastinal mass on chest radiography. Fine linear opacities are often demonstrable in diaphragmatic fat herniations on CT imaging. These are thought to represent omental vessels within the hernia, and they may help differentiate a hernia from a lipoma.[15]

GENERAL APPROACH TO A MEDIASTINAL MASS

INITIAL EVALUATION

With the advent of advanced imaging techniques such as CT, MRI, and nuclear imaging, the evaluation of a mediastinal mass is best made in a multidisciplinary setting involving the pulmonologist or internist, a radiologist, and a thoracic surgeon. The differential diagnosis of a mediastinal mass depends significantly on patient demographics, the presence of clinical symptoms, as well as the anatomic location, size, and morphology. For a mediastinal mass found incidentally, the primary concern for a clinician is to determine whether it is benign or malignant and, if benign, whether it has the potential to cause local symptoms. At a minimum, a chest CT scan with contrast should be obtained to evaluate any mediastinal mass detected by conventional radiography. This narrows the differential diagnosis and suggests further imaging or a diagnostic and/or therapeutic procedure. A stable appearance, in comparison to older films, can obviate the need for further investigation in selected patients. A few benign lesions in the mediastinum can be diagnosed with confidence based on clinical information and CT scan appearance; these include vascular lesions, extramedullary hematopoiesis, pericardial and developmental cysts, and mediastinal lipomatosis. Suspected mediastinal thyroid tissue can be confirmed by radioactive iodine scans.

SURGICAL MANAGEMENT

In most cases the optimal diagnostic and therapeutic maneuver is surgical resection of the mass.[164] The decision to perform a biopsy versus resection is thus based on the presumptive diagnosis based on the imaging characteristics. A suggested approach for evaluation is shown in Figure 115.11.

In the anterior mediastinum, well-encapsulated lesions are resected, whereas biopsy will be performed in those situations where there is a high degree of suspicion for lymphoma. Biopsy is also preferred for locally invasive or frankly unresectable anterior mediastinal lesions. Cervical mediastinoscopy is less useful for anterior mediastinal masses because the anterior mediastinal mass is not

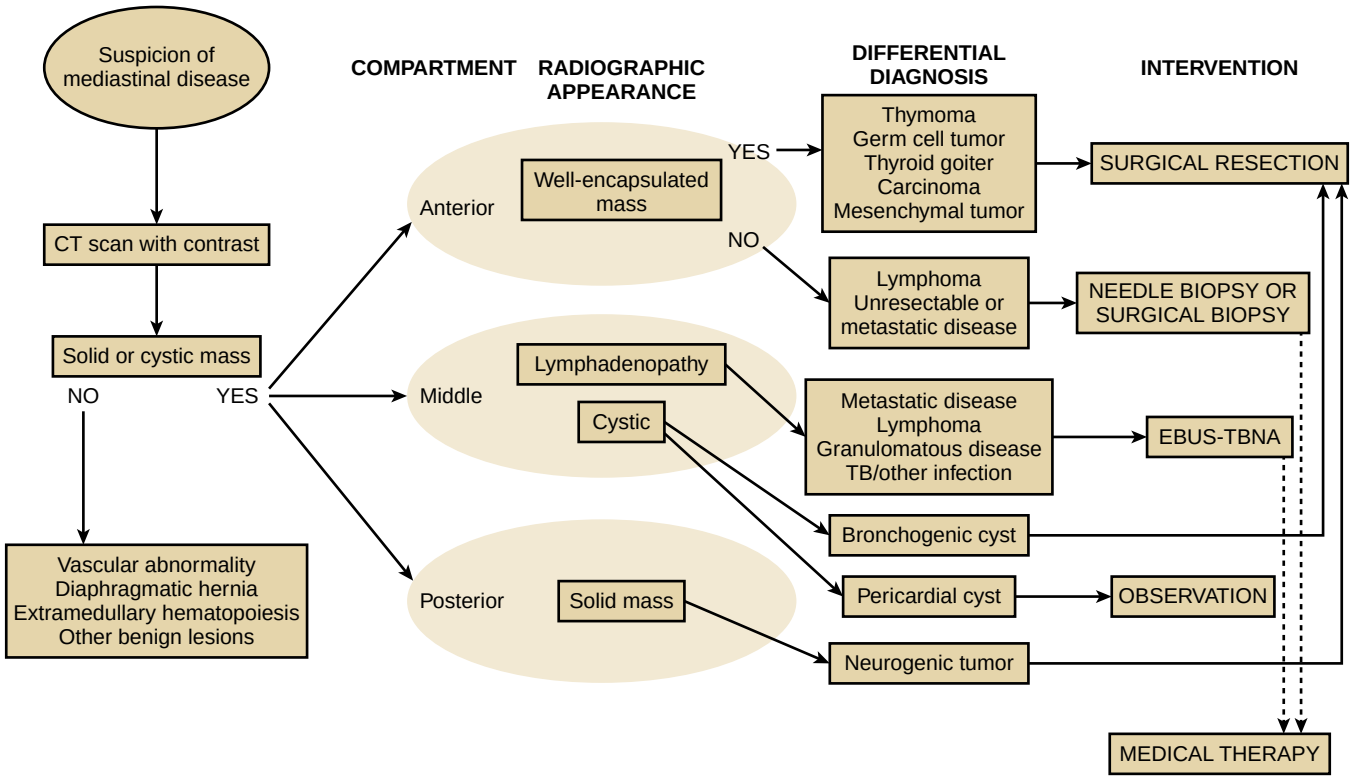

Figure 115.11 Suggested algorithm for the diagnostic approach to mediastinal masses. CT, computed tomography; EBUS-TBNA, endobronchial ultrasound-guided transbronchial needle aspiration; TB, tuberculosis.

near the pretracheal plane used by the mediastinoscope. Interventions by VATS are generally reserved for those lesions amenable to resection. Definitive resection of anterior mediastinal masses can be performed by VATS, median sternotomy, or a transcervical approach (e.g., Cooper thymectomy). A robotic VATS approach offers the advantage of increased instrument maneuverability and visualization and has gained in popularity in recent years for resection of anterior mediastinal masses.[165–167]

In the middle mediastinum, the majority of masses in adults are malignant, the most common being lymphoma or metastatic disease. Hence, for lesions in the middle mediastinum, biopsy is the typical initial approach. Biopsy can be performed by either CT-guided needle techniques, EBUS or EUS-TBNA, or by mediastinoscopy or VATS. Given the proven sensitivity and negative predictive value of EBUS–TBNA, this is the preferred sampling option. When benign-appearing cystic lesions are found by diagnostic imaging, the lesions are removed by either VATS or open thoracotomy.

In the posterior mediastinum, most lesions are resected either with a VATS or thoracotomy approach. A thoracotomy is preferred if there is any suggestion of malignancy (to ensure free resection margins), size greater than 5 cm, or presence of inflammation or infection that can obscure dissection planes. Surgical experience plays a large part in determining the technique utilized for intervention.

Key Points

- The mediastinum, which contains thoracic viscera in the center of the chest, can be divided into three main compartments based on anatomic boundaries seen on axial images of chest computed tomography.
- The majority of all mediastinal masses are benign. However, when symptomatic, a mediastinal mass is more likely to be malignant.
- The most common masses in the anterior or prevascular compartment include thymomas, thyroid tumors, germ cell tumors, and lymphoma.
- The most common masses in the middle or visceral compartment include lymphadenopathy and benign developmental cysts. Isolated mediastinal adenopathy may represent sarcoidosis, tuberculosis, lymphoma, lung cancer, inflammatory lymphadenopathy, or metastatic disease from an extrathoracic malignancy.
- The posterior or paravertebral compartment includes mainly neurogenic tumors.
- Computed tomographic imaging is typically used for initial diagnostic evaluation; however, magnetic resonance and nuclear imaging tests improve the specificity of diagnosis in certain cases.
- Most mediastinal tumors and cysts should be surgically removed due to the potential for malignancy and for local compressive and invasive effects on adjacent vital structures.

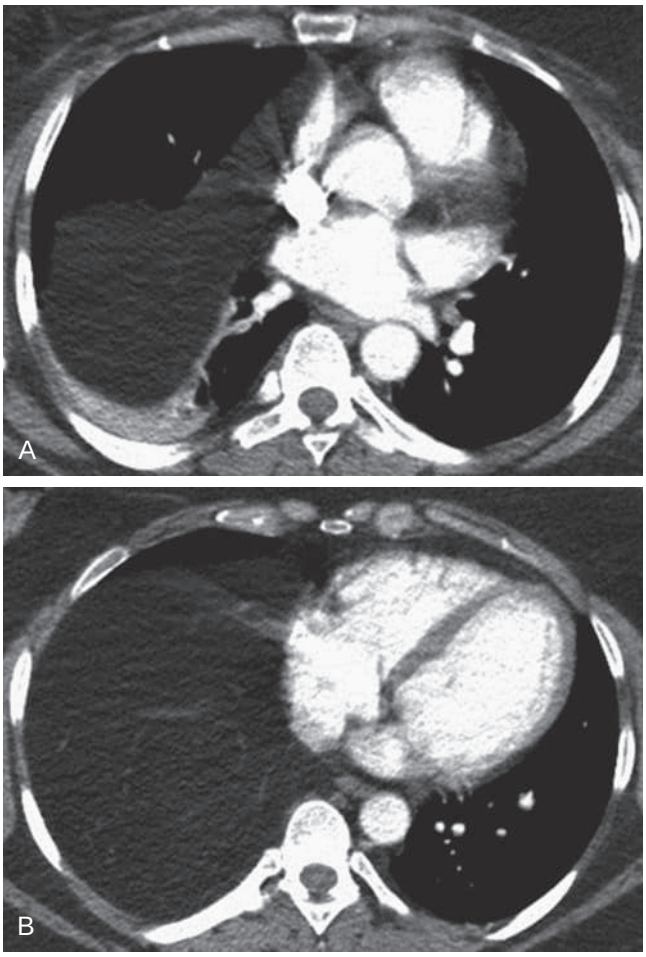
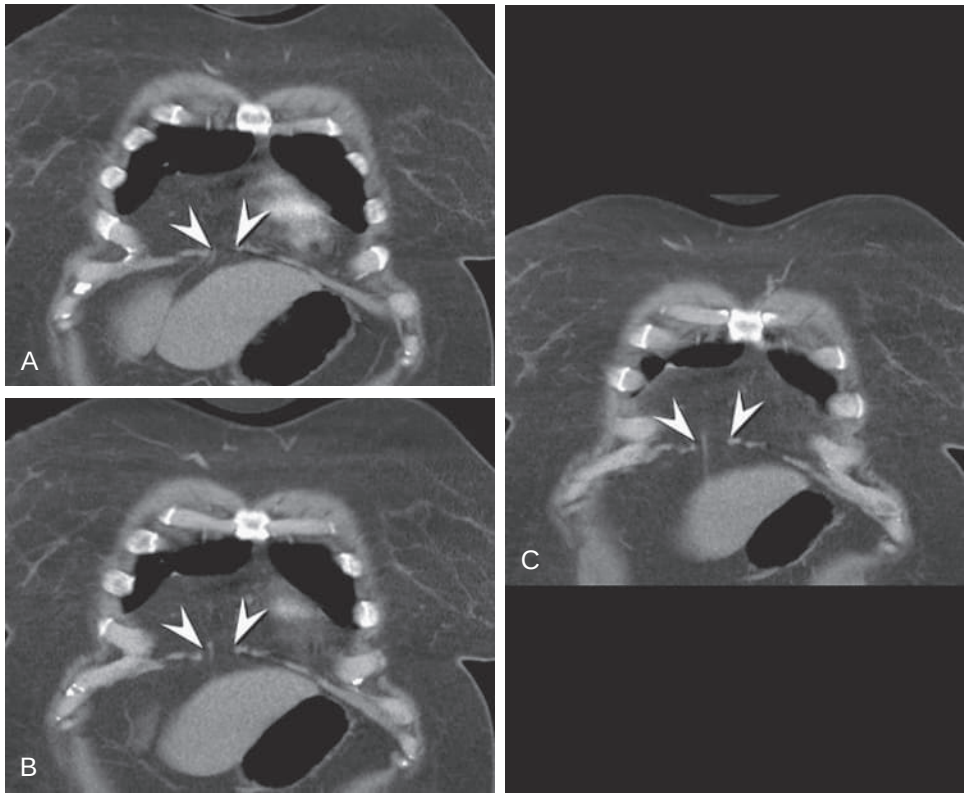
eFigure 115.10 Anterior mediastinal mass due to teratoma. Axial enhanced chest computed tomography in a patient with an anterior mediastinal teratoma shows the excellent visualization of low-attenuation fat and hyperattenuating calcium within the lesion. See Video 115.4 for the full study. (Courtesy Michael B. Gotway, MD.)

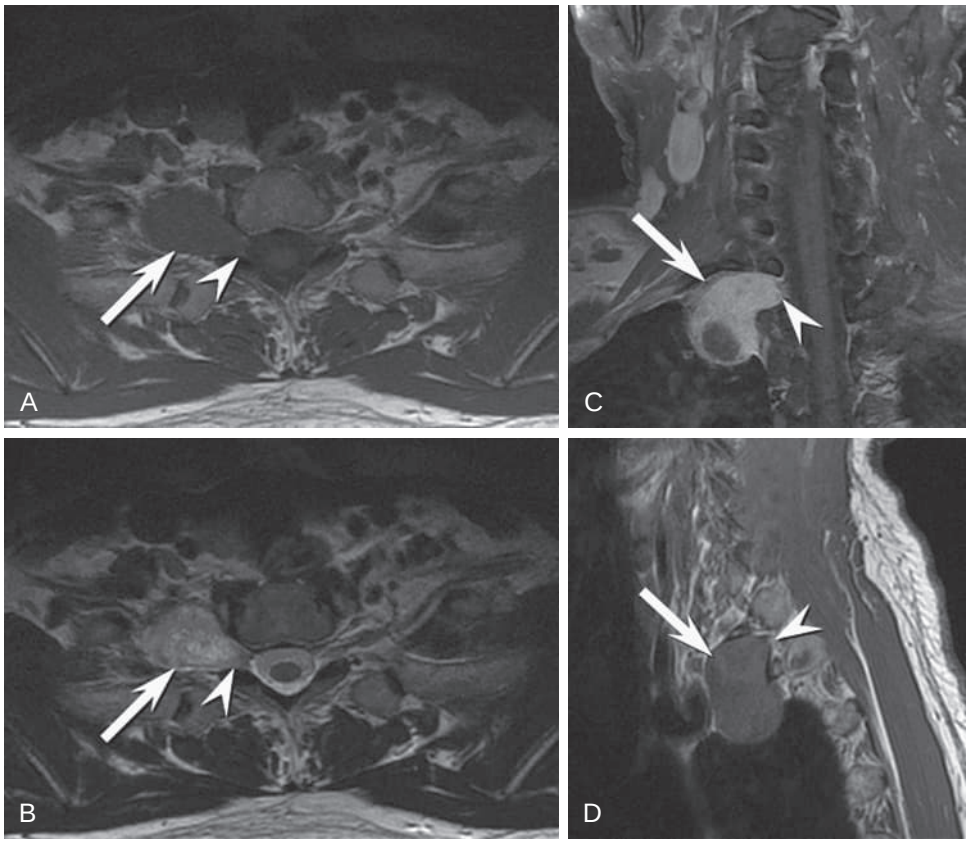


eFigure 115.11 Thymolipoma. Axial enhanced chest computed tomography through the mid (A) and lower (B) thorax shows a fatty mass occupying the right mediastinum. See Video 115.5 for the full study. (Courtesy Michael B. Gotway, MD.)

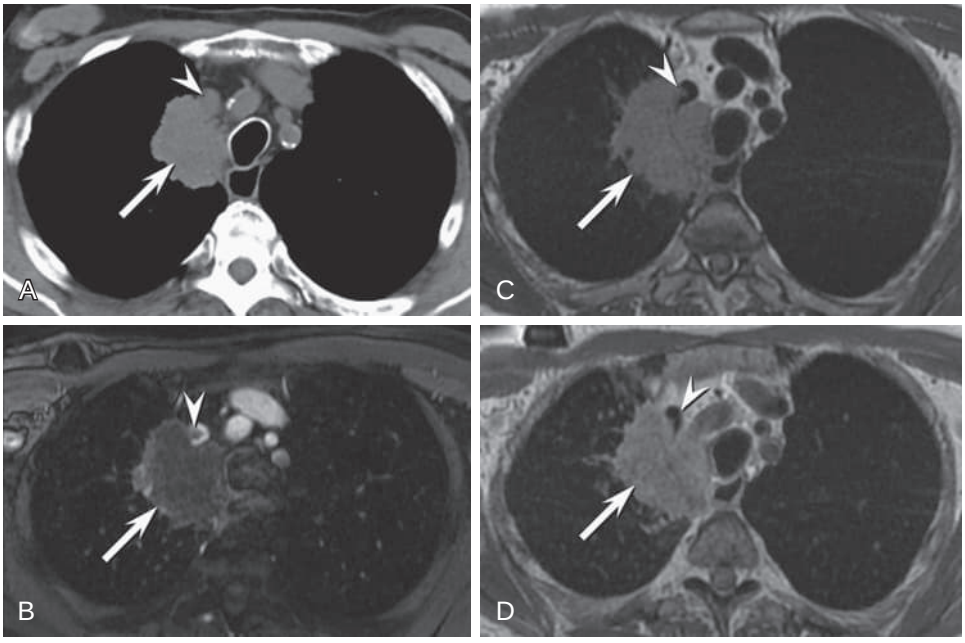


eFigure 115.12 Omental fat hernia due to foramen of Morgagni hernia. Coronal enhanced chest computed tomography through the anterior thorax shows a fatty mass occupying the right mediastinum, arising from the abdomen and extending through a diaphragmatic defect *(arrowheads)* into the thorax. A vessel accompanying the fat herniation is clearly visible in C. See Video 115.6 full the full study. (Courtesy Michael B. Gotway, MD.)

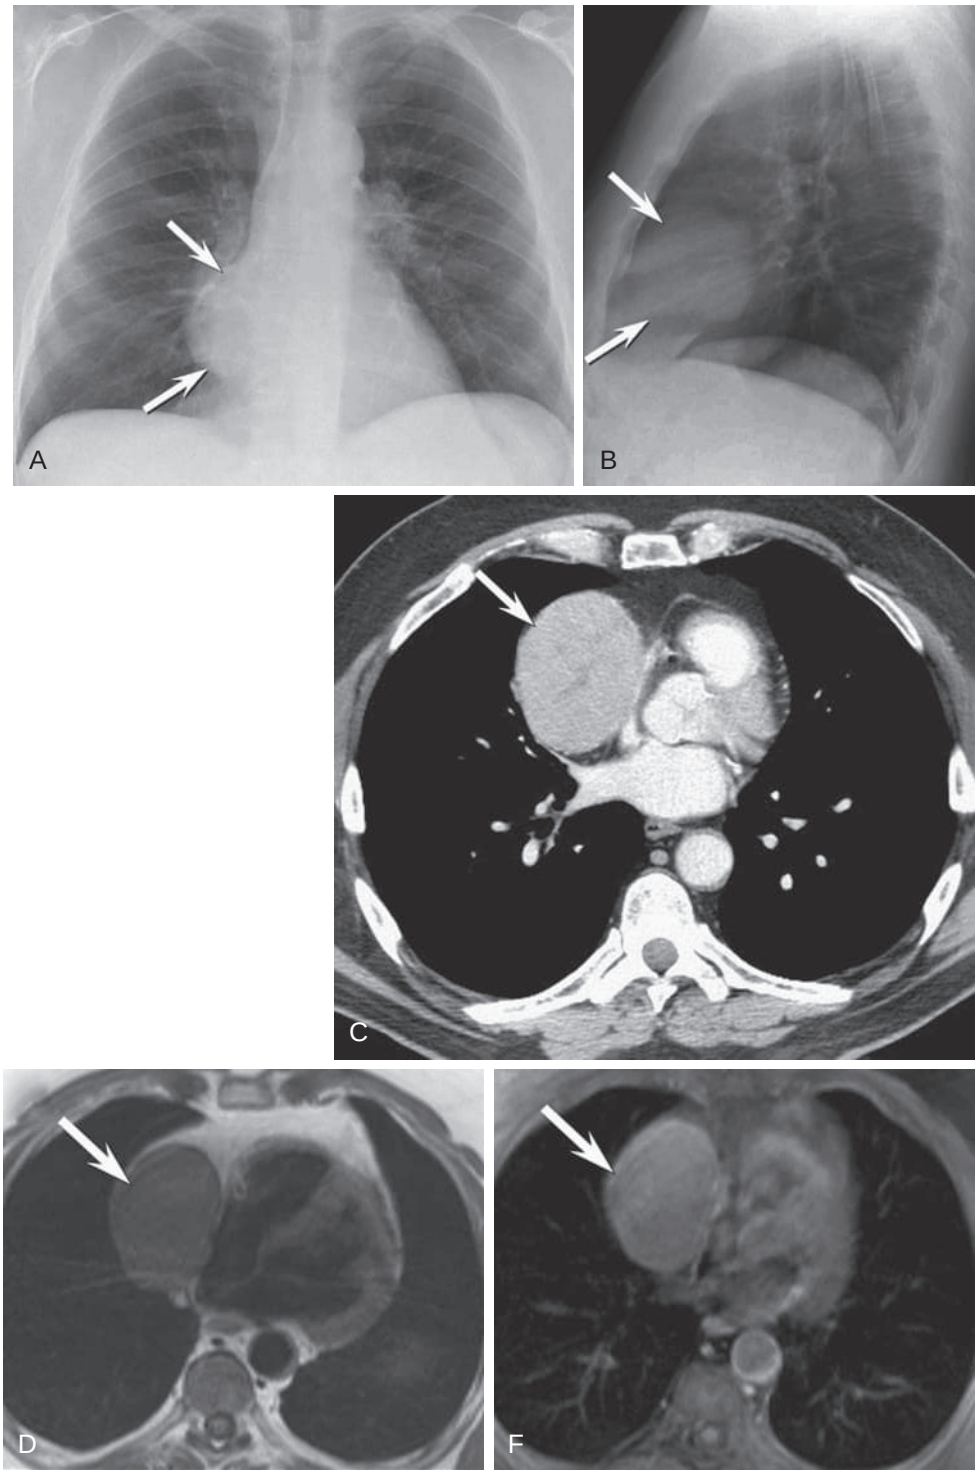
eFigure 115.13 Anterior mediastinal mass due to lymphadenopathy caused by breast cancer. Axial enhanced chest computed tomography in a patient with breast cancer shows left internal mammary lymphadenopathy. (Courtesy Michael B. Gotway, MD.)



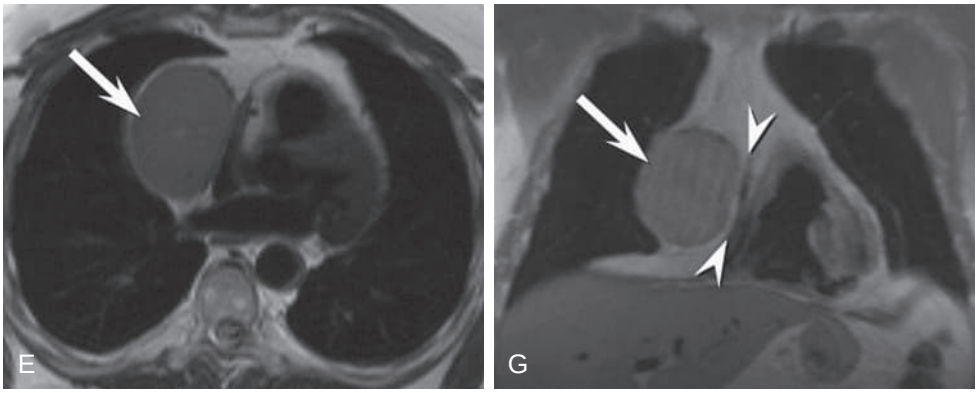
eFigure 115.14 Neurogenic tumor on magnetic resonance imaging. Axial thoracic T1-weighted (A), T2-weighted (B), coronal enhanced T1-weighted (C), and sagittal unenhanced T1-weighted (D) magnetic resonance images show a neurogenic tumor *(arrows)*. Note the tumor extension from the neural foramen *(arrowheads)*. The lesion shows increased signal on T2-weighted images (B) and intense contrast enhancement (C). (Courtesy Michael B. Gotway, MD.)



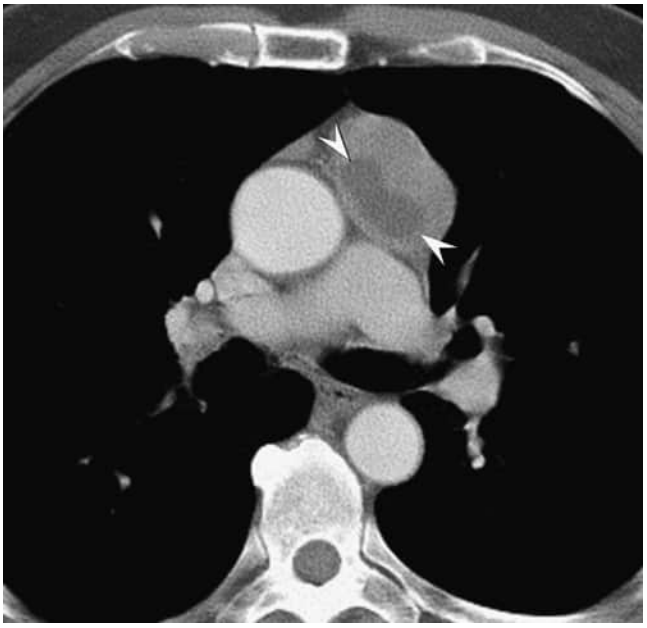
eFigure 115.15 Utility of magnetic resonance imaging for determining mediastinal involvement in bronchogenic malignancy. (A) Axial unenhanced chest computed tomography shows a medial right upper lobe bronchogenic malignancy (*arrow*) with extensive contact with the mediastinum, especially the right brachiocephalic vein (*arrowhead*). (B) Axial thoracic steady-state free precession, unenhanced (C) and enhanced (D) T1-weighted magnetic resonance imaging shows extension of the neoplasm (*arrows*, B–D) into the mediastinal fat with invasion of the right brachiocephalic vein, evidenced by the small intravascular nodule (*arrowheads*, B–D). See Video 115.8 for the full study of part B. (Courtesy Michael B. Gotway, MD.)



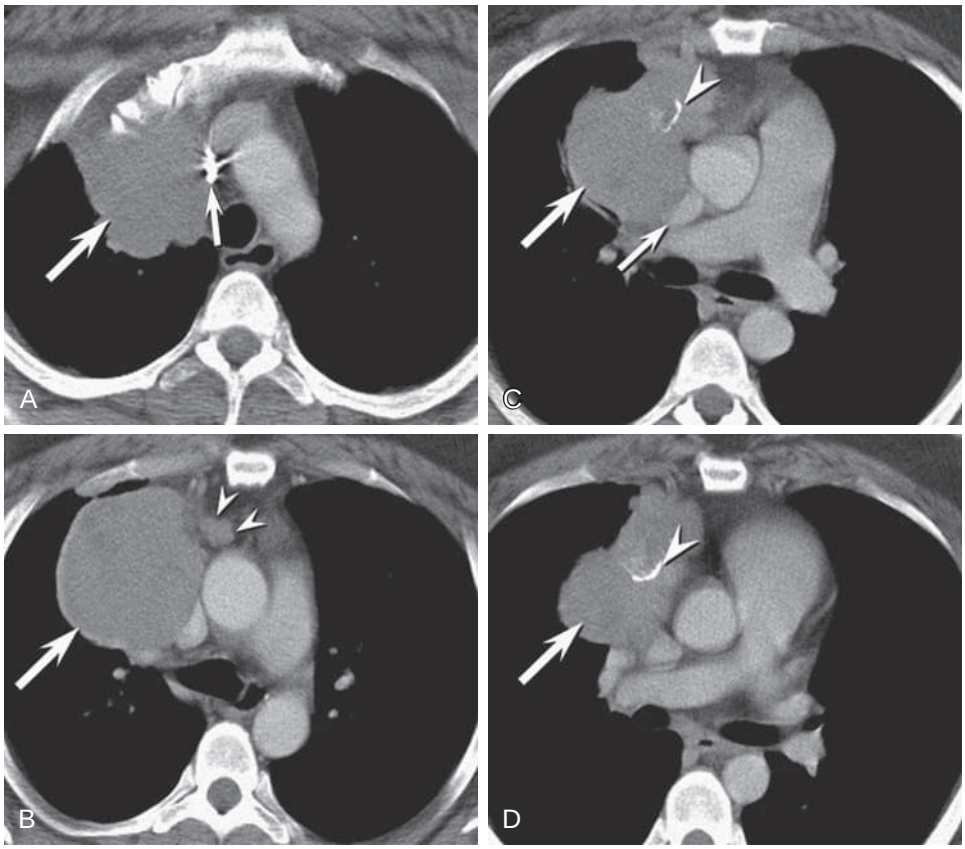
eFigure 115.16 Typical appearance of thymoma at thoracic imaging. Frontal (A) and lateral (B) chest radiographs show a smoothly circumscribed mediastinal mass (*arrows*) at the level of the junction of the heart and great vessels. The obscuration of the right heart border on the frontal projection (A) and the presence of the mass overlying the heart on the lateral projection (B) indicates that the mass is adjacent to the heart. (C) Axial enhanced chest computed tomography shows the smoothly circumscribed, enhancing mediastinal mass (*arrow*). Axial T1-weighted (D), T2-weighted (E), enhanced, fat saturation T1-weighted (F), and coronal T1-weighted (G) images show the mediastinal lesion (*arrows*) to advantage. In particular, the indolent nature of the mass, evidenced by the maintained fat plane between the mass and pericardium (*arrowheads*, G) is well shown. The lesion shows intermediate-to-slightly-decreased signal on T2-weighted imaging (E), consistent with the cellular nature of the neoplasm. (Courtesy Michael B. Gotway, MD.)



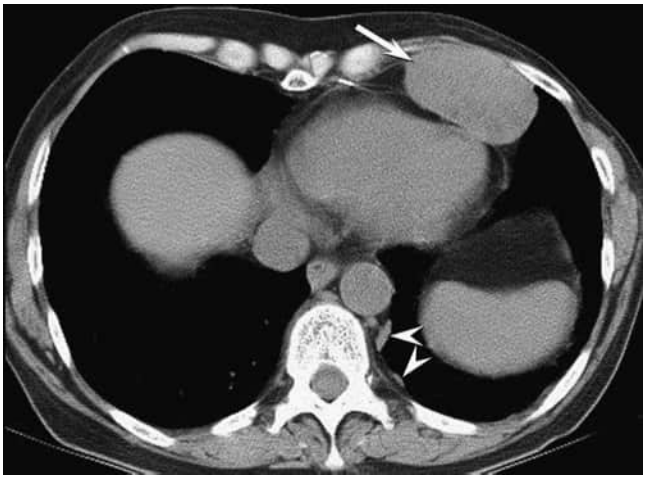
eFigure 115.16, cont'd



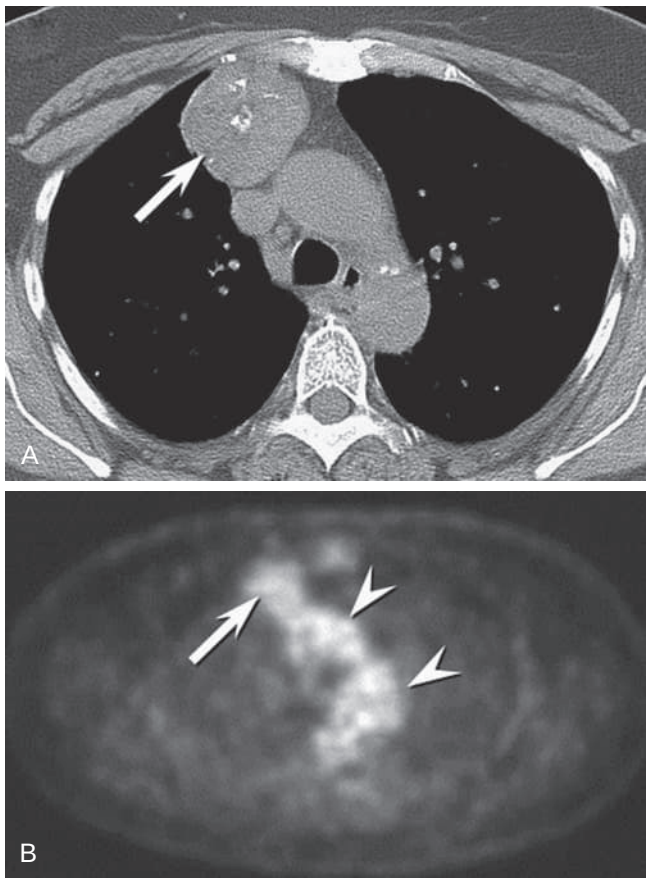
eFigure 115.17 Cystic degeneration within a thymoma. Axial enhanced chest computed tomography shows an enhancing anterior mediastinal mass containing internal low attenuation (*arrowheads*) consistent with cystic change or necrosis. (Courtesy Michael B. Gotway, MD.)



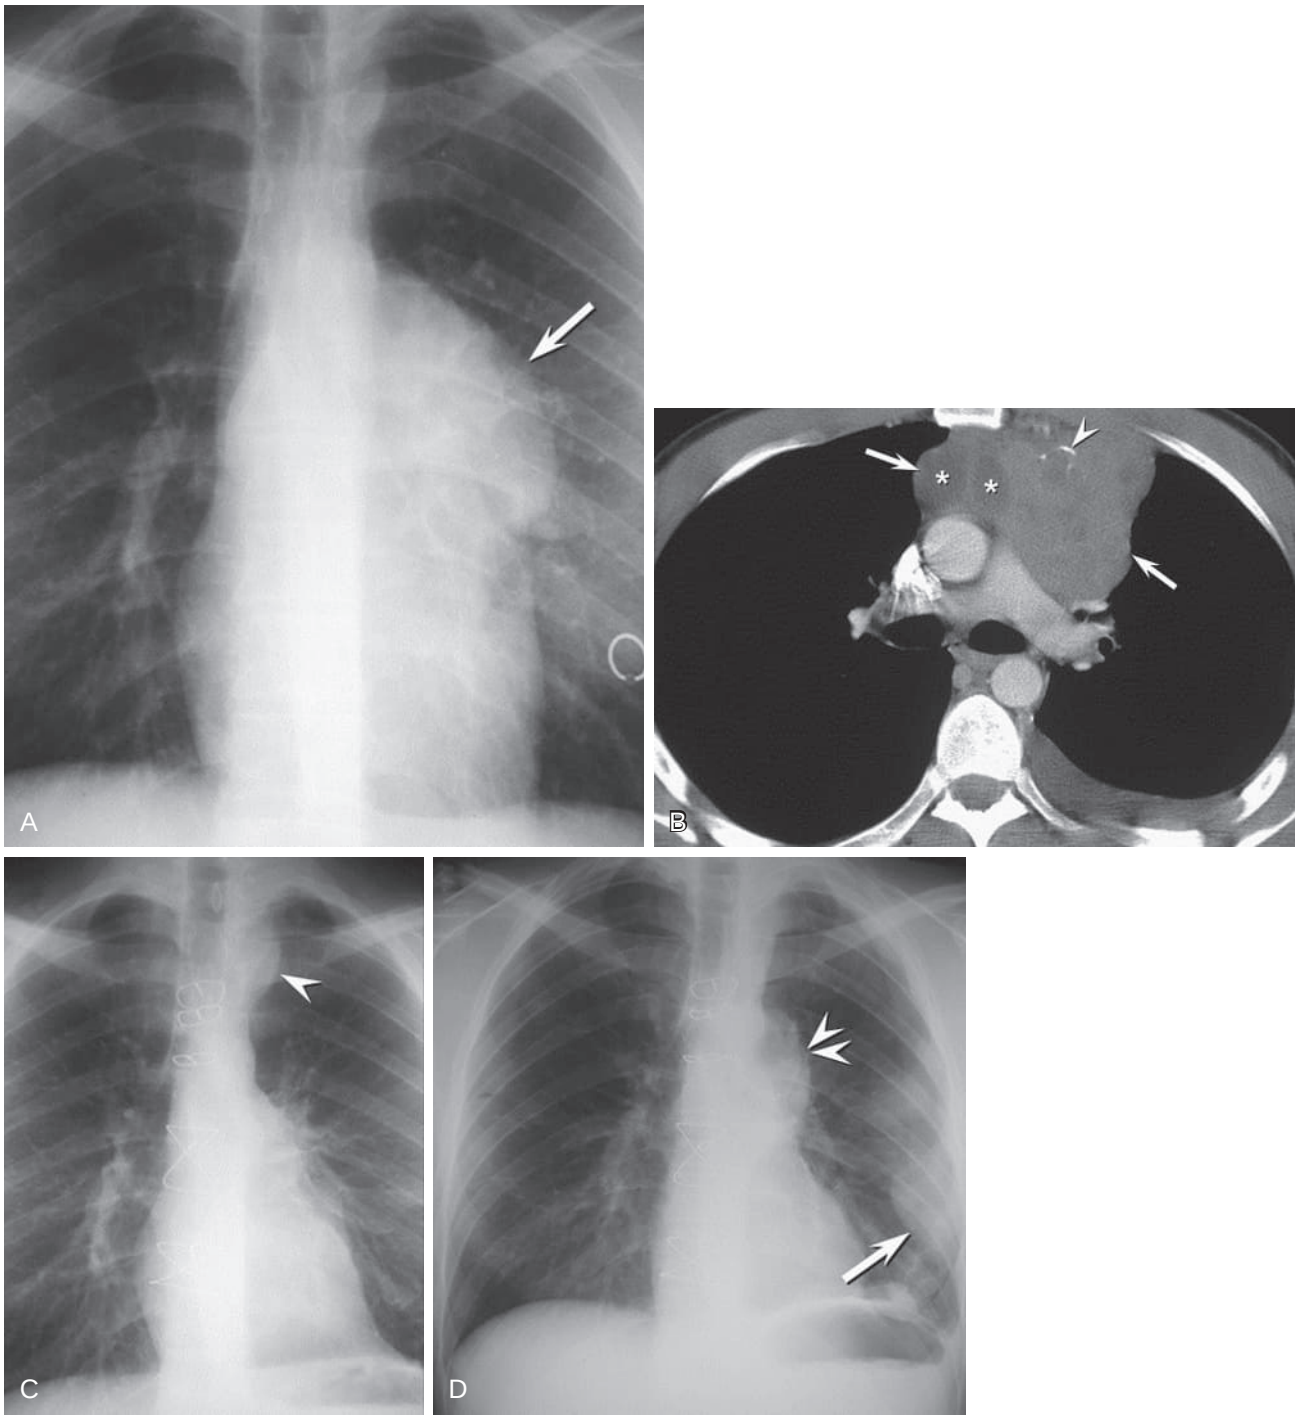
eFigure 115.18 Utility of chest computed tomography for thymic neoplasm staging. (A–D) Axial enhanced chest computed tomography shows a lobulated mass (*large arrows*, A–D) with foci of calcification (*arrowheads*, C–D). The computed tomography scan shows features consistent with an aggressive neoplasm, including lobulation, mediastinal fat infiltration, regional lymphadenopathy (*double arrowhead*, B), and marked vascular compression (*small arrows,* A and C). Compare the appearance of this aggressive neoplasm with the more indolent lesion shown in e-Fig. 115.16. (Courtesy Michael B. Gotway, MD.)



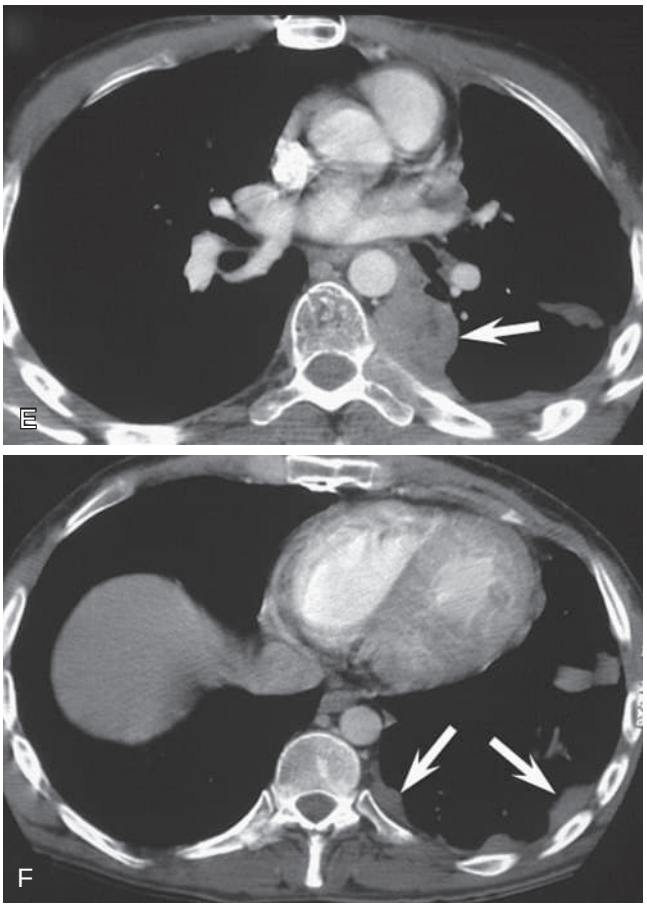
eFigure 115.19 Utility of chest computed tomography for thymic neoplasm staging. Axial chest computed tomography shows a circumscribed anterior mediastinal mass (*arrow*) in contact with the pericardium. While the circumscribed nature of the lesion initially suggests a relatively indolent neoplasm, potentially amenable to surgical resection, chest computed tomography also shows pleural nodules (*arrowheads*) in the left lower medial thorax, representing intrathoracic metastatic disease. (Courtesy Michael B. Gotway, MD.)



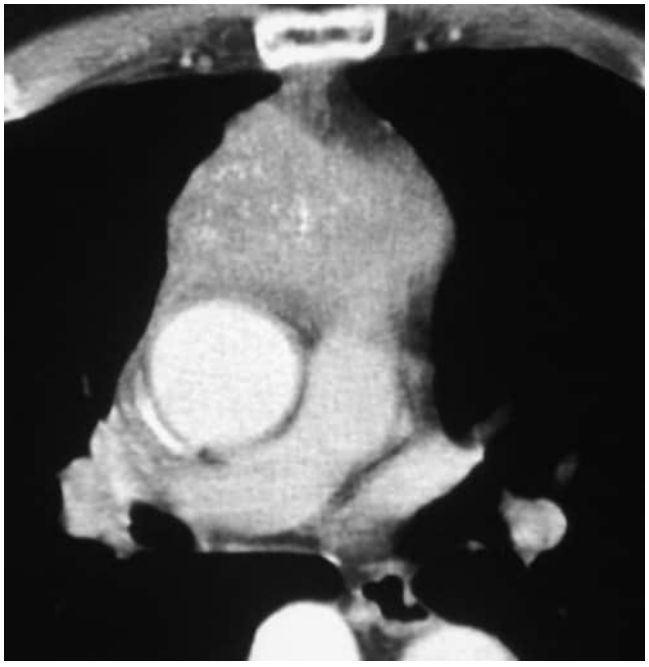
eFigure 115.20 Limited utility of ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) for thymic neoplasm evaluation. (A) Axial unenhanced chest computed tomography shows an anterior mediastinal mass (*arrow*) consistent with a thymic neoplasm; note calcification within the lesion. (B) ^{18}FDG-PET image shows modest glucose utilization within the tumor (*arrow*), but the degree of tracer uptake does not exceed that of mediastinal blood pool (*arrowheads*). In general, tracer activity must exceed that seen within mediastinal blood pool to indicate a malignant process. (Courtesy Michael B. Gotway, MD.)



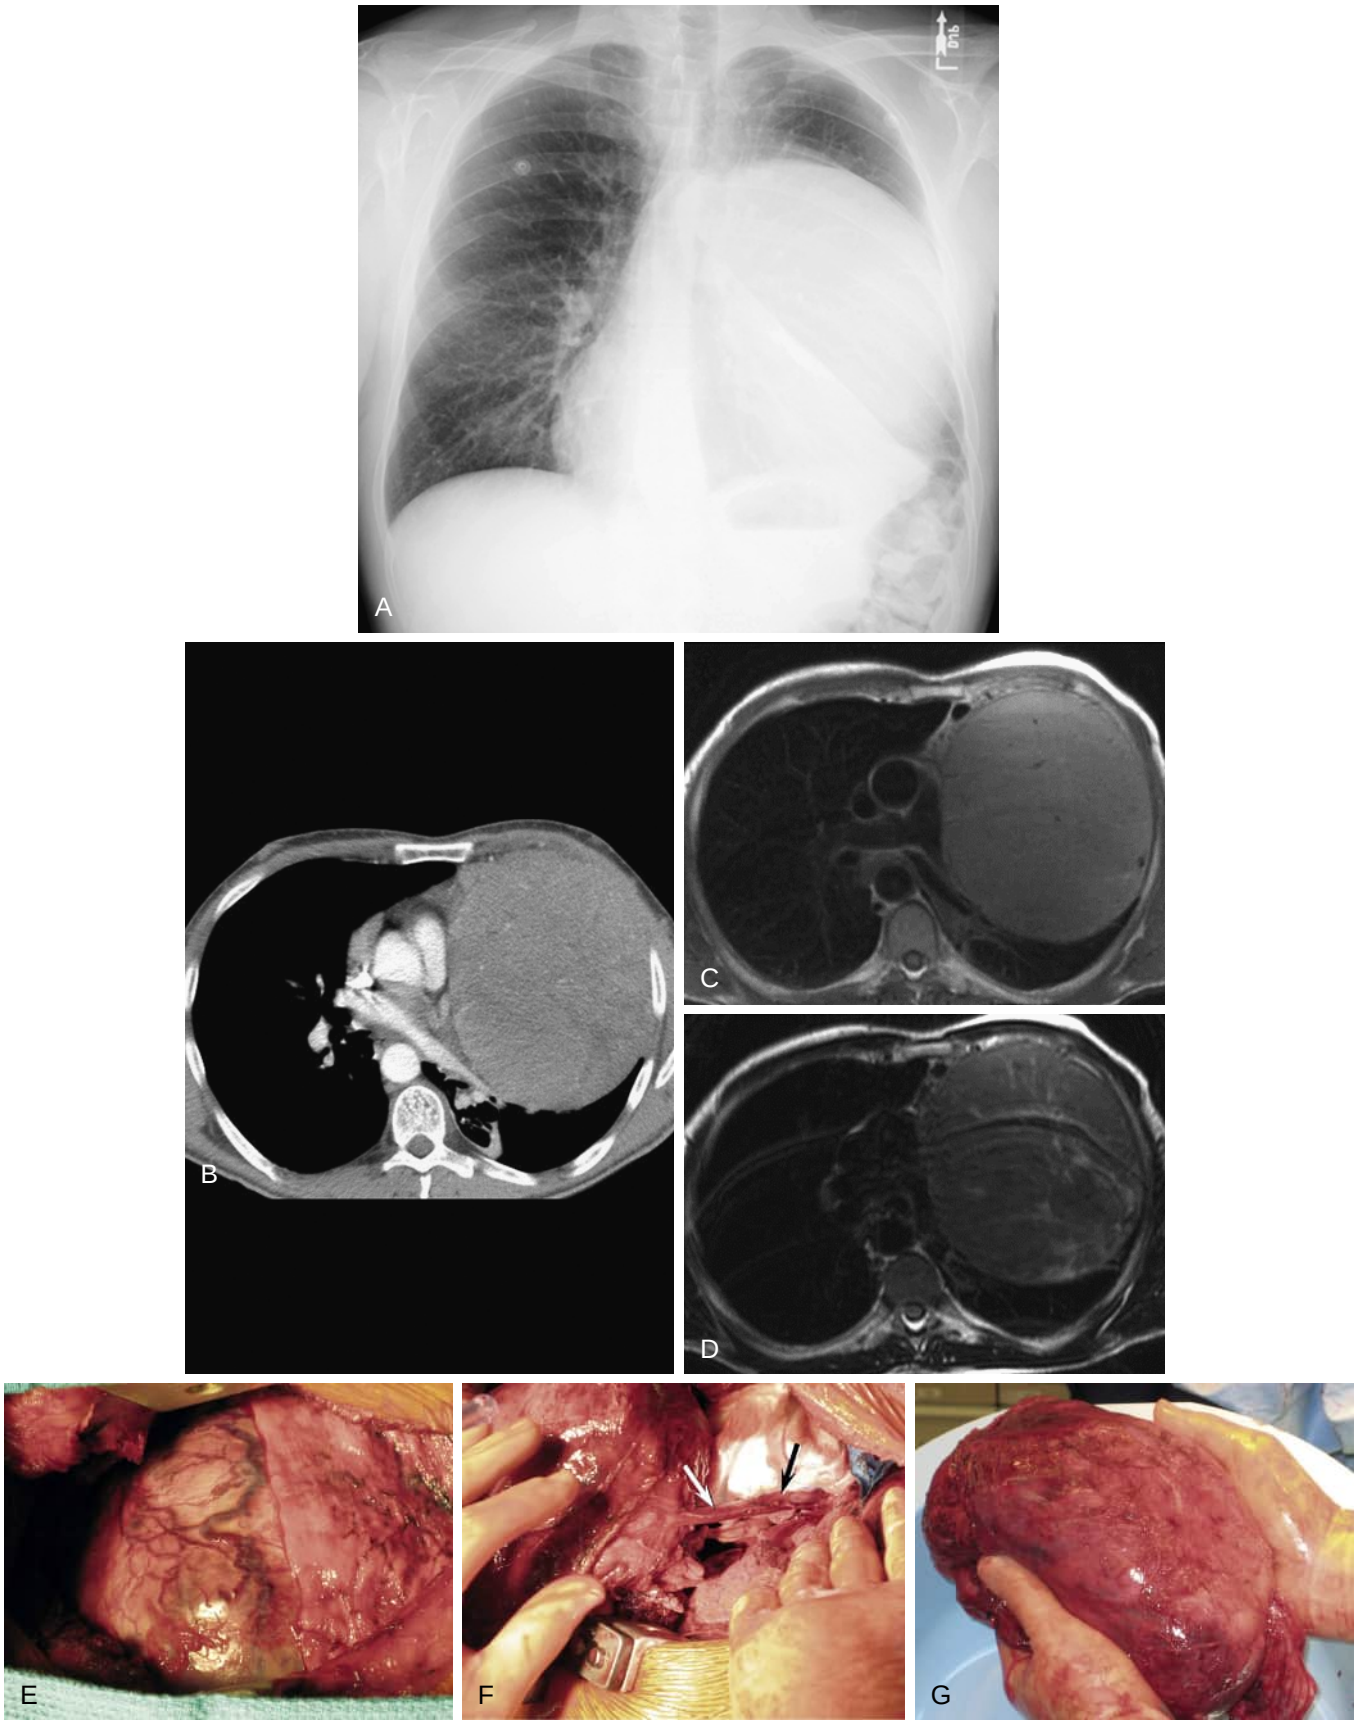
eFigure 115.21 Thymic neoplasm recurrence. Frontal chest radiograph (A) and enhanced chest computed tomography (B) at presentation show a left-sided mediastinal mass (*arrows*) subsequently shown to represent thymic neoplasia; note the lobulation, cystic change (*asterisks*), vascular compression and displacement, and calcification (*arrowhead*) on computed tomography scan (B), all suggestive of an aggressive neoplasm. (C) Frontal chest radiograph performed months following resection of the thymic neoplasm shows a new lesion abutting the posterior mediastinal surface of the left superior thorax (C, *arrowhead*), consistent with tumor recurrence. (D) Frontal chest radiograph several months following C shows an enlarging mediastinal mass (*double arrowheads*) and enlarging pleural metastatic deposits (*arrow*, D). (E and F) Enhanced chest computed tomography confirms pleural metastatic disease (*arrows*). (Courtesy Michael B. Gotway, MD.)



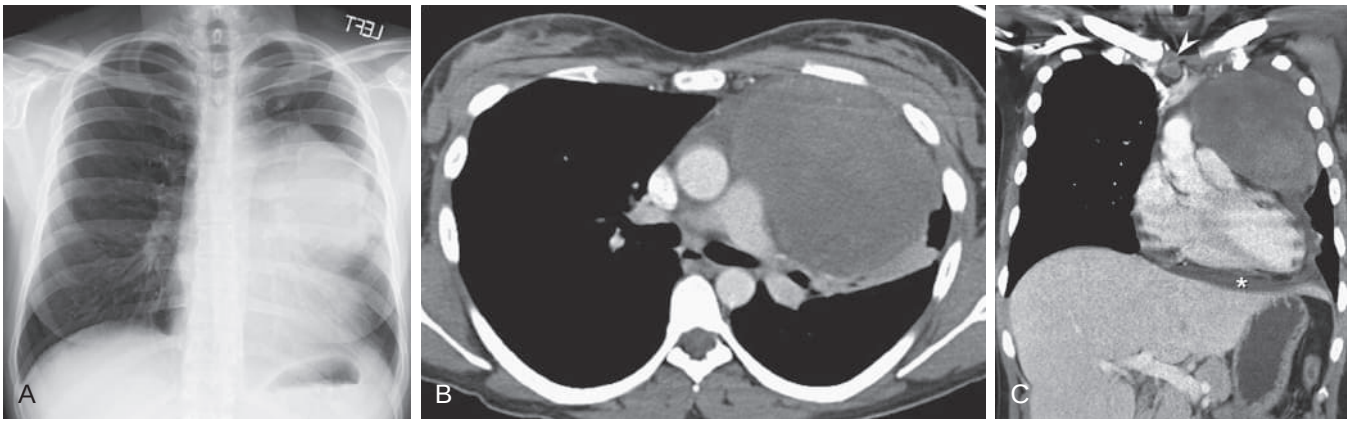
eFigure 115.21, cont'd



eFigure 115.22 Chest computed tomography scan of thymic carcinoma. Focused axial enhanced chest computed tomography shows a lobulated anterior mediastinal mass with foci of stippled calcification and extensive contact between the mass and vessels, in particular with obliteration of the fat plane between the mass and main pulmonary artery. (Courtesy Michael B. Gotway, MD.)

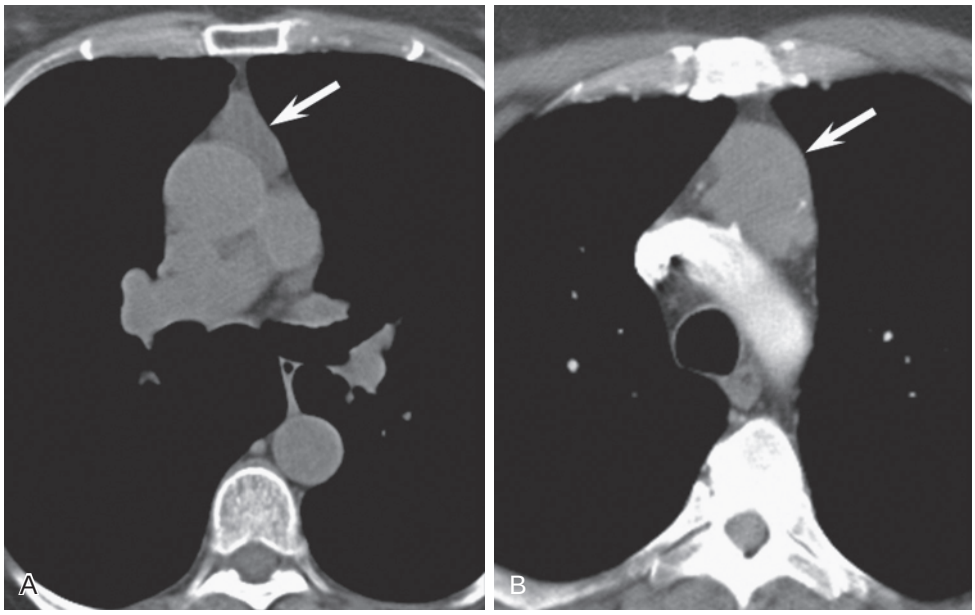


eFigure 115.23 Neuroendocrine thymic malignancy ("thymic carcinoid tumor"). (A) Frontal chest radiograph shows a smoothly circumscribed left-sided anterior mediastinal mass. (B) Axial enhanced chest computed tomography scan shows a solid, homogeneously enhancing left-sided anterior mediastinal mass with contralateral mediastinal shift, but no other overtly aggressive features. Axial double inversion recovery T1-weighted (C) and T2-weighted (D) magnetic resonance images also show the lesion and its mass effect, but no locally invasive behavior. The T2-weighted (D) image shows intermediate signal within the lesion, indicative of a relatively cellular neoplasm. The small black dot anterior and medial to the mass represents a flow void within an enlarged mediastinal vein. (E–F) Intraoperative view of the lesion during resection shows the large vein on the surface of the neoplasm; this vascular pedicle (*arrows*, F) was identified at surgery and ligated. (G) Photograph of the resected specimen. (A–D, Courtesy Michael B. Gotway, MD; E–G, Courtesy Andrew H. Goldstein, MD.)

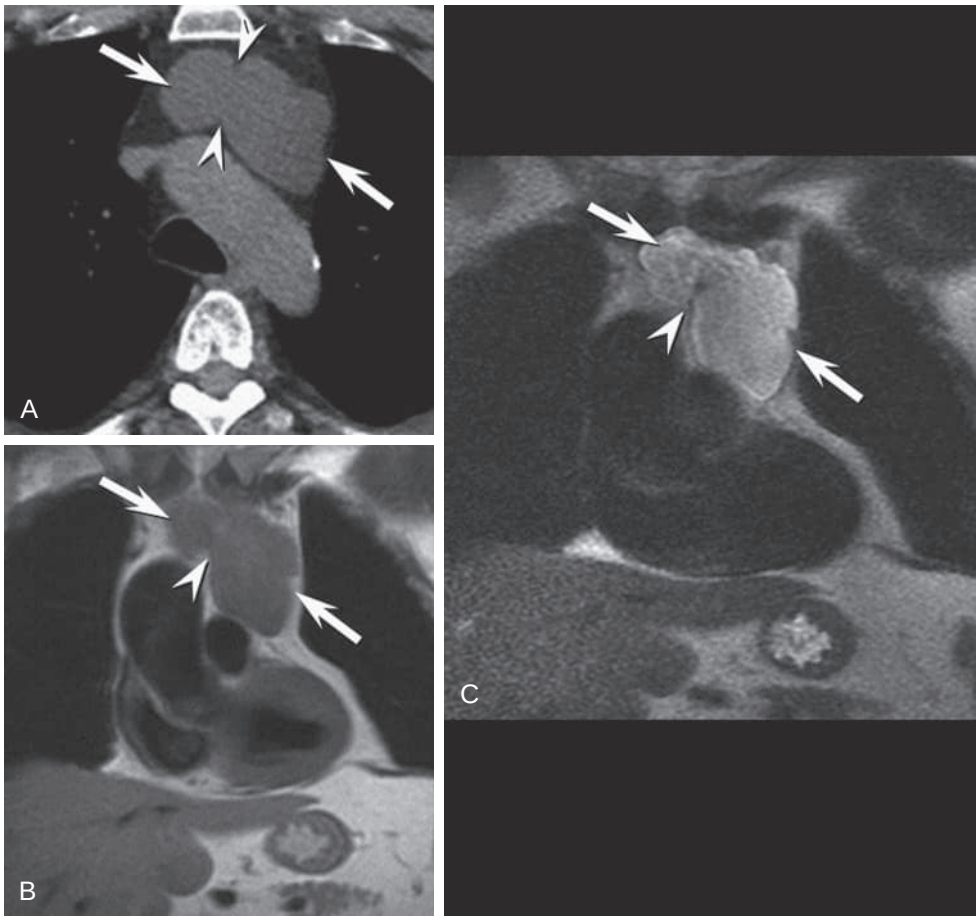


eFigure 115.24 Hodgkin lymphoma involving the thymus. (A) Frontal chest radiograph shows a large left-sided anterior mediastinal mass. Axial (B) and coronal enhanced (C) chest computed tomography scans show a minimally lobulated slightly inhomogeneous left-sided anterior mediastinal mass. The appearance is similar to thymic neoplasia. The pericardial effusion (*asterisk*) and regional necrotic lymph node enlargement (*arrowhead*) are indicative of an aggressive process. (Courtesy Michael B. Gotway, MD.)

eFigure 115.25 Thymic "rebound" hyperplasia. (A) Enhanced chest computed tomography in a young patient with breast malignancy at time of diagnosis shows minimal soft tissue mixed with fat (*arrows*), consistent with normal residual thymus. (B) Axial unenhanced chest computed tomography shows marked increase in the soft tissue within the anterior mediastinum (*arrows*) several months following chemotherapy, consistent with "thymic rebound." The appearance can be difficult to distinguish from neoplasia. (C) Enhanced chest CT 1 year after B shows return to a more normal appearance of the thymus (*arrows*). (Courtesy Michael B. Gotway, MD.)

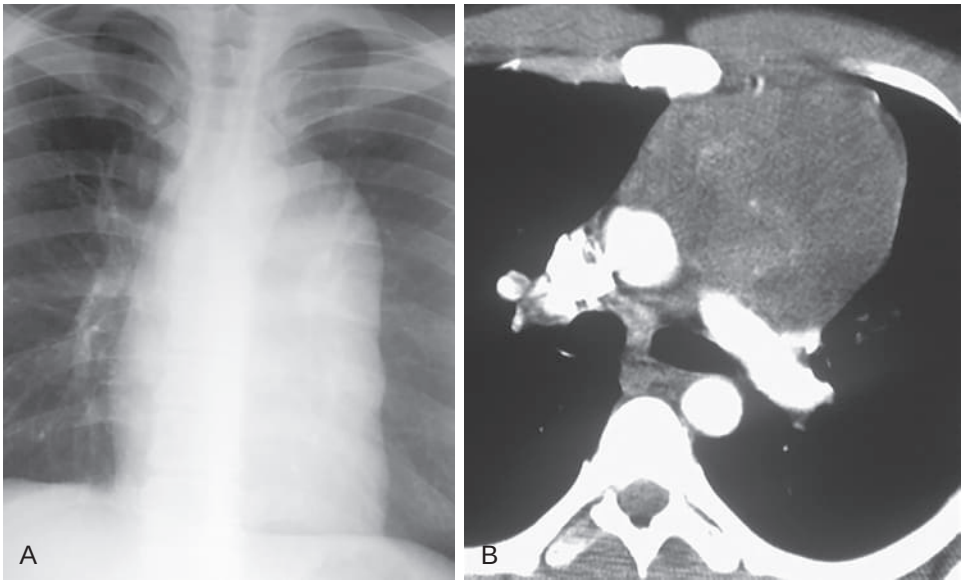


eFigure 115.26 Thymic hyperplasia versus thymoma. (A) Unenhanced chest computed tomography in a patient with thymic hyperplasia shows a homogeneous low attenuation, smoothly circumscribed anterior mediastinal lesion (*arrow*) consistent with thymic hyperplasia; note the morphology of this lesion still resembles normal thymus. This appearance contrasts with (B), the lobulated, irregular appearance of thymoma (*arrow*). (Courtesy Michael B. Gotway, MD.)

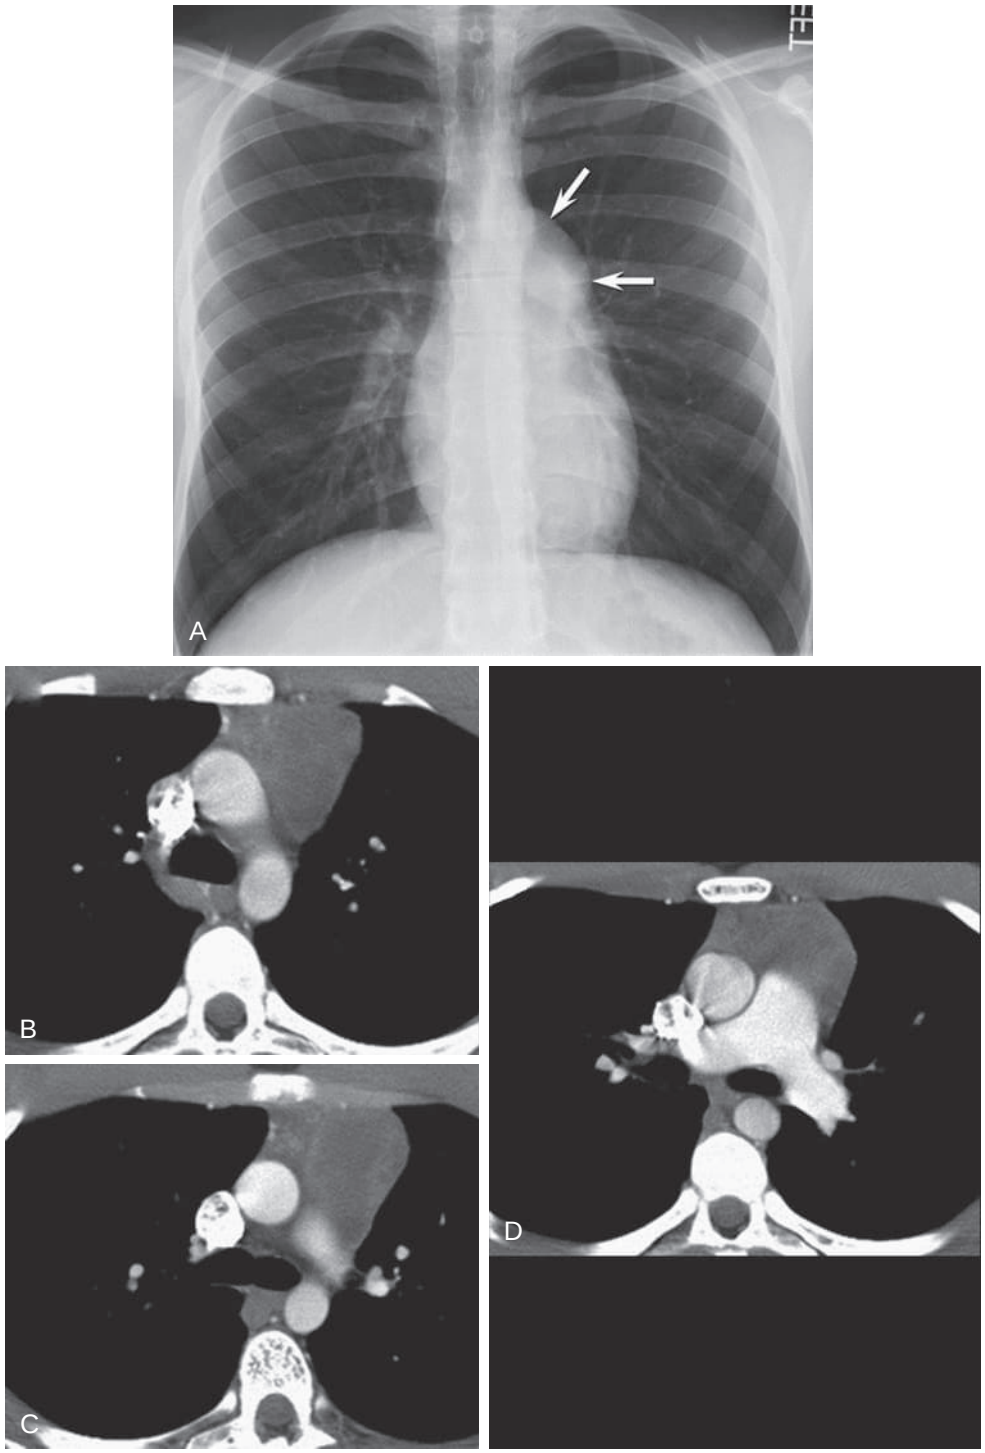


eFigure 115.27 Thymic cyst. (A) Axial unenhanced chest computed tomography shows a homogeneously (water density) low-attenuation anterior mediastinal lesion (*arrows*). Note the cleft in the lesion (*arrowheads*); this morphology is reminiscent of the normal bilobed thymus. Coronal double inversion recovery unenhanced T1-weighted (B) and fast spin-echo T2-weighted magnetic resonance (C) images show low and high signal, respectively, within the lesion (*arrows*), consistent with fluid. This lesion has remained stable for a number of years. Both images show the cleft within the lesion (*arrowheads*). (Courtesy Michael B. Gotway, MD.)

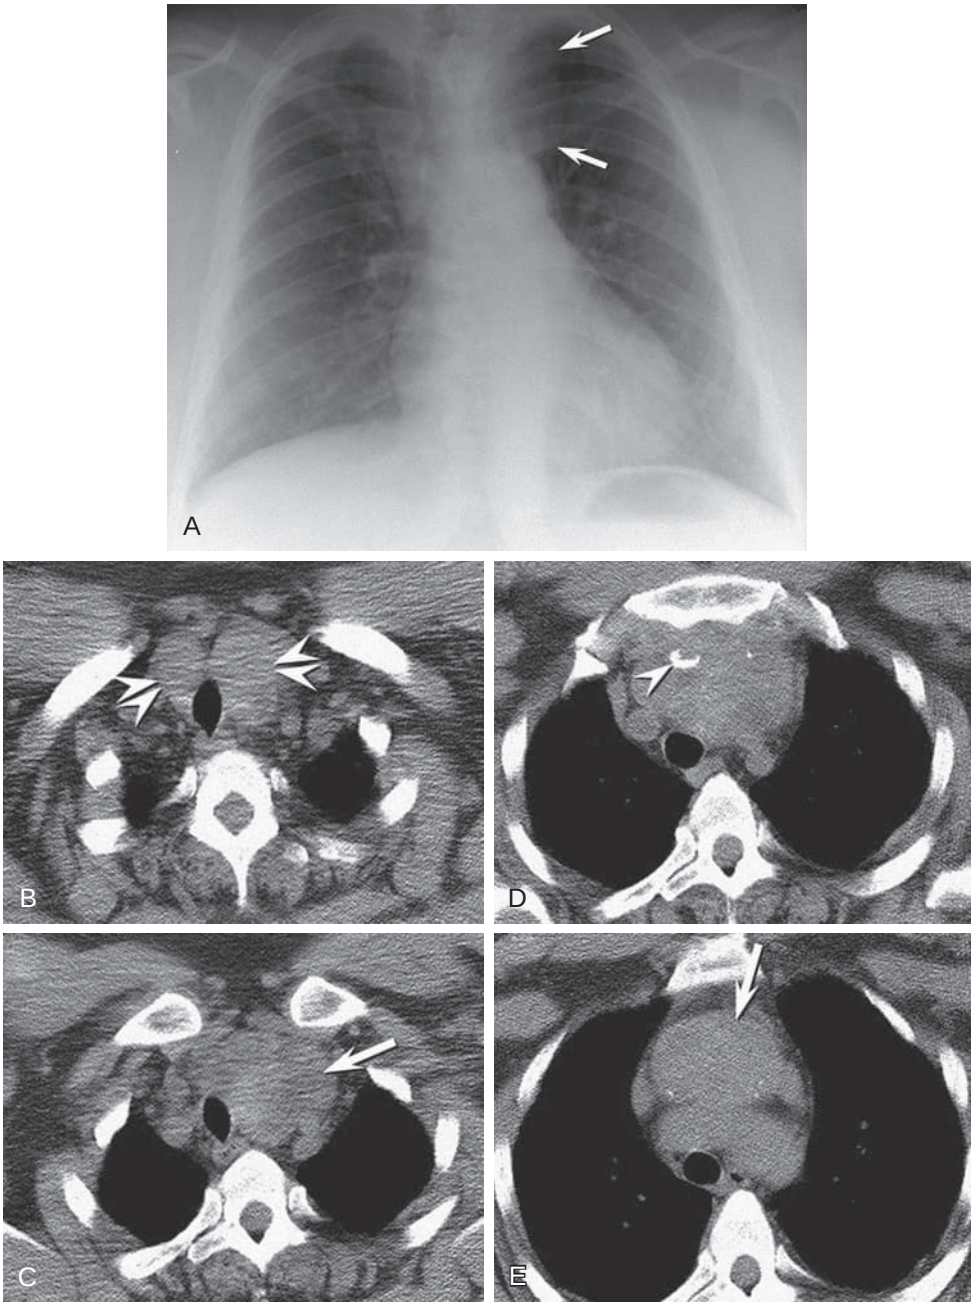
eFigure 115.28 Teratoma. Frontal chest radiograph shows a large right-sided mediastinal mass, representing teratoma. (Courtesy Michael B. Gotway, MD.)



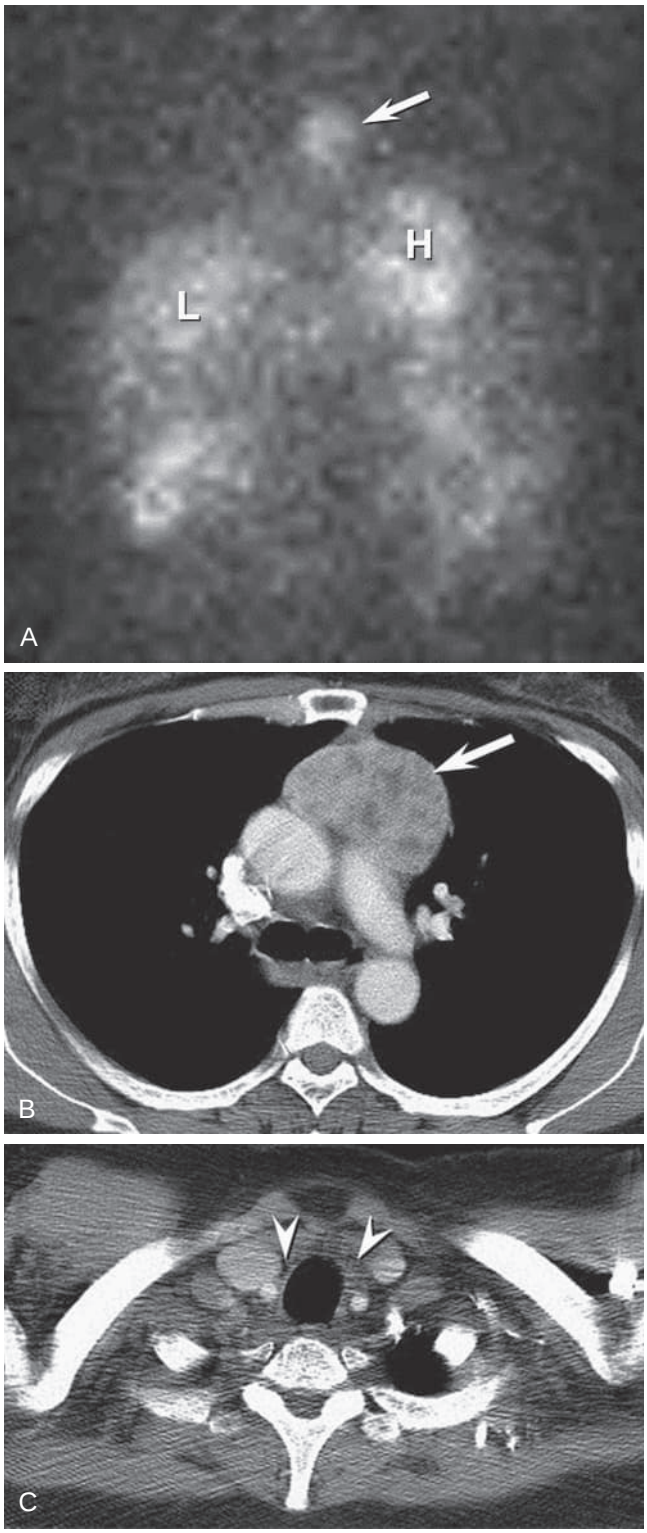
eFigure 115.29 Seminoma. (A) Frontal chest radiograph shows a large left-sided mediastinal mass obscuring the left cardiac border. (B) Axial enhanced chest computed tomography shows a mildly inhomogeneous mass obliterating the fat plane with the ascending aorta and let pulmonary artery. (Courtesy Michael B. Gotway, MD.)



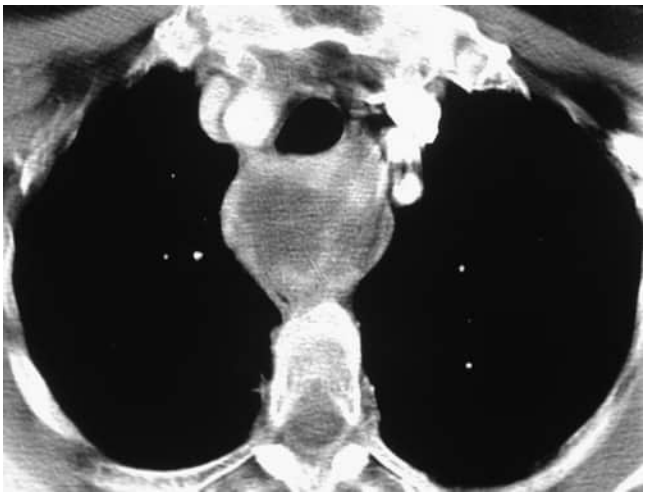
eFigure 115.30 Embryonal cell carcinoma. (A) Frontal chest radiograph shows a circumscribed left-sided anterior mediastinal mass (*arrows*). (B–D) Axial enhanced chest computed tomography shows a heterogeneous anterior mediastinal mass that obliterates fat planes with the adjacent vessels. Internal low attenuation within the tumor, as seen in the example, is more commonly encountered as nonseminomatous mediastinal germ cell neoplasms than seminomas. See Video 115.11 for the full study. (Courtesy Michael B. Gotway, MD.)



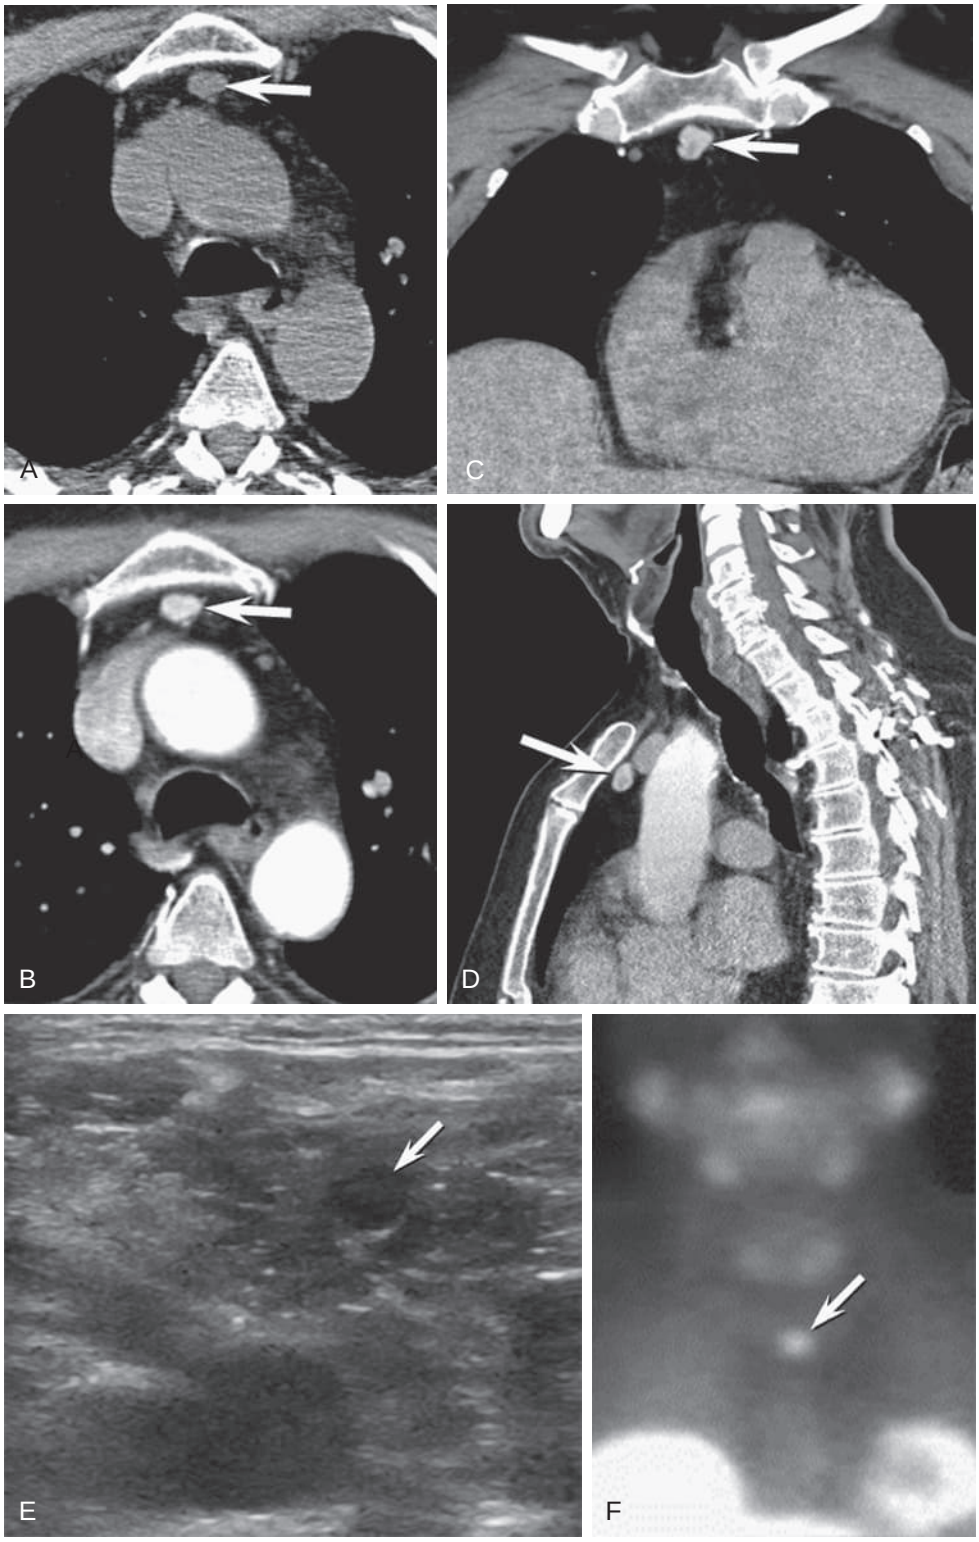
eFigure 115.31 Anterior mediastinal extension of a thyroid goiter. (A) Frontal chest radiograph shows widening of the superior mediastinum with rightward shift of the trachea resulting from a mediastinal mass (*arrows*). The superior mediastinal widening extends into the base of the neck. (B–E) Axial unenhanced chest computed tomography shows enlargement of the cervical thyroid gland (*double arrowheads,* B). The anterior superior mediastinal mass (*arrows*, C and E) extends from the base of the neck, originating from, and in contact with, the cervical thyroid gland. The mass contains calcification (*single arrowhead,* D), a common finding in thyroid goiters. Continuity of a mediastinal lesion with the cervical thyroid gland is key for confidently establishing a mediastinal mass as thyroidal in origin. (Courtesy Michael B. Gotway, MD.)



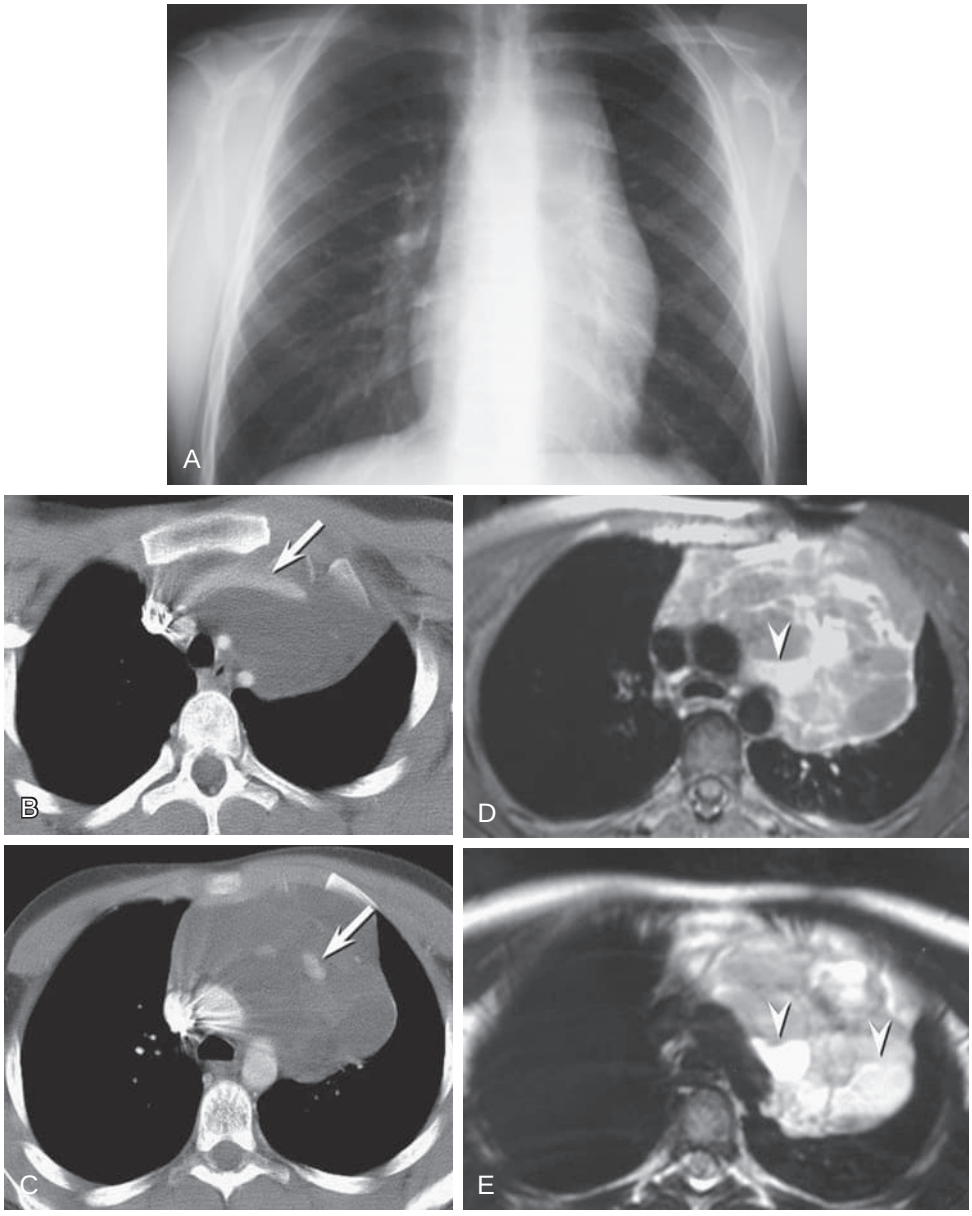
eFigure 115.32 Ectopic mediastinal thyroid tissue. (A) Planar frontal 99m-technetium sestamibi scintigraphy shows faint tracer uptake within the mediastinum (*arrow*), separate from the heart (H) and liver (L). Axial enhanced chest computed tomography shows a heterogeneously enhancing anterior mediastinal mass (*arrow*). (C) Axial computed tomography image through the cervicothoracic junction shows absence of a normal thyroid gland (*arrowheads*, C). (Courtesy Michael B. Gotway, MD.)



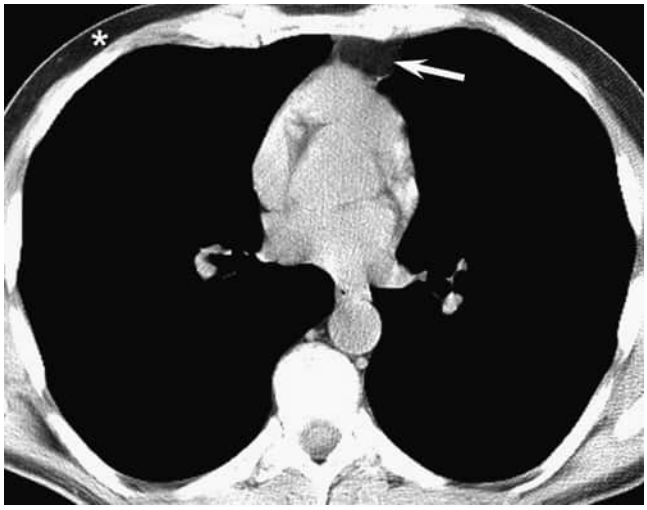
eFigure 115.33 Middle mediastinal extension of a thyroid goiter. Axial enhanced chest computed tomography shows a peripherally hyperenhancing mass with central necrosis posterior to the trachea. This lesion was in contact with thyroid tissue at the base of the neck, establishing it as mediastinal goiter extension. (Courtesy Michael B. Gotway, MD.)



eFigure 115.34 Ectopic anterior mediastinal parathyroid adenoma. Axial unenhanced (A) and axial (B), coronal (C), and sagittal (D) enhanced chest computed tomography shows an intensely enhancing lesion (*arrow*) in the anterior mediastinum. (E) Transverse sonography performed at the level of the suprasternal notch shows a hypoechoic nodule (*arrow*) corresponding to the computed tomography abnormality. (F) Planar frontal 99m-technetium sestamibi scintigraphy shows avid tracer accumulation within the anterior mediastinal lesion (*arrow*), confirming ectopic parathyroid adenoma. (Courtesy Michael B. Gotway, MD.)



eFigure 115.35 Mediastinal lymphangioma. Frontal chest radiograph in a 13-year-old boy shows a circumscribed left mediastinal mass without mediastinal shift. (B and C) Axial enhanced chest computed tomography shows an anterior and superior low-attenuation mediastinal lesion surrounding, but not compressing, the left brachiocephalic vein (*arrows*); this behavior indicates that the lesion is relatively "soft." Axial fat saturation T1-weighted (D) and T2-weighted (E) magnetic resonance images show a mass with heterogeneous signal intensity containing multiple fluid-fluid levels (*arrowheads*). The dependent signal within the areas of fluid-fluid level formation is bright on both T1- and T2-weighted images, consistent with blood. (Courtesy Michael B. Gotway, MD.)



eFigure 115.36 Anterior mediastinal lipoma. Axial enhanced chest computed tomography shows an encapsulated fat-containing lesion (*arrow*) consistent with a small lipoma. (Courtesy Michael B. Gotway, MD.)
