
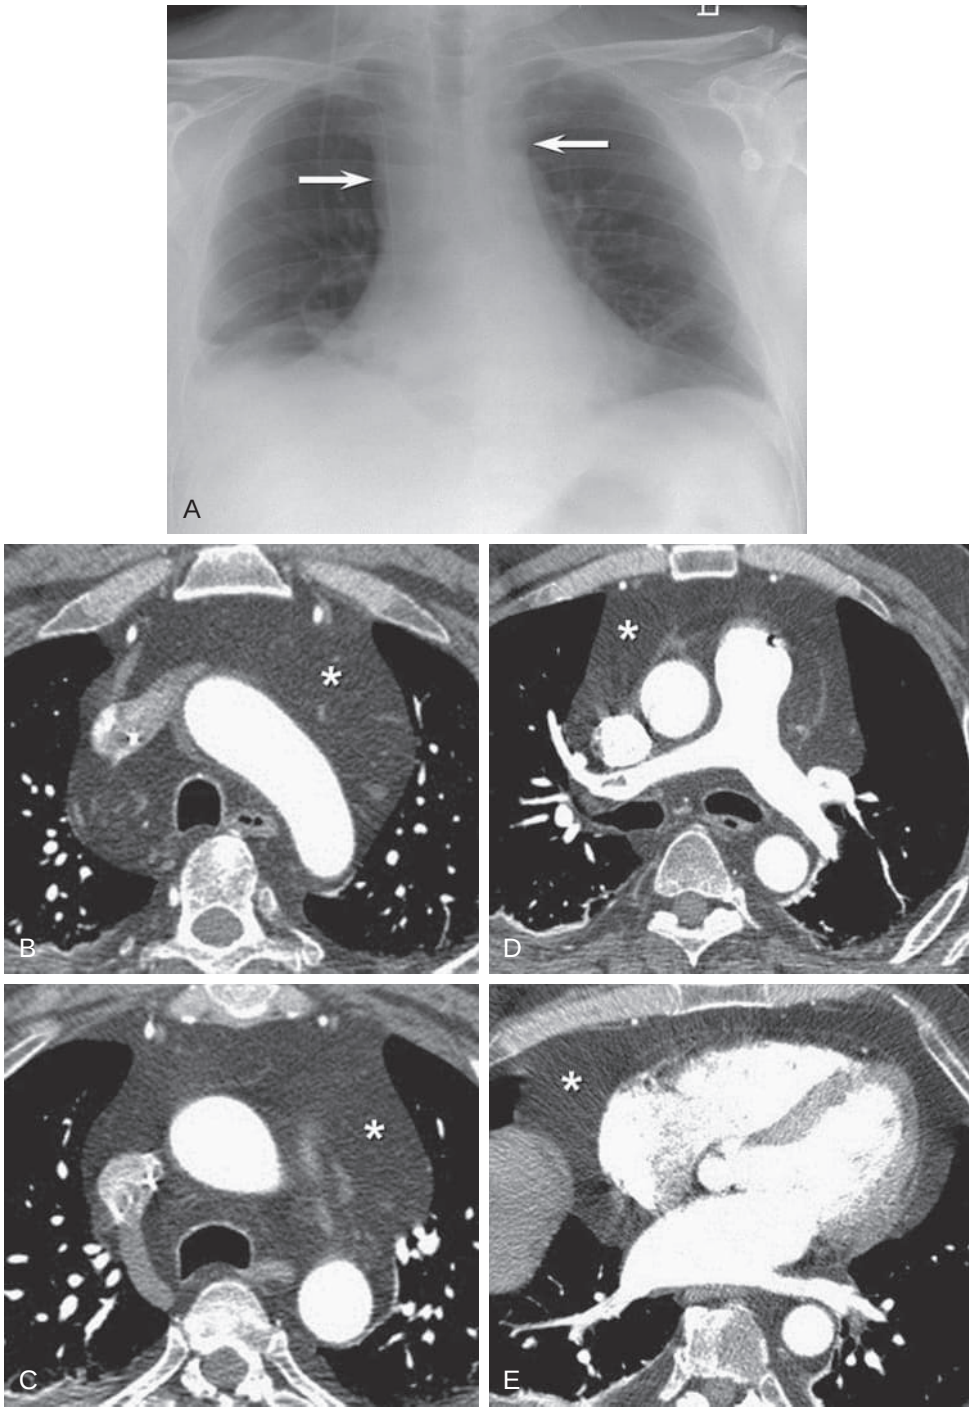
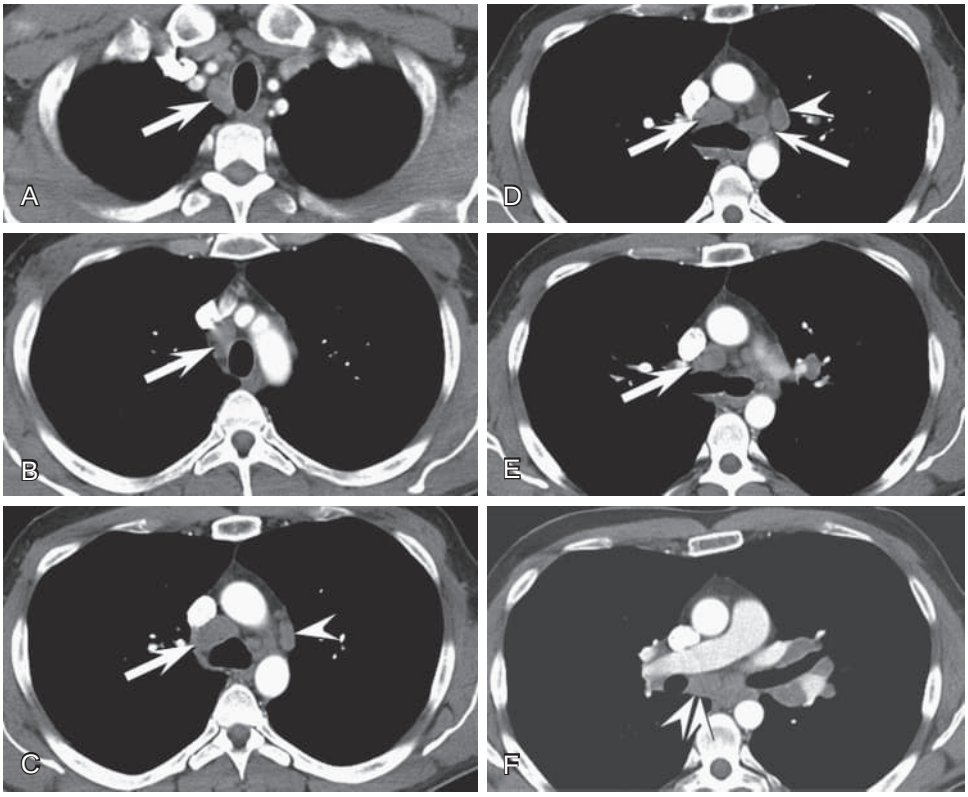
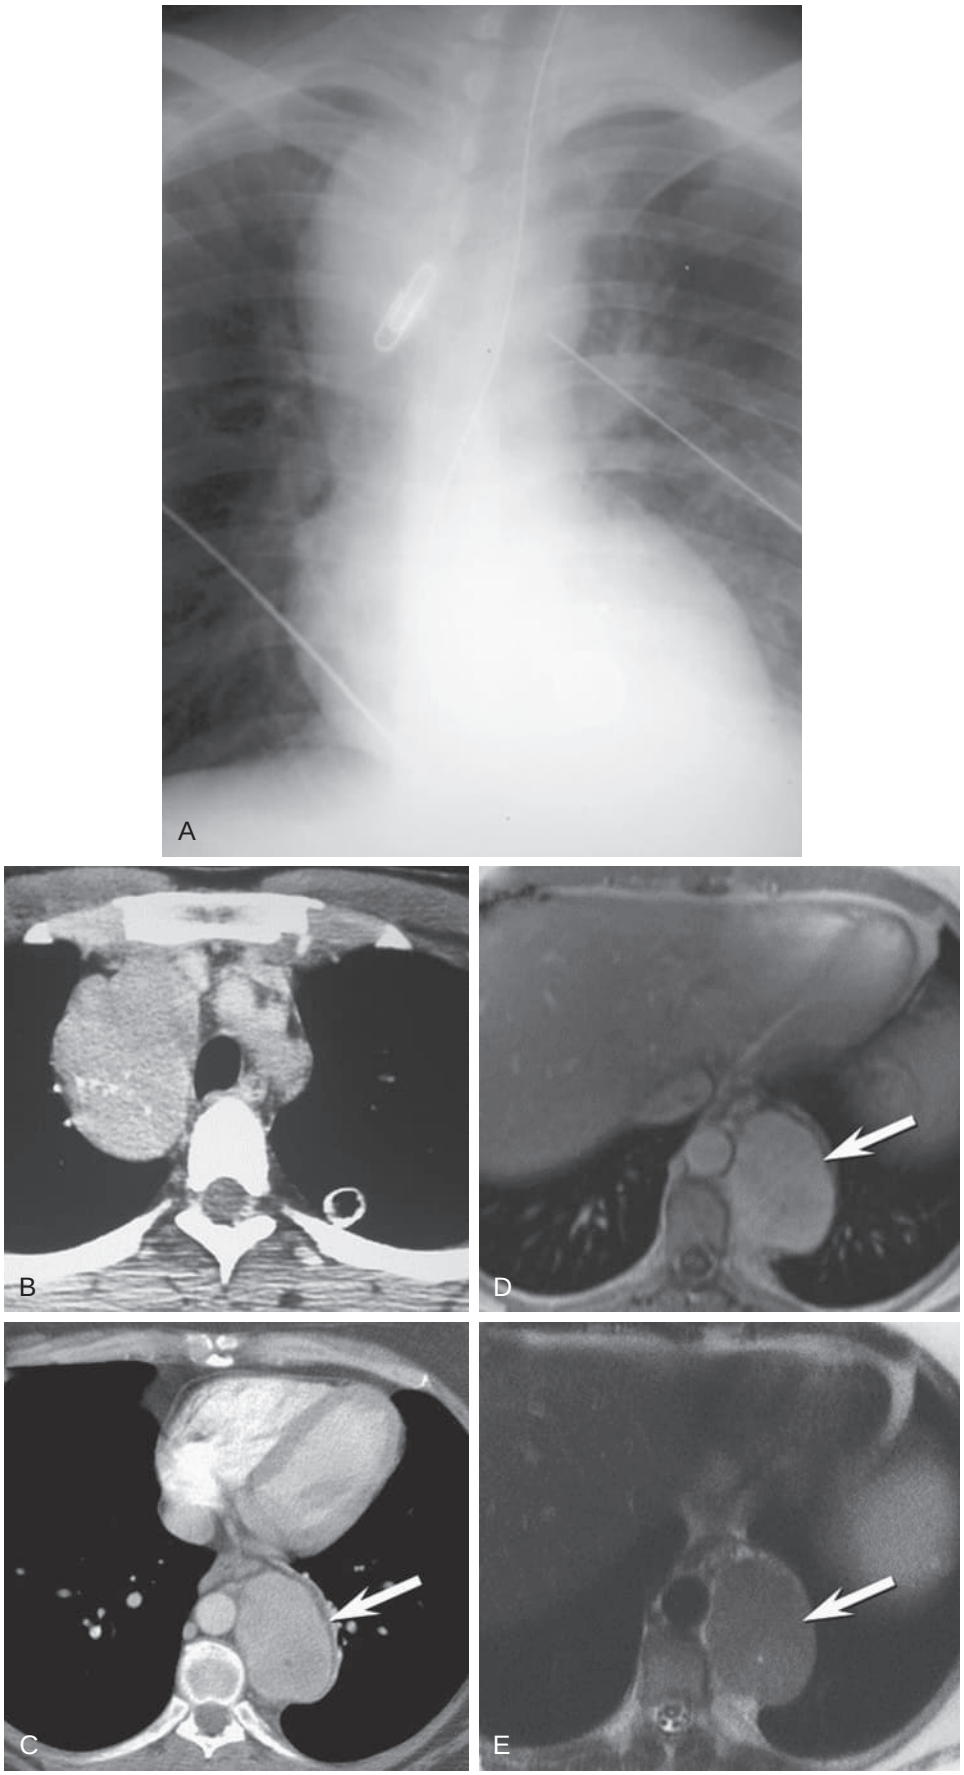
eFigure 115.37 Mediastinal liposarcoma. (A) Axial chest computed tomography shows a predominantly fatty attenuating mass, representing well-differentiated liposarcoma. (B) Axial chest computed tomography shows a mediastinal mass again containing fat, but with considerably more soft tissue than the well-differentiated lesion in A, representing moderately differentiated mediastinal liposarcoma. (C) Axial chest computed tomography shows a large inhomogeneous mass containing fat, but also with soft tissue components and extensive vascularity, representing poorly differentiated mediastinal liposarcoma. (Courtesy Michael B. Gotway, MD.)



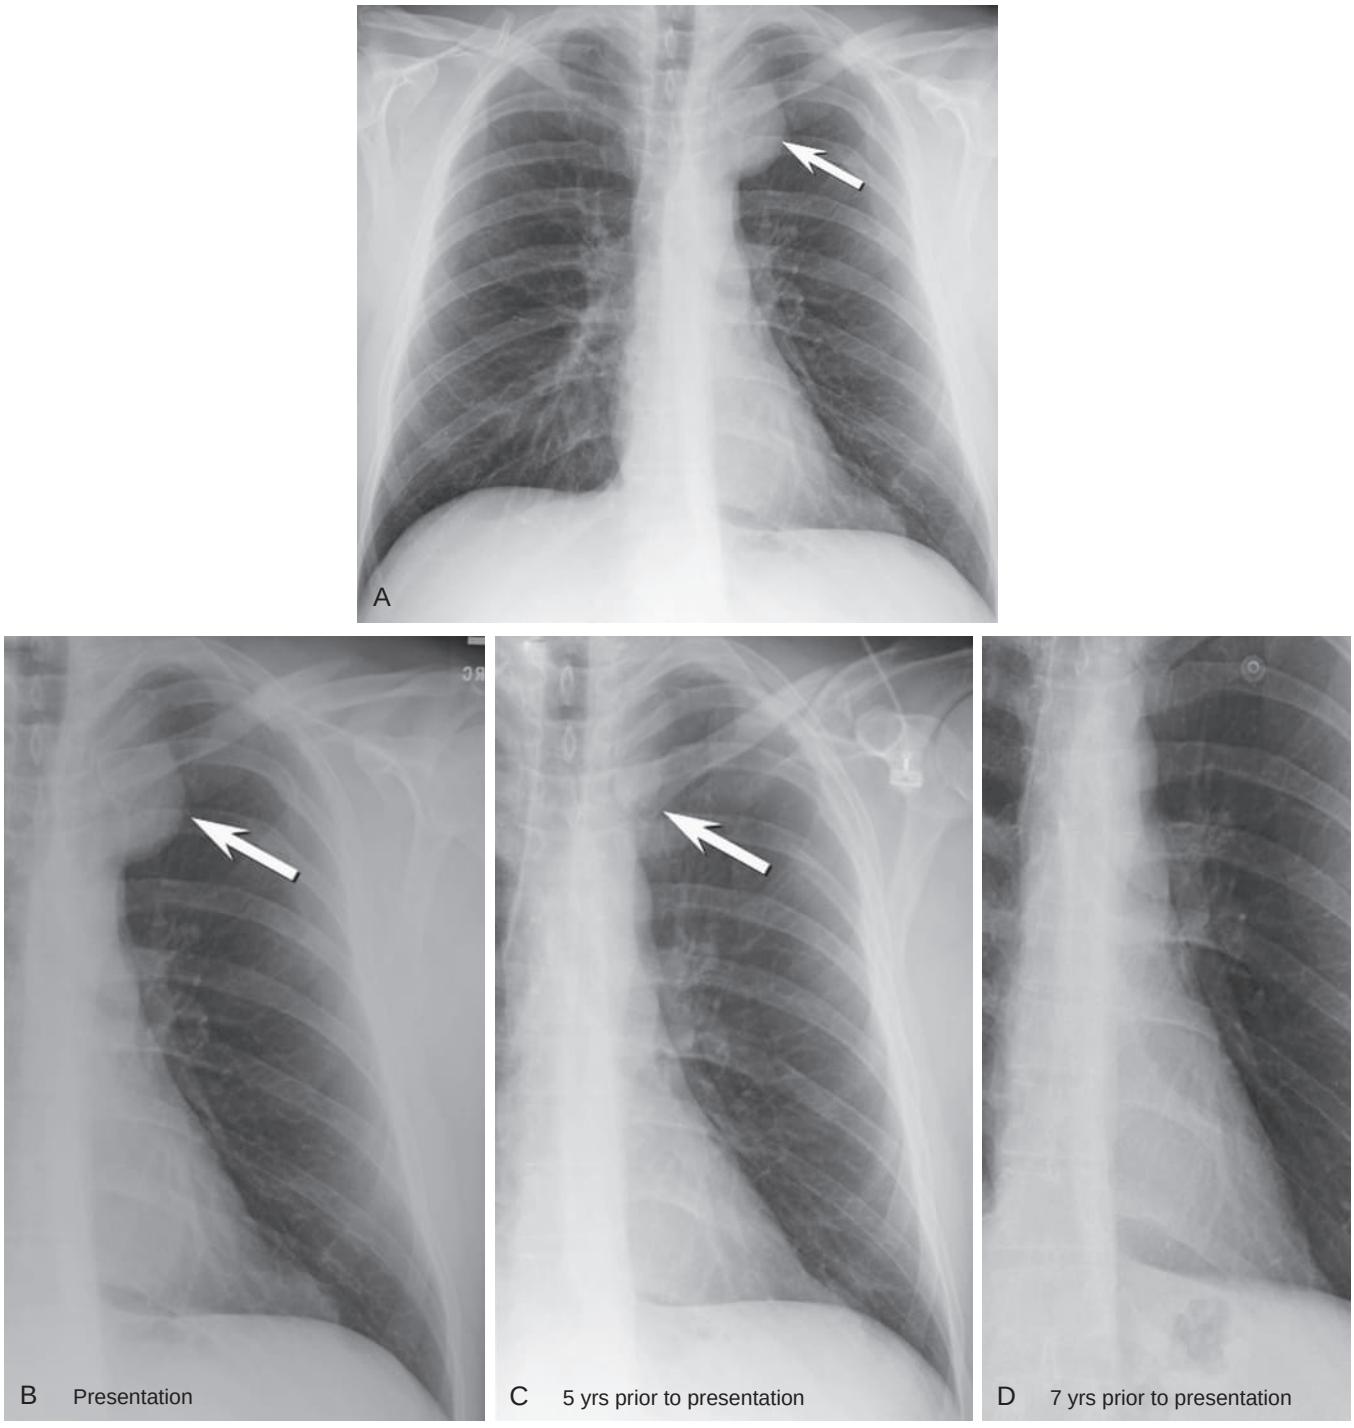
eFigure 115.38 Mediastinal lipomatosis. (A) Frontal chest radiograph shows widening of the superior mediastinum (*arrows*), but the contours of the mediastinum are not lobulated, nor is the mediastinum abnormally dense. (B–E) Axial enhanced chest computed tomography shows abundant, unencapsulated mediastinal fat (*asterisk*) on both sides of midline, without significant nodularity. (Courtesy Michael B. Gotway, MD.)



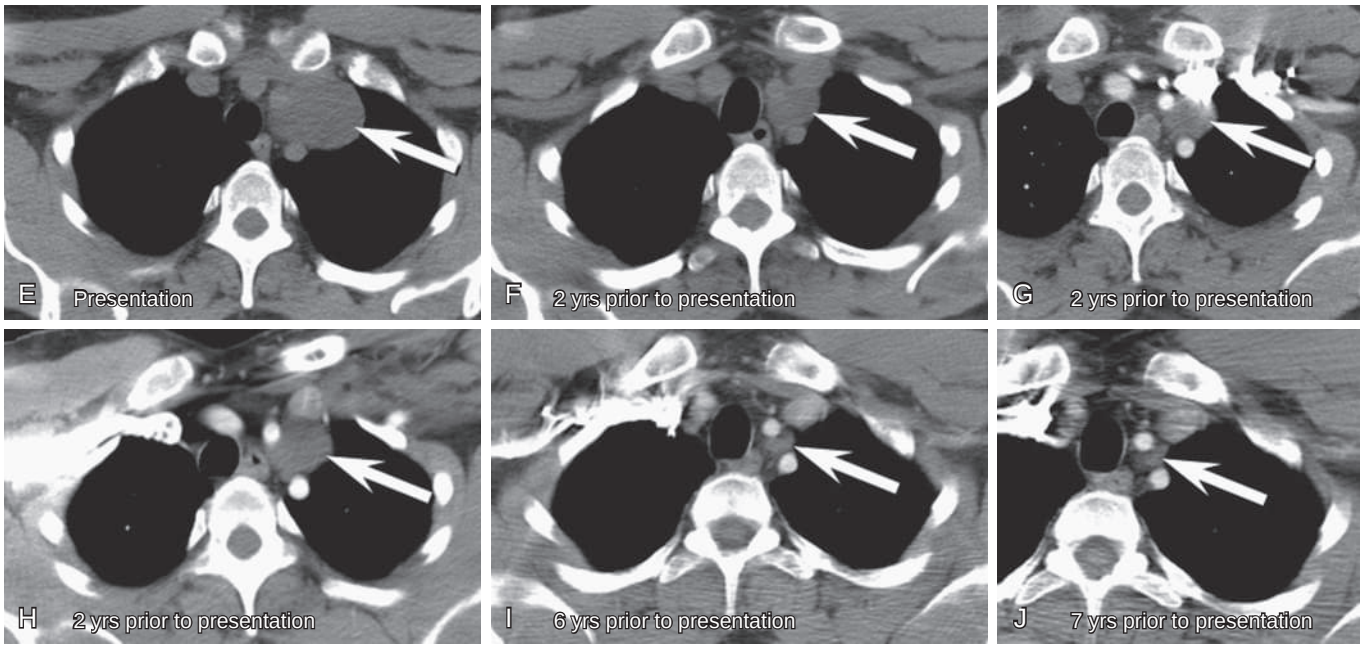
eFigure 115.39 Mediastinal lymphadenopathy in a patient with sarcoidosis. (A–F) Axial enhanced chest computed tomography shows mildly enlarged lymph nodes in multiple mediastinal stations: (A) highest right paratracheal nodes (station 1R, *arrow*); (B) upper right paratracheal nodes (station 2R, *arrow*); (C–E) lower right paratracheal nodes (station 4R, *arrows*); (D) lower left paratracheal nodes (station 4L, *thin arrow*, D) and aortopulmonary window nodes (station 5, *arrowhead*, D); (F) subcarinal nodes (station 7, *double arrowheads*, F). (Courtesy Michael B. Gotway, MD.)



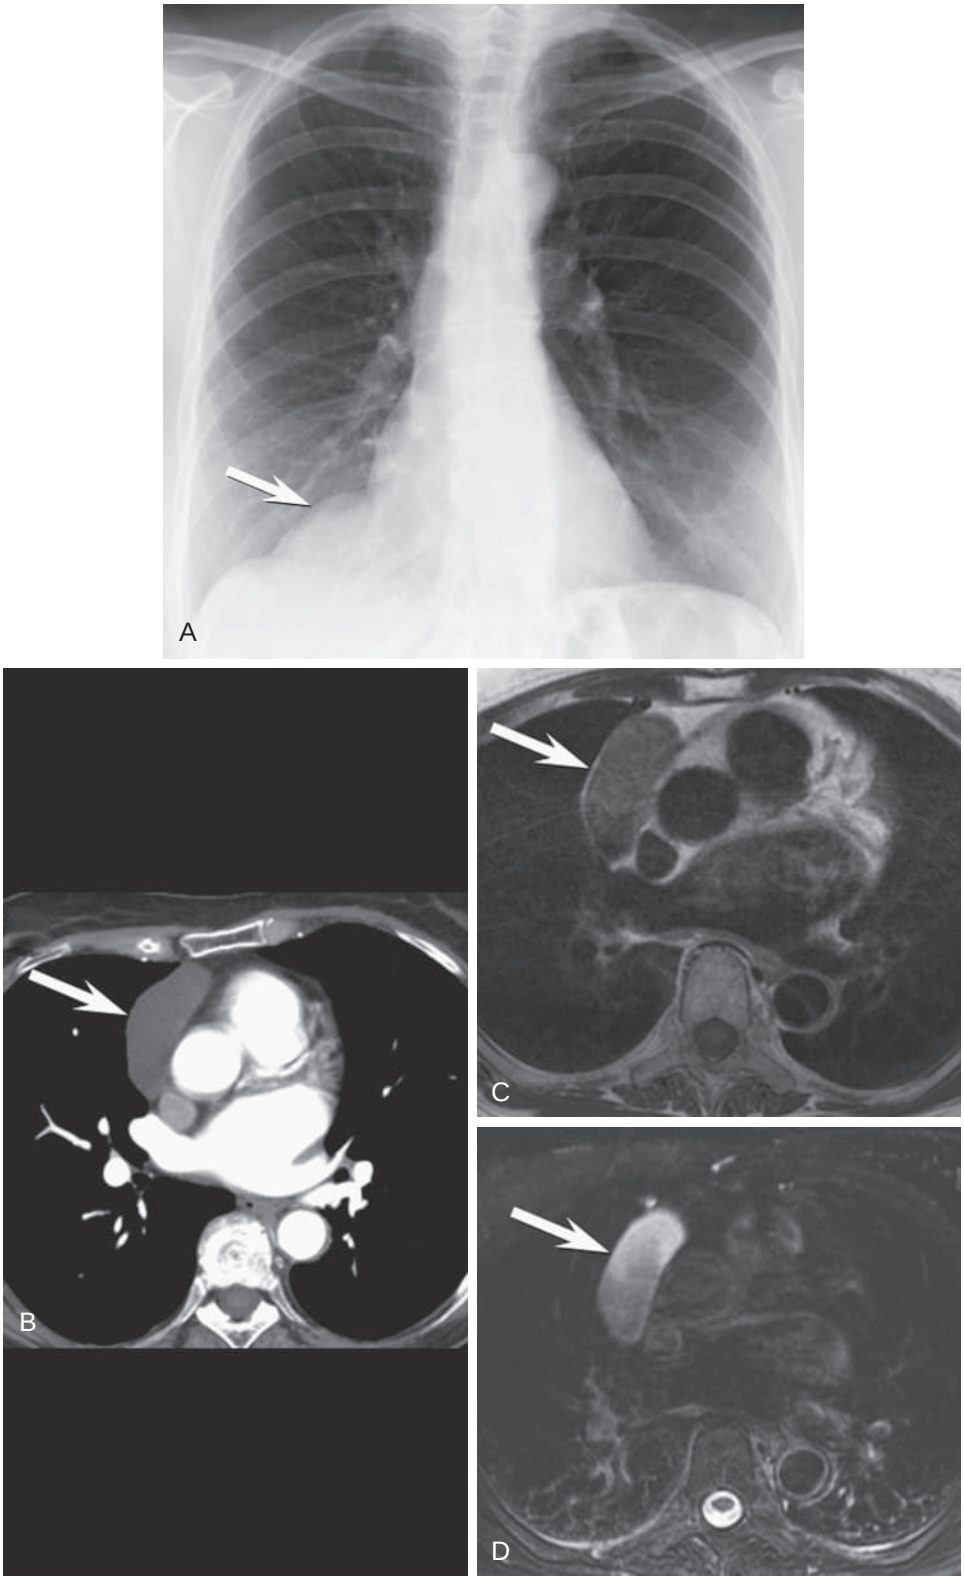
eFigure 115.40 Angiofollicular lymphoid hyperplasia (Castleman disease). (A) Frontal chest radiograph shows a right paratracheal mass in a patient with an anterior chest wall stab wound, with penetrating entry site on the skin marked by a paper clip. (B) Axial enhanced chest computed tomography shows an enhancing right paratracheal mass with small foci of calcification, shown to reflect angiofollicular lymphoid hyperplasia at surgical resection. (C) Axial enhanced chest computed tomography (C), T1-weighted (D) and T2-weighted (E) magnetic resonance images in a different patient show a posterior mediastinal mass (*arrows*) shown to reflect angiofollicular lymphoid hyperplasia at surgical resection. (Courtesy Michael B. Gotway, MD.)



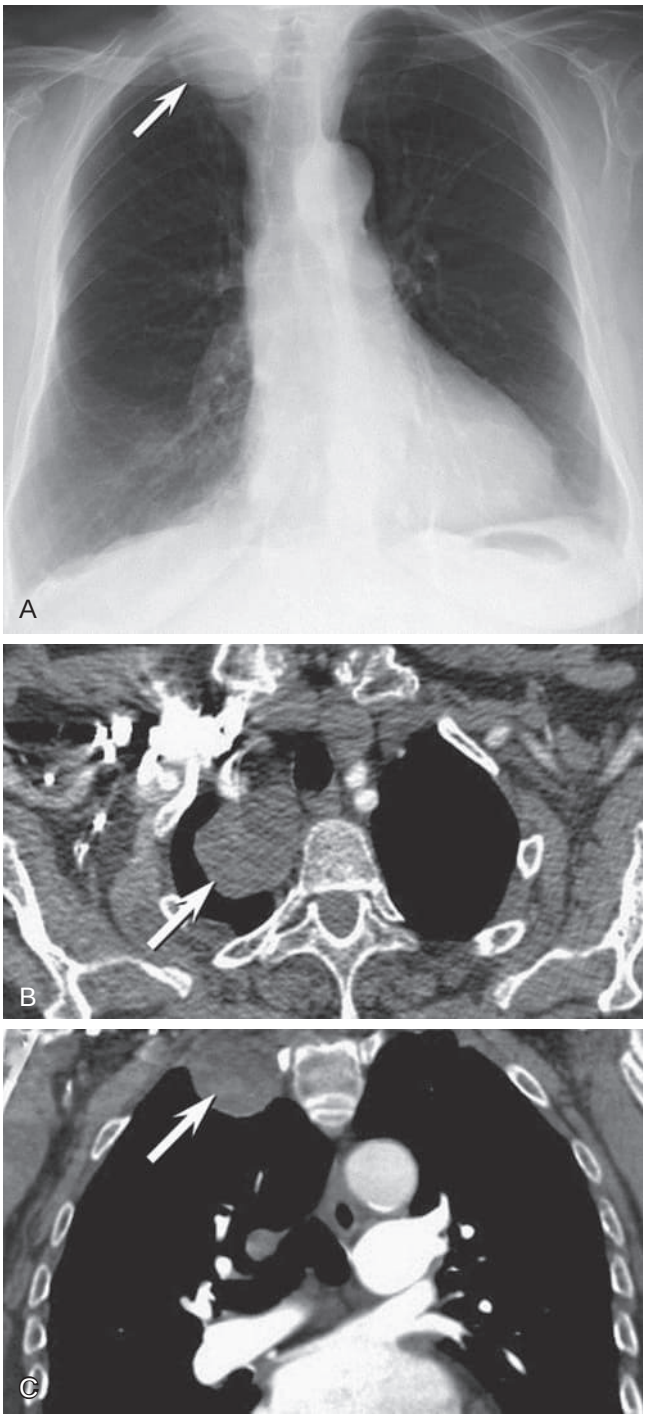
eFigure 115.41 Growth of a bronchogenic cyst over time. (A) Frontal chest radiograph shows a smoothly circumscribed lesion (*arrow*) in the left superior mediastinum. (B–D) Retrospective review of serial chest radiographs obtained over the previous 7 years shows slow enlargement of the lesion (*arrows*). (E–J) Axial chest computed tomography shows serial enlargement of the lesion (*arrows*) over a 7-year period. (Courtesy Michael B. Gotway, MD.)



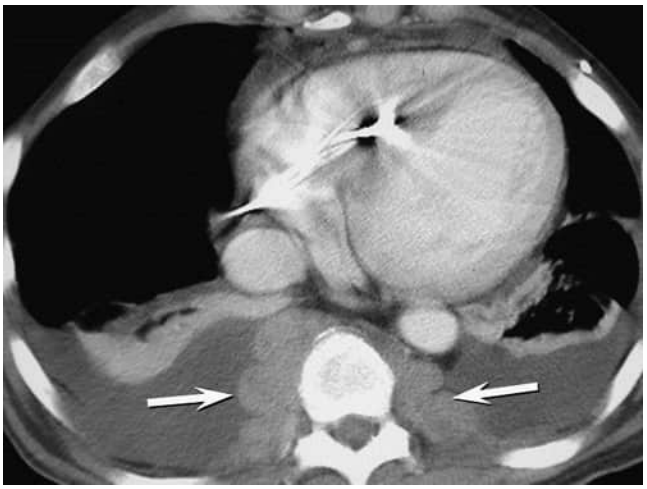
eFigure 115.41, cont'd



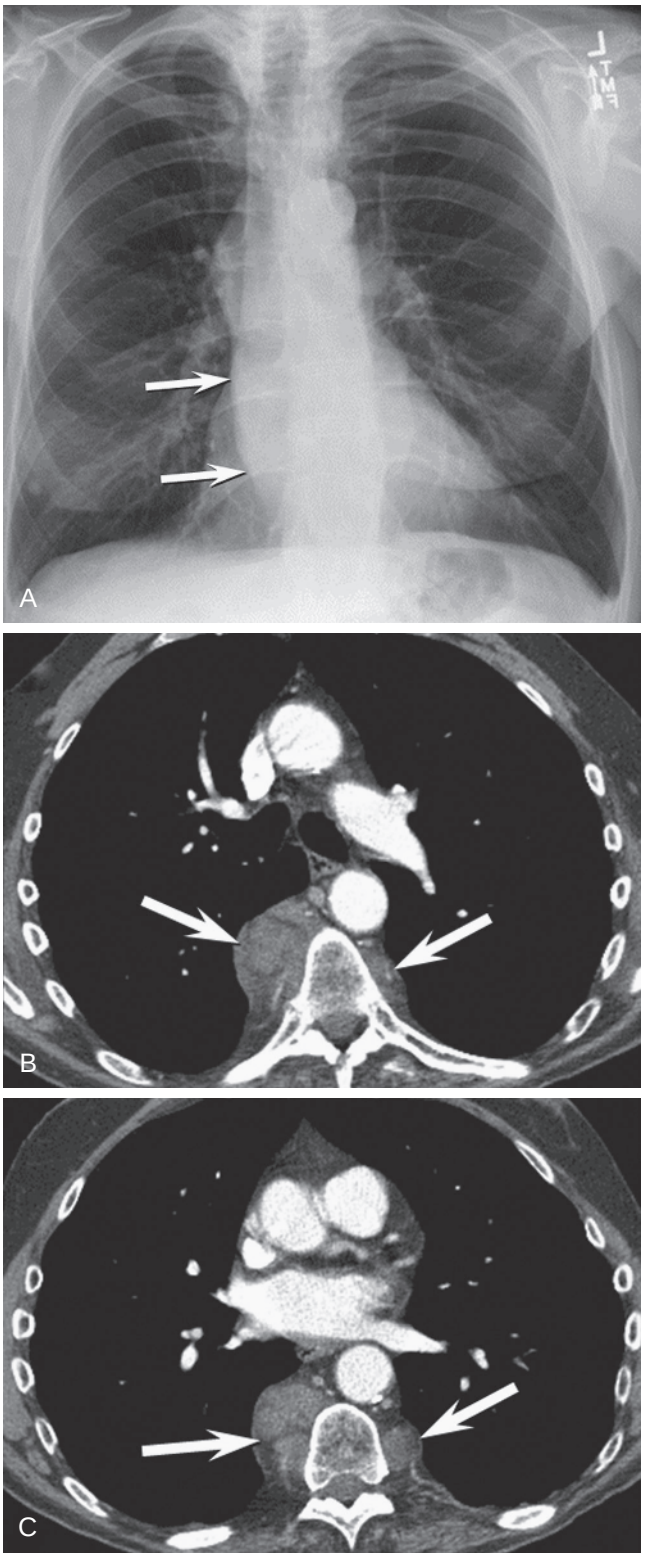
eFigure 115.42 Pericardial cyst. (A) Frontal chest radiograph shows a smoothly circumscribed right cardiophrenic angle mass (*arrow*). (B) Axial enhanced chest computed tomography shows a homogeneous water density mass (*arrow*) abutting the right pericardium. Axial double inversion recovery T1-weighted (C) and axial triple inversion recovery (D) magnetic resonance images show fluid signal within the mass (*arrows*). Triple inversion recovery sequences (D) suppress fat signal, with water signal appearing bright (note the high signal of the cerebrospinal fluid posteriorly). The slight "shading" of the signal intensity posteriorly within the pericardial cyst may reflect debris or hemorrhage. (Courtesy Michael B. Gotway, MD.)



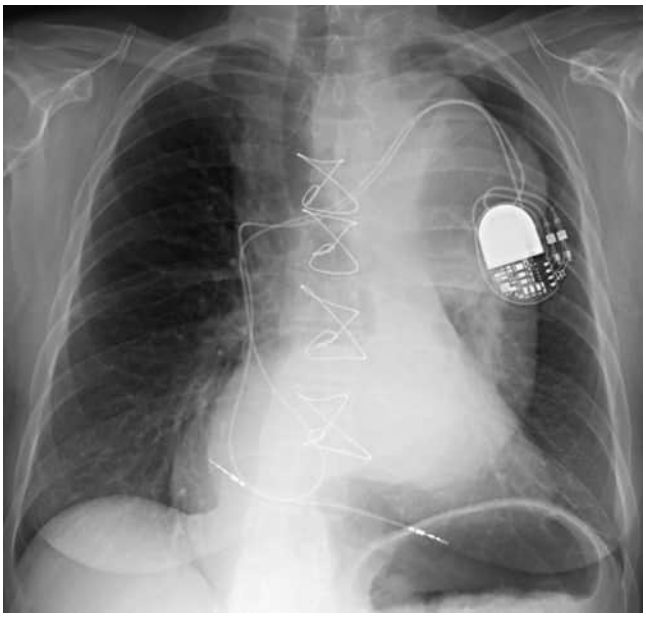
eFigure 115.43 Schwannoma. (A) Frontal chest radiograph shows a smoothly circumscribed lesion (*arrow*) at the right thoracic apex. The extensive contact with the chest wall and lack of visualization of the superior border of the lesion (often referred to as the *incomplete border sign*) are consistent with a non–lung parenchymal origin. Axial (B) and coronal (C) enhanced chest computed tomography shows a homogeneous low-attenuation lesion (*arrows*) in contact with the right superior mediastinum and chest wall. The lesion was shown to reflect schwannoma. See Video 115.12 for the full studies. (Courtesy Michael B. Gotway, MD.)



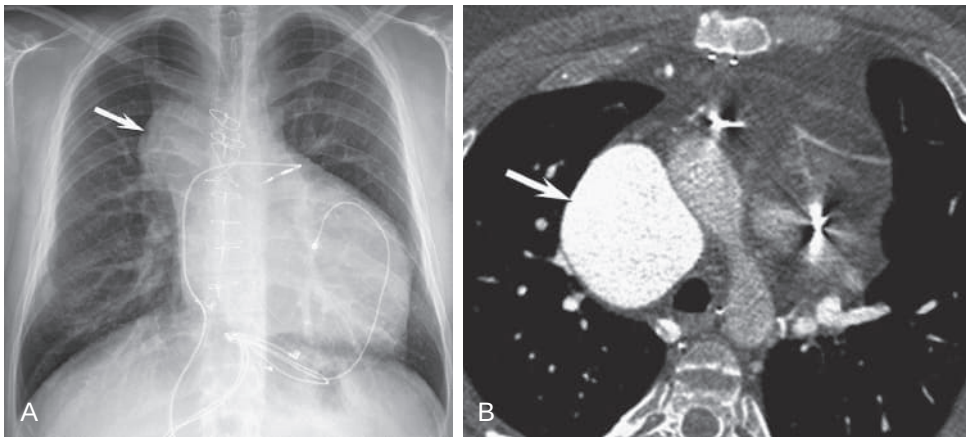
eFigure 115.44 Extramedullary hematopoiesis. Enhanced chest computed tomography in a patient with thalassemia shows enhancing paravertebral soft tissue *(arrows)*, representing extramedullary hematopoiesis. (Courtesy Michael B. Gotway, MD.)



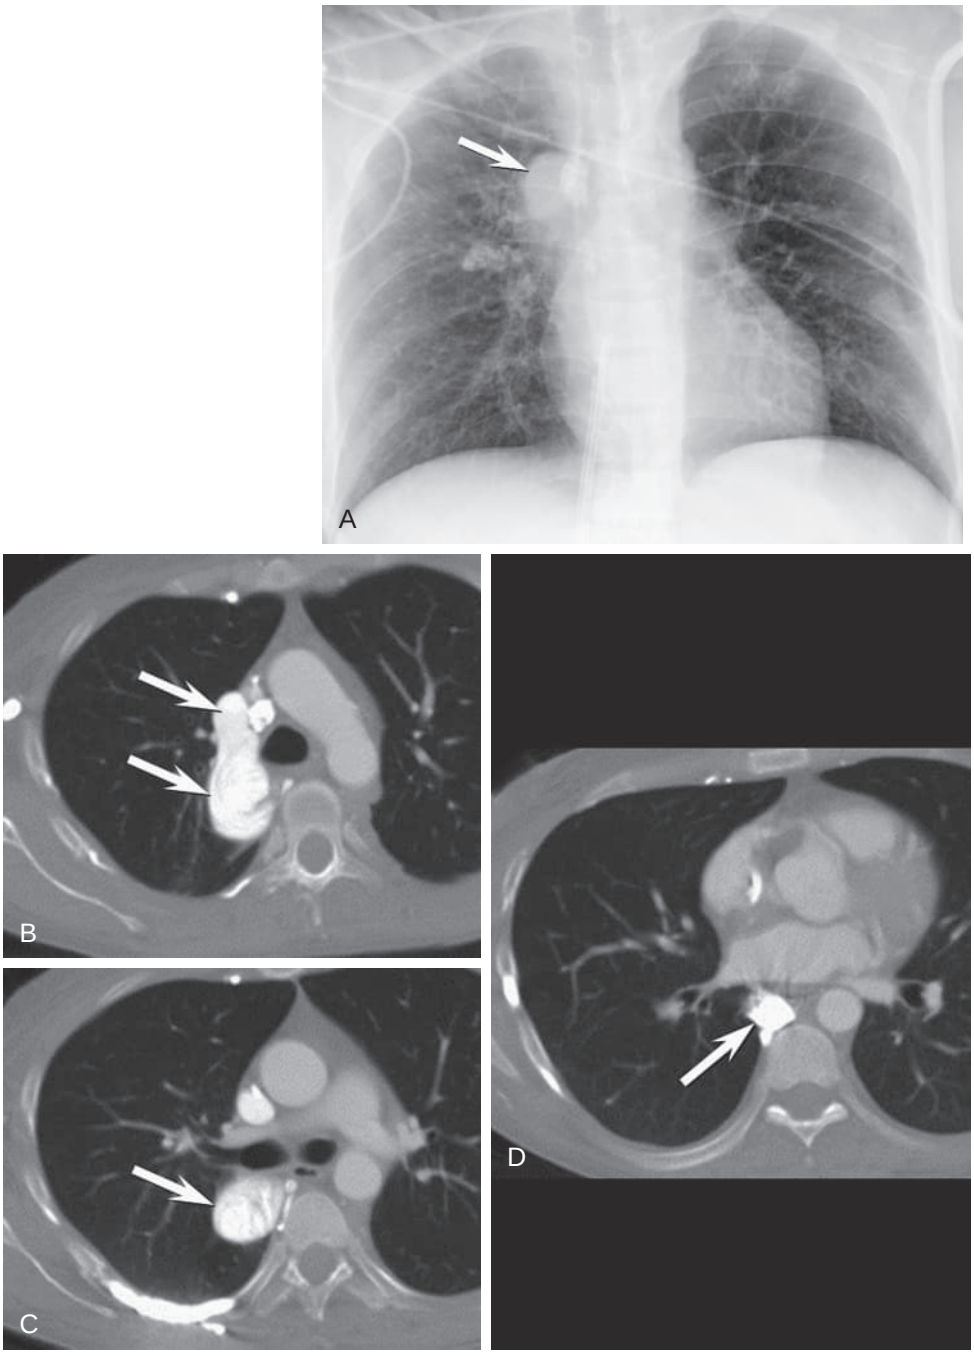
eFigure 115.45 Extramedullary hematopoiesis containing fat. (A) Frontal chest radiograph in a patient with anemia shows an abnormal right-sided posterior mediastinal contour (*arrows*); a similar abnormal contour can be appreciated in the left retrocardiac region. The posterior mediastinal location is suggested by the relatively long contour abnormality without obscuration of the right heart border or lateral displacement of the right hilum. (B and C) Axial enhanced chest computed tomography shows bilateral posterior mediastinal masses (*arrows*) mixed with some areas of low attenuation, the latter consistent with fat. See Video 115.13 for the full study. (Courtesy Michael B. Gotway, MD.)



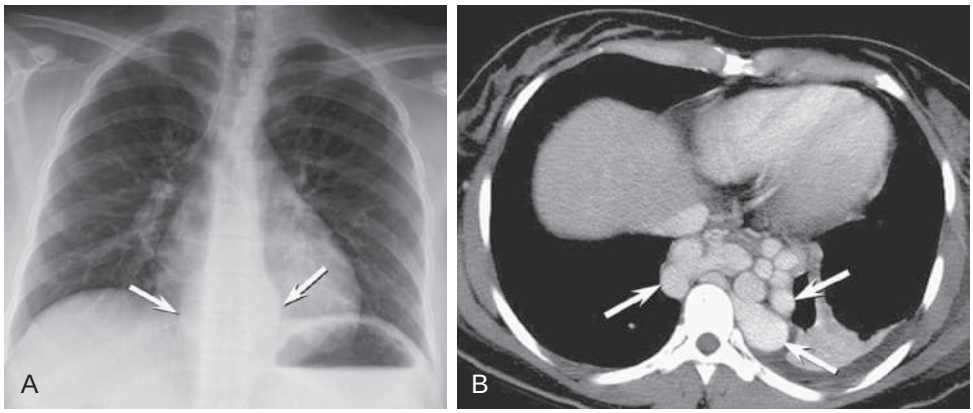
eFigure 115.46 Mediastinal mass caused by aortic aneurysm. Frontal chest radiograph shows a huge left-sided mediastinal mass without visualization of a normal thoracic aorta. See Video 115.14 for an enhanced chest computed tomography showing a huge aneurysm of the descending thoracic aorta with mural thrombus. (Courtesy Michael B. Gotway, MD.)



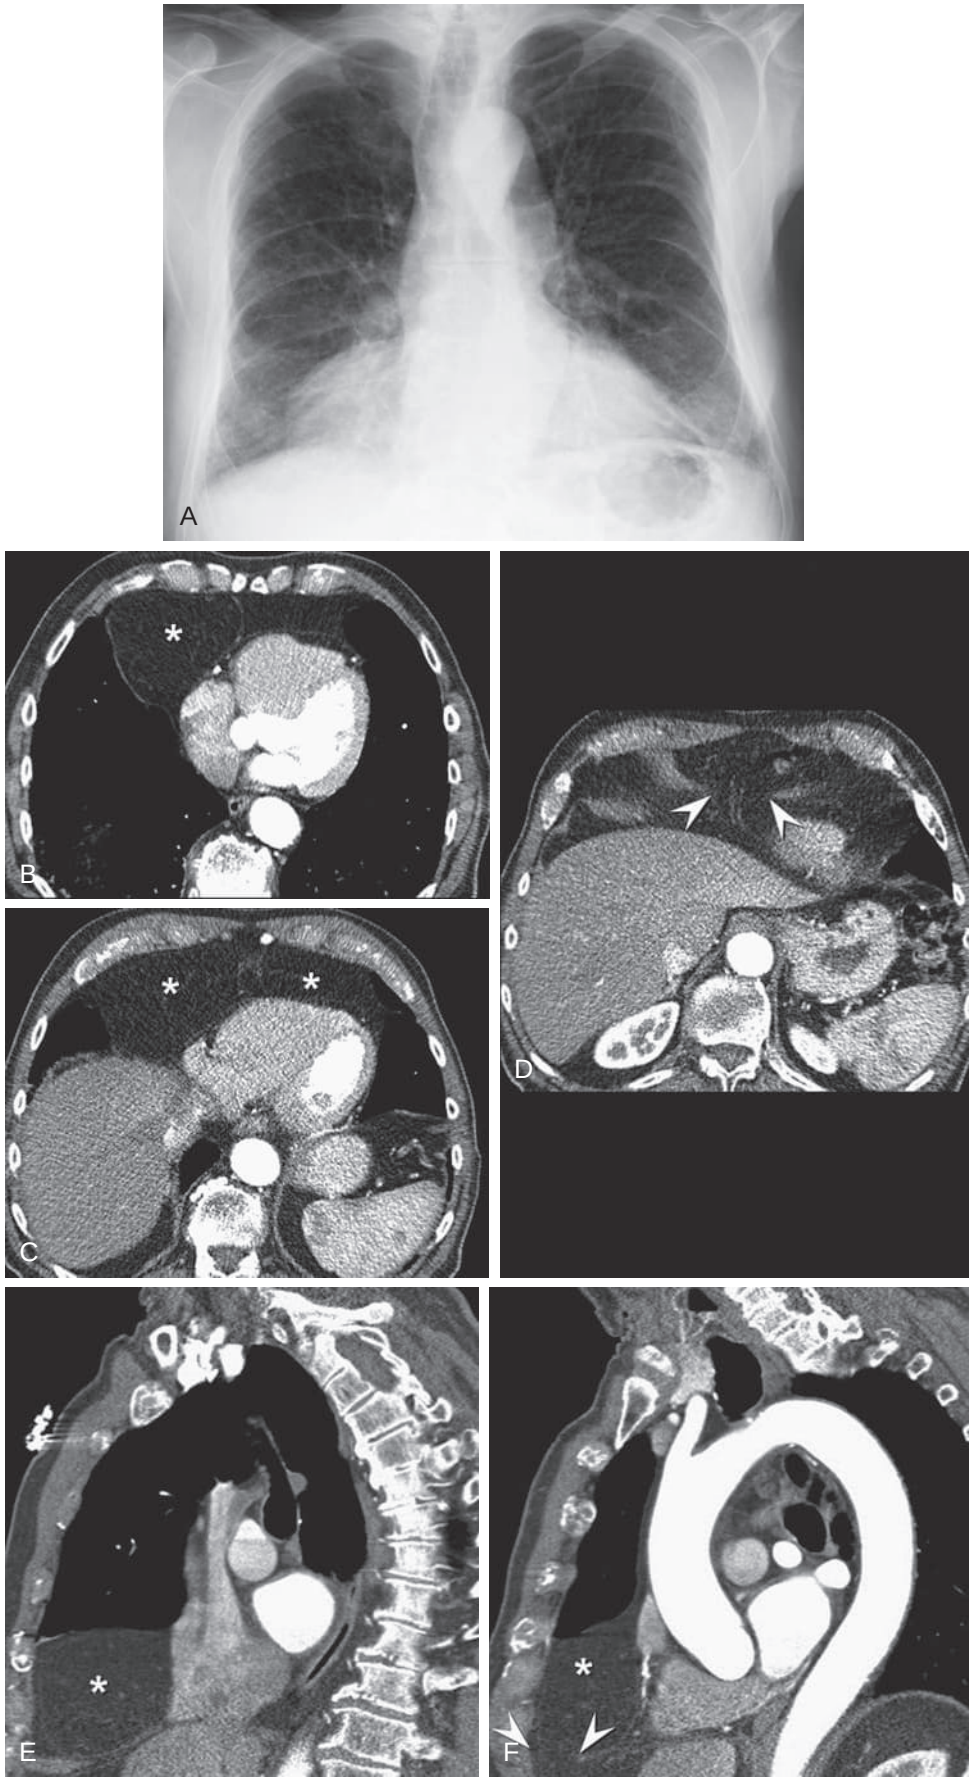
eFigure 115.47 Mediastinal mass caused by superior vena cava aneurysm. (A) Frontal chest radiograph shows a right-sided mediastinal mass (*arrow*). Patient had undergone Glenn shunt (superior vena cava-to-pulmonary artery) for double outlet right ventricle. (B) Axial enhanced chest computed tomography shows a 6-cm aneurysm of the superior vena cava (*arrow*). (Courtesy Michael B. Gotway, MD.)



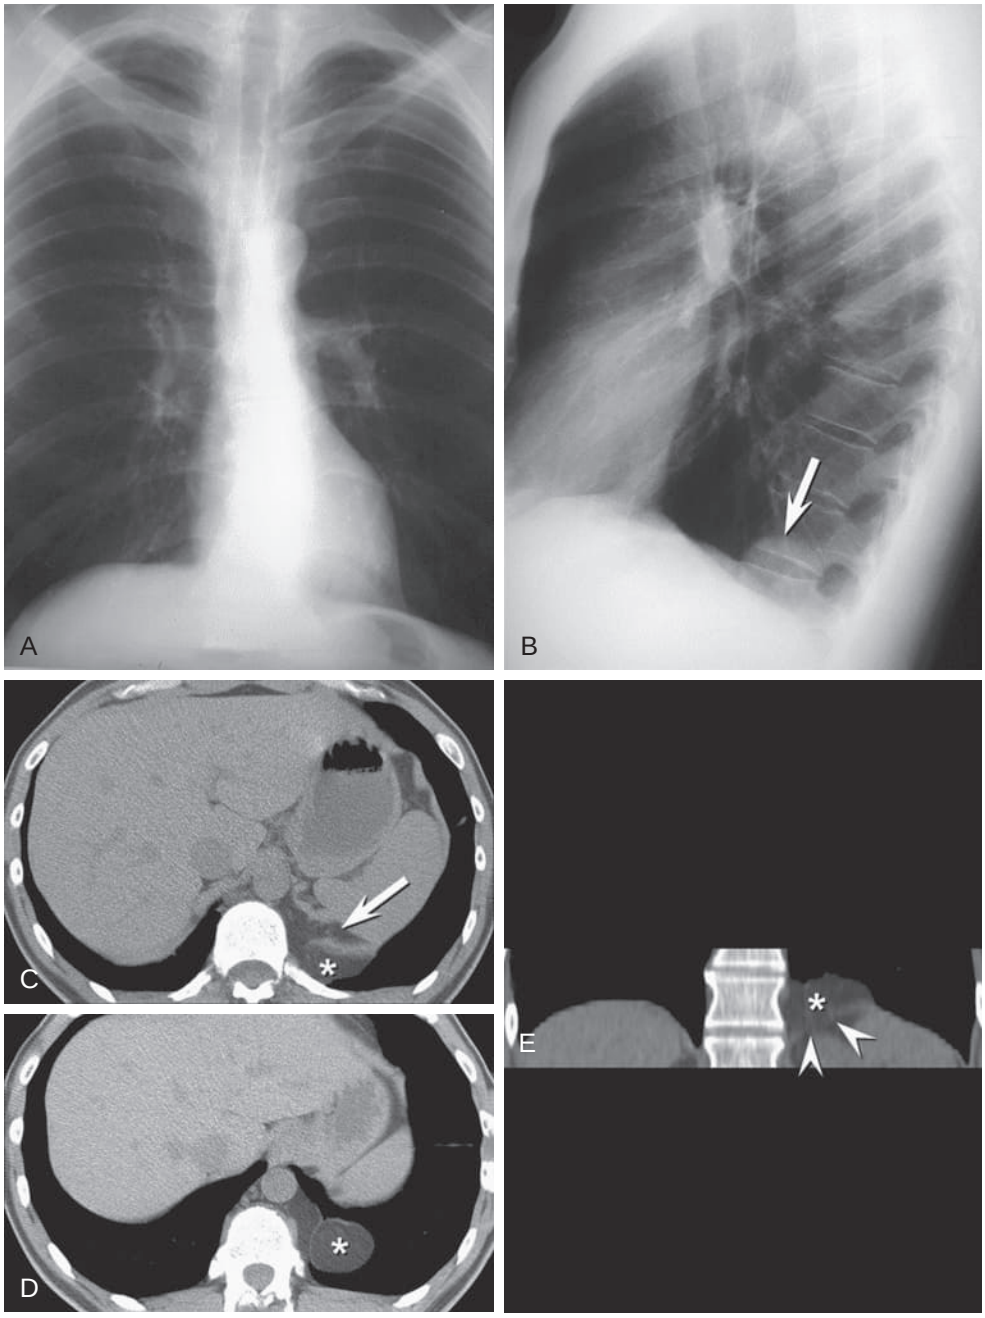
eFigure 115.48 Mediastinal mass caused by enlargement of the azygos vein. (A) Frontal chest radiograph shows a mass (*arrow*) in the right tracheobronchial angle; this is the normal position of the anterior portion of the azygos vein. (B–D) Axial enhanced chest computed tomography shows dense contrast enhancement of the enlarged azygos vein (*arrows*). See Video 115.15 for the full study. (Courtesy Michael B. Gotway, MD.)



eFigure 115.49 Mediastinal mass caused by esophageal varices. (A) Frontal chest radiograph shows bilateral paraspinous line displacement (*arrows*) consistent with a posterior mediastinal mass. (B) Axial enhanced chest computed tomography shows that the posterior mediastinal mass is caused by periesophageal varices (*arrows*). (Courtesy Michael B. Gotway, MD.)



eFigure 115.50 Foramen of Morgagni hernia. (A) Frontal chest radiograph shows a smoothly circumscribed right cardiophrenic angle mass. Axial (B–D) and sagittal (E and F) enhanced chest computed tomography scans show that the right cardiophrenic angle mass (*asterisk*) contains fat and originates within the abdomen, herniating into the thorax through an anteromedial diaphragmatic defect (*arrowheads*, D and F). Note that vessels, seen as thin linear hyperattenuating streaks, can be seen accompanying the fat herniation (D). See Video 115.16 for the full axial study. (Courtesy Michael B. Gotway, MD.)



eFigure 115.51 Foramen of Bochdalek hernia. Frontal (A) and lateral (B) chest radiographs show a smoothly circumscribed contour abnormality along the posterior left diaphragm (*arrow*, B). The finding is difficult to appreciate on the frontal chest radiograph (A) but is readily seen on the lateral projection (*arrow*, B). Axial (C and D) and coronal (E) unenhanced chest computed tomography shows that the lesion (*asterisk*) consists entirely of fat, originating from the abdomen and extending into the posteromedial thorax through a diaphragmatic defect (*arrow*, C, and *arrowheads*, E). (Courtesy Michael B. Gotway, MD.)

Mediastinal Adenitis
KEY POINTS

INTRODUCTION

Mediastinitis refers to an inflammatory insult to the mediastinum of any origin. Inflammation confined within a mediastinal organ or structure but not involving the interstitium of the mediastinum is not considered mediastinitis (e.g., esophagitis, myocarditis, or granulomatous inflammation within lymph nodes secondary to sarcoidosis or contained infection). Acute mediastinitis usually has an infectious component. Several mechanisms underlie the majority of cases, including perforation of a nonsterile hollow viscus or extension of infection from an adjacent site (e.g., neck, abdomen, sternotomy incision). There are also two notable chronic inflammatory and/or fibrotic mediastinal processes, fibrosing mediastinitis and mediastinal granuloma, that may compromise one or more of the vital structures contained within.

ACUTE MEDIASTINITIS

Acute mediastinitis is a serious illness with high rates of morbidity and mortality and usually implies bacterial infection within the mediastinal space. Despite its sometimes dramatic presentation, prompt clinical detection is often challenging and requires a sufficiently high index of suspicion in the evaluation of an acutely ill patient. Diagnostic efforts focus on confirming mediastinitis, identifying the mechanism by which mediastinitis has developed, and elucidating the mediastinal structures involved. Management nearly always includes antibiotics and mechanical débridement via operation or, in selected cases, percutaneous drainage. Endoscopic interventions are emerging as useful adjuncts in specific situations.

The incidence of acute mediastinitis is difficult to determine given the wide range of insults that may result in mediastinitis often reported in distinct literatures and typically in case series format. For example, in Iceland over a 28-year period, esophageal perforation was reported to have an incidence of 3.1 per million per year, with 52% of these cases resulting from iatrogenic injury, 24% spontaneous, and 17% related to foreign body ingestion.[1] Descending necrotizing mediastinitis is widely considered a rare but grave diagnosis without a well-described incidence but with a mortality ranging from 10–15% to 50%.[2–4] Post-sternotomy mediastinitis or deep sternal wound infection has been reported to have an incidence of 1–2%, with an associated mortality of 20–30%.[5,6]

Clinical presentation, useful diagnostic studies, and etiologic mechanisms underlying acute mediastinitis are reviewed here, followed by a discussion of management considerations (Table 116.1).

ANATOMIC CONSIDERATIONS

The mediastinum is the space in the central chest that is situated between distinct left and right pleural cavities and is additionally bound by the sternum anteriorly, the vertebral column posteriorly, the thoracic inlet superiorly, and the diaphragm inferiorly. This space is home to a diverse cast of structures, including the heart, great vessels, esophagus, trachea and proximal mainstem bronchi, thymus, thoracic duct, an extensive network of lymph nodes and connecting lymphatic channels, the sympathetic trunk, and phrenic, vagus, and left recurrent laryngeal nerves, all enveloped by mediastinal fat and loose connective tissue.

Pertinent to potential causes of infectious contamination of the normally sterile mediastinum, it is noteworthy that two nonsterile hollow viscera, the esophagus and trachea with proximal mainstem bronchi, transit the mediastinum. The mediastinum is also contiguous via shared fascial planes with the deep spaces of the neck and the retroperitoneum.

A delineation of the mediastinum into anterior, middle, and posterior compartments is commonly encountered. Because these divisions are not anatomic (or universally agreed on), their consideration is of limited utility in the diagnosis and management of acute mediastinitis, and they are not reviewed here. They may have more value with respect to the diagnosis of mass lesions within the mediastinum (see Chapter 115).

CLINICAL PRESENTATION

The prototypical presentation of acute mediastinitis, and historically the most common cause, is Boerhaave syndrome. A classic case includes overeating and/or overdrinking followed by vomiting forceful enough to cause spontaneous rupture of the esophagus, thus resulting in spillage of gastric contents, oral or enteric flora, and air into the mediastinum.[7–9] This results in immediate and unrelenting retrosternal chest pain, worse on inspiration and with cough, followed rapidly by signs and symptoms of a robust systemic inflammatory response, including fever, chills or rigors, tachycardia and tachypnea, and ultimately shock. Pain radiating to the epigastrium, neck, or interscapular region may also be present, implying involvement of the inferior, superior, and posterior aspects of the mediastinum, respectively. Pneumomediastinum (Fig. 116.1, eFig. 116.1), unilateral or bilateral pneumothorax or hydropneumothorax (progressing rapidly to empyema), and subcutaneous emphysema or palpable neck or chest wall crepitus are frequently present. The Hamman sign, a systolic crunching sound at the cardiac apex caused by cardiac motion within an air-filled mediastinum, is occasionally reported.[10] Mackler's triad of chest pain, vomiting, and subcutaneous emphysema is identified in a minority of patients.[11–13]

Although acute mediastinitis of any origin tends to share aspects of this classic description, not all patients will present in such a dramatic and stereotypical fashion. The presentation varies depending on the mechanism and location of the insult, the magnitude of the infectious and/or noninfectious inflammatory inoculum, and the underlying immune status of the patient. For example, the rapid clinical deterioration often seen in classic Boerhaave syndrome results from substantial polymicrobial contamination by swallowed oral flora in addition to reflux of acidic gastric contents through the esophageal defect, which typically develops near the gastroesophageal junction. Such a fulminant course may not be observed in the setting of an iatrogenic injury during esophageal dilation in a patient with an empty stomach, early institution of antibiotics in response to rapid recognition of a possible complication, and possibly endoscopic intervention.

In cases of direct extension of infection from a compartment in communication with the mediastinum, the initial symptoms of the primary infection may dominate the

Table 116.1 Acute Mediastinitis: Causes and Clinical Settings

PERFORATION OF A THORACIC VISCUS
Forceful vomiting (Boerhaave syndrome)
Direct penetrating trauma to esophagus or trachea
Foreign body ingestion or aspiration
Iatrogenic complication of instrumentation: endoscopy, bronchoscopy, intubation or airway management, transesophageal echocardiography, central venous catheter placement
Erosion of carcinoma or necrotizing infection
DIRECT EXTENSION FROM OUTSIDE MEDIASTINUM
Descending necrotizing mediastinitis from pharyngeal, odontogenic origin
Pancreatitis
Pneumonia or empyema
Osteomyelitis of rib, vertebrae, or paraspinous abscess
MEDIASTINITIS AFTER CARDIOTHORACIC SURGERY
SPONTANEOUS MEDIASTINITIS
Hematogenous seeding, usually by *Streptococcus*
Hemorrhagic mediastinitis of inhalational anthrax

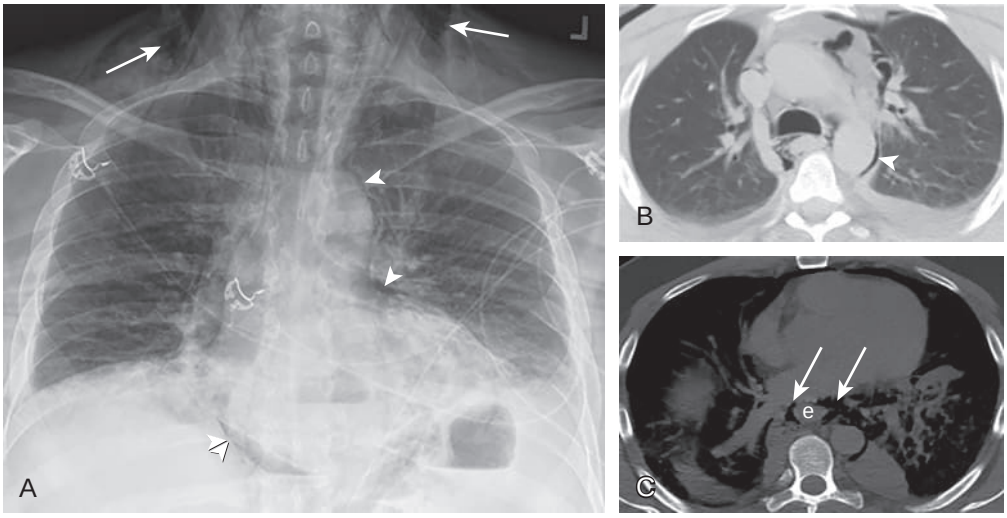

Figure 116.1 Esophageal perforation. (A) Frontal chest radiograph shows pneumomediastinum outlining the aortic arch and left mediastinum (*single arrowheads*) as well as along the diaphragm (*double arrowheads*), and bilateral subcutaneous emphysema (*arrows*). (B–C) Axial unenhanced computed tomography displayed in lung (B) and soft tissue (C) windows shows pneumomediastinum along the aortic arch (*arrowhead,* B) and concentrated more distally around the esophagus (*arrows,* C). e, esophagus. (Courtesy Michael B. Gotway, MD.)

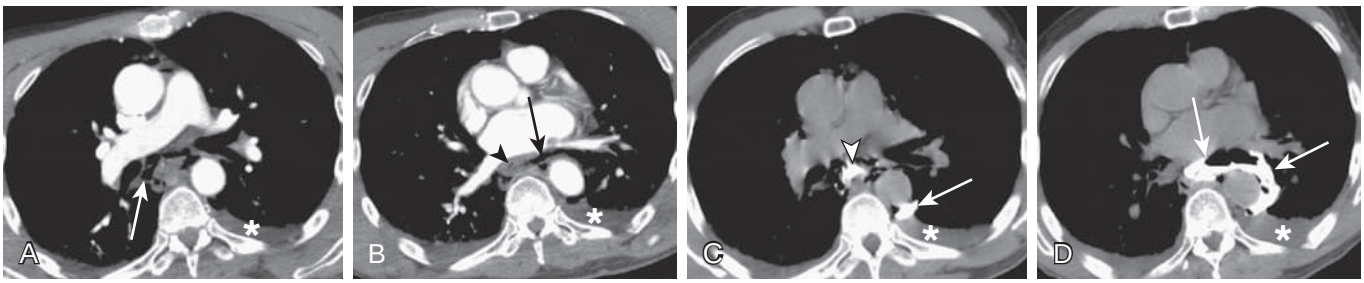

Figure 116.2 Esophageal rupture (Boerhaave syndrome). Axial chest computed tomography initially performed following intravenous contrast administration, before oral contrast administration (A–B), and after administration of oral contrast (C–D) shows pneumomediastinum (*arrows* in A and B) in close proximity to the esophagus (*arrowhead* in B). Left pleural effusion *(asterisks)* is evident. Following administration of oral contrast medium, contrast material can be seen to distend the esophagus (*arrowhead* in C), subsequently opacifying the areas of pneumomediastinum (*arrows* in C–D) and extending toward the left pleural space, thus confirming an esophageal source of the perforation. (Courtesy Michael B. Gotway, MD.)

clinical picture, with early recognition of comorbid mediastinitis reliant on a high index of suspicion combined with recall of pertinent anatomic relationships. Poststernotomy mediastinitis typically manifests with signs and symptoms of systemic infection with signs of local wound infection.

EVALUATION AND USEFUL STUDIES

Evaluation for acute mediastinitis should be tailored to the clinical scenario, with close attention to structures suspected to be involved based on history, including any recent invasive interventions. Chest radiography, contrast esophagram, *computed tomography* (CT) scan of the chest, and pleural fluid analysis frequently assist in the diagnosis. Chest radiography often demonstrates a widened mediastinum. If a hollow viscus has been perforated or there is extensive gas formation from the infection, pneumomediastinum, pneumothorax, and/or hydropneumothorax may be seen. Naclerio's "V" sign, formed by air in the lower left mediastinum that permits V-shaped silhouetting of the descending aorta and left hemidiaphragm, is identified in a minority of patients[14,15] (eFig. 116.1G). In two series including 142 patients, chest radiographs were 90% sensitive for esophageal perforation, with pneumomediastinum and left hydropneumothorax most commonly present.[12,16–18] After an iatrogenic injury, radiologic signs of esophageal perforation were discernable in some patients after 1 hour and were present in 75% after 12 hours.[12,16,18,19]

If esophageal injury is suspected, or no other cause of acute mediastinitis is apparent, contrast esophagography should be pursued. Contrast extravasation into the mediastinum and/or pleural space(s) confirms the diagnosis of esophageal perforation or rupture. Water-soluble agents such as Gastrografin (diatrizoate meglumine and diatrizoate sodium solution) are suggested by many investigators instead of barium sulfate out of concern that the barium could induce further inflammation if extravasated.[20] However, barium, with higher density and better mucosal adherence, is more sensitive, with a false-negative rate for detection of esophageal perforation of 10% versus 20% for Gastrografin.[12,18,21] Thus, despite some concerns about the risks of using barium, some investigators prefer barium esophagram as the initial test when a confident diagnosis of esophageal perforation would lead to lifesaving surgery.[12]

Chest CT is the most sensitive single study for mediastinitis of any origin and offers the first radiographic indication of mediastinitis in up to one-third of cases.[22] In esophageal perforation, extraluminal air is detected in up to 92% of cases. Other suggestive findings include esophageal wall thickening, periesophageal fluid collection or abscess, extravasated contrast material from prior examinations, frank pneumomediastinum, and pleural abnormalities[12,22–24] (Fig. 116.2, eFig. 116.2). However, the perforation site is definitively identified in as few as 15% of cases in some series, demonstrating the continued need for contrast esophagram.[12,22]

In descending necrotizing fasciitis, CT of the chest and neck is nearly 98% sensitive, with common findings including fluid collections with or without gas bubbles in the mediastinum, soft tissue thickening, loss of fat planes, and pericardial and pleural effusion.[2] In post-sternotomy mediastinitis, CT may reveal fluid collections or air along with edema (eFig. 116.3). In a series of 50 patients, CT noting such abnormalities was 100% sensitive for mediastinitis within 2 weeks of surgery but only 33% specific because some postoperative air and fluid collection is expected. After postoperative day 14, such findings were 100% sensitive and specific for mediastinitis.[25]

Pleural fluid analysis may provide valuable information in the context of an acutely ill patient with pleural effusion or hydropneumothorax secondary to undiagnosed esophageal perforation. A high level of amylase or pH less than 6.0 is suggestive of the diagnosis.[26] Food particles may also be recovered. In resource-poor settings, esophageal rupture has been established by asking the patient to drink a colored liquid and then observing passage of the liquid out of a previously placed chest tube.

MEDIASTINITIS RESULTING FROM VISCERAL PERFORATION

Two hollow nonsterile viscera transit the mediastinum: the esophagus and the trachea (continuing into proximal mainstem bronchi). Perforation or rupture of either structure, whether from disease, procedural complication, or trauma, can result in mediastinal contamination and subsequent mediastinitis.

Spontaneous Esophageal Rupture (Boerhaave Syndrome)

Hermann Boerhaave's exuberantly verbose 1724 index description of the death of 51-year-old Baron John van Wassenaer, Great Admiral of the Dutch Navy, remains a classic anecdote in medical history.[15,27,28] The Baron, experiencing indigestion following a large meal of duck, experienced sudden severe chest pain while retching after taking bitter *Carduus* (thistle root extract) to induce emesis for relief. Prescribed treatments, in addition to bloodletting and an enema, included a large volume of orally administered liquid consisting of olive and almond oil, Danzig spruce beer, oats in water, wine, and a variety of herbal tinctures and teas, each exacerbating his pain. Finally, additional emetogenic agents yielded little emesis but rapid unconsciousness and death in the 18th hour of illness. Suspecting a gastric malady, Boerhaave marveled, "What reason could there be for an empty stomach into which so much liquid had gone?" Bilateral hydropneumothoraces were discovered, and "on both sides the [fluid] color was of Danzig beer thinned with Carduus and dark red and there was distinct odor of duck flesh." A left-sided esophageal defect was discovered near the diaphragm and was correctly identified as the source of his dramatic illness.

The pathophysiology of spontaneous esophageal rupture, also referred to as effort-associated or postemetic rupture, relates to increased intraesophageal pressure during intense vomiting or, less commonly, other maneuvers (weightlifting, forceful cough or sneeze, straining, childbirth, seizure, external blast injury), such that a bubble of esophageal mucosa dissects through longitudinal esophageal muscle fibers and ruptures.[7–9,29] This most commonly happens along the left posterolateral wall of the distal esophagus, accounting for 90% of cases, although the esophagus may also rupture at its mid-thoracic and cervical walls.[7,30,31] The distal left posterolateral wall weak point is at the margin of two sets of muscle fibers and is the reliable location of rupture in experiments involving human cadaveric esophagi, in which the pressure required to cause rupture was noted to be 270 to 340 mm Hg.[30] Defects average 2 to 6 cm in length but may be up to 10 cm.[7,8]

A high index of suspicion for spontaneous esophageal rupture is required to ensure prompt recognition and rapid initiation of treatment, including surgical planning. When an acutely ill patient reports the abrupt onset of typical symptoms associated with forceful emesis, suspicion for this diagnosis tends to be appropriately high. However, altered or intoxicated critically ill patients may be incapable of providing classic historical clues and therefore may present with less differentiated chest and/or abdominal pain, with differential considerations including acute coronary syndrome, aortic dissection, perforated gastric or duodenal ulcer, and pancreatitis (see Chapter 38).

In the largest series to date, including 989 cases, the mean age was 52 years and 82% of patients were men. The most common comorbidities were alcohol abuse and peptic ulcer disease, at 40% each.[8] Historically, mortality exceeded 50%, although more contemporary series report a mortality of 10% or less with urgent management within 24 hours of onset.[8,12,32–34]

Other causes of noniatrogenic esophageal perforation include malignancy-related perforation and acute esophageal necrosis. With approximately 40 case reports since the 1960s, acute esophageal necrosis is an uncommon, likely ischemic syndrome manifesting as a black, necrotic esophagus at endoscopy; this condition is associated with vascular disease, diabetes, and malnutrition and has a poor prognosis in part related to the development of mediastinitis.[35]

Iatrogenic Injuries

Iatrogenic injury of the esophagus or trachea now accounts for the majority of cases of mediastinitis caused by visceral perforation.[1,12,18,34,36] Of various procedures conducted within these structures, therapeutic esophageal maneuvers, such as dilation or endoscopic mucosal resection, are associated with the highest incidence of perforation, at 2–6%.[36] Of the various causes, malignant lesions and benign strictures caused by caustic ingestion are at greater risk for perforation.[37–39]

Mediastinitis following diagnostic endoscopy is rare but represents an important cause given the frequency with which these procedures are performed. Esophageal perforation complicates less than 0.03% of upper endoscopies.[40] In contrast, tracheal perforation during diagnostic flexible bronchoscopy, in the absence of significant disease or intervention, has not been reported, a finding related to the greater tensile strength of the large cartilaginous airways. Airway perforation may, however, complicate therapeutic bronchoscopy. In a retrospective study of 775 rigid bronchoscopies performed over a 7-year period, there was one case (0.13%) of pneumothorax, attributed to airway laceration from laser and mechanical débridement of an endobronchial tumor, and no cases of mediastinitis.[41] It is common practice to administer antibiotics if therapeutic bronchoscopy exposes tracheal cartilaginous rings, although there are few data to guide this practice.

The esophagus and large airways are intentionally perforated during two common, analogous procedures: transesophageal endoscopic ultrasound-guided fine-needle aspiration and endobronchial ultrasound-guided transbronchial needle aspiration. During these procedures, 19- to 25-gauge needles are directed through the esophagus and airway, respectively, into lesions of interest (typically, enlarged lymph nodes) within the mediastinum under ultrasound guidance. Despite making repeated small perforations and moving needles from a nonsterile lumen through the mediastinal interstitium en route to the biopsy targets, mediastinitis develops only rarely, at a rate of 0.09% for endobronchial ultrasound-guided

transbronchial needle aspiration.[42] Sampling cystic structures, highly necrotic nodes, or mediastinal granulomas (reviewed in detail later in this chapter) may increase the risk for subsequent mediastinitis, likely related to an introduction of bacteria into the interior of a lesion with poor immune surveillance.[43–46]

Another cause of tracheal or esophageal injury is iatrogenic injury during airway management. Tracheal injuries during intubation or percutaneous tracheostomy tend to involve the muscular posterior membrane of the trachea, which lacks cartilaginous support, resulting in longitudinal tracheal defects.[47] Treatment ranges from conservative management with antibiotics alone, particularly when ongoing mechanical ventilation is not required, to airway stenting or surgical repair.[48] Esophageal perforation has been described when airway adjuncts that engage the esophagus, such as the esophageal obturator airway, are used.

Other rare iatrogenic causes of esophageal perforation include transesophageal echocardiography, reported at a rate of 0.01% in a study of more than 7200 cardiac surgical patients, and central venous catheter migration into the mediastinum[49,50] (eFig. 116.4, Video 116.1).

Other Visceral Insults

Other mechanical or chemical trauma to the esophagus or trachea may result in perforation and mediastinitis (eFig. 116.5, Video 116.2). Penetrating and blunt trauma to the chest results in airway disruption with an incidence of 0.5–2% for both mechanisms of injury.[51] Penetrating cervical injury is more likely to result in tracheal injury than is thoracic trauma, with an incidence of up to 8%.[51] Esophageal injury accompanies airway injury in approximately 30% of penetrating cervical trauma cases and 10% of cases of penetrating chest trauma.[51] Injurious ingestions are another cause of esophageal injury. One series described six prison inmates who swallowed hypodermic needles fashioned into the shape of stars to win temporary reprieves from incarceration, all of whom required surgical intervention.[52] Intentional and accidental ingestions of corrosive agents, including alkaline ingestions such as lye or alkaline batteries, acidic compounds, or paraquat (an herbicide that causes tissue injury via oxidative stress) are well-described causes of esophageal injury.[38]

MEDIASTINITIS SECONDARY TO EXTENSION FROM OUTSIDE THE MEDIASTINUM

Although its lateral aspects are enclosed by the mediastinal portion of the parietal pleura on either side, the mediastinum is contiguous superiorly with deep spaces of the neck and inferiorly with the abdomen. The same fascial plane investing the trachea, esophagus, and carotid sheaths extends through the thoracic inlet with these structures, then through the diaphragm with the descent of the esophagus, aorta, and inferior vena cava into the retroperitoneum, thus comprising the visceral space. Additional deep spaces in the neck are contiguous with the mediastinum, including the prevertebral, retrovisceral (divided into the "retropharyngeal" and "danger" spaces by the alar fascia), and pretracheal spaces[3,53] (Fig. 116.3).

Descending Necrotizing Mediastinitis

Acute mediastinitis caused by direct extension of an oropharyngeal or cervical infection is most commonly referred to as descending necrotizing mediastinitis, so named because the infection descends via one of the deep spaces in the neck into the mediastinum and is classically polymicrobial, including gas-producing organisms that effect rapid tissue necrosis.[4] This life-threatening complication of periodontal, peritonsillar, odontogenic, or pharyngeal infection is rare, with approximately 400 cases reported between 1960 and 2008.[2] The preantibiotic mortality rate of 50% has steadily declined but remains significant at 10–15% in more contemporary series.[2,4,54,55] Pharyngeal infections have overtaken odontogenic infections as the most common source.[2] Extension into the posterior mediastinum via the "danger space" subdivision of the retrovisceral space appears most common, up to 70% in some series, where infection may also access both pleural spaces, the pericardium, and the abdomen.[2,4,54–56] Gravity and negative intrathoracic pressure rapidly propagate infection into the mediastinum once pathogens violate fascial planes to gain access to a deep space in the neck. Infection descending into one mediastinal compartment often does not remain confined there, given the necrotizing nature of this infection.[2]

Clinical manifestations of descending necrotizing mediastinitis may be masked by symptoms of the cervical or oropharyngeal infection, thereby causing a delay in diagnosis. In one series, one-third of patients had already been hospitalized at another institution before the diagnosis was established.[2] Dyspnea, chest discomfort, and signs of worsening sepsis should prompt further investigation for mediastinitis. Involvement of the pericardium may lead to tamponade. Patients with descending necrotizing mediastinitis may have widening of the retrovisceral space, with or without associated air-fluid levels. CT scans of the neck and chest are usually definitive[2,4] (Fig. 116.4).

Ascending and Other Uncommon Causes of Mediastinitis From Direct Extension

Rarely, mediastinitis may result from intra-abdominal processes. Pancreatic disease is a rare but well-known cause of pleural disease, typically by way of pancreaticopleural fistulas extending through the esophageal or aortic hiatus connecting pancreatic pseudocyst to the left pleural space. Acute or recurrent pancreatitis can lead, by similar mechanism, to enzymatic mediastinitis, a rare example of a noninfectious cause of acute mediastinitis.[57,58] Ascending mediastinitis has also been associated with emphysematous pyelonephritis.[59] Benign gastric or esophageal ulcers have rarely been reported to rupture into the mediastinum or sometimes into the pericardium, with subsequent mediastinitis or pneumopyopericardium.[60,61] Tuberculous osteomyelitis involving the vertebrae (Pott disease) or ribs has rarely been reported to contaminate the mediastinum by direct extension.

MEDIASTINITIS FOLLOWING CARDIAC SURGERY

Mediastinitis after cardiac surgery is another significant manifestation of iatrogenic acute mediastinitis in the modern era. Most cases result from direct extension via an infected median sternotomy incision. Mediastinal infection

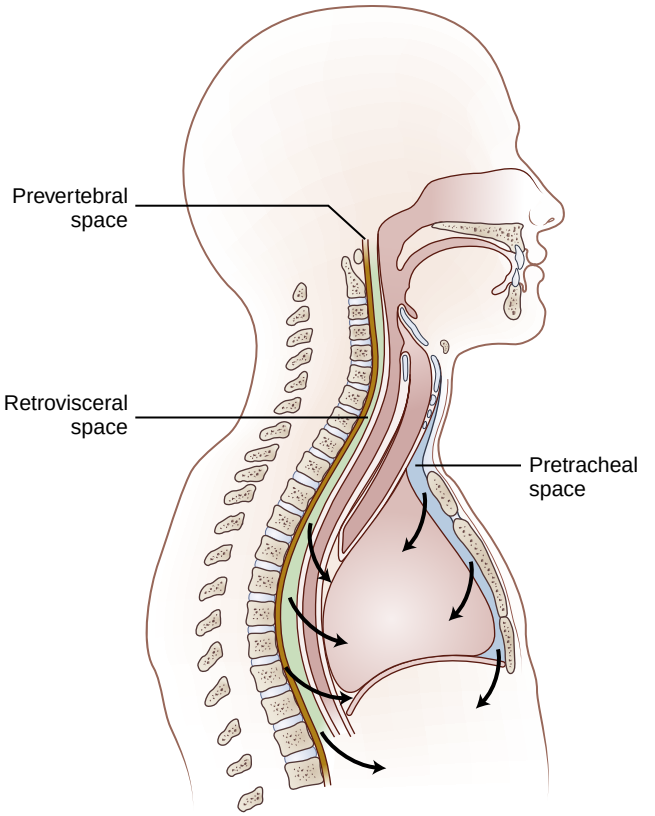

Figure 116.3 Deep spaces of the neck and their communication with the mediastinum. The retrovisceral space is commonly divided into the danger space (extending to the diaphragm) and the retropharyngeal space (terminating at T1), which are separated by loose alar fascia. (Modified from Freeman RK, Vallières E, Verrier ED, et al. Descending necrotizing mediastinitis: an analysis of the effects of serial surgical debridement on patient mortality. *J Thorac Cardiovasc Surg.* 2000;119:260–267.)

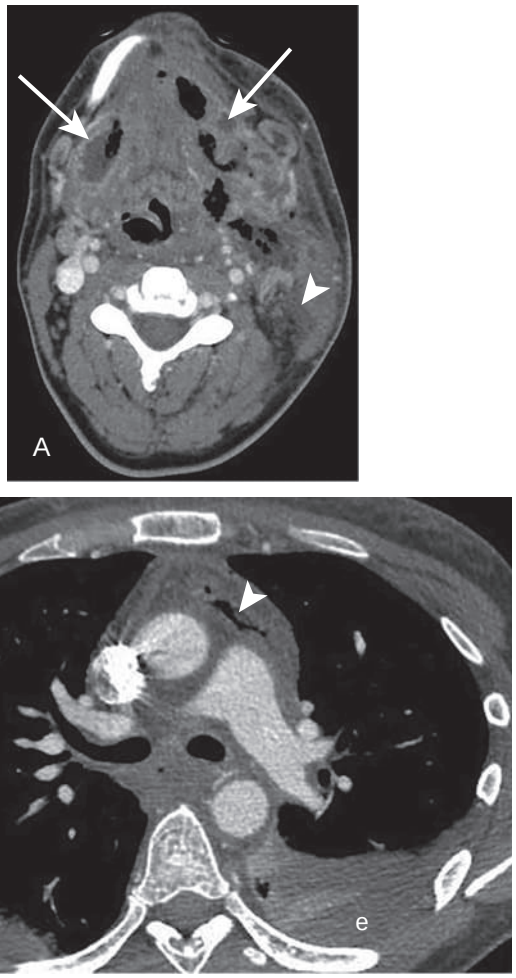

Figure 116.4 Descending necrotizing mediastinitis. (A) Axial enhanced neck computed tomography shows bilateral abscesses near the submandibular spaces (*arrows*) with soft tissue gas and fat stranding (*arrowhead*) in the left posterior triangle. (B) At the level of the main pulmonary artery, pneumomediastinum (*arrowhead*) is evident. Soft tissue infiltration is present throughout the anterior mediastinum and left-greater-than-right pleural effusions (e) are present.

following cardiac surgery is uncommon, with an estimated incidence of approximately 1% in most contemporary series.[5,62] Given the frequency with which cardiac surgery is performed and the widespread use of median sternotomy, post-sternotomy mediastinitis has become a substantial clinical problem, with a mortality rate of 20–30%.[5,6]

Risk factors associated with the development of mediastinitis after cardiac surgery in several large series consisting of more than 40,000 patients included diabetes mellitus, obesity, use of internal mammary arteries (higher risk if bilateral), prolonged operation, postoperative intensive care unit stay exceeding 5 days or ventilation exceeding 48 hours, need for reexploration, and assist device implantation.[5,6,63–66] Other comorbidities, such as COPD, advanced age, and renal failure, have been reported in some studies. Diabetic patients undergoing coronary artery bypass grafting in which both internal mammary arteries are used appear to be at especially high risk for post-sternotomy mediastinitis and have a higher mortality than nondiabetic patients experiencing the same complication.[5] Guidelines developed to reduce the risk of postoperative deep sternal wound infections include the use of topical nasal mupirocin to curb *Staphylococcus* carriage, a preoperative chlorhexidine bath or shower, strict perioperative glycemic control, appropriate perioperative antibiotic use and application of topical antibiotics to the cut edges of the sternum, avoidance of bone wax, and careful attention to techniques to maintain sternal stability in patients at higher risk for sternal malunion (including patients with obesity or COPD).[67] Several series report nearly total elimination of post-sternotomy mediastinitis after institution of some of these suggested best practices.[68,69] The use of a skeletonized rather than pedicled internal mammary graft harvest technique has also been suggested to reduce the risk.[70] The reason for this difference may be that skeletonized grafts, in which the artery is dissected away from associated lymphatic and venous drainage, preserve more collateral circulation to the sternum than do pedicled grafts.

Cardiac surgery–related mediastinitis tends to be less acutely devastating than in the settings described previously. The clinical course consists of fever and systemic signs, followed by bacteremia and local signs of wound infection.[71] The diagnosis is usually made at the time of reexploration of the sternotomy wound and rests on a high clinical suspicion in the appropriate setting. CT is particularly helpful in identifying and discerning soft tissue swelling, fluid

collections, and sternal erosion or dehiscence[72] (see eFig. 116.3). Patients with fever, positive blood culture results, and wound abnormalities in the post-sternotomy period should be evaluated surgically to confirm the presence of mediastinitis, and any necessary débridement should be performed.

"SPONTANEOUS" OR "PRIMARY" MEDIASTINITIS

Acute mediastinitis in the absence of visceral perforation, descending or ascending infection, recent cardiac surgery, trauma, or another obvious direct-extension mechanism is extremely rare but has been reported. Such cases fall into two categories: spontaneous mediastinitis typically involving *Streptococcus* species and inhalational anthrax.

Spontaneous Mediastinitis

Acute mediastinitis has been reported in the absence of the typical predisposing and etiologic factors reviewed earlier in this chapter. Known in the literature predominantly by case reports, such cases have been labeled "spontaneous mediastinitis" or "primary mediastinitis." Some cases coincide with known foci of infection, such as pneumonia, empyema, or bacteremia,[73–76] whereas others have been reported in isolation of any known infectious source.[77,78] The mechanism of mediastinal infection is presumed to be bacteremia or extension directly or via lymphatic transit in patients with comorbid pneumonia and/or empyema.

Hemorrhagic Mediastinitis Secondary to Inhalational Anthrax

Anthrax, caused by *Bacillus anthracis* infection, is primarily a disease of livestock and is historically most prevalent in the Middle East, although it remains endemic in the soil with sporadic but worldwide distribution.[79] More recently, anthrax has emerged as an important disease of bioterrorism. Clinical syndromes are classified by the primary site of infection: cutaneous, gastrointestinal, injectional, or inhalational.

Inhalational anthrax, or *woolsorter's disease*, is contracted by inhaling *B. anthracis* spores, which are highly resistant to environmental degradation.[79] Spores inhaled into distal conducting airways and alveoli are ingested by pulmonary macrophages and are transported to hilar and mediastinal lymph nodes. Here, *B. anthracis,* which resists killing because of its capsule, produces large amounts of two toxins, lethal factor and edema factor, leading to local edema, necrosis, and hemorrhage characteristic of hemorrhagic mediastinitis, followed by pathogen and toxin leakage into the systemic circulation, with resulting septic shock and death.[79,80]

Sporadic inhalational anthrax is rare. Before bioterrorism-related incidents in 2001, the last fatal domestic case, attributed to yarn imported from Pakistan, was in 1976.[81] Modern clinical knowledge of inhalational anthrax has been derived from several outbreaks. An accidental release of weapons-grade anthrax in Sverdlovsk, Russia, in 1979 resulted in at least 42 deaths.[82,83] In 2001, intentional dispersion of *B. anthracis* spores via the U.S. Postal Service resulted in 11 cases each of cutaneous and inhalational anthrax, with five deaths in the latter group.[84,85] Incubation time is typically 4 to 6 days, followed by onset of a biphasic illness with an initial prodromal flu-like phase lasting 2 to 4 days characterized by fever, malaise, myalgias, and nonproductive cough. This is followed by a fulminant phase of acute mediastinitis, respiratory distress, chest pain, and septic shock culminating in death within days.[80,84–86] Antibiotics in the prodromal phase may be lifesaving, but treatment initiated in the fulminant phase is unlikely to change the clinical course.[86]

Chest radiographs and chest CT scans typically show mediastinal widening and pleural effusions.[87] The triad of hemoconcentration, widened mediastinum, and altered mental status is characteristic.[88] The diagnosis is established by demonstration of gram-positive, boxcar-shaped bacilli in tissue or body fluid specimens or in the blood buffy coat. Direct fluorescent antibody testing, polymerase chain reaction, and serologic tests are available for confirmation. Prompt antibiotic administration at the first suspicion of anthrax is the cornerstone of treatment. Historically, inhalational anthrax is a devastating disease even with appropriate treatment: 12 of 13 well-documented sporadic cases in the United States had fatal outcomes.[81] In the 2001 bioterrorism outbreak, prompt diagnosis and initiation of antibiotic therapy in addition to aggressive drainage of mediastinal and pleural collections resulted in survival of 6 of 11 patients.

MANAGEMENT OF ACUTE MEDIASTINITIS

Acute mediastinitis management nearly universally focuses on two interventions: prompt initiation of appropriate antimicrobial coverage and timely mechanical débridement. Additionally, patients with suspected esophageal perforation should immediately cease oral intake and be started on gastric acid suppression.

Microbiology and Antimicrobial Selection

The microbiology of mediastinitis varies according to the mechanism of infection. In mediastinitis complicating esophageal perforation or descending necrotizing mediastinitis, the predominant microorganisms are oral and upper aerodigestive tract flora. An estimated 40–60% of such infections are polymicrobial, most often a mix of anaerobic and aerobic bacteria.[2,89] Most nonmixed infections are anaerobic, with aerobic infections accounting for approximately 20% of cases.[2,89] Commonly isolated anaerobes include *Bacteroides*, *Peptostreptococcus*, *Fusobacterium*, *Propionibacterium*, and *Prevotella* sp. *Streptococcus* sp dominate among aerobic isolates in most series, with *Staphylococcus*, *Haemophilus*, *Klebsiella*, and *Pseudomonas* sp isolated with less frequency.[2,89] Accordingly, broad antibiotic coverage, including agents active against gram-negative, gram-positive, and anaerobic organisms, is prudent in such cases.

Post-sternotomy mediastinitis is most often caused by skin flora. *Staphylococcus epidermidis* and *Staphylococcus aureus* are the most frequent isolates in most series.[65,90–93] Polymicrobial infections are present in a significant proportion of cases (6–20%). More contemporary series also report that significant numbers of infections are caused by gastrointestinal pathogens, with *Enterobacteriaceae*

accounting for 25% of deep sternal wound infections in one series.[92] Methicillin-resistant *S. aureus* remains an uncommon cause, accounting for approximately 0.5–2% of cases.[92,94]

Fungal mediastinitis related to any etiologic mechanism is rare but can be devastating. *Candida* species are uncommonly recovered from mediastinal cultures following esophageal violation or cardiac surgery, with mortality rates reported in excess of 70%.[95] *Aspergillus* mediastinitis has also been reported in the context of recent cardiac surgery or descending necrotizing mediastinitis, and it has a high fatality rate.[96,97] Other angioinvasive fungi are reported as infrequent causes of fungal mediastinitis, such as mediastinal mucormycosis, with mortality exceeding 85%.[98] Tuberculous and nontuberculous mycobacteria are other uncommon causes of post-sternotomy mediastinitis, with tuberculosis accounting for 95% of mycobacterial sternal wound infections in a study involving cases from 23 countries but dominated by cases from India.[99]

When hemorrhagic mediastinitis of inhalational anthrax is suspected, ciprofloxacin or doxycycline with a second agent, either clindamycin or penicillin, is recommended.[88] Anthrax is resistant to third- and fourth-generation cephalosporins. Most patients in the bioterrorism outbreak were treated with multiple agents including a fluoroquinolone.[84] For postexposure prophylaxis, ciprofloxacin or doxycycline orally along with immunization with antitoxin antibodies is recommended.[88,100]

Mechanical Débridement: Operative, Percutaneous, and Endoscopic Interventions

Débridement and/or percutaneous drainage of infected or inflamed mediastinal tissues is typically necessary in acute mediastinitis, although the approach and urgency of débridement may vary widely, reflective of the wide variation in causes of mediastinitis.

Mediastinitis with frank uncontrolled sepsis requires urgent surgical intervention. Such is typically the case in classic Boerhaave syndrome and descending necrotizing mediastinitis. In esophageal rupture, mortality has been reported to increase from 10–15% to 40–60%, because of the onset of multiorgan dysfunction, when intervention (or presentation) is delayed more than 24 hours.[12,32–34] The surgical approach varies according to the location of the esophageal defect and other affected mediastinal or pleural structures.[12] Rarely, nonoperative management in the setting of a significant esophageal defect may be considered. Several investigators have reported successful medical management when sepsis is absent several days after the injury, a wide-mouthed defect is well encapsulated within the mediastinum and contents can freely drain back into the esophagus, and the pleural spaces are uninvolved, among other criteria.[101–103] In descending necrotizing mediastinitis, delay in diagnosis, delay in operative intervention, and lack of thoracotomy to permit comprehensive mediastinal exploration and débridement, in addition to transcervical drainage, have been associated with worse outcomes. With prompt intervention, including thoracic exploration, mortality rates of 10–15% have been reported, with one meta-analysis suggesting a mortality of 47% with the transcervical approach alone.[2–4,54]

Similarly, post-sternotomy mediastinitis requires early surgical exploration with débridement and drainage, in addition to appropriate antimicrobial therapy.[5,66,71,90,96] The clinical course of severe mediastinitis secondary to visceral perforation, descending infection, or post-sternotomy status often includes reoperation and prolonged hospitalization.

Because most mediastinitis cases from perforated viscus in the modern era relate to endoscopic injuries or surgical anastomotic complications that often have a more indolent course and/or more focal mediastinal involvement, percutaneous and endoscopic interventions have emerged as options in selected cases. Percutaneous intervention can be used to drain focal abscesses or fluid collections related to perforation if more widespread mediastinal contamination is absent (eFig. 116.6). In one series describing 51 patients, 3 patients died before intervention, 31 underwent standard thoracotomy and repair that led to 11 deaths, and 17 highly selected patients with contained mediastinal contamination by imaging and endoscopic inspection were managed successfully with targeted drainage and antibiotic therapy.[13] Endoscopic therapies include clips, stents, tissue adhesives, endoscopic stitching, and vacuum therapy. Reports of these treatments often suggest success rates higher than 80% in selected patients, although these reports are generally case series and so are limited in methodologic vigor.[18,36,104,105]

FIBROSING MEDIASTINITIS AND MEDIASTINAL GRANULOMA

There are two notable syndromes of chronic mediastinal inflammation and/or fibrosis: *fibrosing mediastinitis* (FM) and *mediastinal granuloma* (MG). A third subacute inflammatory syndrome, mediastinal adenitis, is also reviewed, given a degree of clinical overlap with early MG.

FM describes a progressive fibrotic mass typically emanating from a mediastinal lymph node station that causes fusion of adjacent tissue planes and invasive incorporation into and stenosis or obliteration of nearby structures, including pulmonary arteries, veins, airways, *superior vena cava* (SVC), or esophagus[106] (Fig. 116.5). MG refers to a thinly encapsulated collection of semiliquid granulomatous debris typically comprising coalesced necrotic mediastinal lymph nodes, which often become partially or entirely calcified with time[106,107] (Fig. 116.6). Mediastinal adenitis refers to robust enlargement of an involved hilar or mediastinal lymph node related to acute or subacute granulomatous pulmonary infection[106] (eFig. 116.7).

All three syndromes are most commonly attributed to aberrantly robust and persistent immune responses to *Histoplasma*, an environmental fungus with wide distribution worldwide and the most common endemic mycosis in the Americas.[106] A syndrome similar to post-*Histoplasma* FM has been described in association with IgG4-related disease, granulomatosis with polyangiitis, and rare histiocytic disorders. MG and mediastinal adenitis can also result from other granulomatous infections, namely from tuberculosis in endemic areas.

Distinguishing these syndromes from one another and, in the case of FM, determining whether the syndrome is a

post-*Histoplasma* condition or has another cause, is imperative prognostically and therapeutically because there is wide variation in appropriate treatments and prognosis among these entities[108–110] (Table 116.2). Chapter 115 discusses mediastinal tumors and cysts, which may also occasionally be challenging to distinguish on presentation.

FIBROSING MEDIASTINITIS

Most of the population of several millions in the middle of the United States has been infected with *Histoplasma capsulatum*, usually with no recognized symptoms. The most severe late complication of *Histoplasma* exposure or infection is *post-Histoplasma fibrosing mediastinitis* (PHFM). Twenty percent of all PHFM patients have involvement of both lungs, a condition that carries a very high mortality.[111,112] If mediastinal structures are involved bilaterally, the disease is almost uniformly fatal.[113] The prevalence of PHFM has not been described; however, as an indication of its prevalence, in a single institution in Tennessee an average of 10 new PHFM patients have been evaluated annually for several decades.[112,114]

No other infection triggers a syndrome like PHFM. Even before modern imaging, observant clinicians noted 4 decades ago, "it is difficult to prove that all cases of MG and FM are due to histoplasmosis when the cultures and

Table 116.2 Key Distinguishing Features of Fibrosing Mediastinitis and Mediastinal Granuloma

Fibrosing Mediastinitis	Mediastinal Granuloma
Solid fibrotic mass	Large, heterogeneous mass composed of thinly encapsulated semiliquid debris
Usually contains calcification, from punctate to highly calcified	No calcification in early MG; late MG with pathognomonic speckled, subcapsular, or uniform calcification
Invasive stenosis or obstruction of vasculature or airways	No stenosis or stenosis by extrinsic compression
Age >10 yr, usually 20–40 yr	Age >2 yr, incidental finding at any age
Unilateral loss of lung function in 80%; lethal in 20% with bilateral disease	Mostly asymptomatic; rarely fistulizes and drains to nearby structures; mortality very rare
Surgery high risk; vascular stenting may increase survival in bilateral disease	Resection is indicated for symptomatic disease
Most commonly post-*Histoplasma*; rare idiopathic noncalcified form associated with IgG4-RD, GPA, histiocytic disorders that may respond to medical therapy	Most commonly post-*Histoplasma*; can be precipitated by other granulomatous infections (e.g., tuberculosis)

GPA, granulomatosis with polyangiitis; *IgG4-RD,* immunoglobulin G4–related disease; *MG,* mediastinal granuloma.

silver stains are so often negative; however, we have not seen FM with tuberculosis or sarcoidosis."[115] The report bearing those words was the final in a series describing 124 patients with PHFM or MG during 25 years at a single institution. The investigators provided remarkable insight, but their hypothesis that FM is caused by rupture of fibrocaseous material from mediastinal lymph nodes has been shown to be incorrect.[112] The premise that MG was the basis for PHFM led to an era of frequent resection of MGs to prevent FM, a practice that, unfortunately, still has some advocates.[116] PHFM and MG are distinctly different clinical syndromes, with distinct natural history, which are clearly distinguishable in most cases and have different therapies.[112]

Although the basis for PHFM remains unknown, it is hypothesized that rare individuals carry a predisposition to respond excessively to *Histoplasma* cell wall remnants in mediastinal lymph nodes, thus provoking dense scar formation that invades deep within vital mediastinal structures.[108] PHFM is associated with human leukocyte antigen DQB1*04:02. In 58 PHFM patients who were studied using genome-wide association, loci were identified that provide possible clues to the location of a profibrotic genetic variant.[117,118]

Clinical Features

PHFM typically affects young adults in the second through fourth decades of life. Symptoms are often acute but belie a slow, silent progression of fibrosis to a threshold that leads to first symptoms when flow is critically reduced in vessels or airways. Hemoptysis, chest pain, and dyspnea are common.[112] Most PHFM patients (80%) ultimately experience loss of function of one lung; among those patients, most (80%) lose function of the right lung, typically by occlusion of the proximal right pulmonary artery.[112] Unilateral loss of lung function from PHFM has a generally favorable prognosis, except when serious hemoptysis caused by systemic collateral arteries arises, which may be life-threatening.[106] In contrast, bilateral involvement with PHFM has very high mortality, although this may be improved by vascular stenting.[111,113,114]

Diagnosis

The features necessary to confirm a clinical diagnosis of PHFM include (1) invasive obstruction of pulmonary arteries or veins, SVC, or airways, in nearly any combination, resulting from a (2) mediastinal mass usually containing calcification (from punctate to highly calcified), in the (3) absence of emboli, cancer, radiation, or another cause.[112]

When all features of PHFM are present, a confident diagnosis may be made without the need for tissue sampling, especially when results of *Histoplasma* serologic tests (by complement fixation and/or immunodiffusion) are positive, as seen in about one-half the patients.[106] CT imaging is typically diagnostic in the appropriate clinical setting. In the past, diagnostic thoracotomy was often conducted, at significant risk.[112] An operative finding of fibrotic tissue within the mediastinum does not, by itself, indicate FM because focal mediastinal scarring has many potentially causes.

Only a few PHFM patients report a history of acute *Histoplasma* infection, a finding that is not surprising because most of the population in the middle of the United States is routinely infected without identifiable symptoms.[109] The burden of organisms in FM is typically very low, and organisms are not viable in culture, so antigen testing results are negative, and surgical biopsy rarely identifies organisms.

Treatment

PHFM patients with obstruction of vessels of both lungs are at greatest risk and may benefit the most from cardiac catheterization at expert centers to attempt intravascular stenting of pulmonary arteries, veins, or both.[114] Pulmonary veins are commonly involved but may be easily overlooked because they are sites not commonly affected by other diseases. SVC occlusion may have surprisingly few symptoms when adequate collateral flow has developed, which speaks to the indolent nature of this disease. When SVC syndrome does develop, stenting may provide significant symptom relief.[119]

Presumably, fibrosis in PHFM progresses in the period before clinical presentation because clinically important disease progression is uncommon after diagnosis. Disease progression is sometimes observed at sites that were formerly affected but typically has little clinical impact; for instance, subsequent occlusion of a pulmonary vein has no significant physiologic impact when the ipsilateral pulmonary artery is already occluded. Although progression of the disease to involve new sites is uncommon, some centers pursue annual CT angiography to screen for new involvement of structures in the contralateral unaffected lung.

Antifungal and other medical therapies including steroids have no apparent impact on the development or

progression of PHFM. Treatment with rituximab has been associated with decreased activity on positron emission tomography scan in three patients.[120] Convincing evidence that rituximab has a clinical impact on the course or outcome of PHFM, however, has not been reported to date.

Hemoptysis may be severe and even life-threatening, related to systemic bronchial arterial collateral formation in the setting of pulmonary artery compromise or to pulmonary venous hypertension in the setting of venous obstruction. The former can usually be controlled by bronchial artery embolization, whereas the latter, typically caused by disruption of fragile engorged submucosal veins that result from impaired venous drainage, can be temporized by ablative bronchoscopic interventions, although these procedures also risk precipitation of more airway hemorrhage.

Surgery with a therapeutic intent in PHFM is rarely beneficial and is very high risk because the tissues are hypervascular and normal tissue planes are fused, thus making blunt dissection impossible. This can be a particular problem in uncommon situations in which it is difficult to distinguish PHFM from MG because surgery is the only clearly effective treatment for symptomatic MG.

Idiopathic Fibrosing Mediastinitis and Fibrosing Mediastinitis From Other Causes

In the United States, PHFM comprises more than 95% of FM cases. *Idiopathic fibrosing mediastinitis* (IFM) is clinically distinct and important to distinguish because some patients with IFM respond to medical therapy, unlike in PHFM.[110] IFM is typically more diffuse and bulkier, less invasive, and not calcified, and it affects extrathoracic sites such as the retroperitoneum in one-half of patients. When imaging suggests IFM, then IgG4-related disease, granulomatosis with polyangiitis, Erdheim-Chester disease, and other rare conditions should be sought. Unlike PHFM, IFM may regress spontaneously or with medical therapy. The distinction of IFM from PHFM is not well delineated in the literature. In at least one series describing IFM, a CT image was included showing a large, heavily calcified subcarinal node, the classic clinical signature of PHFM, but that was not identified as such by the pathologist investigators.[121] The absence of identifiable organisms in pathology samples does not exclude *Histoplasma* as the original trigger.

MEDIASTINAL GRANULOMA

MG is the gross pathologic term for a conglomerate mass of caseous lymph nodes. A resected MG may not contain any microscopic granulomas or organisms on staining or culture, and it may be hilar in location rather than mediastinal. MGs may be quite large (5 to 10 cm) and single or multiple, and they typically contain semiliquid contents with the consistency of toothpaste or putty inside a thin, 2-mm capsule.[115] MGs comprise as many as 10% of resected mediastinal masses in some series.[115] Mycobacteria are known to cause MG, and these organisms should be sought in the appropriate demographic circumstances. The pathogenesis of MG, akin to that of FM, appears to result from an excessive host response rather than from active proliferation of organisms because antifungal treatment has no demonstrable impact on the course, and the organism fails to grow in culture. Whereas PHFM is presumed to develop late (years) after infection, MG may be seen either late (with calcification) or early, within months of infection, in which case no calcifications are yet present and it may be difficult to distinguish from mediastinal adenitis.

Clinical Features

MG can manifest at any age, even in children as young as 2 years, sometimes with calcifications even at that age. Historical *Histoplasma* skin testing in the 1950s showed positive results in one-half the children by the age of 1 year in some regions.[122] In contrast, FM is very rare at ages younger than 10 years. MGs may extrinsically compress vessels or airways, especially in young children, but because MGs are not invasive they can generally be dissected away from mediastinal structures.

Diagnosis

MGs are most often located in the right paratracheal region, where they are apparent on plain radiography (see Fig. 116.6), but they also commonly manifest in the subcarinal region, which may be hidden on a chest radiograph. CT has much greater sensitivity and specificity than plain radiography, so studies performed before the widespread use of CT in the chest (before ~1980) have serious limitations. Heterogeneity of the density is the most characteristic feature, and late MGs also exhibit pathognomonic speckled, subcapsular, or uniform calcification (eFig. 116.8; see also Fig. 116.6). Serologic titers for *Histoplasma* are positive in one-half of patients, and antigen testing results are usually negative.

MGs, for unclear reasons, occasionally become reinflamed and may attach, fistulize, and drain their contents into an adjacent structure such as the esophagus, bronchus, lung parenchyma, pleural space, subcutaneous space in the neck or, rarely, the pericardial space.[123] Specific imaging findings to indicate that an MG has drained may include a decrease in size, new air density within the MG, or a decrease in the number of individual calcifications within an MG (Fig. 116.7). Spontaneous marked decrease in size is occasionally observed and sometimes is erroneously attributed to successful antifungal treatment, although silent fistulization to the esophagus is the more likely explanation, especially if the calcification burden has decreased, which should never happen with antifungal therapy (Fig. 116.7, eFig. 116.9). When MG drains to an airway, to the soft tissue of the neck, or along the tract of a mediastinoscopy scar, recognizable clinical signs of the drainage are obvious. Sometimes there is recurrent drainage, typically to the same site. New chest pain seems to be a harbinger of fistulization and drainage in patients with late MG.

Despite their often pathognomonic appearance, MGs may not be recognized as such. When a radiologist incorrectly characterizes MG as FM, appropriate surgery may not be pursued because of the widely recognized surgical risk of FM. Conversely, when a radiographically classic MG is construed to be an indeterminate lesion, unnecessary tissue sampling may result in infectious complications (see the earlier discussion of acute mediastinitis secondary to visceral perforation).[46] In patients with early MG, when calcifications have not yet developed, suspicion of lymphoma and lack of awareness of MG and the possible therapeutic role for surgery can lead to a suboptimal operation in which only a diagnostic procedure is attempted.

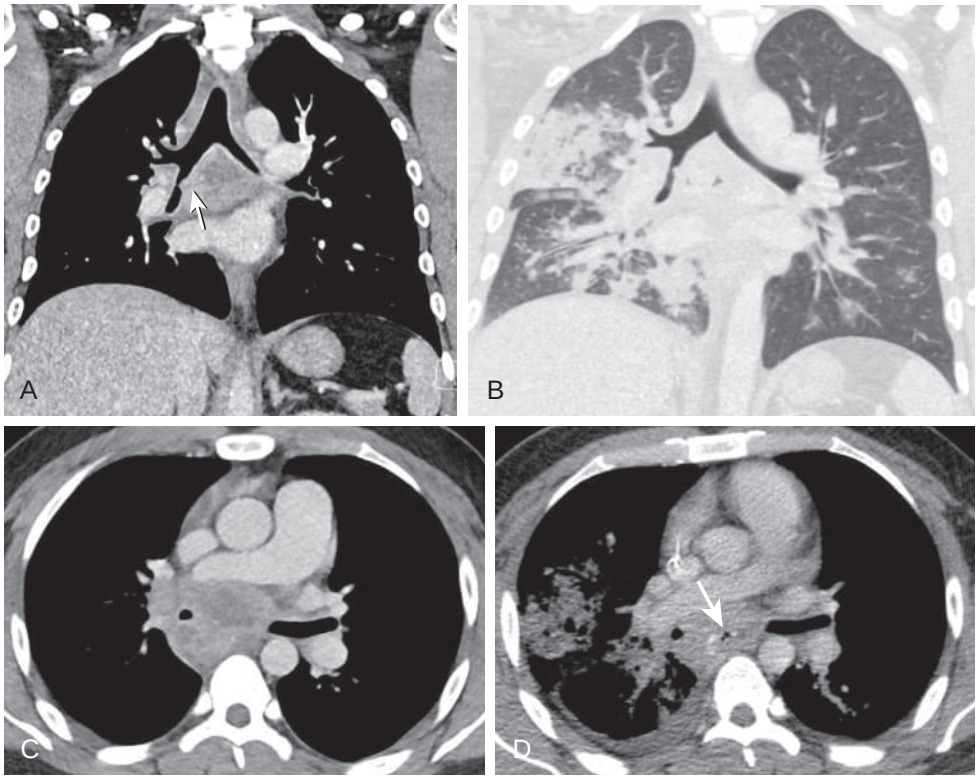

Figure 116.7 Mediastinal granuloma in a 23-year-old man with spontaneous fistulization to esophagus, bacterial superinfection, and then fistulization to bronchus intermedius. (A and C) Large, heterogeneous subcarinal mediastinal granuloma with punctate calcifications and nodular protrusion into the bronchus intermedius (*arrow* in A). (B and D) Following fistula formation at the site of nodular bronchus intermedius protrusion, the subcarinal mediastinal granuloma has decompressed part of its contents into the right-sided airways, thus causing multifocal consolidations. Residual mediastinal granuloma is smaller and has fewer calcifications, and foci of air (*arrow* in D) are now present within it. (Courtesy Robert J. Lentz, MD.)

Treatment

Surgical drainage is the most effective therapy, and it is appropriate when MGs are symptomatic because they can usually be resected at low risk, sometimes by a thoracoscopic approach. Resection should remove the free wall and semiliquid contents; components adherent to vital mediastinal structures may be left in place without apparent consequence. If MG contents are spilled, such as to the pleural space, they do not appear to be inflammatory.

Treatment of MG with antifungal agents is often recommended because it is generally safe, but evidence of efficacy is minimal. In general, MGs are avascular, so it seems unlikely that antifungal agents reach therapeutic concentrations in their interior, but no data exist.

MG drainage to central airways, into prior surgical sites such as a tract left by the mediastinoscope, or into the soft tissues of the neck is usually apparent and often bothersome but generally not dangerous. When MGs drain into the esophagus, they sometimes develop retrograde superinfection with enteric bacteria and require broad-spectrum antibiotics and possibly resection[124] (see Fig. 116.7). MGs may also become infected from bacteria inoculated during endobronchial ultrasound-guided transbronchial needle aspiration sampling, where immune surveillance and antibiotic therapy do not appear to be sufficient to handle the introduced bacteria[46] (see eFig. 116.8). Rarely, MGs may drain into the pericardium and cause pericardial tamponade or fistulize to multiple sites including esophagus and pericardium[123] (see eFig. 116.9). These life-threatening scenarios are very rare and are amenable to surgical correction, so mortality from MG is extremely rare, a finding contrasting with the very high lethality of bilateral PHFM involvement.

MEDIASTINAL ADENITIS

Histoplasma is unique in many respects, including its propensity to cause inflammatory mediastinal adenopathy. Because the late syndromes FM and MG involve the same lymph node sites, they seem likely to be related to prior adenitis, although serial imaging from the early stage through late complications is hardly ever available.

It is not known why some individuals are predisposed to develop symptomatic mediastinal adenitis. The burden of inhaled spores does not seem to be the explanation because massive inhalation can cause dozens of nodules affecting both lungs, but with no higher rate of mediastinal adenitis. Similarly, there is essentially no understanding why some individuals develop FM and other individuals develop MG, whereas most persons who are exposed to *Histoplasma* develop only small calcifications distributed throughout mediastinum, hilum, and lung parenchyma, faithfully reported as incidental "old granulomatous disease" on subsequent imaging studies.

Clinical Features

Severe central chest pain, typically worse during inspiration, which accompanies fever in a young adult, along with imaging showing enlarged mediastinal lymph nodes without calcification, is a typical presentation. There are no data on whether symptomatic mediastinal adenitis is required to produce late complications after *Histoplasma* infection.

Diagnosis

Clinical features in the appropriate radiographic setting are highly suggestive, so that with a characteristic presentation, experienced physicians recognize the syndrome and then confirm it with serologic titers, which are positive in 80% of patients[109,125] (see eFig. 116.7).

Other organisms, including mycobacteria, certainly cause mediastinal or hilar adenopathy and should be sought in appropriate clinical settings; however, patients with these disorders do not present with severe inspiratory pain. Deposition of calcification eventually develops in most affected nodes but it may require years, so an early MG that has not yet developed calcification may be difficult to distinguish from adenitis. CT imaging demonstrating coalescence of nodes and heterogeneous density of contents would argue for transition to early MG.

Treatment

The symptoms of mediastinal adenitis remit spontaneously after a few weeks. However, the enlargement of affected nodes often persists because MGs with characteristic calcifications are evident after several years.

Oral antifungal agents are commonly recommended, and they seem prudent to use to avoid dissemination when corticosteroids are given for symptomatic relief. There remains, however, no evidence that antifungal treatment alters the incidence of late complications (i.e., development of FM or MG).

ACKNOWLEDGMENTS

We thank Erin A. Gillaspie, MD, for her critical review and support of this work.

Key Points

- Acute mediastinitis, a severe clinical syndrome with high morbidity and mortality, most commonly results from spontaneous or iatrogenic perforation of the esophagus, descending necrotizing infection of pharyngeal or odontogenic origin, or deep poststernotomy wound infection.
- All forms of acute mediastinitis are life-threatening and require prompt diagnosis, imaging, mechanical débridement most commonly in the form of surgical intervention, and antimicrobial treatment.
- Fibrosing mediastinitis and mediastinal granuloma are late sequelae of *Histoplasma* infection (rarely, other causes) resulting from an aberrant immunologic response rather than the result of progressive infection.
- Fibrosing mediastinitis describes dense invasive scarring that integrates into adjacent vasculature or airways in violation of normal tissue planes, thus resulting in stenosis or obliteration of these structures. Bilateral lung involvement, present in 20%, is highly lethal. Vascular stenting may improve survival.
- Mediastinal granuloma is a coalesced group of caseous lymph nodes with semiliquid contents contained within a thin capsule and characterized by heterogeneous density on computed tomography and, in most cases, an eventual pathognomonic calcification pattern. Although usually asymptomatic, they may fistulize and drain to airways, esophagus, or other sites. Symptomatic mediastinal granuloma can be managed by resection.

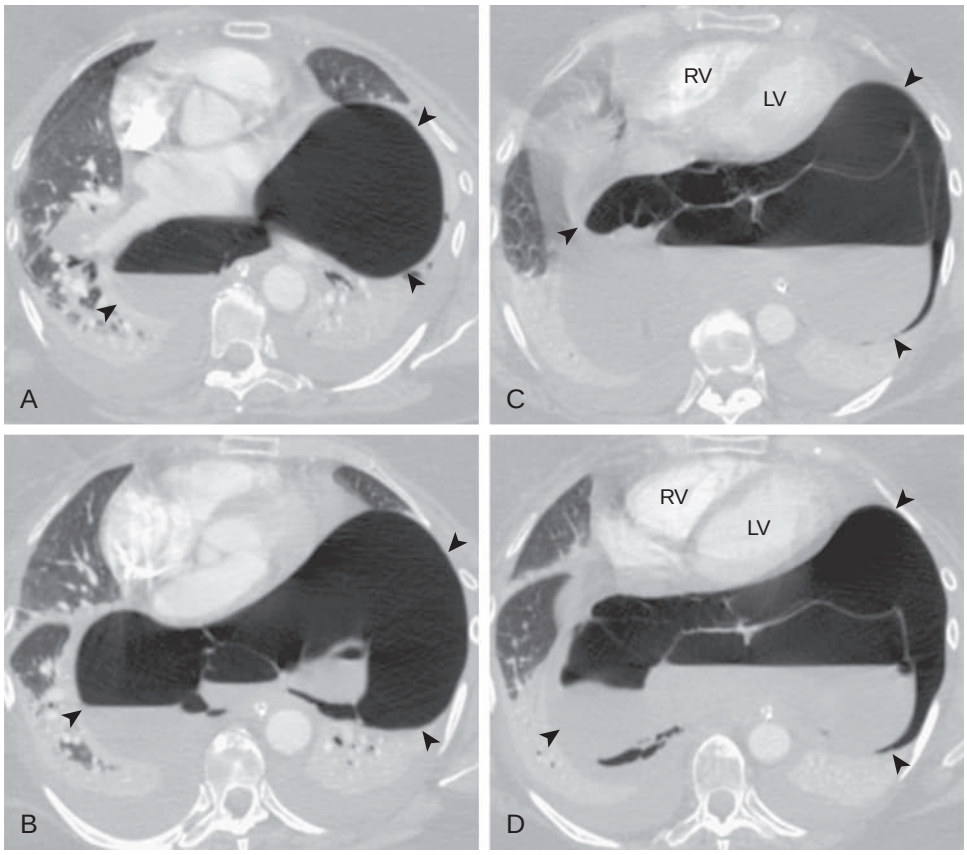
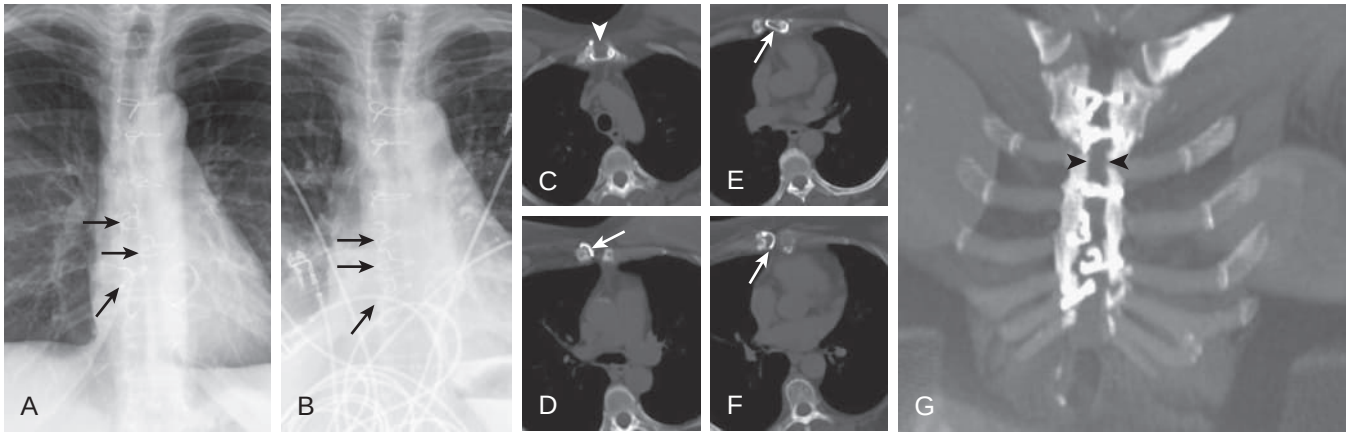
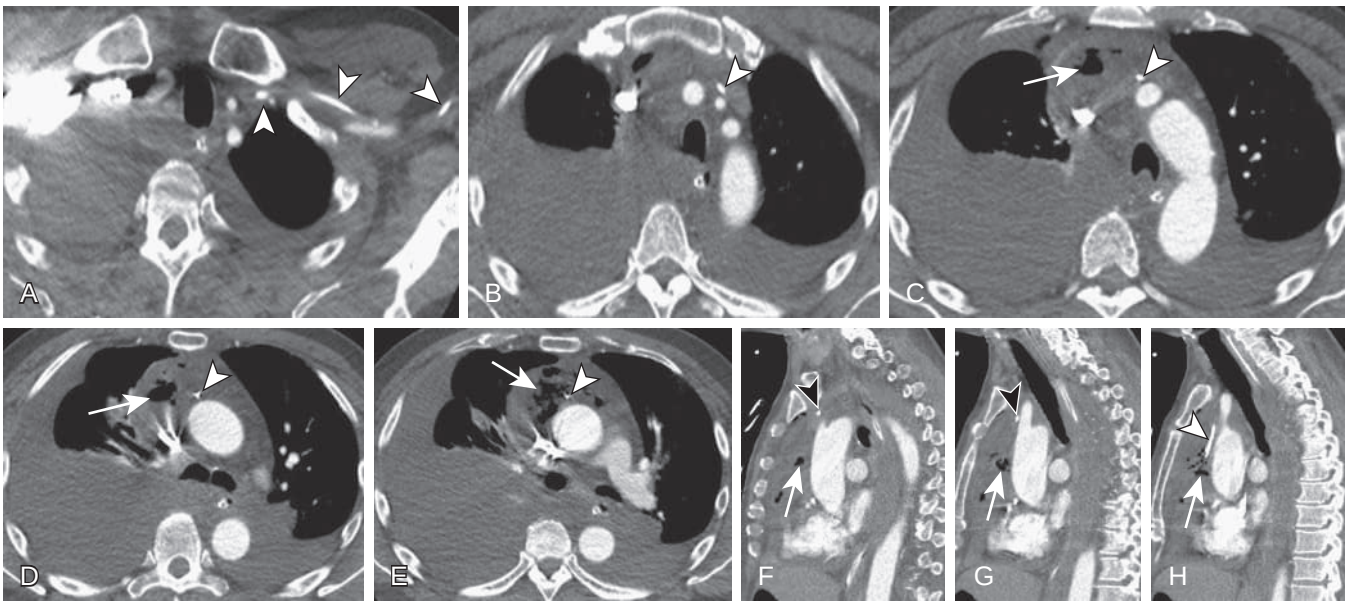
eFigure 116.1 Chest radiographic findings of pneumomediastinum. (A) Frontal chest radiograph shows abnormal lucency interposed between the left cardiac border and left mediastinal pleura *(arrows)* secondary to the presence of mediastinal gas. Gas outlines the superior mediastinum and extends into the neck as well. (B) The "continuous diaphragm" sign. Frontal chest radiograph shows a linear gas lucency between the heart and diaphragm *(arrowheads),* thus rendering the diaphragm visible where it is normally obscured because of contact with the inferior pericardium and heart. (C–D) Chest radiographic findings of pneumomediastinum: "ring-around-the-artery" sign. (C) Frontal chest radiograph shows few features that allow the confident diagnosis of pneumomediastinum. (D) Lateral chest radiograph shows gas surrounding and sharply outlining the extrapericardial segment of the right pulmonary artery *(arrowheads).* (E–F) Chest radiographic findings of pneumomediastinum: the "extrapleural air" sign. (E) Frontal chest radiograph shows gas lucency separating the diaphragm from the combined parietal and visceral pleural layers *(arrowheads).* (F) Axial chest computed tomography displayed in lung windows shows gas, representing pneumomediastinum outlining both sides of the medial left hemidiaphragm *(arrowheads).* (G) Chest radiographic findings of pneumomediastinum: Naclerio's "V" sign. Frontal chest radiograph shows lucency extending along the descending thoracic aorta *(arrowheads)* and extending laterally between the parietal pleura and medial left hemidiaphragm, intersecting gas lucency along the latter *(arrows).* Other chest radiographic features of pneumomediastinum, such as sharp outlining of the aortic arch and left mediastinum, are evident. (H) Chest radiographic findings of pneumomediastinum: note that the gas lucency "elevates" the thymus (*asterisk*), causing the "thymic spinnaker-sail" sign. Frontal chest radiograph in an infant shows abnormal mediastinal lucency that forms an interface *(arrowheads)* with superior mediastinal tissue, representing the thymus *(T);* note that the gas lucency "elevates" the thymus. (I–J) Frontal and lateral chest radiographs in an older child show gas lucency along the left mediastinum *(arrowhead)* on (I) the frontal projection, and sharply outlining *(arrowheads)* the thymus *(T)* on the lateral projection (J). (K) Chest radiographic findings of pneumomediastinum: gas in the pulmonary ligament. Frontal chest radiograph shows triangular gas lucency in the retrocardiac area *(arrowheads),* the apex of which points superiorly. This finding resolved on repeat chest radiography 1 week later. (Courtesy Michael B. Gotway, MD.)



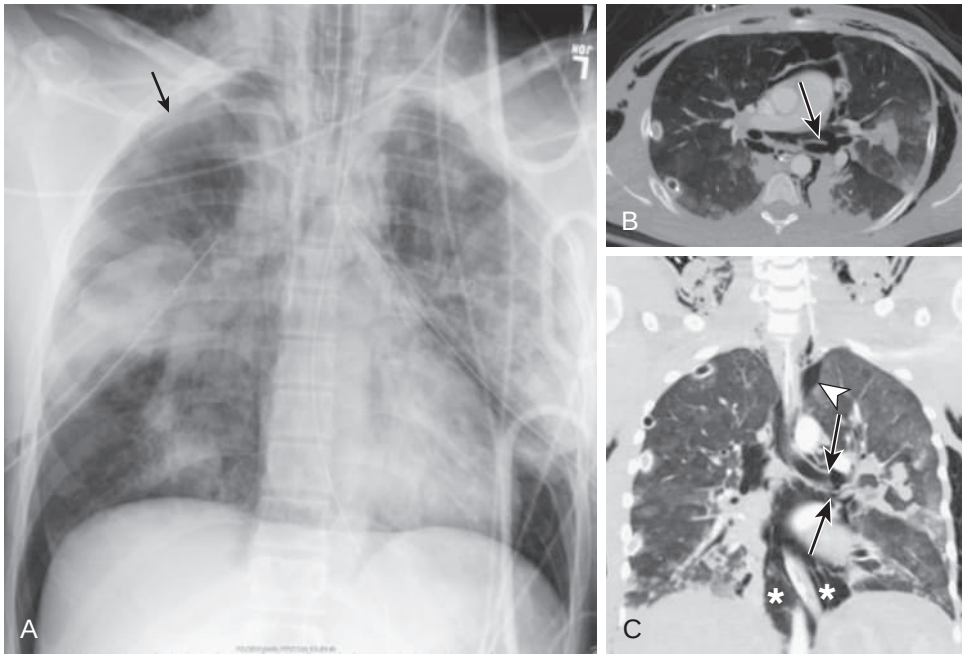
eFigure 116.2 Tension pneumomediastinum. (A–D) Axial chest computed tomography images displayed in lung windows show a large gas collection with numerous internal loculations in the middle mediastinum *(arrowheads)* resulting from esophageal perforation. The gas collection exerts significant mass effect on the heart, compressing and distorting the ventricles. Mediastinitis from the esophageal rupture was present, and the mediastinal gas and fluid were decompressed through placement of several thoracostomy tubes followed by repair of the esophageal laceration. LV, left ventricle; RV, right ventricle. (Courtesy Michael B. Gotway, MD.)



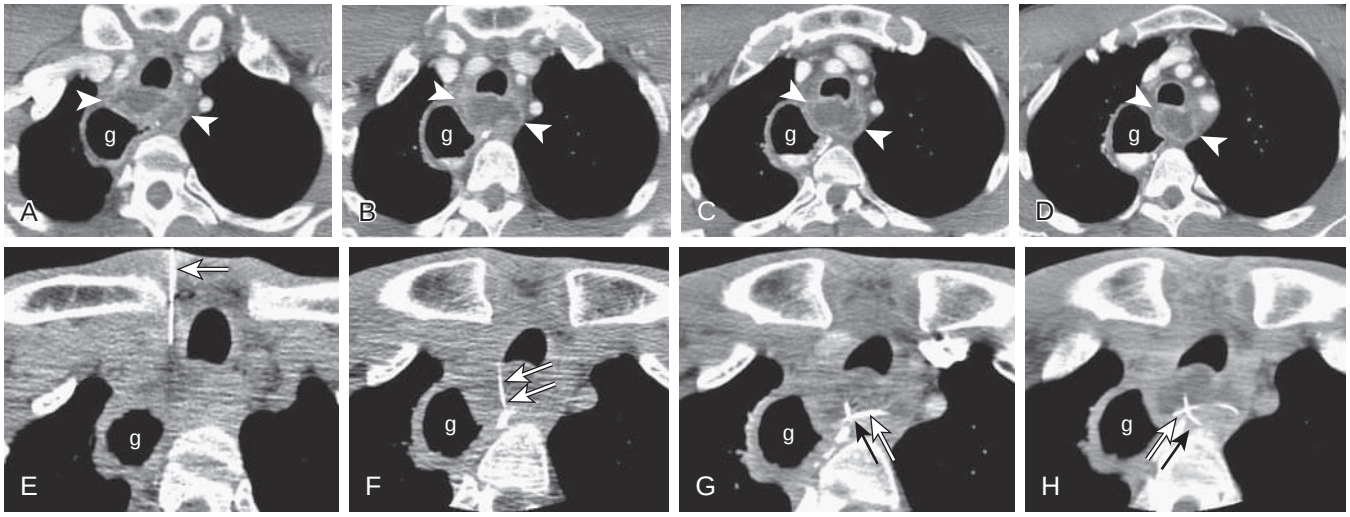
eFigure 116.3 Sternal dehiscence: imaging findings. (A) Frontal chest radiograph obtained at presentation in a patient complaining of increasing chest pain and tenderness several months after a sternotomy. (B) Frontal chest radiograph obtained shortly after the sternotomy, prior to symptoms, is shown for comparison. Note migration of sternal wires *(arrows)* on part A, the presentation image, compared with part B. (C–F) Axial unenhanced chest computed tomography shows that the sternal wires have "pulled through" the sternum (*arrows* in D–F), resulting in marked widening of the space between the two sternal halves (*arrowhead* in C). (G) Coronal unenhanced chest computed tomography shows sternal widening *(arrowheads)*. (Courtesy Michael B. Gotway, MD.)



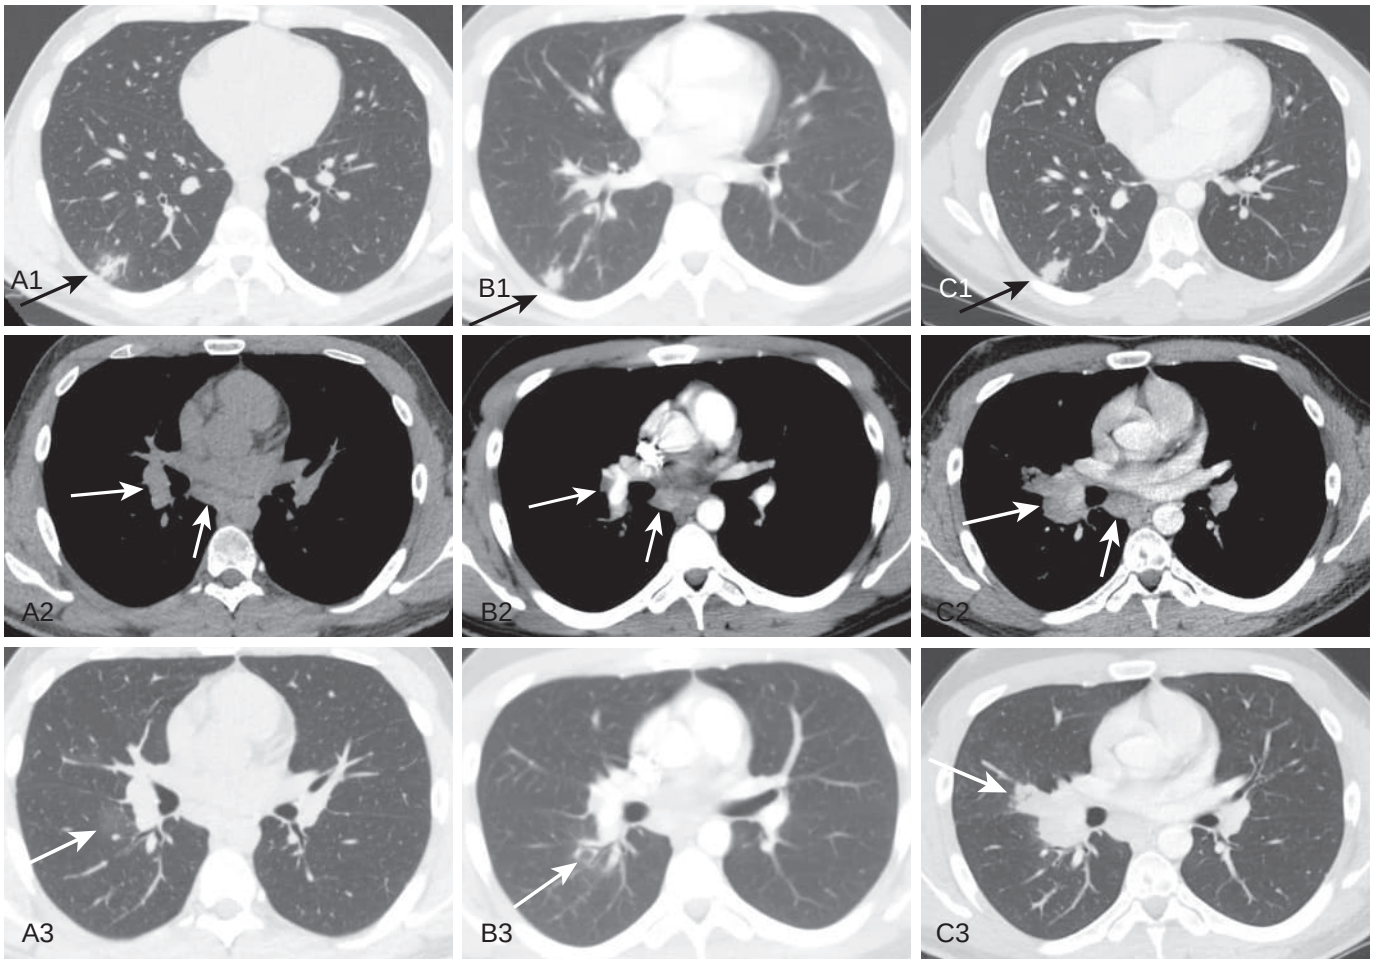
eFigure 116.4 Venous perforation of a peripherally inserted venous catheter with entry into the mediastinum. (A–E) Axial (see Video 116.1) and (F–H) sagittal enhanced chest computed tomography show a left upper extremity peripherally inserted venous catheter *(arrowheads)* coursing through the left subclavian and brachiocephalic veins (*arrowheads* in A–C), but then coursing caudally into the anterior mediastinum (*arrowheads* in D–H). A mediastinal gas collection *(arrows)* represents a developing abscess. (Courtesy Michael B. Gotway, MD.)



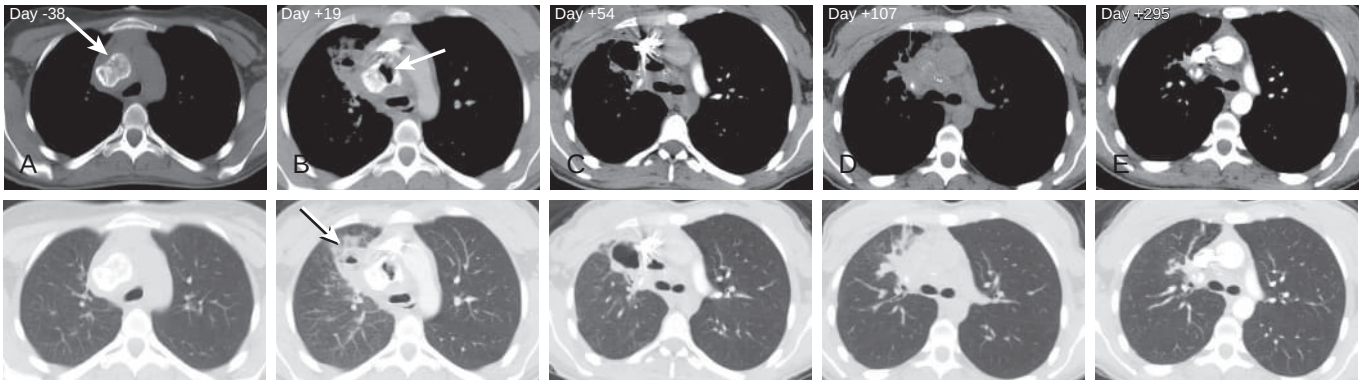
eFigure 116.5 Left mainstem bronchial fracture following motor vehicle collision. (A) Frontal chest radiograph shows subcutaneous emphysema with pneumomediastinum with a right apical pneumothorax *(arrow)* and a deep sulcus sign, also on the right. A left pneumothorax has been addressed with a left thoracostomy tube, although clinically a persistent air leak from this tube was present. (B–C) Axial (see Video 104.3) and coronal (see Video 116.2) chest computed tomography displayed in lung windows shows subcutaneous emphysema with pneumomediastinum *(asterisks)* with a complete fracture of the left mainstem bronchus *(arrows).* A residual left apical pneumothorax (*arrowhead* in C) remains. (Courtesy Michael B. Gotway, MD.)



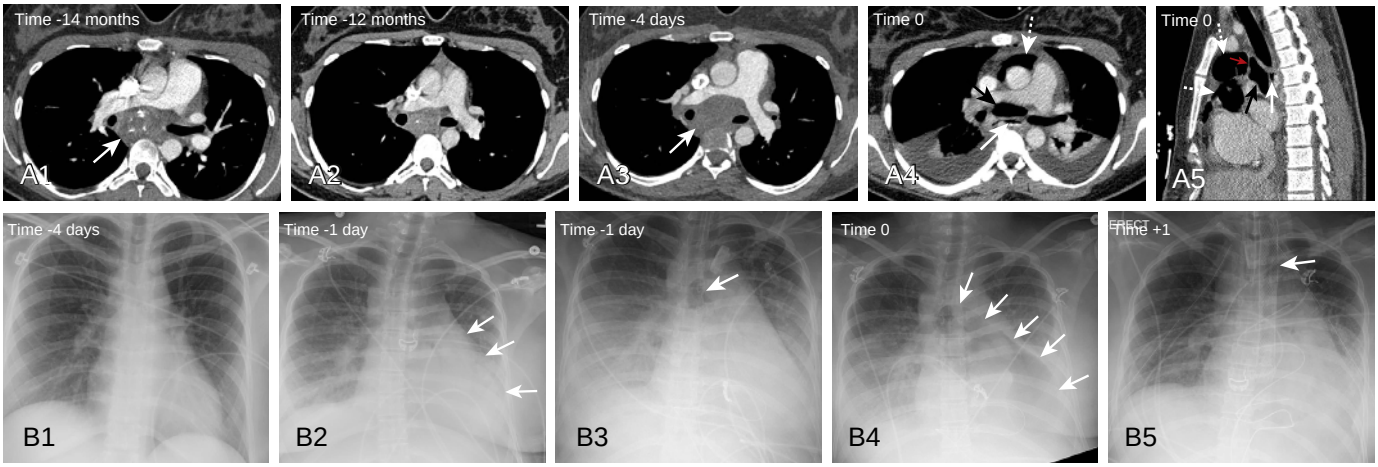
eFigure 116.6 Percutaneous drainage of mediastinal abscess: computed tomography findings. (A–D) Axial contrast-enhanced chest computed tomography displayed in soft tissue windows shows an enhancing fluid collection *(arrowheads)* in the mediastinum, representing an abscess that was seen after attempted dilation of a stricture following esophageal resection and gastric pull-through. (E–H) Computed tomography images of the percutaneous drainage of the mediastinal abscess. Axial chest computed tomography obtained during percutaneous drainage of the mediastinal abscess shows placement of a coaxial needle (*arrow* in E) into the anterior margin of the abscess through a paratracheal approach. (F–H) Subsequent images show a wire *(double arrows)* coiling in the abscess, over which a small drainage catheter was placed. g, intrathoracic stomach following gastric pull-through. (Courtesy Michael B. Gotway, MD.)



eFigure 116.7 Evolving *Histoplasma*-associated mediastinal adenitis over 6 months. (A) Initial computed tomography scan. (B) Scan at 3 months. (C) Scan at 6 months. *Row 1* demonstrates slow organization and enlargement of a peripheral right lower lobe nodule, representing the site of initial *Histoplasma* infection. *Row 2* demonstrates enlarging right hilar and subcarinal adenopathy (*arrows*). *Row 3,* at the same level as *row 2,* demonstrates evolving perihilar parenchymal inflammation associated with the adenopathy, starting with subtle ground-glass opacity (*arrow* in A3), more prominent ground-glass opacity (*arrow* in B3), and then worsening consolidative changes (*arrow* in C3). This young European patient, studying in the southeastern United States, experienced a 2-week febrile illness with cough 1 month before the first computed tomography scan. *Histoplasma* antibody titers to mycelial and yeast antigens both exceeded 1:128 and immunodiffusion detected precipitans to both H and M *Histoplasma* protein antigens. The imaging changed despite treatment with itraconazole and corticosteroids. (Courtesy Robert J. Lentz, MD.)



eFigure 116.8 Superinfection of a mediastinal granuloma by endobronchial ultrasound-guided transbronchial needle aspiration, with fistulization to right upper lobe. (A–B) Image columns are dated with respect to when endobronchial ultrasound-guided transbronchial needle aspiration of a mediastinal granuloma exhibiting pathognomonic calcification pattern (*arrow* in A) was performed. On day +19, air can be seen within the mediastinal granuloma as well as loss of some of its calcified contents (*arrow* in B; soft tissue windows). There is new cavitary lesion, as well as consolidation within the right upper lobe (*arrow* in B; lung windows). (C–E) Slow resolution subsequent to mediastinal débridement and washout on day +20. Operative cultures grew viridans streptococci. (Courtesy Robert J. Lentz, MD.)



eFigure 116.9 Mediastinal granuloma in a 24-year-old woman with spontaneous fistulization to esophagus and pericardium resulting in pneumopericardium with tamponade. (A) Computed tomography. (B) Radiography. Dates with respect to the date of A4. (A1) Diagnosed with subcarinal mediastinal granuloma *(arrow)* 14 months earlier. (A2) Two months later, mediastinal granuloma was noted to be smaller, attributed to itraconazole treatment, but a significant decrease in the number of internal calcifications indicates that the mediastinal granuloma must have fistulized and drained (almost certainly to the esophagus, given it was clinically silent). A year later she presented with several months of pleuritic chest pain. (B1) Chest radiograph was unremarkable, but (A3) computed tomography noted an increase in mediastinal granuloma size *(arrow)*. On hospital day 3, she had abrupt onset of tachycardia, hypotension, and hypoxemia, with (B2) chest radiograph revealing a significant increase in size of the cardiac silhouette *(arrows)*. (B3) Echocardiogram revealed pericardial debris with tamponade, for which a pericardial window was performed with clinical improvement, although new air was noted in the subcarinal space postoperatively *(arrow)*. (B4) The next day, she experienced another abrupt clinical decompensation and was found to have pneumopericardium *(arrows)*. (A4) and (A5) Air now occupied the decompressed subcarinal mediastinal granuloma cavity *(white arrows)*, with new precarinal air collection *(black arrows)* connecting to pneumopericardium *(dashed arrows)* at the *red arrow* (in A5). (B5) Urgent operation with pericardial and mediastinal exploration was performed, with intraoperative esophagoscopy notable for a 1-cm fistula to the mediastinal granuloma, for which an esophageal stent was placed *(arrow)*. She has since recovered with no recurrence of mediastinal granuloma, which was unroofed and débrided. (Courtesy James Loyd, MD.)

KEY POINTS

INTRODUCTION

Some of the key brain circuits that generate the states of wakefulness, *non–rapid eye movement* (non-REM) sleep and *rapid eye movement* (REM) sleep, are summarized in this section. Knowledge of these mechanisms leads to understanding the principle of the "sleep switch."[1,2] This principle is used to explain how the common, serious, and at times life-threatening problems associated with sleep and drug-induced brain sedation and respiratory depression can work through common brain pathways.

GENERATION OF WAKEFULNESS AND SLEEP

Wakefulness

Figure 117.1A illustrates some of the main neuronal clusters involved in the regulation of brain activity in wakefulness and sleep. Serotonin, noradrenaline, histamine, dopamine, orexin (also called hypocretin), acetylcholine, and glutamate-containing cell groups collectively contribute to the brain activation of wakefulness. Such brain activation manifests as relatively low-voltage and fast-wave activity in the *electroencephalogram* (EEG) and resting motor tone in the electromyogram recorded from postural muscles.

Some of the neuronal clusters that contribute to the brain activation of wakefulness include dorsal and caudal raphe neurons located in the pons and medulla respectively (serotonin containing), the locus coeruleus (noradrenaline containing), the tuberomammillary nucleus (histamine containing), the ventral periaqueductal gray (dopamine containing), the perifornical region of the lateral hypothalamus (orexin/hypocretin containing), the pedunculopontine and laterodorsal tegmental nuclei in the pons as well as regions of the basal forebrain (acetylcholine containing), and several of the aforementioned cell clusters plus distributed neurons in the pons and midbrain, including the parabrachial nucleus (glutamate containing).

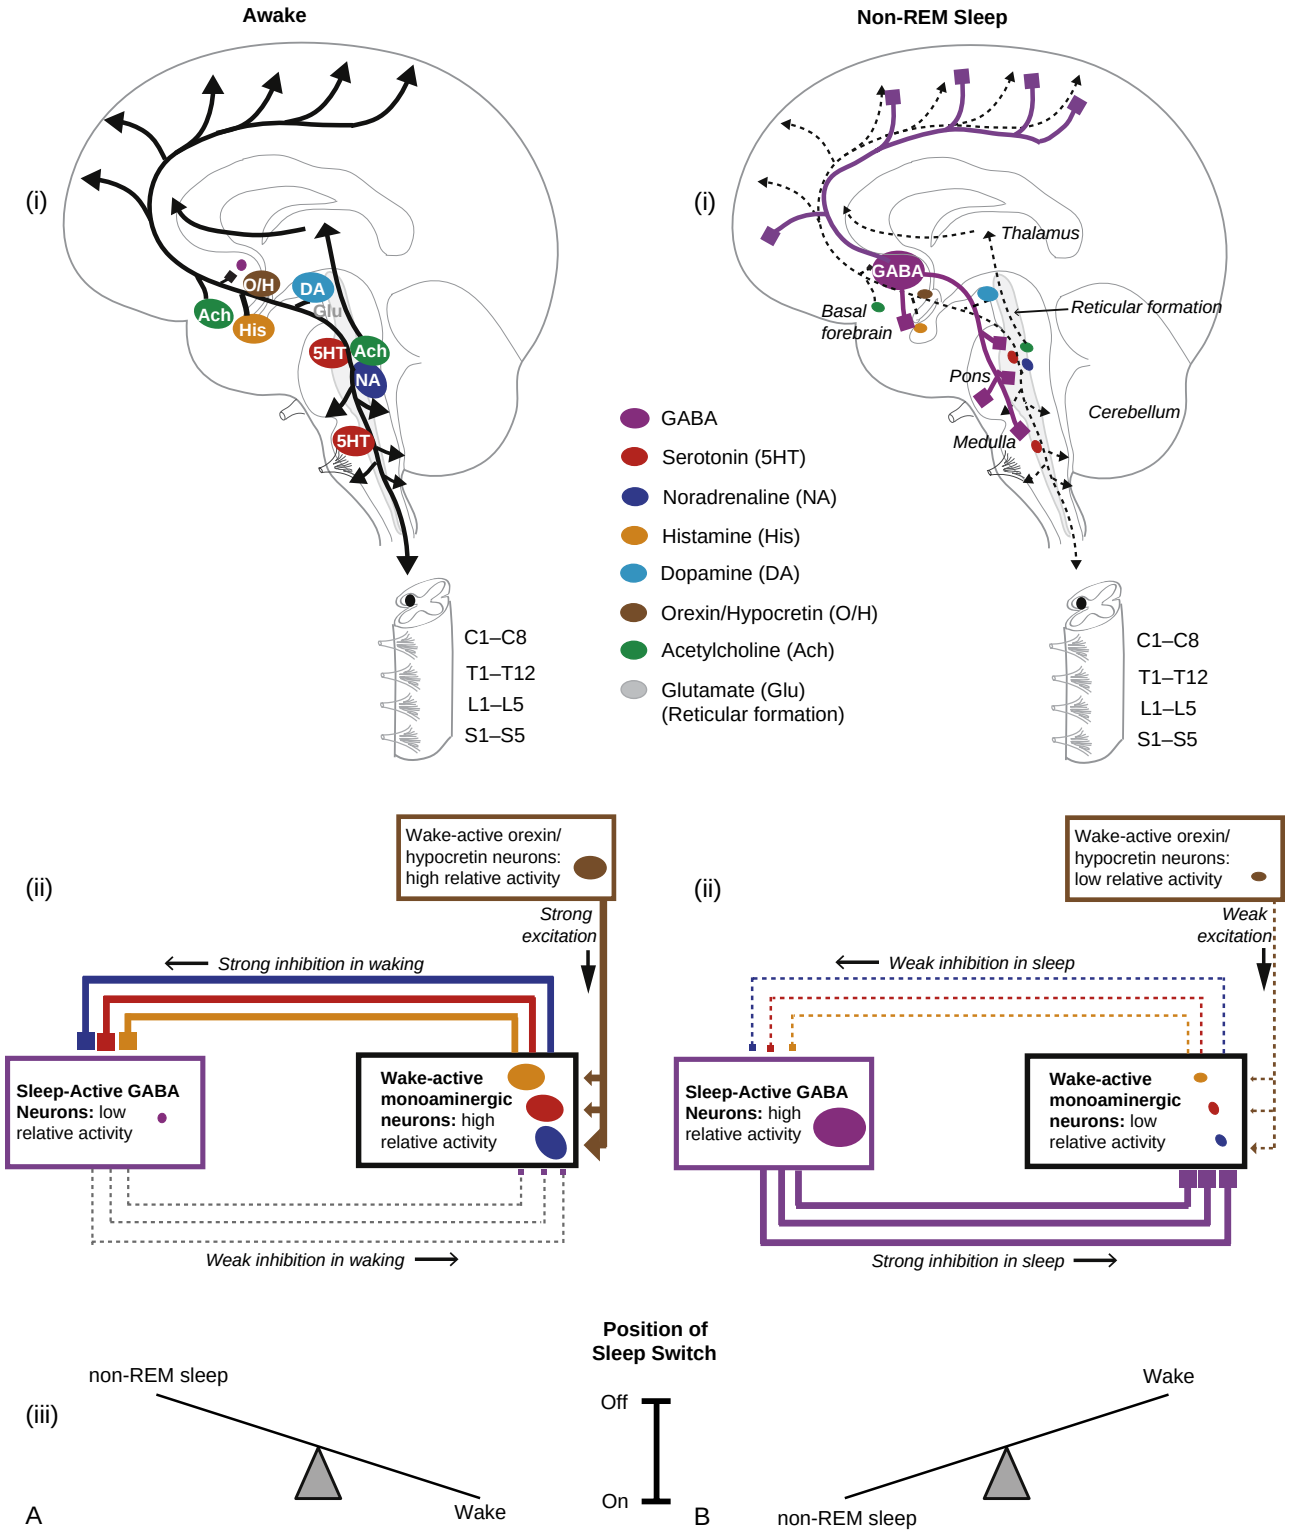

Figure 117.1 Schema showing the main neuronal groups and their organizational interactions for generating the brain states of wakefulness (A, left panels) and *non–rapid eye movement* (non-REM) sleep (B, right panels). Shown are the major neuronal clusters (*i*) whose ascending projections are responsible for producing the electrocortical arousal of wakefulness and whose descending projections influence brainstem autonomic networks and spinal motor activity. Non-REM sleep is generated when these wakefulness-generating systems are inhibited by clusters of neuronal groups containing the inhibitory neurotransmitter *gamma-aminobutyric acid* (GABA). The organizational structure for the maintenance of wakefulness and non-REM sleep, and the switch between the two states, are also shown (*ii* and *iii*). Mutual inhibitory interactions between wakefulness and sleep-promoting neuronal groups lead to the "switch" being stable in either position, thus producing consolidated periods of sleep at night and wakefulness during the day. The propensity to transition to a consolidated period of sleep at night (and later a consolidated period of wakefulness in the morning) is linked to the circadian-mediated decrease (and then the later increase) in body temperature; the decrease in body temperature activates the GABA sleep-promoting neuronal systems, whereas the increase deactivates them. The non-REM sleep-active GABA neuronal groups include those in the ventrolateral preoptic region of the thalamus as well as those in the basal forebrain and anterior hypothalamus. The relative position and sizes of neuronal groups are shown for visual clarity and are not meant to represent their strict anatomic positions. Relatively high levels of neuronal activity are represented by large symbols and solid lines, whereas relatively low levels of neuronal activity are represented by small symbols and dashed lines. Inhibitory neuronal projections from cell groups are indicated by *squares,* and excitatory projections by *arrowheads.* (Modified from Horner RL. Emerging principles and neural substrates underlying tonic sleep-state-dependent influences on respiratory motor activity. *Philos Trans R Soc Lond B Biol Sci.* 2009;364:2553–2564; Horner RL. Central neural control of respiratory neurons and motoneurons during sleep. In: Kryger MH, Roth T, Dement WC, eds. *Principles and Practice of Sleep Medicine,* ed 5. St Louis: Elsevier; 2011:237–249; Horner RL. Respiratory physiology. In: Kushida C, ed. *Encyclopedia of Sleep*, vol. 1. Waltham, MA: Academic Press; 2013:517–524; and Saper CB, Scammell TE, Lu J. Hypothalamic regulation of sleep and circadian rhythms. *Nature.* 2005;437:1257–1263. Copyright Richard L. Horner, PhD, University of Toronto.)

Non-REM Sleep

Non-REM sleep is often thought of as the "restorative" non-dreaming phase of sleep. It is promoted and sustained by a system of neurons that inhibit the brain arousal systems of wakefulness (Fig. 117.1B). The chief cell groups that comprise this non-REM sleep-active inhibitory system include neurons in the ventrolateral preoptic area and anterior region of the hypothalamus, and regions of the basal forebrain. The cell groups that comprise this non-REM sleep-active inhibitory system synthesize and secrete the inhibitory amino acid *gamma-aminobutyric acid* (GABA) and the neuropeptide galanin. GABA is one of the chief inhibitory neurotransmitters in the brain. The direct GABA-mediated inhibition of the brain arousal systems, in combination with activation of cortically projecting inhibitory GABA neurons, is responsible for the relatively higher-voltage and slower-wave EEG activity that typifies non-REM sleep.

REM Sleep

REM sleep is associated with the dreaming phase of sleep and is accompanied by paralysis (atonia) of the skeletal musculature, an effect that can also impact breathing (particularly accessory muscle function). There are two major circuits involved in REM sleep generation (Fig. 117.2). The activation of these circuits produces the defining signs of REM sleep: (1) low-voltage and fast-wave EEG activity and (2) suppression of postural motor tone. Important for the changes in EEG activity is reactivation of the cholinergic cell groups in the pons and basal forebrain that were relatively inactivated during non-REM sleep. The spinal motor activity in REM sleep is suppressed through recruitment of descending neural circuits that involve glycine (principally) and GABA. However, the upper airway muscle activity in REM sleep is suppressed through processes

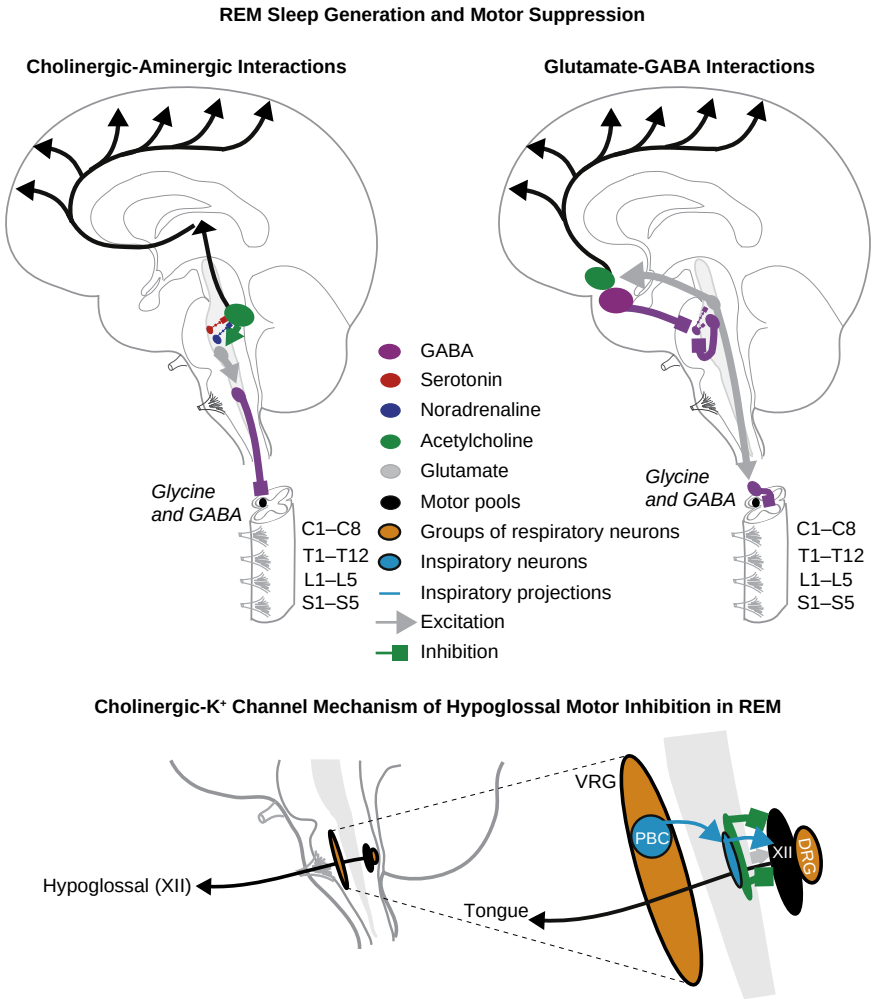

Figure 117.2 Schema showing the main neuronal groups and their organizational interactions for generating the brain state of REM sleep. There are currently two explanations of *rapid eye movement* (REM) sleep generation: one involving interactions of cholinergic and aminergic cell clusters (*top left*) and the other involving interactions of glutamatergic and *gamma-aminobutyric acid* (GABA)-ergic cell clusters (*top right*). Although the finer details are discussed in the text, the main point is that each can explain the cardinal features of REM sleep: ascending cortical activation and descending spinal motor inhibition. The inhibition of spinal motor activity in REM sleep is mediated by descending projections to the medial and ventral horn of the spinal cord and increased release of the inhibitory amino acids glycine (predominantly) and GABA onto spinal motoneurons. The mechanism of upper airway motor suppression in REM sleep appears different. For the hypoglossal motor pool, for example, which innervates the musculature of the tongue via cranial nerve XII, a cholinergic mechanism mediates the strong motor inhibition of REM sleep. This inhibition counteracts the inspiratory drive to this motor pool that originates from the ventral respiratory group (VRG) via the pre-Bötzinger complex (PBC) and pre-motoneurons in the brainstem (the latter two indicated as inspiratory neurons and shown in *blue*). The dorsal respiratory group (DRG) is also shown for completeness. The hypoglossal motor pool also receives tonic state-dependent drive from the brainstem (shown in *gray*). Inhibitory neuronal projections are indicated by *squares* and excitatory projections by *arrowheads*. (Copyright Richard L. Horner, PhD, University of Toronto.)

of (1) *disfacilitation* (i.e., withdrawal of excitatory inputs), mediated principally by reduced noradrenaline and serotonin excitation at the hypoglossal motor pool, and (2) *inhibition*, mediated by a muscarinic receptor mechanism linked to G-protein–coupled potassium channels.[3]

THE "SLEEP SWITCH"

As discussed, there are *mutually opposing* interactions between the wakefulness-promoting neuronal systems and the non-REM sleep-promoting neuronal systems. This organization leads to wakefulness being associated with both a relatively high level of activity in the wake-promoting neuronal arousal systems combined with a relatively low level of activity in the opposing sleep-promoting GABA system (see Fig. 117.1A, panel ii). In contrast, non-REM sleep is associated with both a relatively high level of activity in the sleep-promoting GABA system combined with a relatively low level of activity in the opposing wake-promoting neuronal arousal systems (see Fig. 117.1B, panel ii).

The mutually opposing interactions between the wake-promoting and sleep-promoting neuronal systems produce a situation in which the brain is in a stable state when either one of the respective neuronal systems dominates. This arrangement constitutes the "sleep switch" in which the position of the "switch" is stable in either state because, when one side is active, the alternate state is simultaneously inhibited. In non-REM sleep, for example, the activation of GABA neurons reinforces their own activation via inhibition of the wake-active neuronal systems at the same time.

EFFECTS OF COMMON NEURODEPRESSIVE DRUGS ON BRAIN AROUSAL STATE

The balance of brain neurochemicals involved in the opposing wakefulness and sleep-promoting systems, however, is not only changed across natural states of wakefulness and sleep; the balance is also changed in predictable ways by the ingestion of commonly used neurodepressive drugs. Such drugs include benzodiazepines, imidazopyridines (non-benzodiazepine sedative hypnotics), barbiturates, ethanol, and some general anesthetics that are either inhalational (e.g., isoflurane) or injectable (e.g., propofol or etomidate). All these listed agents interact with binding sites on GABA receptors that enhance neuronal inhibition.[4] There are several sites within the endogenous sleep-wake circuitry where such neurodepressive GABAergic drugs act to depress the brain arousal state and promote sedation and/or loss of consciousness.[4] Such agents therefore effectively tip the balance within the endogenous sleep-wake circuitry "toward" sedation and "away" from brain arousal.

The principle of the sleep switch helps us understand that the depression of brain arousability in both natural sleep and with neurodepressive drugs is the product of two mechanisms. The first is the augmentation of inhibitory GABAergic influences, and the second is the concomitant depression of arousal-related stimulatory influences. There is a dual effect because these inhibitory and excitatory mechanisms cannot operate independently because of their inherent interconnectedness. This principle has further implications for understanding sleep and drug-induced respiratory depression.

APPLICATION TO SLEEP AND DRUG-INDUCED RESPIRATORY DEPRESSION

During both natural sleep and in the presence of many commonly used sedative and anesthetic drugs, there is both augmentation of the GABAergic inhibitory system and corresponding reductions in excitatory influences from the brain arousal systems (as outlined earlier). The net result is a tipping of the balance in the sleep switch toward low brain arousability plus alteration of drives to the respiratory network. These state-dependent drives affect the musculature particularly of the upper airways, thus predisposing to obstructive sleep apnea and hypopnea in susceptible individuals.[5] In essence, the brain functions as a "gain setting" device for breathing by altering brain neurochemistry of the key elements of respiratory control: the respiratory neurons, the motoneurons, and the sites involved in the reflex modulation of breathing.

Opioid drugs can also produce profound sedation, an effect clinically important in their contribution to both respiratory depression and the failure to arouse. Opioids such as fentanyl contribute to respiratory depression via direct inhibitory effects on the major components of the respiratory network, including respiratory neurons, motoneurons, chemosensors, and reflexes, as well as depress the aforementioned brain arousal systems. Research is ongoing to address the mechanisms behind these adverse physiologic responses.

BREATHING AND ITS CONTROL

The complexity of the brainstem respiratory network can be distilled into three essential elements:

1. *Respiratory neurons* that generate respiratory rhythm and drive the expression of rhythmic activity in other components of the respiratory network.
2. *Respiratory motor pools* that innervate and activate the primary and secondary muscles of breathing. The primary respiratory muscles are so designated because they generate airflow (e.g., the diaphragm). In contrast, the secondary (accessory) muscles of breathing do not generate airflow but either importantly modulate its passage (e.g., pharyngeal muscles that maintain a patent upper airway) or otherwise support the act of breathing (e.g., the intercostal muscles that contribute to the maintenance of lung volume).
3. *Chemosensors* that detect alterations in blood gases and elicit a physiologic response. In the case of hypoventilation during sleep, for example, the appropriate physiologic response includes both an attempted chemoreceptor-mediated increase in ventilation and arousal from sleep. The importance of arousal from sleep is critical to survival in some situations when the ventilatory response is futile by itself (e.g., to shake off a suffocating blanket in the case of a sleeping infant to prevent asphyxia and sudden infant death syndrome).

RESPIRATORY NEURONS

Organization

Figure 117.3 illustrates the main components of the respiratory network generating respiratory rhythm and motor activation. The *ventral respiratory group* (VRG) contains

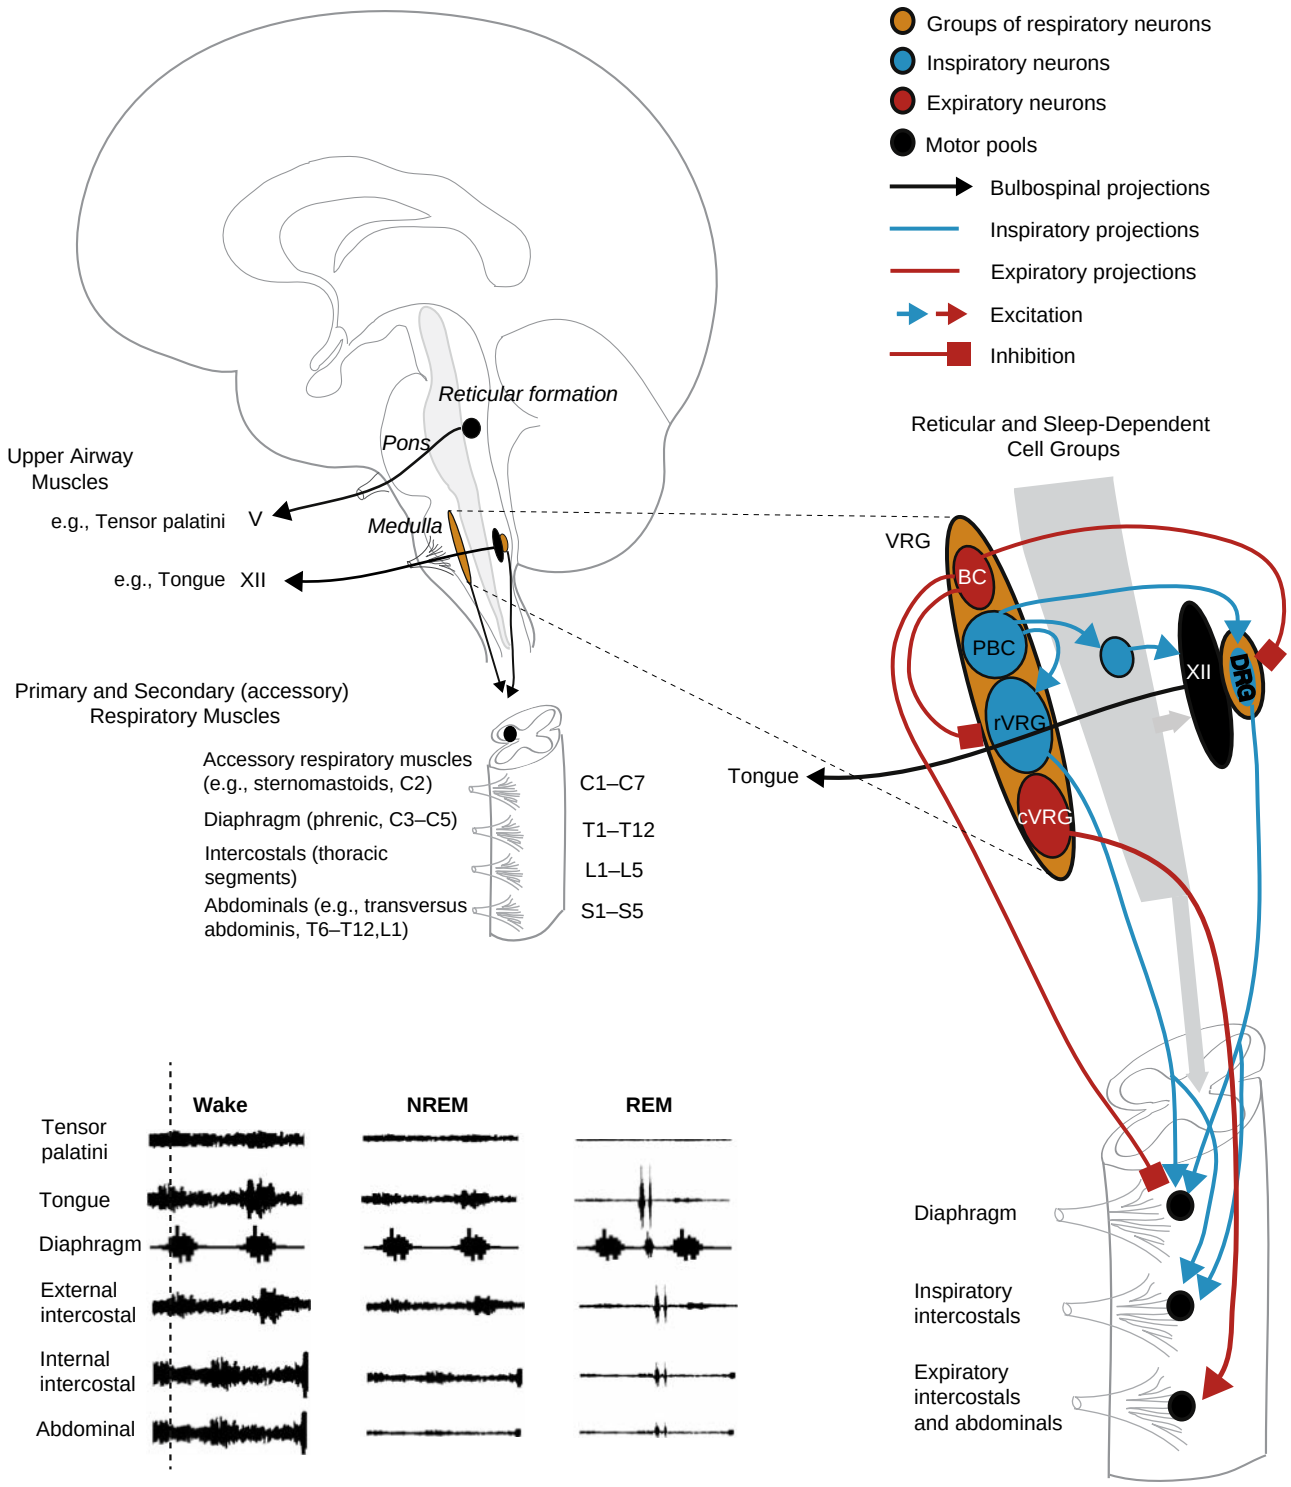

Figure 117.3 Schema showing some of the main neuronal groups and their organizational interactions for the generation of efferent motor output to different respiratory muscles. On the upper left are shown the main neuronal groups and selected motor pools innervating the muscles of the upper airway and the primary and secondary (accessory) muscles of the respiratory pump. On the right, at higher magnification, are shown the main clusters of neurons comprising the *ventral and dorsal respiratory groups* (VRG and DRG, respectively), and their projections to other neurons comprising the respiratory network. The innervation of the hypoglossal motor pool by state-dependent neurons of the reticular formation is also shown. See text for further details on the relevance of this latter point. The electromyographic activities of various respiratory-related muscles are also shown: palatal, tongue, diaphragm, and the accessory, intercostal, and abdominal respiratory muscles. Note that the level of respiratory-related and tonic activities varies for different muscles, with some muscles such as the tensor palatini expressing mainly tonic activity and others, such as the tongue and intercostals, expressing both tonic and respiratory activity. This relative balance of tonic and respiratory-related activity can change across sleep-wake states, with tonic activity being typically suppressed in sleep. The onset of muscle activity with respect to the diaphragm is shown by the *dashed line*. The rootlets of cranial nerves V (trigeminal) and XII (hypoglossal) and the *cervical* (C), *thoracic* (T), *lumbar* (L) and *sacral* (S) segments of the spinal cord are included. BC, Bötzinger complex; NREM, non–rapid eye movement; PBC, pre-Bötzinger complex; REM, rapid eye movement; rVRG, rostral VRG; cVRG, caudal VRG. (Modified from Horner RL. Emerging principles and neural substrates underlying tonic sleep-state-dependent influences on respiratory motor activity. *Philos Trans R Soc Lond B Biol Sci.* 2009:364;2553–2564; Horner RL. Central neural control of respiratory neurons and motoneurons during sleep. In: Kryger MH, Roth T, Dement WC, eds. *Principles and Practice of Sleep Medicine*, ed 5. Horner, PhD, University of Toronto.)

Bötzinger complex (expiratory) neurons, pre-Bötzinger complex (inspiratory) neurons, rostral VRG (predominantly inspiratory) neurons, and caudal VRG (predominantly expiratory) neurons. The *dorsal respiratory group* (DRG) contains mainly inspiratory neurons. The DRG and its associated regions of the nucleus tractus solitarius are also the projection sites for afferents important to the reflex control of breathing: the carotid and aortic chemoreceptors and baroreceptors and lung vagal afferents.

The brainstem also includes motoneurons of the hypoglossal and trigeminal motor nuclei that innervate muscles important to the maintenance of upper airway patency.[5] Regions of the nucleus ambiguous also contain motoneurons that innervate the muscles of the larynx and pharynx via the vagus, glossopharyngeal, and accessory nerves. Respiratory neurons in the pons also modulate the activity of medullary respiratory neurons.

Respiratory Rhythm and Motor Activation

Some respiratory neurons are identified as propriobulbar, that is, neurons that project to, and influence the activity of, other medullary respiratory neurons but do not themselves project to motoneurons.[5] Others are identified as bulbospinal respiratory pre-motoneurons, that is, neurons that project to spinal motoneurons, which in turn innervate the respective respiratory pump and abdominal muscles of breathing.

Inspiration. The pre-Bötzinger complex is often emphasized given its role in respiratory rhythm generation. The pre-Bötzinger complex is a propriobulbar respiratory neuronal group that plays a key role in generating the fundamental respiratory rhythm in mammals.[6] Pre-Bötzinger complex neurons drive activation of bulbospinal neurons of the DRG and VRG during inspiration, which then activate spinal inspiratory phrenic and intercostal motoneurons. Inactivation of pre-Bötzinger complex neurons in animal models leads to ataxic breathing and central apneas, especially in sleep.[7,8] The pre-Bötzinger complex is also a critical site mediating respiratory rate depression by opioids.[9]

Expiration. In expiration, the expiratory neurons of the Bötzinger complex inhibit inspiratory pre-motoneurons and motoneurons. Caudal VRG neurons also increase excitability of spinal expiratory motoneurons in expiration, although this excitation does not necessarily manifest as demonstrable expiratory muscle activation at rest.

Respiratory Rhythm Generation and Central Apnea

The automatic and nonconscious rhythm of breathing is ultimately generated by the intrinsic membrane properties and connections of the individual neurons that comprise the respiratory network. Essential to expression of this rhythmicity, however, is provision of a sufficient level of underlying tonic excitation. Key sources of tonic excitation are from the aforementioned wakefulness-dependent neural systems as well as the peripheral and central chemoreceptors (eFig. 117.1).

An important physiologic principle that emerges from identification of the necessity and sufficiency of tonic excitation for respiratory rhythm generation is that removal of such tonic excitation can abolish respiratory rhythm. Sleep or neurodepressive drugs (such as GABAergic sedative hypnotics and/or opioid drugs), or reduced chemoreceptor inputs, can each lead to cessation of respiratory rhythm and development of central sleep apnea.

RESPIRATORY MOTOR POOLS AND MUSCLE ACTIVITY

Respiratory Muscles Vary in the Degree of Their Relationship to Breathing

Different respiratory muscles express varying degrees of respiratory-related activity and/or tonic (i.e., nonrhythmic, continuous or background) activation. The diaphragm, for example, is almost exclusively respiratory related, whereas the palatal, tongue, intercostal, and abdominal muscles express both respiratory and tonic activities to varying degrees. The physiologic basis for this variation is that the respiratory neurons that ultimately drive the respective respiratory muscles themselves vary in the strength of their relationship to breathing.[10] Some respiratory neurons, for example, are almost exclusively driven by respiratory rhythm-generating neurons and are weakly influenced by other inputs. In contrast, some respiratory neurons are weakly influenced by respiratory rhythm-generating neurons but more strongly influenced by tonic nonrespiratory inputs.[10] Such tonic nonrespiratory inputs can arise from sleep state–dependent cell groups.

Effects of Sleep

The identification of respiratory neurons and motoneurons that vary in the strength of their relationship to breathing assumes greater significance because of a key physiologic principle.[10] This principle states that respiratory neurons that are most strongly driven by respiratory rhythm-generating neurons are least affected by the transition from wakefulness to non-REM sleep, whereas respiratory neurons that are more strongly influenced by tonic nonrespiratory inputs are most affected by the change from wakefulness to sleep. In the latter case, activity within certain respiratory muscles can cease or be markedly depressed during sleep, especially those showing prominent tonic muscle activity in wakefulness, such as the muscles of the upper airway and chest wall. The key physiologic and clinical implications of this effect explain the susceptibility to obstructive sleep apnea; the major suppression of upper airway muscle activity in sleep is because those muscles are most strongly influenced by tonic nonrespiratory inputs that are decreased in sleep.

CHEMOSENSORS AND CHEMOREFLEXES

Location and State Dependence of Responses

Arterial oxygen and *carbon dioxide* (CO_2) levels are regulated by peripheral chemoreceptors located at the bifurcation of the common carotid arteries and central chemoreceptors located in the brain. More specifically, the central chemoreceptors are located close to the ventral surface of the medulla in the caudal region of the retrotrapezoid nucleus (eFig. 117.1).[11] Cells in this region of the retrotrapezoid nucleus are intrinsically sensitive to changes in CO_2/H^+. These CO_2/H^+-sensitive neurons have dendrites that extend to the ventral medullary surface by which they sense the pH of the surrounding cerebrospinal fluid. They also have

axons that project to the rostral region of the VRG by which they drive respiratory network activity.

In addition to the retrotrapezoid nucleus, some wakefulness-active/sleep-inactive cell groups, such as serotonergic and noradrenergic neurons, are also responsive to alterations in CO_2/H^+ levels. For any given inspired CO_2, the activity and responsivity (i.e., slope of response) of such neurons are reduced in sleep compared to wakefulness. As discussed later, this change in cell activity in response to hypercapnia from wakefulness to sleep parallels the change in overall ventilatory response.

INTEGRATIVE PHYSIOLOGIC MECHANISMS UNDERPINNING RESPIRATORY DYSFUNCTION AND INSTABILITY DURING SLEEP

BREATHING IS DEPENDENT ON FEEDBACK REGULATION IN SLEEP

Principle

A prevailing level of tonic excitation into the respiratory network is essential to drive respiratory rhythm and muscle activation (see "Respiratory Rhythm Generation and Central Apnea"). The brain arousal systems of wakefulness provide a major source of such excitation to modulate breathing volitionally and/or nonvolitionally, together termed *behavioral influences* or the *wakefulness stimulus* to breathing[12] (Fig. 117.4). Overall, the term behavioral influences encompasses wakefulness-dependent mechanisms that influence breathing whether one is aware of them or not, or whether they are conscious acts or not (e.g., conscious hyperventilation or unconscious continuous excitation of the respiratory system provided simply by the presence of wakefulness). Such behavioral influences on respiratory network activity are reduced or withdrawn when moving from wakefulness to non-REM sleep. As a result, the respiratory system becomes dependent on feedback regulation in non-REM sleep to sustain sufficient activity.

Tonic activity of the peripheral and central chemoreceptors is normally sufficient to sustain effective breathing in non-REM sleep. Without that tonic activity (e.g., caused by any reduction or defect in feedback chemoreceptor control for any reason), there will be respiratory disturbance in non-REM sleep because the stimulatory effects of wakefulness on the respiratory system are withdrawn. Interestingly, compared to the situation in non-REM sleep, in REM sleep the heightened state of brain arousal can restore sufficient nonspecific behavioral drives to the respiratory network to restore breathing.

Application

Hypocapnia is a potential cause of central apnea. Interestingly, hypocapnia by itself is not sufficient to elicit central apneas in wakefulness or in REM sleep because of the concomitant presence of the behavioral influences on breathing. However, in non-REM sleep, hypocapnia can elicit central apneas because the stimulatory effects of brain arousal (i.e., behavioral influences) to the respiratory network are absent. This critical combination of factors—hypocapnia and absence of behavioral influences to breathing in non-REM sleep—removes two of the crucial sources of tonic drives to the brainstem network that normally generate and sustain breathing. Hypocapnia may be present at the onset of sleep as a result of hyperventilation during wakefulness caused, for example, by heightened chemoreceptor drive (e.g., resulting from congestive heart failure) or by exaggerated behavioral influences on breathing (e.g., caused by anxiety). Hypocapnia at sleep onset can also result from the transient hyperventilation caused by sleep disturbance and brief arousal from prior sleep: the hyperventilation predisposing to unstable breathing by depleting the carbon dioxide reserve (defined later in the section "Loop Gain and Its Importance"). Whenever there is hypocapnia at sleep onset, central apneas may become clinically important in non-REM sleep.

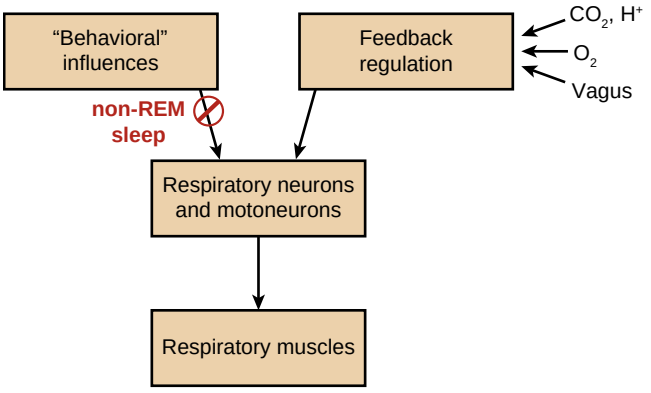

Figure 117.4 Conceptual model showing how behavioral influences and feedback regulation control the efferent output from respiratory neurons and motoneurons. Feedback regulation includes control by CO_2/H^+, O_2 levels, and responses to mechanical and ventilatory events in the airways and lung via the vagus nerves. Notably, the behavioral influences are significantly reduced or withdrawn in *non–rapid eye movement* (non-REM) sleep. The physiologic principle that arises from this effect is that breathing is essentially dependent on metabolic (CO_2 and O_2) control in non-REM sleep. The consequence is that any defect in metabolic control, for any reason, will cause severe respiratory disturbance in sleep but not necessarily in wakefulness. Behavioral influences include both volitional and nonvolitional (but wakefulness-dependent) mechanisms that influence breathing. (Copyright Richard L. Horner, PhD, University of Toronto.)

As a second example of the importance of tonic stimulation, patients with *congenital central hypoventilation syndrome* (CCHS) have a defect in chemoreception and exhibit major disturbances of ventilation in non-REM sleep but ventilate normally during wakefulness and during REM sleep. In more than 99% of CCHS patients, mutations have been found in the *PHOX2B* gene, a gene expressed by neurons involved in peripheral and central chemoreception.[13] That *PHOX2B* is expressed in chemoreceptor neurons and not in respiratory neurons is thought to explain the ability of these patients to breathe during wakefulness[14] (i.e., the state of wakefulness itself provides sufficient excitatory drive to the respiratory system to mask the major defect in chemoreceptor activity caused by the *PHOX2B* mutation). The ability of the CCHS patients to breathe normally in REM sleep further reinforces the principle that the relatively high levels of brain activation inherent to REM sleep can provide sufficient restoration of the behavioral drives to the respiratory network to reinstitute breathing.

As a final example that highlights the powerful effect of wakefulness as an independent driver of respiratory activity, it is noted that deep non-REM sleep and anesthesia are the most vulnerable states for respiratory rate depression by opioids.[9] In this situation, breathing can be sustained by wakefulness even when opioids are present at the pre-Bötzinger complex, a key site for respiratory rhythm generation in mammals, as well as other components of the respiratory network that together generate rhythmic breathing and lung ventilation. However, loss of this important wakefulness stimulus to breathing can lead to hazardous respiratory depression in non-REM sleep and anesthesia. This example further emphasizes the principle that wakefulness per se can provide sufficient excitatory drive to the respiratory system to mask (at least partially) otherwise important defects in respiratory control—in this case, defects induced by drugs. The clinical relevance of this principle is that sedating agents and opioid drugs can be deemed well tolerated in the initially alert patient but, when the stimulating effects of wakefulness are withdrawn during sleep, the patient may sustain major respiratory depression (i.e., "crash"). Such a scenario is particularly dangerous when patients with sleep-related breathing problems use opioids for pain management, especially if taken in combination with benzodiazepines and/or alcohol at home.

LOOP GAIN AND ITS IMPORTANCE

Principle

Loop gain is an engineering term that describes the overall gain, or sensitivity, of a feedback control system. A high gain system is one prone to instability, whereas a low gain system is intrinsically stable. The major factors contributing to overall loop gain are plant gain and controller gain (Fig. 117.5). *Plant gain* largely reflects the effectiveness of breathing to eliminate carbon dioxide, that is, how much a given change in ventilation itself affects arterial carbon dioxide. *Controller gain* largely reflects chemoresponsiveness, that is, how much a given change in arterial carbon dioxide itself affects ventilation. The equilibrium point for resting breathing (sometimes called the set point) is defined as the intersection of the ventilatory response to arterial P_{CO_2} and the change in arterial P_{CO_2} that results from a change in ventilation.

Overall, a high loop gain promotes ventilatory instability because it predisposes to a situation whereby a perturbation in ventilation can trigger cessation of breathing because the larger drop of the arterial P_{CO_2} due to a robust ventilatory response makes it more likely to reach the apnea threshold. Loop gain is defined and quantified as the magnitude of the ventilatory response to a given disturbance in breathing divided by the magnitude of the causal disturbance in ventilation itself. In practical terms, for example, this can be measured by how much a level of reduced ventilation (e.g., caused by an apnea or hypopnea) elicits a subsequent level of hyperpnea (i.e., response divided by disturbance).

If loop gain is less than 1, then the system corrects itself (i.e., breathing normalizes) but, if loop gain is 1 or greater, then the system remains unstable. In the latter case, a large ventilatory response to a particular perturbation in breathing can itself become a subsequent disturbance and therefore precipitate persistent instability. Overall, an increase in plant and/or controller gains can destabilize breathing because it increases the risk of lowering arterial P_{CO_2} below the chemical apnea threshold.[15]

Application

There are several situations in which altered plant and/or controller gains can predispose to sleep-disordered breathing. An increased plant gain can be seen, for example, when there is low functional residual capacity, or low dead space. Of note, the baseline level of arterial P_{CO_2} has an important effect on plant gain (e.g., a high arterial P_{CO_2} has a higher plant gain because the efficiency of carbon dioxide excretion is impacted accordingly). In each setting of high plant gain, a given increase in ventilation will more effectively lower arterial P_{CO_2} toward the apnea threshold. The increase in plant gain leads to a corresponding increased tendency to unstable breathing by virtue of the effectively reduced carbon dioxide reserve.[15] Interventions such as *continuous positive airway pressure* (CPAP) or positive end-expiratory pressure can help stabilize breathing in this context by increasing both functional residual capacity and dead space, thereby effectively reducing plant gain. Acetazolamide, a carbonic anhydrase inhibitor, can stabilize breathing in part via a lowering of P_{CO_2} with a concomitant fall in plant gain. Subtler distinctions between steady state and dynamic plant gains have been discussed elsewhere.[16] Patients with alveolar hypoventilation secondary to central nervous system disturbances or neuromuscular weakness are also predisposed to unstable breathing in sleep via increased plant gain.[15] This predisposition is also explained by virtue of their lowered carbon dioxide reserve, despite having an elevated resting arterial P_{CO_2}, due to a shift to the right in their equilibrium position for resting breathing[15] (see Fig. 117.5).

In contrast, an increased controller gain can be seen in patients with heart failure who also experience unstable breathing during sleep. In these patients, the increased chemoresponsiveness associated with heart failure–induced sympathetic nervous system activation leads to increased controller gain and lowered carbon dioxide reserve and thus predisposes to instability.

AROUSAL FROM SLEEP: A CONSEQUENCE AND CAUSE OF RESPIRATORY DISTURBANCE

Principle

The ventilatory responses to hypoxia and hypercapnia are fundamental to the homeostatic regulation of arterial blood gases. These ventilatory responses are reduced in non-REM sleep compared to wakefulness and are further reduced in REM sleep[17] (Fig. 117.6). The threshold level of hypercapnia to provoke arousal from sleep is similar, on average, between non-REM and REM sleep in humans, whereas the level of asphyxial hypoxia (e.g., hypoxia of the type experienced in obstructive sleep apnea) often elicits arousal at lower arterial oxygen saturations in REM sleep than in non-REM sleep[17] (see Fig. 117.6). Isocapnic hypoxia, however, is generally a weak stimulus to elicit arousal from sleep and the threshold is similar, on average, between non-REM and REM sleep.[17]

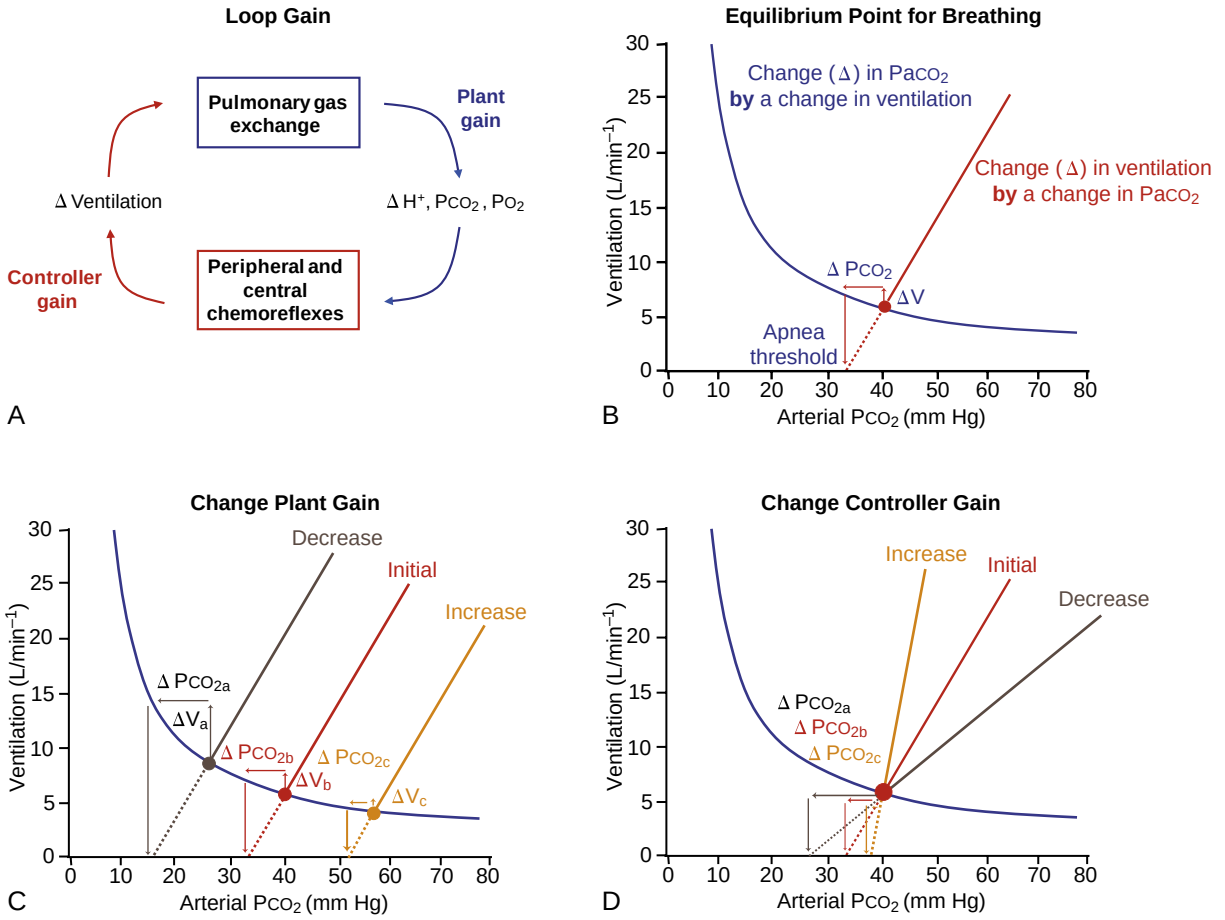

Figure 117.5 Schema illustrating how loop gain (comprised of plant and controller gains) determines the equilibrium point for breathing and influences breathing stability/instability. (A) Pulmonary gas exchange changes ventilatory variables, which themselves influence breathing. *Plant gain* largely reflects the effectiveness of ventilation to eliminate CO_2 (e.g., with a low functional residual capacity, low dead space, or low metabolic rate). *Controller gain* is largely a result of chemoresponsiveness (e.g., increased in heart failure). (B) The equilibrium point for stable breathing is illustrated by the *red circle*. This equilibrium point for resting breathing sits at the intersection of the ventilatory response to increased arterial P_{CO_2} (*red line*) and the change in arterial P_{CO_2} that results from a change in ventilation (the metabolic hyperbola; *blue line*). Reductions in arterial P_{CO_2} reduce ventilation according to the ventilatory response (*dashed red line*), until apnea develops (the apnea threshold). The magnitude of the increase in ventilation that will lower arterial CO_2 to the apnea threshold is termed the CO_2 reserve. (C–D) The predisposition to unstable breathing based upon the equilibrium position for resting breathing and the apnea threshold. Decreases in plant or controller gains produce a situation in which a larger increase in ventilatory disturbance is necessary to deplete the CO_2 reserve before apnea (*brown line*). In contrast, increases in plant or controller gains produce a situation in which a smaller increase in ventilatory disturbance is necessary to deplete the CO_2 reserve before apnea (*orange line*). The physiologic principle that arises from this effect is that the predisposition to ventilatory instability and disordered breathing in sleep is significantly determined by the plant and controller gains. For example, patients with alveolar hypoventilation secondary to central nervous system disturbance or neuromuscular weakness are predisposed to periodic breathing in sleep despite having an elevated resting arterial CO_2 (*yellow circle* in C). Likewise, patients with heart failure who have sympathetic nervous system–mediated increases in chemoreflex responsiveness are also predisposed to periodic breathing in sleep (*yellow line* in D). (Modified from Phillipson EA, Bowes G. Control of breathing during sleep. In: Cherniack NS, Widdicombe JG, eds. *Handbook of Physiology, section 3, The Respiratory System, Vol II, Control of Breathing, part 2*. Bethesda, MD: American Physiological Society; 1986:649–689; Dempsey JA, Veasey SC, Morgan BJ, O'Donnell CP. Pathophysiology of sleep apnea. *Physiol Rev* 2010;90:47–112. Copyright Richard L. Horner, PhD, University of Toronto.)

The normal decrease in ventilation from wakefulness to sleep usually results in trivial changes in arterial oxygen saturation because the starting alveolar P_{O_2} is on the flat portion of the oxyhemoglobin dissociation curve. However, the arterial oxygen saturation can decrease more from wakefulness to sleep if an individual is *initially* hypoxemic and therefore initially positioned on the steep portion of the dissociation curve (see Fig. 117.6). This situation can happen with an individual at altitude, with lung disease, or with depressed ventilation and/or impairments in breathing for any reason. The physiologic principle that arises from these relationships is that any situation that lowers alveolar P_{O_2} in wakefulness for any reason (e.g., altitude, lung disease, etc.) predisposes to worsening hypoxemia in sleep, especially during REM sleep.

Application

Interactions between the ventilatory responses to hypercapnia and hypoxia, and arousal from sleep, can provoke unstable breathing and central apneas. Figure 117.7 outlines these interactions using the ventilatory responses to hypercapnia as the example (see legend for additional details specific to this figure). As a general rule, however, the same predisposition to unstable breathing via arousal from sleep also applies to the ventilatory responses to hypoxia or to combined hypercapnia and hypoxia (i.e., asphyxia as seen in sleep-disordered breathing). The physiologic principle that arises from these interactions is that any separation of equilibrium points for stable breathing in wakefulness and non-REM sleep for any reason can lead to unstable

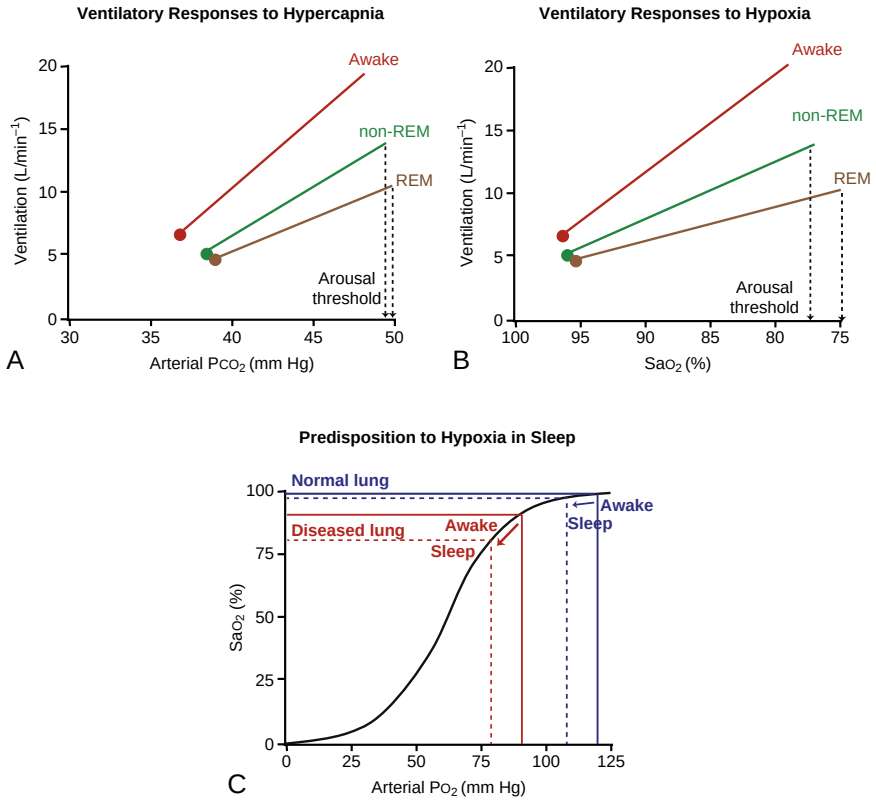

Figure 117.6 Ventilatory and arousal responses to hypercapnia (A) and hypoxia (B). Note the following points: (1) the decrease in basal ventilation from wakefulness (*red circle*) to *non–rapid eye movement* (non-REM; *green circle*) and REM (*brown circle*) sleep, (2) ventilation is greater in wakefulness at any given elevated arterial CO_2 or lowered arterial oxygen saturation (Sa_{O_2}) compared to non-REM sleep and REM sleep, and (3) the slope (gain) of the ventilatory responses to hypercapnia and hypoxia is also greater in wakefulness than in non-REM sleep and is most depressed in REM sleep. Also shown are the thresholds for hypercapnia (A) and asphyxial hypoxia (B) to elicit arousal from sleep (see text for additional details). (C) Also shown is the relationship between the starting (waking) arterial partial pressure of O_2 and the magnitude of the decrease in Sa_{O_2} from wakefulness to sleep. Normal decreases in ventilation from wakefulness to sleep lead to normal decreases in Pa_{O_2} but only modest or trivial decrease in Sa_{O_2} in sleep; this is because the starting Pa_{O_2} is on the flat portion of the oxyhemoglobin dissociation curve (*blue lines* in C). Such a situation, for example, would be typically experienced by individuals living at sea level or with healthy lungs and/or with normal ventilation and lung perfusion. The same magnitude of decrease in ventilation and Pa_{O_2} from wakefulness to sleep, however, can lead to a large decrease in Sa_{O_2} if an individual is initially hypoxic and therefore initially positioned on the steep portion of the dissociation curve (starting Sa_{O_2} of ≈90%). (Modified from Douglas NJ. Respiratory physiology: understanding the control of ventilation. In: Kryger MH, Roth T, Dement WC, eds. *Principles and Practice of Sleep Medicine,* ed 5. St Louis: Elsevier; 2011:250–258; Thompson SR, Ackermann U, Horner RL. Sleep as a teaching tool for integrating respiratory physiology and motor control. *Adv Physiol Educ.* 2001;25:101–116; Horner RL. Pathophysiology of obstructive sleep apnea. *J Cardiopulm Rehabil Prev*. 2008;28:289–298; Horner RL. Respiratory physiology. In: Kushida C, ed. *Encyclopedia of Sleep*, vol. 1. Waltham, MA: Academic Press; 2013:517–524. Copyright Richard L. Horner, PhD, University of Toronto.)

breathing and central apneas at sleep onset, especially when sleep onset follows a perturbation to breathing such as arousal from sleep (see Fig. 117.7). Such a separation could be seen in one or more clinically relevant scenarios. For example, the equilibrium point for waking ventilation could shift to the left (i.e., expressed as decreased waking arterial PCO_2 and increased ventilation) in situations of acute or chronic hyperventilation caused by anxiety, congestive heart failure, sympathetic nervous system overactivity, or other causes. Likewise, the equilibrium point for sleeping ventilation could shift to the right (i.e., expressed as increased sleeping arterial P_{CO_2} and lowered ventilation) with drug-induced respiratory depression due to the neurodepressive effects on respiratory network activity and chemoresponses. In either case, the arousal from sleep per se acts as the initial perturbation to elicit the unstable breathing and central apnea.

Another important clinical implication of the above physiology is that there is an expected reduction in arterial P_{O_2} in patients with parenchymal lung disease at sleep onset. Even patients without hypoxemia during wakefulness may experience clinically significant hypoxemia during sleep, leading some clinicians to screen for desaturation in such patients. Data would indicate that sleep-induced hypoxemia is a more sensitive metric for clinically significant hypoxemia than is exercise-induced hypoxemia, leading some to advocate for sleep testing, for example, in patients with COPD who do not meet criteria for supplemental oxygen based on baseline measurements during wakefulness. However, interventional data are currently lacking to support the use of supplemental oxygen to treat nocturnal hypoxemia. Nonetheless, several studies have suggested a major role for noninvasive ventilation for hypercapnic COPD patients (covered in Chapters 45, 119, and 122).

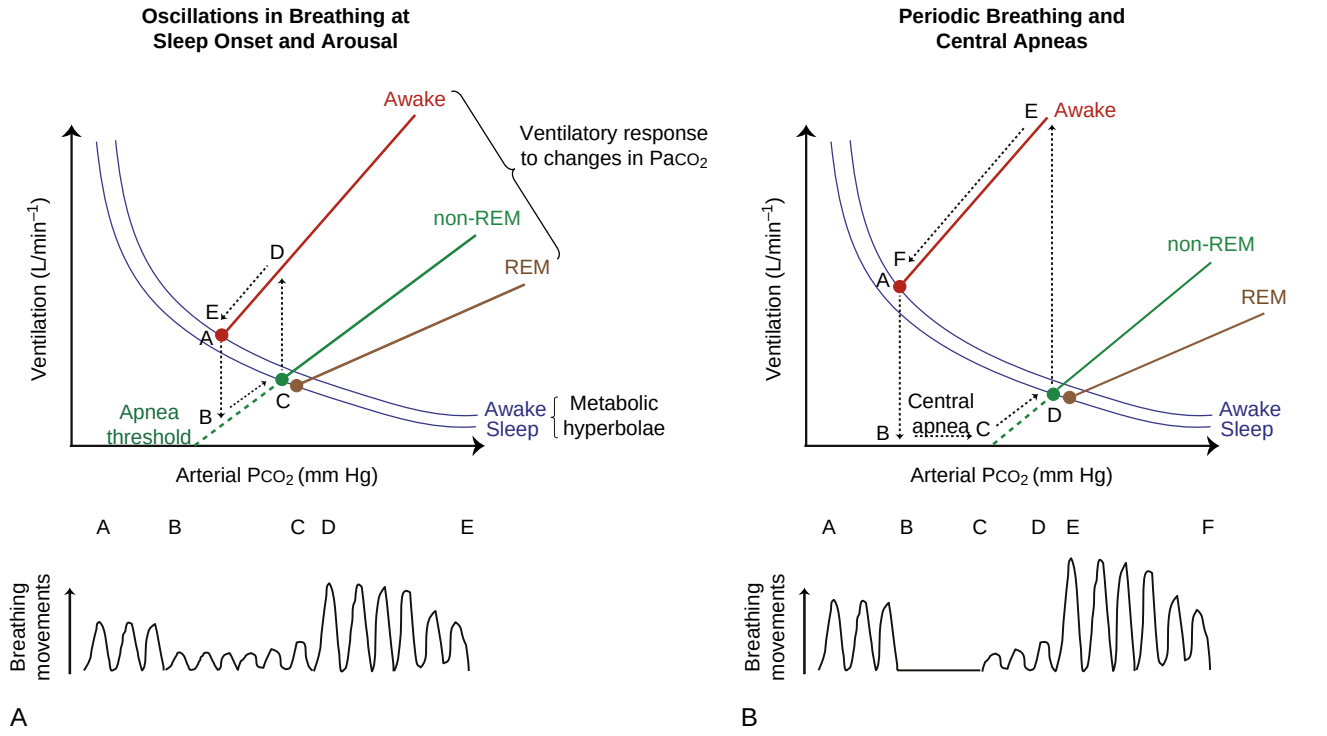

Figure 117.7 How interactions between the ventilatory responses to hypercapnia and transitions between sleep and wakefulness can provoke unstable breathing and central apneas. The equilibrium point for stable breathing in wakefulness is illustrated by point A (*red circle,* A). This equilibrium point intersects the ventilatory response to increased arterial P_{CO_2} (*red line*) and the change in arterial P_{CO_2} that results from a change in ventilation (metabolic hyperbola; *blue line*). The ventilatory response to increased arterial P_{CO_2} in *non–rapid eye movement* (REM) and REM sleep are also shown (*green line* and *brown line,* respectively). Also shown is how a decrease in arterial P_{CO_2} in non-REM sleep can result in reduced ventilation and eventually apnea (*dashed green line*). At sleep onset, the arterial P_{CO_2} that was previously present in wakefulness (*point A*) produces lesser ventilation in sleep according to the extrapolation of the ventilatory response to CO_2 in sleep (*dashed green line, point B*). This decrease in ventilation is out of proportion to metabolic rate so ventilation progressively increases toward the new sleeping equilibrium position (point C, *green circle*). If there is arousal from sleep, then the arterial P_{CO_2} that represents the equilibrium point for breathing in sleep (*green circle*) now represents a hypercapnic stimulus according to the ventilatory response to CO_2 in wakefulness, so that ventilation increases dramatically (points C to D). The elevated level of ventilation at point D is out of proportion to the prevailing metabolic rate so ventilation progressively decreases toward the waking equilibrium position (points D to E, *red circle*). The cycle of waxing and waning of ventilation with the waxing and waning of wakefulness and sleep will continue until sleep is established. The physiologic principle that arises from this effect is that any separation of equilibrium points in wakefulness and non-REM sleep (*red circle* and *green circle*), for any reason can lead to periodic breathing and central apneas at sleep onset. Such periodicity and central apnea is shown in B. (Copyright Richard L. Horner, PhD, University of Toronto.)

UPPER AIRWAY MOTOR TONE AND COMPENSATORY REFLEX RESPONSES ARE PARTICULARLY SENSITIVE TO DEPRESSION IN SLEEP

Principle

The key source of respiratory drive to the hypoglossal motor pool is brainstem sleep-sensitive neurons, whereas the source of drive to spinal respiratory neurons is bulbospinal respiratory neurons. As a consequence of this and other organizational features, hypoglossal motoneurons are not inhibited in expiration, unlike spinal inspiratory motoneurons. Thus, the activity of the genioglossus muscle in expiration is simply a manifestation of the prevailing tonic inputs. It is important to reiterate that the brainstem contains cell groups with sleep state–dependent activity. This organizational feature imparts an important modulation of excitability of the hypoglossal motor pool across natural sleep-wake states as well as a particular susceptibility to the suppressant effects of neurodepressive drugs.

Although change in brainstem neural activity in sleep exerts major effects on the excitability of the upper airway motor pools, it also influences the spinal motor pools via the reticulospinal tract. Notably, this sleep-wake state–dependent influence on the phrenic motor pool is significantly reduced compared to the upper airway motor pools because of the reduced density/impact of those reticulospinal connections. The key physiologic and clinical implications of this organizational feature are that the upper airway muscles are more susceptible to changes in activity across the sleep-wake states and with neurodepressive drugs than is the diaphragm. This notion explains the principle that activity of the diaphragm is relatively preserved across sleep-wake states compared to other respiratory muscles, especially those that serve dual respiratory and nonrespiratory or postural functions such as the muscles of the tongue and chest wall.

Application

Several implications arise from the differential effects of sleep on the respiratory and tonic components of respiratory muscle activity, particularly for the upper airway muscles. For example, the tonic activity of the tongue and palatal musculature contributes to both baseline airway size and stiffness, and the decreased activity in sleep is linked to airway narrowing and the pathogenesis of obstructive

sleep apnea. Suppression of chest wall muscle activity in sleep is thought to increase the compliance of the chest wall (i.e., lower elastic recoil) and contribute to a decreased functional residual capacity; these effects can contribute to hypoventilation, especially in infants because of the already highly compliant chest wall.

OVERARCHING PRINCIPLE: VARIOUS TRAJECTORIES CAN LEAD TO A SLEEP-DISORDERED PHENOTYPE

As outlined in the previous sections, different individuals can experience respiratory dysfunction in sleep for varying reasons; that is, different combinations of factors contribute to both pathogenesis and severity in varying degrees. Given that the involvement of these factors in the pathogenesis of respiratory dysfunction in sleep can also vary within and between subjects— including across the night, between sleep states, at different ages and body weights, and with prescription and nonprescription drugs—there is no single critical mechanism for pathogenesis and no single critical target for therapy for all types of sleep-disordered breathing. The clinical challenge is to devise simple and effective ways to identify the physiologic phenotype of each patient and target the relevant mechanisms operating in each individual. In short, various trajectories can lead to a sleep-disordered phenotype, and the specific mechanisms mediating the trajectories should be identified for each individual to achieve the goal of personalizing therapy.

CLINICALLY RELEVANT CONCEPTS IN RESPIRATORY CONTROL

OBESITY

The high and increasing global prevalence of obesity has led to an increasing appreciation of its important effects on respiratory function. Whereas the obesity-related syndromes of obstructive sleep apnea and obesity hypoventilation are fairly well defined, obesity also impacts other conditions such as asthma and COPD.

Principle

The respiratory effects of obesity can be broadly classified into mechanical influences on the upper airway and chest wall, neurohumoral effects of various adipocytokines, and the possible effects on central respiratory drive as described by the arterial P_{CO_2} set point. By its mechanical effects, obesity has an impact on the upper airway via fat accumulation around the airspace (in the tongue and soft tissues) that increases the propensity for airway collapse.[18] The transmural pressure across the pharyngeal airway is an important variable determining its patency; fat deposition leads to a more negative (less positive) transmural pressure, favoring its collapse. Abdominal fat deposition can further worsen pharyngeal patency by causing small end-expiratory lung volumes that increase upper airway collapsibility through reduced caudal traction forces. Lowered lung volumes also increase the plant gain (i.e., efficiency of carbon dioxide excretion) and thereby increase the tendency to unstable breathing in response to a given perturbation. By its generation of proinflammatory cytokines, obesity has also been implicated in airway inflammation, perhaps contributing to the development of asthma in obese people. Mouse models have suggested an important role for leptin in the control of breathing because ob/ob leptin-deficient mice hypoventilate, and leptin repletion restores their ventilation. However, the impact of leptin on ventilation in humans with obesity is less clear.[19] Finally, by altering arterial P_{CO_2} equilibrium points (or set points, as defined earlier), obesity may affect central respiratory drive. A subset of morbidly obese individuals has elevated arterial P_{CO_2} equilibrium points, likely as a result of cumulative carbon dioxide retention during sleep. It is thought that the elimination of carbon dioxide following arousal is insufficient to eliminate the carbon dioxide that has accumulated during antecedent sleep; the result is a gradual elevation of arterial P_{CO_2} during sleep that eventually persists into wakefulness. However, the underlying genetic and/or neurobiologic mechanisms of obesity hypoventilation syndrome remain to be established (see also Chapter 45).

Application

Obesity is the major reversible risk factor for obstructive sleep apnea. Substantial data show the importance of weight loss in reducing apneas and arterial oxygen desaturations. However, several points about this relationship between obesity and obstructive sleep apnea deserve further emphasis. First, weight loss is difficult to achieve through diet and exercise, and thus bariatric surgery has been receiving an increasingly prominent role in the management of obstructive sleep apnea. Second, even with substantial weight loss, the magnitude of improvement in obstructive sleep apnea severity is often quite modest. For example, in one study, weight loss of 10.7 ± 0.7 kg led to a reduction in the apnea-hypopnea index of only 9.7 ± 2.0 events per hour of sleep.[20] Thus, considerable weight loss may be required to resolve apnea for many patients. Third, several studies have shown that, following either medical or surgical weight loss, obstructive sleep apnea can redevelop over time even without regain of weight. Presumably redistribution of fat and aging both contribute to the recurrence of sleep apnea in these patients. Fourth, some data as well as clinical experience suggest that treatment of sleep apnea is often associated with weight gain.[21] The mechanisms underlying this observation have been debated but are likely related to the fact that treatment of obstructive sleep apnea reduces energy expenditure during sleep and restores social behaviors associated with calorie intake, such as dining out. Regardless of the underlying mechanism, diet and exercise instructions should be provided to the majority of obstructive sleep apnea patients regardless of the treatment approach.

HEART FAILURE

Accumulating literature has suggested a bidirectional relationship between sleep disturbance and heart disease[22] (see also Chapters 119, 120, and 121). Sleep deprivation and sleep apnea have both been associated with an increased incidence of cardiovascular disease. In addition, patients with cardiovascular disease have a very high prevalence of

sleep-disordered breathing. For example, roughly two-thirds of patients with impaired left ventricular systolic function have either obstructive or central sleep apnea. Obstructive apnea and central apnea exist on a spectrum; they often manifest in the same patient and may have similar underlying mechanisms. Although some physiologic literature exists regarding the mechanisms underlying unstable breathing in congestive heart failure, the underlying neurobiology and clinical relevance are less well defined.

Principle

Multiple mechanisms underlie disordered breathing in patients with heart disease. First, chemoreceptor activity is high in patients with congestive heart failure and central sleep apnea compared to that of matched heart failure patients without central apnea.[23] Thus, controller gain, a major component of overall loop gain, is likely high in congestive heart failure patients with central sleep apnea. In patients with pulmonary edema, hypoxemia is commonly present, which may further increase ventilatory drive. Second, because baseline arterial P_{CO_2} is often low in patients with congestive heart failure, these patients are closer to their apnea threshold than are patients with more stable breathing patterns.[24] Third, elevated left atrial pressure can increase ventilatory drive (via reflex mechanisms) and the propensity for apnea by reducing the carbon dioxide reserve.[25] Fourth, accumulation of extravascular lung water has the effect of lowering end-expiratory lung volume (by increasing elastic lung recoil) as well as stimulating juxta-capillary receptors to drive ventilation. Edema formation around the upper airway may also be important in the predisposition to upper airway closure seen in congestive heart failure.[26] Thus, both obstructive and central sleep apnea can develop in these patients due to unstable ventilatory control as well as impaired pharyngeal mechanics.

Application

The treatment of sleep-disordered breathing in congestive heart failure is focused on therapy for the underlying heart failure. In addition, other therapies such as oxygen (which lowers controller gain) and acetazolamide (which lowers circulating CO_2 tension and thus lowers plant gain) can help stabilize breathing,[27] particularly for patients with elevated loop gain. CPAP therapy can benefit some patients, although disordered breathing can frequently persist despite adherence to treatment.[28] In theory, positive airway pressure should be beneficial for these patients because it can reduce cardiac preload and afterload as well as decrease plant gain by increasing functional residual capacity and dead space. Multicenter trials assessing the impact of positive-pressure therapy on clinical outcomes are still ongoing. The data thus far are suggestive, but not definitive, that treatment of obstructive or central sleep apnea is beneficial for patients with congestive heart failure.

AGING

Aging is a major risk factor for both obstructive and central sleep apnea. Other than for children, who have risk of obstructive sleep apnea if they have adenotonsillar hypertrophy, obstructive sleep apnea increases in prevalence with increasing age. Menopause is a risk factor in women.[29] Central sleep apnea also increases in prevalence with increasing age. However, the mechanisms underlying these observations are unclear.

Principle

Aging influences many of the physiologic traits underlying sleep apnea. Aging has been associated with impairment in many reflexes, including those relevant to the upper airway such as the negative pressure reflex that increases pharyngeal dilator muscle activity in response to subatmospheric airway collapsing pressures.[30] Such reflex impairments plus loss of tensile tissue strength over time both likely contribute to the observed increase in collapsibility of the pharyngeal airway during sleep in older as compared to younger individuals. Because fat also tends to deposit preferentially around the upper airway with aging, the parapharyngeal fat pads are increased in size in older versus younger individuals, independent of overall body weight. Aging is also known to reduce lung elastic recoil, although the impact of this finding on pharyngeal mechanics remains unclear. Regarding control of breathing, several studies have shown no major impact of aging on overall loop gain,[31] although ongoing research is further examining this issue.

Application

Given that the mechanisms underlying sleep apnea in older individuals may be different from those in younger individuals, there may be clinical implications to these findings. For example, an individualized approach to therapy may target an impaired negative pressure reflex in an older individual by pharmacologic manipulation of the sensory or central neural components, whereas other approaches may be more fruitful in younger obstructive sleep apnea patients. In addition, because the mechanisms underlying apnea may differ in older individuals, the adverse consequences may well be different in older versus younger obstructive sleep apnea patients. For example, esophageal pressures become less negative in elderly obstructive sleep apnea patients compared to younger patients,[32] presumably due to aging-related differences in either the arousal threshold or ventilatory drive. Because esophageal pressure is a surrogate for the pressure outside the heart, it would be predicted that transmural cardiac pressures (and hence cardiac wall stress/afterload) would be lower in elderly as compared to younger obstructive sleep apnea patients for a given respiratory event. Such pathophysiologic findings may help explain the fewer consequences to obstructive sleep apnea in the elderly as compared to younger patients.[33] Indeed, sleep apnea in the elderly may have a different underlying pathophysiology than in younger individuals and both the causes and consequences may vary with age.

OTHER CLINICAL CONDITIONS

Most respiratory disorders show deterioration in gas exchange during sleep. Although the neurobiologic basis underlying the observed abnormalities is less well understood, several principles can be discussed further regarding hypoventilation syndromes, neuromuscular disease, and parenchymal lung disease.

Principles

At least three factors are likely essential to the deterioration of gas exchange frequently observed during sleep in patients with respiratory disorders. First, the behavioral influences or the wakefulness stimulus to breathing is withdrawn upon transition from wakefulness to non-REM sleep. Accordingly, with the onset of sleep the drive for ventilation is reduced almost immediately. As a result, arterial P_{CO_2} levels tend to rise in sleep, and hypoventilation tends to get worse in patients with chronic respiratory acidosis. During REM sleep, however, the behavioral influences may be restored to some extent compared to non-REM sleep, leading to improvement in gas exchange in some patients. Second, as discussed earlier, the upper airway narrows during non-REM sleep so that controller gain as defined by chemoresponsiveness is reduced. This reduction of controller gain leads to lower change in minute ventilation for any given increase in arterial P_{CO_2}. Third, during REM sleep, there is atonia of the accessory muscles of respiration so that patients reliant on these muscles become more dependent on diaphragmatic activity to achieve ventilation. For some patients, REM sleep thus leads to marked hypercapnia and hypoxemia due to a concomitant fall in chemosensitivity compared to non-REM sleep. End-expiratory lung volume also decreases in various stages of sleep, likely as a function of decreased motor output to the muscles of the chest wall, leading to a reduced functional residual capacity and increased propensity for oxygen desaturation and unstable breathing by increases in plant gain.

Application

The aforementioned conditions lead to deterioration of gas exchange in patients with most respiratory conditions, including those with alveolar hypoventilation, neuromuscular disease, and parenchymal lung disease.

Hypoventilation. Patients with baseline hypercapnia often experience worsening hypercapnia during non-REM sleep. The effect of REM sleep is quite variable, however, because some patients, such as those with CCHS, actually show improvement in gas exchange during REM sleep. On the other hand, some hypoventilation patients, such as those with obesity hypoventilation, may experience further worsening of gas exchange during REM sleep compared to non-REM sleep. In general, bilevel ventilation is effective at maintaining gas exchange during non-REM and REM sleep in hypoventilation patients, although CPAP alone has been effective in obesity hypoventilation syndrome. Various respiratory stimulants have also been considered but, in general, the results have been disappointing.

For patients using chronic opioids, central sleep apnea and hypoventilation are common, although mechanisms are not well studied. In theory, the elevated baseline arterial P_{CO_2} seen with opioids can lead to breathing instability via an increased plant gain. Sleep-disordered breathing (both obstructive sleep apnea and central sleep apnea) is common in patients using chronic opioids, affecting up to 50% of patients in some series. Sleep disturbance has been associated with worsening pain, which leads some patients to seek increased analgesia. Some authors have shown a dose dependence to opioid-induced central apnea, so that a reduction in dose should be a first-line measure. Other treatment options have been considered, including adaptive/auto-servoventilation, but rigorous outcome data are lacking.

Neuromuscular Disease. Patients with neuromuscular disease also experience deterioration of gas exchange during non-REM sleep with further worsening during REM sleep (see also Chapter 130). The loss of the wakefulness stimulus, compromise of upper airway motor tone, atonia of the accessory respiratory muscles during REM sleep, and fall in functional residual capacity may all contribute to respiratory compromise in these patients. Treatment of these patients involves addressing the underlying cause (if possible) and using bilevel noninvasive ventilation as part of supportive care.

Parenchymal Lung Disease. In patients with parenchymal lung disease, such as emphysema or pulmonary fibrosis, similar mechanisms can underlie the worsening gas exchange experienced during non-REM and REM sleep. Treatment is again supportive; it should also address the underlying lung disease to the extent possible. A subset of patients also exists with the so-called overlap syndrome, which consists of the combination of COPD with obstructive sleep apnea. These patients are known to have excess cardiovascular mortality, although no clinical trials to date have addressed the optimal treatment of such overlap patients (see Chapters 119 and 122).

INDIVIDUALIZED THERAPY TARGETING UNDERLYING MECHANISMS

The current treatment of choice for obstructive sleep apnea is nasal CPAP. This treatment option has excellent efficacy and is generally well tolerated, but results can be somewhat variable in clinical practice. Alternative therapies exist, but these also have limited effectiveness and can be expensive and cumbersome for the patient. As a result, many investigators have advocated for further mechanistic-based research to define new therapeutic approaches based on the individual predisposition to sleep-disordered breathing. The recent appreciation for the multifactorial nature of obstructive sleep apnea[34] has opened the way to treatment for this disorder based on underlying endotypes or mechanisms; for example, there may be anatomic abnormalities at the level of the soft palate (the velopharynx) or behind the tongue (the retroglossal airspace). Clinical studies show that the upper airway almost always collapses at the level of the velopharynx in patients with obstructive sleep apnea, but in about half of these patients the obstruction also extends caudally to the retroglossal airspace.[35] In REM sleep, the lower level of the obstruction can extend to even more caudal levels compared to non-REM sleep, most likely due to the greater suppression of pharyngeal muscle activity in REM sleep. For individuals with a primary problem of velopharyngeal compromise, palatal surgery such as uvulopalatopharyngoplasty would be predicted to have reasonable efficacy, but less so for individuals with retroglossal airway collapse.

For those individuals with obstructive sleep apnea driven primarily by increased loop gain, interventions that effectively lower loop gain, such as inhaled oxygen or oral acetazolamide, would be predicted to improve respiratory abnormalities. However, the conceptual and clinical utility of loop gain is in the experimental research and validation stages and requires sophisticated interventional and analytic tools, which has limited more widespread application at this time. Some individuals may have a primary problem of upper airway muscle tone in sleep and/or reflex compensatory responses; such individuals may respond to pharmacologic approaches to increase hypoglossal output[36] or potentially to efforts to stimulate the hypoglossal nerve.[37] Although some recent studies have suggested drug combinations that may have utility,[38] we would advocate for larger well-designed studies showing improvements in clinical outcomes before making clinical recommendations. Individuals who have multiple predisposing factors contributing to obstructive sleep apnea may benefit from combinations of therapies to resolve the underlying abnormalities. The potential for an individualized approach to obstructive sleep apnea therapy based on underlying mechanisms has received recent attention using the concept of personalized medicine. This concept can be applied to the spectrum of respiratory abnormalities during sleep.

Key Points

- Obstructive sleep apnea is common; combinations of upper airway anatomic abnormalities, instabilities in ventilatory control, and variations in upper airway dilator muscle control all contribute to the predisposition to upper airway obstruction within an individual.
- *Rapid eye movement* (REM) sleep is associated with generalized skeletal muscle atonia that also affects the tone in the upper airway dilators such as the genioglossus. Mechanisms of genioglossus muscle atonia are thought to include withdrawal of excitatory inputs from wakefulness-dependent cell groups and active inhibition.
- Non-REM sleep plus sedative and anesthetic-induced neurodepressive brain states are associated with reduced hypoglossal motor output and tongue muscle activity that contribute to upper airway obstruction, particularly in individuals who are anatomically predisposed.
- Opioid narcotics contribute to central apnea and respiratory depression by activating opioid receptors and thereby suppressing the output from the pre-Bötzinger complex, a key site for respiratory rhythm generation in mammals, as well as from other components of the respiratory network that together generate rhythmic breathing and lung ventilation. Opioid narcotics can also contribute to severe respiratory depression in sleep by blunting the tonic excitatory stimulation of arousal-related inputs to the respiratory network, dampening the compensatory ventilatory responses to asphyxia, and causing sedation and failure to arouse.
- The normal decrease in ventilation from wakefulness to sleep usually results in trivial decreases in arterial oxygen saturation because the starting alveolar P_{O_2} is on the flat portion of the oxyhemoglobin dissociation curve. However, any situation that lowers alveolar P_{O_2} in wakefulness (e.g., altitude, lung disease) predisposes to hypoxemia in sleep, especially in REM sleep, if the awake alveolar P_{O_2} is on or close to the steep portion of the oxyhemoglobin dissociation curve.
- Obesity contributes to obstructive sleep apnea primarily through anatomic effects on the upper airway and the chest wall, although influences of adipocytokines on ventilatory control may also be important.
- Loop gain is a term used to describe the predisposition to instability in a feedback control system. Elevated loop gain defines a system prone to instability (i.e., one that can develop periodic behavior after even minor perturbations). Conditions such as congestive heart failure may be associated with increased loop gain as manifested by unstable breathing patterns.
- Aging is associated with impaired protective upper airway reflexes and anatomic changes that may make the pharyngeal airway vulnerable to collapse.

eFigure 117.1 There are multiple sites of chemoreception/responsivity to changes in CO_2/H^+ in the brain. Some of these sites are intimately associated with regulation of brain arousal in sleep and wakefulness (e.g., serotonin and noradrenaline containing cell clusters; see Figure 117.1). Other sites are intimately associated with respiratory neuronal activity and reflex responses (e.g., nucleus tractus solitarius and ventral respiratory group; see Figure 117.3). A key site intrinsically sensitive to alterations in CO_2/H^+ is the retrotrapezoid nucleus located near the ventral surface of the medulla. This region of the brain is magnified in the panel at *right*. Branching dendrites from retrotrapezoid neurons "taste" the cerebrospinal fluid at the medullary surface and are activated by increased CO_2 (lowered H^+). Activity related to CO_2/H^+ influences several brain regions, including the ventral respiratory group, thus driving breathing. The *inset* shows the response of a brainstem serotonergic neuron to increases in inspired CO_2. There are several features of note: (1) baseline activity (i.e., at zero inspired CO_2) is higher in wakefulness than in sleep; (2) the neuronal activity at any given inspired CO_2 is greater in wakefulness than in sleep; and (3) the slope (gain) of response is also greater in wakefulness than in sleep. Together, these three features parallel with the changes in the overall respiratory responses to CO_2 as measured by changes in ventilation (compare with Figure 117.6). (Copyright Richard L. Horner, PhD, University of Toronto.)

INTRODUCTION

Sleep is an integral part of health and well-being. It is an active process that is highly regulated and evolutionarily conserved. Sleep is required for preservation of energy, restoration, reparation, and rejuvenation of normal physiologic function, including immunity, muscle growth, tissue repair, protein synthesis, and clearance of brain metabolites such as adenosine. Sleep facilitates brain neural plasticity, the process by which the central nervous system alters itself both structurally and functionally in response to experiences, which is important for consolidating memories and learning.

Healthy sleep is characterized by optimal regularity of sleep over many days, satisfaction with sleep quality, daytime alertness (i.e., restorative capacity), proper timing (i.e., aligned with one's circadian rhythm), high efficiency (i.e., a low number of awakenings and time spent awake after falling asleep), and sufficient duration.[1] Sleep disruption can therefore be defined as any process that threatens healthy sleep. Many of the causes of sleep disruption are behavioral or environmental and can include staying up late to watch television or engage on social media, loud noises or lights that interfere with the ability to sleep (common in inpatients), and caregiving requirements for spouses, children, or others who have care needs through the night. Primary sleep disorders are another important cause of sleep disruption that impacts sleep across multiple domains. For example, *obstructive sleep apnea* (OSA) fragments sleep; it decreases continuity, reduces quality, and impairs daytime alertness. Shift work (i.e., work outside the standard 9 AM to 5 PM business day) adversely impacts all sleep health domains. Finally, comorbid illnesses can impair sleep either directly (e.g., nocturnal asthma causing frequent awakenings or depression causing early morning awakenings) or indirectly (e.g., nighttime β-agonist use causing insomnia or diuretic use causing frequent awakenings).

Sleep-wake patterns are regulated for the most part by two strong drivers—circadian rhythms and homeostatic pressures.[2] Circadian output from the suprachiasmatic nucleus in the hypothalamus tends to maintain a regular daily timing for sleep and wakefulness as well as a wide range of other physiologic processes. While the intrinsic circadian period in humans is about 24.3 hours, regular light exposure, a major modulator of the circadian rhythm, maintains circadian rhythms on a 24-hour period in normal humans. In addition, homeostatic forces regulate sleep so that the drive to sleep increases as time since the last period of sleep increases. These two forces interact to support a regular daily sleep pattern over time. Sleep itself can be further divided into two separate states, *rapid eye movement* (REM) and *non-REM* (NREM) sleep, different from each other and from wakefulness in their unique *electroencephalogram* (EEG) patterns and physiologic characteristics. REM sleep is characterized by an EEG pattern similar to wakefulness (mixed frequency, low amplitude), but with skeletal muscle atonia (except for the extraocular muscles and diaphragm). NREM sleep, in contrast, is characterized by a slowing of EEG frequency as compared to wakefulness (stage N1), synchronized EEG signals (sleep spindles, K complexes in stage N2), and slower delta frequency EEG activity (stages N3, slow-wave sleep, delta sleep). Both REM and NREM sleep have their own circadian and homeostatic regulation interacting to produce the typical sleep architecture of normal sleep, which displays a pattern of four to five cycles of sleep approximately 90 minutes in duration. Each of these *ultradian* (less than 24 hours) cycles consists of NREM sleep (in progressively deeper stages) followed by a period of REM sleep, with each progressive ultradian cycle exhibiting longer periods of REM sleep and less slow-wave sleep (Fig. 118.1). Sleep disruption that interferes with normal sleep architecture can reduce amounts of REM and/or slow-wave sleep, resulting in physiologic perturbations.

Sleep health can be assessed across at least six dimensions (regularity, satisfaction, daytime alertness, timing, efficiency, and duration). The pattern of deficits can be helpful in identifying the underlying etiology. A combination of interview and standardized questionnaires from the patient, as well as objective testing, can be used to assess each of these dimensions (Table 118.1). This information

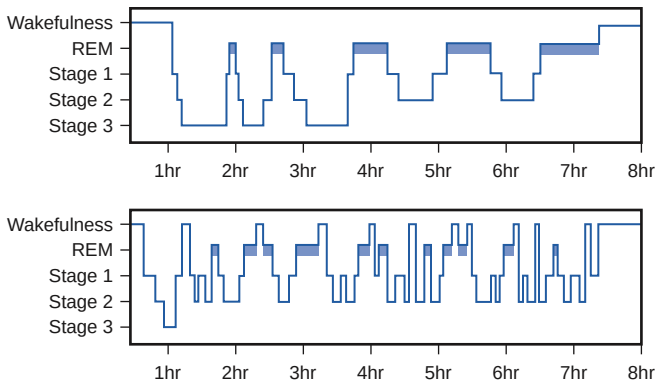

Figure 118.1 Hypnograms of normal sleep architecture and severe sleep fragmentation. Hypnograms and sleep stages of a healthy individual (*top*) are distinct from those of a patient with obstructive sleep apnea (*bottom*). The patient with obstructive sleep apnea has severe fragmentation with disrupted sleep architecture characterized by loss of stage 3 sleep, significantly reduced rapid eye movement (REM) sleep, and frequent awakenings.

can then narrow the differential diagnosis. For example, reduced sleep satisfaction and alertness associated with adequate duration are suggestive of reduced sleep efficiency from a sleep fragmentation disorder such as OSA. Reduced alertness in the setting of normal sleep efficiency and normal to increased duration indicate a primary hypersomnia disorder such as narcolepsy.

EFFECTS OF SLEEP DISRUPTION ON ACUTE AND CHRONIC DISEASE

The effects of sleep disruption on acute illness have been examined through observational studies and short-term intervention trials, often with experimentally induced sleep disruption. The evidence for long-term effects of chronic sleep disruption is primarily derived from observational longitudinal cohort studies. Sleep disruption results in various pathophysiologic disturbances, causing short- and long-term consequences (Fig. 118.2). Increased recognition of the impact of sleep disruption on safety and health has led to greater efforts to develop robust, randomized long-term evidence to evaluate the effectiveness of sleep-focused interventions to improve health.

NEUROCOGNITIVE CHANGES

Acute Effects

The fact that even a single night of sleep disruption can cause significant disturbance in memory, concentration, and attentiveness should not come as a surprise to anyone who has experienced a sleepless night. The cognitive dysfunction associated with sleep restriction for 28 hours has been shown to be roughly equivalent to that associated with consuming alcohol up to a blood alcohol concentration of 0.10%, which is considered legally impaired if driving.[3] Neurocognitive testing in patients with acute total or partial sleep deprivation reveals global cognitive impairment, but certain cognitive domains, including executive function, sustained attention, and long-term memory, are particularly susceptible.[4] Persons with sleep deprivation are therefore prone to cognitive limitations such as decreased insight, inability to integrate emotion and cognition to guide moral judgments, decreased flexibility in thinking, a propensity for perseveration, difficulty with understanding the temporal order of information, and difficulty assimilating and integrating new information.[5–7]

Imaging studies have been employed to identify the regions of the brain responsible for the neurocognitive impairments seen with sleep disruption. The prefrontal cortex, thalamus, and posterior parietal cortices appear to be regions of the brain responsible for attention and higher-order cognition.[8] With sleep deprivation, there are global decreases in activity in these cortical and subcortical structures,[9–10] which may explain the findings of reduced attention and working memory with sleep disruption.

Impaired neurocognition is likely a major factor in the increased incidence of work-related injuries and death in persons with sleep disorders. Extremely sleepy workers are 70% more likely to be involved in accidents than non-sleepy workers.[11] In a large 20-year Swedish prospective cohort study, sleep disruption in the previous 2 weeks was associated with nearly double the risk of fatal occupational accidents.[12] Sleep disruption has been implicated, at least in part, in some of the most devastating human and environmental health accidents around the world, including the nuclear reactor meltdowns at Three Mile Island and Chernobyl; the chemical plant leak in Bhopal, India; the grounding of the Exxon Valdez oil tanker; and the space shuttle Challenger explosion.[13] The Agency for Healthcare Research and Quality has identified both fatigue and sleep deprivation of health care providers as threats to patient safety, primarily as a result of errors in medical decision making and clinician burnout.[14]

Chronic Implications

Chronic sleep disruption is implicated as both a cause and an effect of cognitive impairment, and the body of supporting

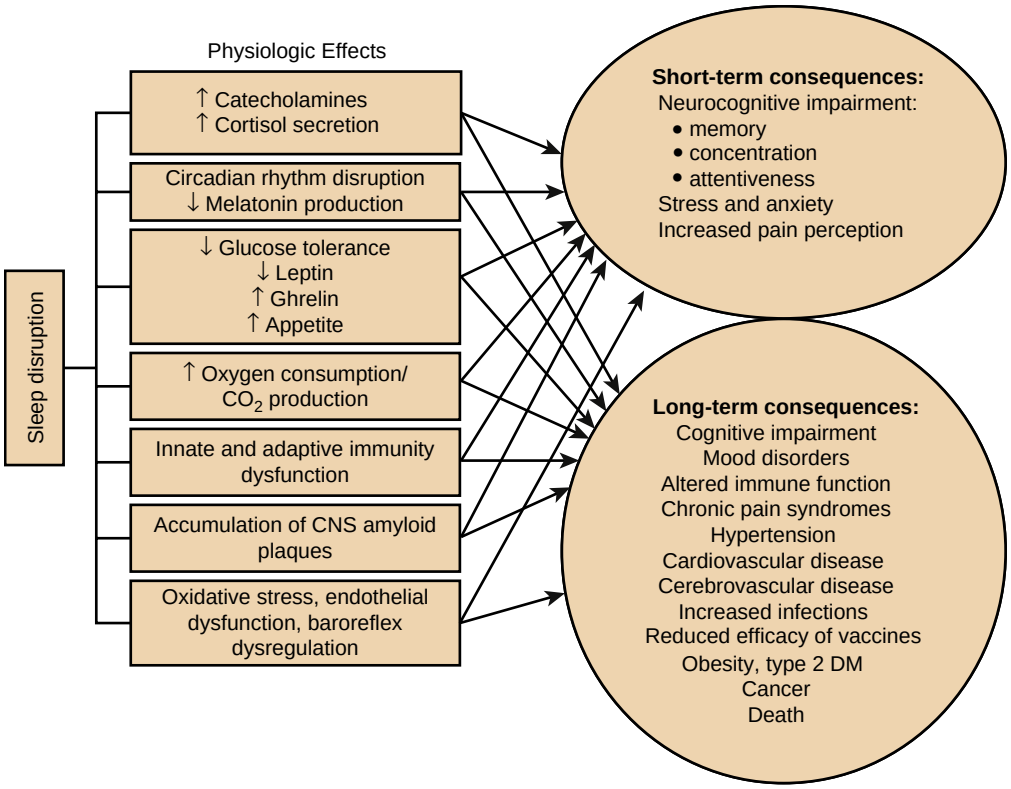

Figure 118.2 Physiologic effects and consequences of sleep disruption. Sleep disruption leads to multiple physiologic changes. These changes lead to short-term and long-term consequences for health. CNS, central nervous system, DM, diabetes mellitus.

evidence is growing. Sleep disruption is common in patients with preclinical Alzheimer disease, mild cognitive impairment, Parkinson disease, and Lewy body dementia, as manifested by disordered sleep architecture, excessive daytime sleepiness, and daytime napping.[15–18] Alterations in physiologic circadian rhythms, reduced melatonin secretion, degeneration of retinal ganglion cells, and dysregulation of circadian clock gene expression have been demonstrated in Alzheimer disease patients.[19] The clinical significance of this is less straightforward given that polymorphisms in these clock genes have not yet been associated with sleep-wake disturbances.[20] Chronotherapy, particularly bright light therapy, targeted to treat circadian rhythm disturbances in patients with Alzheimer disease, has been shown to improve the duration and continuity of nighttime sleep, reduce sundowning agitation, and improve cognition.[21] Characteristic pathophysiologic changes of amyloid-β deposition and neurofibrillary tangles in the *central nervous system* (CNS) often affect the hypothalamus, where hypocretin-1, a sleep-wake regulating polypeptide, is synthesized.[22,23] The prevalence of OSA is more than 40% in patients with Alzheimer disease and other dementias, further contributing to sleep fragmentation in these patients.[15,24]

Sleep disruption may contribute to the development and progression of cognitive decline through numerous mechanisms. One of the proposed teleologic functions of sleep is to provide time for clearance of metabolites and compounds from the CNS. Mouse models have been used to demonstrate that amyloid-β is cleared most efficiently during sleep through the glymphatic system of the CNS; with chronic sleep deprivation, accumulation of amyloid plaques is accelerated.[25] Consistent findings are found in human studies, with self-reported sleep deprivation or poor sleep quality associated with increased amyloid-β deposition in the CNS.[26] The intermittent hypoxia and sleep fragmentation characteristic of OSA may also cause neurodegeneration through inflammation and cell signaling impairment, but these mechanisms require further investigation. Nevertheless, the rate of progression in cerebrospinal fluid amyloid-β levels over 2 years correlates with OSA severity.[27]

PSYCHIATRIC DISORDERS

Sleep is an integral part of mental health. Indeed, sleep disruption is included as part of the diagnostic criteria for many psychiatric diseases.[28] Sleep disturbances are a risk factor for onset and exacerbation of psychiatric disorders, particularly depression, bipolar disorder, posttraumatic stress disorder, and alcoholism, emphasizing the need to address sleep disorders in parallel with treatment of the psychiatric condition. Conversely, many psychiatric diseases can impair sleep. In addition, common pharmacologic therapies for psychiatric disorders, including benzodiazepines, antidepressants, and antipsychotics, have adverse effects on sleep, including both sedation and insomnia that can limit the effectiveness of these medications.

Acute sleep deprivation can exacerbate psychiatric disease and has been demonstrated to increase anxiety levels.[29] This increase in anxiety along with emotional dysregulation and disrupted circadian rhythms caused by a lack of sleep may explain why acute sleep deprivation can serve as a trigger for acute mania in patients with bipolar disorder as well as a trigger for suicidal behavior.[30,31]

Major depressive disorder is the most extensively studied mood disorder with regards to sleep. Self-reported poor

sleep quality is present in 90% of individuals in a depressive episode, with two-thirds reporting insomnia and about 15% reporting hypersomnia.[32,33] Polysomnographic characteristics of sleep in patients during a depressive episode include longer sleep latency, increased *wake (or wakefulness) after sleep onset* (i.e., the periods of wakefulness after sleep onset), and more early morning arousals—all resulting in poorer sleep efficiency. Changes in sleep architecture are common in mood disorders. REM sleep abnormalities are the most consistent finding in depression, including reduced REM latency, prolonged duration of the first episode of REM, increased REM density (frequency of eye movements during REM), and reduced time in NREM slow-wave sleep.[34] Many classes of antidepressant medications are linked to suppression of REM sleep.[35] Patients with bipolar disease demonstrate similar polysomnographic findings of frequent arousals, reduced slow-wave sleep, shortened REM latency, and increased REM density.[36] Changes in sleep architecture in patients with major depressive disorder and bipolar disease may persist even after an acute episode, and persistence of these sleep abnormalities predicts an increased risk of relapse.[37–40]

There is strong evidence that poor sleep predisposes to, exacerbates, and perpetuates mood disorders. One meta-analysis found that patients with insomnia symptoms are 2.6 times more likely to develop new-onset depression as compared to those without insomnia symptoms.[41] A population-based cohort study that included polysomnography data showed that frequent complaints of difficulty falling asleep accompanied by abnormalities in sleep latency, continuity, and duration all predicted development of incident depression.[42] Reduced sleep efficiency predicted worsening of manic symptoms over 19 months in a longitudinal cohort study of patients with either depression or bipolar disorder.[43] Treatments targeting sleep disruption are associated with improved outcomes in patients with mood disorders. In patients with comorbid major depressive disorder and insomnia, randomized trials have shown insomnia therapy combined with antidepressant therapy improves depressive symptoms more than antidepressant therapy alone.[44] Circadian phase also plays an important role in mood disorders; individuals with delayed sleep phase are at higher risk for depressed mood, and morning light therapy, which advances sleep phase, can improve mood. In fact, morning bright light therapy is the first-line treatment for seasonal affective disorder.

Sleep disruption is a hallmark of posttraumatic stress disorder and may include nightmares, insomnia, dream enactment, and sleep apnea. Flashbacks of trauma are experienced as nightmares that disrupt normal sleep and may incite and perpetuate fear of sleeping. A constant state of excessive hyperarousal frequently leads to an inability to fall asleep or return to sleep during middle-of-the-night awakenings. Daytime hypersomnia may or may not be present, depending on the degree of the underlying state of hyperarousal. Nightmares and insomnia are often refractory to medications (antidepressants and α-antagonists), but sleep-focused behavioral interventions, including image rehearsal therapy and cognitive behavioral therapy for insomnia, have proven successful in improving both sleep symptoms and overall posttraumatic stress disorder severity.[45] Treatment of comorbid OSA may also improve sleep symptoms and posttraumatic stress disorder severity.[46]

Alcohol is a common drug used to self-medicate in an attempt to treat insomnia, and alcohol use is considered a marker of severity of insomnia. As a soporific, alcohol promotes sleep at the beginning of the night by inducing drowsiness, but it disrupts sleep later in the night by lowering the arousal threshold as blood alcohol levels fall, increasing the likelihood of early morning awakenings.[47] It also worsens snoring and sleep apnea, further disrupting sleep through arousals related to disordered breathing events. Patients with alcohol-induced sleep disruption may escalate their alcohol consumption in an attempt to treat the early morning awakenings, contributing to a vicious cycle of abuse. Consumption of alcohol may delay circadian rhythms and further increase the risk of alcohol use disorder.[48] Insomnia is a strong predictor of relapse in patients with alcohol use disorder,[49] highlighting the importance of treating comorbid insomnia in this population.

PAIN PERCEPTION

Chronic pain is a highly prevalent condition, with 20.4% of U.S. adults reporting chronic pain and 8% of U.S. adults reporting pain severe enough to interfere with their ability to engage effectively in employment, self-care, social interactions, and recreational activities.[50] Chronic pain is associated with substantial health care costs, reduced quality of life, and indirect societal costs such as job absence, reliance on opioid pain medications, and reduced work productivity. There is a bidirectional relationship between pain and sleep quality. Pain can be a significant reason for interruption of sleep. Conversely, disturbed sleep can result in increased pain perception, particularly hyperalgesia. Possible hypotheses for pain amplification due to sleep disruption include (1) exacerbation of the underlying painful condition due to sleep disruption (e.g., worsening headache related to insufficient sleep syndrome), (2) increased sensitivity of peripheral nociceptors, (3) heightened sensitivity for pain signals in the CNS, and (4) reduced inhibitory mechanisms of pain perception in the CNS.[51–53]

Acute Effects

The effects of short-term sleep disruption on pain perception have been studied in experimentally altered sleep conditions, primarily with complete and partial acute sleep deprivation. Just 1 or 2 nights of total sleep deprivation results in increased pain perception in response to exposure to both cold and heat, as well as in both superficial and deep tissues, when compared to habitual sleep (i.e., average nightly sleep duration).[54–56] Studies examining stage-selective sleep deprivation (targeted deprivation of just slow-wave sleep or REM sleep) have resulted in mixed and inconclusive results about whether sleep stages are important in perception of pain and, if so, which ones.[52]

Chronic Implications

Chronic sleep disruption in conditions such as untreated sleep-disordered breathing, insomnia, sleep insufficiency, and shift work may also affect pain thresholds. While acute sleep disruption affects immediate sensitivity to pain, chronic sleep disorders interfere with the ability to habituate to chronic pain.[57] Persons without pain at baseline are also at greater risk of developing pain disorders with chronic

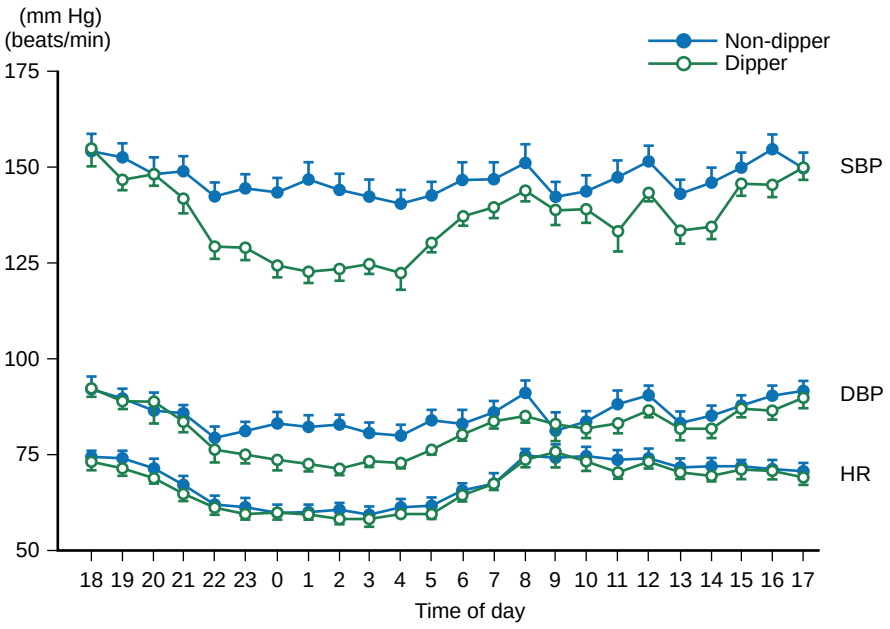

Figure 118.3 Demonstration of dipper and non-dipper patterns of blood pressure during sleep. Diurnal changes in blood pressure in dipper and non-dipper essential hypertensive subjects. The changes in *systolic blood pressure* (SBP) and *diastolic blood pressure* (DBP) were significantly different between the two groups. The changes in *heart rate* (HR) were not different between dipper and non-dipper hypertensive subjects. (From Kohara K, Nishida W, Maguchi M, Hiwada K. Autonomic nervous function in non-dipper essential hypertensive subjects. Evaluation by power spectral analysis of heart rate variability. *Hypertension*. 1995;26[5]:808-814.)

sleep disruption. In a 2-year longitudinal study, nurses who were free of pain at baseline were more likely to develop lower back pain if they were shift workers, and the effects were amplified in shift workers who were overweight/obese.[58]

OSA has been implicated in altering pain processing through both sleep fragmentation and recurrent nocturnal hypoxemia, although the differential effects of these two mechanisms on chronic pain are unclear. Some evidence suggests that chronic sleep fragmentation results in hyperalgesia, although other studies do not support this association.[59,60] Interestingly, intermittent hypoxemia may actually reduce opioid requirements for pain control by increasing expression of opioid receptors.[61] Extension of sleep duration over a 4-day period in patients with objective evidence of mild hypersomnia reduced pain sensitivity and improved daytime somnolence, suggesting a potential therapeutic sleep intervention.[62] Patients with chronic pain and chronic sleep insufficiency randomized to no sleep intervention had more postoperative pain and more postoperative narcotic pain medication requirements after hip or knee surgery than those who were randomized to extension of their sleep by 1 hour/night for a week prior to surgery.[63]

CARDIOVASCULAR DISEASE

The complex association between sleep and cardiovascular health has been a topic of interest for researchers for decades. Elevated blood pressure is the most common cardiovascular condition associated with disrupted sleep and likely contributes to other cardiovascular morbidities. Both sleep fragmentation, with recurrent sympathetic activation from sleep arousals, as well as sleep deprivation, increase nocturnal blood pressure and dampen the normal "nocturnal dipping" pattern of blood pressure seen with healthy sleep (Fig. 118.3).[64,65] Non-dipping is also associated with untreated OSA. Any disruption to sleep, whether from sleep-disordered breathing, sleep-related movement disorders, or primary insomnias, may lead to persistent elevation of blood pressure at night. This persistent elevation of blood pressure in non-dippers is thought to contribute to cardiovascular sequelae and is independent of perceived sleep quality. For example, insufficient sleep duration and poor sleep consolidation have been identified as independent predictors of incident hypertension.[66,67] Shift workers with night work have interference with the nocturnal dipping in blood pressure, resulting in elevated blood pressure the following shift, and increased risk for chronic hypertension and cardiovascular disease.[68] Potential mediators of cardiovascular pathology due to sleep disruption include oxidative stress, inflammation, endothelial dysfunction, and baroreflex dysregulation.[69,70] Sympathetic nervous system activity is likely to be increased as well, although this is not a consistent finding in clinical studies.[71–73]

There is growing evidence identifying sleep disruption as a predictor of subsequent cardiovascular disease. Self-reported short sleep duration has been associated with incident coronary artery disease and increased coronary artery calcification.[74,75] In subjects with established coronary artery disease, objectively measured short sleep duration (less than 6 hours) and long sleep duration (greater than 8 hours) are both associated with increased atherosclerotic burden even after controlling for multiple known cardiovascular risk factors.[76] Short sleep duration is also associated with atrial fibrillation, with each hour of sleep reduction associated with 1.09- and 1.17-fold increase in risk of incident and prevalent atrial fibrillation, respectively.[77] Observational studies have demonstrated an association of insomnia with coronary artery disease as well as with congestive heart failure.[78] The conditioned hyperarousal state, which predisposes a person to chronic insomnia, is characterized by increased sympathetic nervous system activity and hypothalamic-pituitary-adrenal axis stimulation, which may be causally related to coronary artery disease risk.[78,79]

Sleep disruption is also associated with increased incidence of cerebrovascular disease. Self-reported sleep duration appears to be strongly associated with stroke risk, with an overall hazard ratio for stroke in short sleep duration of 1.15 (95% confidence interval, 1.07 to 1.24) and hazard ratio for stroke in long sleep duration of 1.45 (95% confidence interval, 1.30 to 1.62).[80] Insomnia is also a predictor of stroke risk. Those who reported insomnia symptoms had a 54% higher risk of stroke over a 4-year follow-up period compared to an age- and gender-matched control group.[81]

Multiple epidemiologic studies have demonstrated a U-shaped curve of the association of self-reported habitual sleep duration and mortality; both subjective short sleep duration and long sleep duration are associated with higher mortality.[74,82–84] Interestingly, however, studies that quantify sleep duration with objective measures (e.g., actigraphy [i.e., activity monitoring] or polysomnography) have not consistently found an association between longer sleep and mortality, suggesting this paradoxical association with self-reported long sleep may not be due to prolonged sleep per se. Instead, the excess mortality associated with habitual self-reported long sleep may be due to coexisting OSA, poor sleep efficiency, or other sleep disorders, which may cause the perception of long sleep duration.[85]

IMMUNE FUNCTION

Sleep plays an integral role in the normal function of the immune system. Both circadian and homeostatic drives have important effects on immune function, with sleep regulating both innate and adaptive immunity. Circadian rhythms, independent of nocturnal sleep, are responsible for regulation of both innate and adaptive immune cells, with maximum circulating cell counts in the evening followed by reductions through the night. This regularity is driven by various systems, primarily changes in both the hypothalamic-pituitary-adrenal axis and the sympathetic nervous system.[86] Sleep-dependent changes happen in both innate and adaptive immunity. Natural killer cellular activity, an innate immune response, increases with sleep. Similarly, production of adaptive cytokines, including *interleukin* (IL)-2, interferon-γ, and IL-12, and a reduction of IL-10, an anti-inflammatory cytokine, are observed with nocturnal sleep.[86]

Disturbances of sleep thus can impact both the innate and adaptive immune systems. These conclusions are drawn from numerous supportive studies resulting in impaired response to infectious challenges as well as cellular and gene markers of inflammation. For example, with a single night of sleep deprivation, natural killer cell function and activity are reduced. Increased wake (or wakefulness) after sleep onset is associated with reduced natural killer cell mobilization after a stressor, and impaired recovery to baseline natural killer cellular function even after 30 minutes.[87] Similarly, circulating inflammatory markers, such as tumor necrosis factor and vascular endothelial activation markers, are elevated after a single night of total sleep deprivation, whereas other inflammatory markers, including IL-6 and C-reactive protein, show elevations after more prolonged periods (4 to 7 nights) of sleep restriction.[86,88] In contrast, adaptive immunity is suppressed after a single night of sleep deprivation, including reduced T cell production of IL-2, reduced helper T cell 1:2 ratios, and reduced monocyte production of IL-12.[86,89] Elevated levels of corticosteroids associated with sympathetic nervous system activation and sleep disruption result in hyperglycemia and increased susceptibility to infection, and also suppress function and numbers of both B and T cell lymphocytes.[90]

One clinical consequence of chronic poor sleep, therefore, is an increased susceptibility to infection. Extremes of sleep duration, both habitual short (5 hours or less) and long sleep (9 hours or greater) duration, as well as perceived poor sleep quality, are risk factors for community-acquired pneumonia.[91] Short sleep duration and sleep fragmentation, but not long sleep duration, have been linked to an elevated risk of development of the common cold after intranasal inoculation with rhinovirus in healthy patients.[92]

Sleep deprivation also blunts the immune response to vaccinations. In healthy mice, sleep deprivation blocks the expected immune response to an influenza vaccine.[93] In humans, the hepatitis B secondary antibody response (6 months after a series of three immunizations) was lower in persons with shorter sleep duration, independent of the response to initial therapy.[94] Influenza vaccination–induced H1N1 antibody titers were also reduced after a single night of sleep deprivation but, with healthy sleep, antibody levels recovered by day 10 postimmunization.[95] These findings suggest that poor sleep during infections may compromise inherent immune responses to combat infections.

ENDOCRINE AND METABOLIC DYSFUNCTION

Healthy sleep is vital for normal metabolism, endocrine function, and glucose tolerance. Disrupted sleep predisposes an individual to diabetes and obesity by altered glucose metabolism and dysregulation of appetite control via neuroendocrine pathways. Pituitary hormone secretion is also deranged as a result of sleep disruption.

Acute Effects

Altered glucose metabolism is observed even with short periods of partial sleep deprivation. In one study of 11 healthy men, 6 days of partial sleep deprivation (4 hours sleep/night) was associated with impaired glucose tolerance and reduced beta cell responsiveness when compared to 6 days with full nights (up to 12 hours in bed/night) of sleep.[96] Interestingly, selective suppression of slow-wave sleep for 3 consecutive nights, without reducing total sleep time, also resulted in decreased insulin sensitivity, reduced glucose tolerance, and increased risk of type 2 diabetes mellitus.[97] This highlights the importance of slow-wave sleep in glucose metabolism and potentially explains the increased risk of glucose intolerance with increased age, because there is also a reduction in slow-wave sleep with age.

Regulation of appetite control is also affected by acute sleep disruption. Leptin and ghrelin work in opposing manners to affect metabolism, energy expenditure, appetite, and wakefulness. Leptin is secreted by adipocytes and acts on the hypothalamus to suppress food intake. Ghrelin, which stimulates appetite and hunger via the hypothalamus, is released by gastric parietal cells tonically; release is inhibited by gastric stretch following a meal.[98] Although some studies have shown a reduction in leptin and elevation of

ghrelin levels with short-term partial sleep deprivation, not all studies have replicated these findings.[99,100]

Pituitary hormones and their targets are linked to sleep and can have abnormal secretion profiles with sleep disruption. With healthy sleep, cortisol secretion is suppressed, while *growth hormone* (GH), thyroid-stimulating hormone, and prolactin all increase during sleep. Estrogen levels have been shown to be suppressed by melatonin.[101] With a night of total sleep deprivation, the rate of decline of cortisol levels in the evening is attenuated, and cortisol levels remain elevated at night. Conversely, GH and thyroid-stimulating hormone levels are reduced with total sleep deprivation. In habitually healthy sleepers, with a single night of total sleep deprivation followed by subsequent daytime recovery sleep, cortisol, GH, and thyroid-stimulating hormone levels trend back to normal.[102,103]

Chronic Implications

Chronic sleep disruption can lead to increased risk of type 2 diabetes mellitus and obesity. Sleep disruption, as seen with OSA, is associated with an increased odds of developing diabetes (odds ratio, 1.4 to 2.2).[104–106] Another study found a dose-response association between OSA severity and glycemic control in diabetic patients, with higher hemoglobin A1c levels in patients with more severe OSA.[107] Many population-based longitudinal studies have shown a robust association of chronic sleep deprivation with weight gain and obesity risk.[108–110] However, clinical trials have not yet robustly demonstrated that OSA treatment or interventions to increase sleep duration can reduce metabolic risk.

Over time, there appears to be longitudinal adaptation of GH secretion in the setting of chronic sleep deprivation, with the suppression of GH secretion with acute sleep deprivation gradually evolving into two small pulses of GH secretion (one before and one after sleep).[100] Chronic partial sleep deprivation is also associated with reduced leptin and ghrelin levels, independent of weight.[108,111]

CANCER RISK

There is a growing body of literature to support the association of sleep disruption and cancer incidence, particularly with solid tumors. The potential mechanisms linking sleep disruption and oncologic risk are mostly speculative, including (1) dysregulation of normal metabolism of hormones (such as estrogen), (2) systemic inflammation and immune dysfunction, and (3) potential DNA damage and oxidative stress.[112] The strongest evidence is in the link between circadian rhythm disorders and risk of breast cancer. There is consistent evidence that incident breast cancer risk is inversely associated with elevated melatonin metabolite levels (6-sulfatoxymelatonin, aMT6), and that night-shift workers have reduced aMT6 levels compared to day-shift workers.[113,114] The majority of the population-based cohort data regarding circadian rhythm disruption and breast cancer supports an overall increased incidence of breast cancer (increase ranging from 5–48%).[112] In fact, melatonin has been studied as a promising oncostatic agent in breast cancer due to its ability to inhibit breast cancer cell growth.[101] Whereas many of the studies were carried out on nurse cohorts, particularly on nurses involved in active shift work, the definition of circadian rhythm disturbance has included any lifetime exposure to night-shift work and nocturnal light exposure. So, despite a wide range of exposures with potentially opposing circadian directional shifts, the association of breast cancer risk with circadian rhythm disorders remains robust. Beyond the association with breast cancer, night-shift work has been associated with an increased risk of prostate and colorectal cancer. Based on the total body of literature to date, a working group of the International Agency for Research on Cancer concluded night-shift work is probably carcinogenic in humans.[115]

OSA has also been postulated to be a novel cancer risk factor. Using mouse models, both intermittent hypoxemia and sleep fragmentation have been found to promote tumor growth and metastasis.[116,117] Epidemiologic studies have suggested patients with OSA are at greater risk for cancer.[118] Some, but not all, studies suggest OSA may be a risk factor for lung cancer in particular.[119,120] Altered sleep habits have also been postulated to increase lung cancer risk. A meta-analysis of 32 prospective cohort studies found both short and long sleep durations were associated with elevated lung cancer risk.[121] These findings are limited by inadequate characterization and accounting for known lung cancer risk factors, particularly tobacco exposure.

SPECIAL PATIENT POPULATIONS

MATERNAL-FETAL HEALTH

The impact of sleep disruption on maternal and fetal health is an area of growing interest. Pregnancy is a condition involving normal maternal physiologic changes of increased estrogen and progesterone levels, increased minute ventilation, and increased abdominal girth. Healthy sleep during pregnancy may be compromised by a number of sources, including (1) physical symptoms, such as nausea, discomfort, and pain; (2) exacerbation of chronic medical conditions, such as asthma or pulmonary hypertension[122]; (3) care of other family members, particularly young children; and (4) development of new sleep disorders during pregnancy, such as restless legs syndrome or OSA. There is a growing body of knowledge that sleep disruption may interfere with both the mother's health and fetal development.

A review of the consequence of sleep disruption on maternal-fetal health can be found at ExpertConsult.com.

CRITICALLY ILL PATIENTS

The acute effects of poor sleep are well illustrated, and perhaps magnified, in critically ill patients (see also Chapter 119). Disrupted sleep can suppress immune function, resulting in more frequent and more severe infections. Cardiovascular consequences of sleep disruption (including OSA) include elevated blood pressure, arrhythmias, and worsened pulmonary hypertension, all of which can aggravate a patient's underlying critical illness. Insufficient sleep can lower the seizure threshold, increasing the likelihood of seizures in patients who are predisposed. Short-term neurocognitive impairment is associated with poor sleep and includes slowed response times and reduced situational awareness. This, in turn, can significantly impair patient recovery by leading to development of delirium,

Maternal Health

During pregnancy, sleep duration, timing, and continuity in the first two trimesters have been shown to be associated with increased maternal health complications. Studies of self-reported short sleep duration in the first and second trimesters of pregnancy reveal an association between sleep duration and risk of gestational diabetes mellitus with a relative risk ratio of 5.6 among women reporting 4 hours or less per night versus 9 hours per night as well as mean third-trimester blood pressure.[123,124] In a prospective cohort study of nulliparous pregnant women, both short sleep duration and delayed sleep timing, objectively measured by actigraphy, were associated with increased risk of gestational diabetes mellitus but not hypertensive disorders.[125]

Sleep-disordered breathing is more frequent in pregnant women compared to prepregnant women due to weight gain, hormonal changes to ventilatory control, and hyperemia to the upper airway resulting in upper airway narrowing. Maternal sleep-disordered breathing, as determined by clinical symptoms and studied objectively by polysomnography, is associated with gestational diabetes mellitus, gestational hypertension, and preeclampsia.[126]

Maternal sleep disruption is also associated with pain perception and mood disorders. Sleep duration in the third trimester may impact the perception of pain during labor and the duration of labor. Women with less than 6 hours of sleep in the third trimester as measured by actigraphy are more likely to have longer labor durations and 4.5 times more likely to have a cesarean section compared to those obtaining at least 7 hours of sleep.[127] Sleep insufficiency is associated with higher levels of proinflammatory cytokines, and the proinflammatory state during pregnancy is associated with postpartum depression risk.[128] Insomnia during pregnancy is common, with 40–60% of pregnant women reporting significant distress due to difficulty with sleep initiation or maintenance, and is related to postpartum depression. Cognitive behavioral therapy for insomnia during pregnancy results in improvement in insomnia severity, faster remission of insomnia, and a small but significant reduction in postnatal depression symptoms.[129]

Fetal Development

Fetal health is dependent on maternal health and behaviors. The findings of a meta-analysis on the topic of maternal sleep and fetal outcomes indicate that OSA, short sleep duration, and poor sleep quality during pregnancy may be associated with preterm birth and stillbirth but do not predict fetal growth or birth weight.[130] Differences in definitions of fetal outcomes severely limited the findings of the meta-analysis. Further research is clearly needed to understand the potential impact of poor maternal sleep during pregnancy on fetal outcomes.

interference with patient cooperation during spontaneous breathing trials for extubation, and inability to participate in physical rehabilitation.

A more in-depth review of the consequence of sleep disruption in critically ill patients can be found at ExpertConsult.com.

TREATMENT OF SLEEP DISRUPTION

Treatment of sleep disruption entails behavioral interventions that promote sleep health, evaluation and treatment of primary sleep disorders, and evaluation and optimization of treatment of comorbid illnesses from a sleep-centered framework. This includes addressing iatrogenic causes of sleep disruption, most commonly medications prescribed for comorbid illnesses.

SLEEP HYGIENE

Sleep hygiene is the term used to describe the adoption of behaviors that promote sleep health across dimensions. A healthy sleep-wake pattern is established in part by increasing knowledge and awareness of the multiple dimensions necessary for restorative sleep. In addition, utilizing and enhancing the underlying biologic drivers of sleep, namely the homeostatic and circadian forces that promote sleep, are key components to sleep hygiene.

A necessary foundation for healthy sleep is having a quiet, dark, comfortable, and safe place to sleep and having sufficient time allocated for sleep at the same time every night. The time allocated for sleep should ideally match the individual's underlying circadian tendency. This is of particular relevance in institutionalized populations who are not allowed to determine their own sleep environment. This includes hospitalized patients, for whom bright lights, noise, frequent disruption for vital sign checks, and early morning awakenings for phlebotomy or imaging commonly produce massive disruptions in sleep.

Activities that promote wakefulness or that combat daytime sleepiness may impede nighttime sleep onset. Daytime naps, a common compensatory mechanism for poor sleep, will reduce the homeostatic pressure for sleep the next night and, in general, should be avoided. Caffeine consumption in the morning or in the afternoon is common to promote wakefulness but should be avoided at least 6 hours prior to sleep time. Coffee, tea, and soda are the most common caffeine-containing beverages, but even "decaffeinated" versions of these beverages and cocoa-containing foods and beverages contain enough caffeine to impede nighttime sleep. Exercise is an energizing activity that promotes wakefulness and has numerous health benefits, but because it increases adrenergic activation and can delay sleep onset, exercise should be avoided in the 2 to 3 hours prior to bedtime.

Circadian rhythms are reinforced by maintaining a regular 24-hour schedule. This includes keeping a regular bedtime and wake-up time, thereby allowing for optimal duration of time in bed sleeping, both during work or school days and during weekends, vacations, or less-structured days. Exposure to light during the daytime and a dark environment at night are the strongest factors signaling the physiologic secretion of melatonin in the evening, facilitating sleep initiation. Whereas light is the strongest *zeitgeber* ("time-giver," synchronizer), other external cues fortify the circadian rhythm, including regular meal times, physical activity, social interactions, and environment. Thus keeping a regular schedule in all of these daytime activities can improve sleep. A bedtime routine, such as quiet reading time or writing in a journal, can also become a zeitgeber and facilitate nighttime sleep. These behaviors also allow the individual to disconnect from the physical and emotional stresses of the day, facilitating sleep onset. A warm shower or bath prior to bedtime will augment the natural cooling of the core body temperature in the evening, a circadian cue to initiate sleep.

Some activities co-opted during times of stress are maladaptive behaviors. Alcohol consumption should be avoided for at least 4 hours before bedtime due to its effects on lowering the arousal threshold as blood alcohol levels fall, increasing the likelihood of early morning awakenings and delaying circadian rhythms. Nicotine is a stimulant drug that will delay sleep onset and should be avoided altogether, but especially 2 hours prior to bedtime. Large meals eaten close to bedtime may interfere with sleep onset by causing discomfort and requiring ongoing digestion.

Electronics, including televisions, laptops, tablets, and smartphones, can contribute to nighttime light exposure and mental stimulation, hindering the process of sleep initiation. As a result, these should ideally be kept out of the sleep environment. The use of social media in particular near bedtime can be a problem. The algorithms underlying these applications are designed to increase use by activating the cortex and thereby can prevent sleep.

PRIMARY SLEEP DISORDERS

General treatment approaches to common sleep disorders are given in Table 118.2. Sleep-disordered breathing can contribute to sleep fragmentation, poor sleep quality, and impaired daytime functioning. Treatment options, as described in Chapter 122, include weight loss, lateral positioning, and avoidance of alcohol as well as more aggressive measures such as positive airway pressure and oral appliance therapy. Restless legs syndrome can cause sleep-onset insomnia and reduced sleep duration. Treatment options include iron supplementation (in the setting of iron deficiency), behavioral interventions, discontinuation of medications that may exacerbate the condition, and pharmacologic therapies. Jet lag disorder and shift-work disorder can be anticipated by scheduled travel or work hours and may be treated with a combination of behavioral interventions, melatonin, and light therapy, although pharmacologic sleep aids or stimulants may be indicated.[157]

Insomnia impairs sleep quality and daytime alertness and can also reduce sleep duration and regularity. *Cognitive behavioral therapy for insomnia* (CBT-I) has been demonstrated in randomized trials to treat insomnia effectively and is recommended as first-line therapy instead of pharmacologic approaches due to minimal side effects.[158] The most effective components of CBT-I are stimulus control, preventing anxiety and frustration in bed by avoiding clockwatching, getting out of bed if one cannot sleep, and

The *intensive care unit* (ICU) setting has historically not been an environment conducive for healthy sleep. Noise pollution from equipment, hospital staff, and other patients, as well as interruptions of sleep for periodic nursing assessments and provider examinations, impede healthy sleep. Furthermore, the timing of blood draws and diagnostic tests in the early morning hours to facilitate morning rounds curtails sleep and can disrupt circadian rhythms. Environmental light at night also compromises sleep onset and maintenance, and lack of sunlight exposure during daytime may contribute to shifts in circadian rhythms. Medications frequently used in the ICU setting, such as sedatives, analgesics, β-adrenergic receptor antagonists, vasopressors, and antiepileptic medications, interfere with normal sleep patterns. Ventilator dys-synchrony may also cause sleep disruption among patients requiring mechanical ventilation.[131] Air leaks from noninvasive ventilators may disrupt sleep by impairing respiratory sufficiency or by stimulating orofacial sensory mechanoreceptors.[132] Circadian rhythms in hospitalized patients are frequently misaligned. Lack of sunlight exposure as well as critical illness (particularly sepsis) alter melatonin secretion. Additionally, secondary circadian cues, such as intermittent meals (versus continuous feeding) and social interactions (daytime versus all day/night) are absent in critically ill patients and further misalign the circadian rhythm of critically ill patients. Other patient factors, including pain, anxiety, critical illness, and preexisting comorbid conditions, are additional factors that limit healthy sleep in the ICU.

ICU survivors report poor subjective sleep and inadequate sleep duration as major sources of stress and anxiety during hospitalization.[133] Studies with objective sleep characterization by polysomnography show that, instead of the normal sleep pattern with a major sleep period (7 to 8 hours) at nighttime, critically ill patients experience markedly fragmented sleep, with sleep bouts averaging 15 ± 9 minutes throughout the 24-hour period, including half of sleep bouts during the daytime. REM sleep and NREM stage 3 restorative deep sleep are often completely absent in critically ill patients.[134–136]

The causal relationship between lack of sleep among ICU patients and ICU-associated delirium is suspected but not firmly established. Many observational studies establish an association between both the reduction of total sleep and REM sleep and the presence of delirium.[137–139] There is significant overlap in the symptoms of sleep disruption and delirium, including inattention, fluctuating mental status, and cognitive dysfunction. Delirium and insufficient wakefulness are implicated in the prolonged duration of intubation. Successful extubation is more likely in patients with higher levels of wakefulness and when there is correlation between the two cerebral hemispheres with respect to depth of sleep.[140] (The depth of sleep is not routinely compared between the sides of the brain, and the pathophysiologic implications of this finding are not known.) Pharmacologic interventions intended to improve sleep, such as nocturnal dexmedetomidine, have shown promising results in preventing delirium, but larger clinical trials with better assessment of sleep are needed.[141,142] Delirium has been associated with longer ICU length of stays, increased costs, increased mortality, and increased risk for the development of dementia.[143–145]

Sleep inadequacy may also contribute to poor respiratory mechanics, resulting in prolonged intubation time. In a study of healthy men who were sleep deprived for 30 hours, muscle endurance, as measured by pressure-time index, and maximum voluntary ventilation were both significantly reduced.[146] Studies evaluating the effect of sleep deprivation on ventilatory response to hypercapnia have shown mixed results.[147–149] Atelectasis and low lung volumes can predispose patients to upper airway collapsibility. Sleep disruption can further compromise upper airway patency, causing OSA physiology and possible respiratory compromise.[150]

Of interest are the strategies to improve sleep in critically ill patients. While most ICU providers acknowledge the importance of sleep for patient recovery, only a minority of ICUs in the United States report protocols for sleep-promoting interventions.[151] Interventions to improve sleep quality in ICU patients should include optimization of the environment (minimizing noise and light during sleep time), judicious use of medications that alter sleep quality (including minimizing sedation), and promotion of wakefulness and physical activity during the day. Among patients requiring ventilator support, preventing ventilator asynchrony has been recognized to improve sleep. The use of proportional assist ventilation instead of traditional pressure support ventilation can improve sleep quality (reduced sleep arousals, increased REM and slow-wave sleep).[152] The benefit of proportional assist over pressure support modes of ventilation was not seen, however, when studied in patients with ventilator synchrony.[153] In patients with tracheostomy undergoing a protracted ventilation liberation, sleep duration and sleep efficiency (though not sleep quality) seem to be improved when patients are on ventilator support at night.[154]

Insufficient, disrupted, and mistimed sleep may contribute to depression, long-term cognitive dysfunction, and possibly impaired exercise tolerance among ICU survivors.[155] Sleep disturbances that begin during hospitalization often persist after hospitalization and are reported in 10–61% more than 6 months after hospital discharge.[156] Some centers have implemented ICU survivor outpatient clinics to manage the chronic sequelae of ICU hospitalization, including sleep disruption.

Table 118.2 Most Common Sleep Disorders and Initial Management Approaches

Sleep Disorder	First-Line Therapy	Second-Line and Adjunctive Therapy
Insufficient sleep syndrome	Sleep hygiene	
Insomnia	In person CBT-I	BBT-I Internet-based CBT-I Pharmacotherapy
Obstructive sleep apnea	PAP, oral appliance	Weight loss and exercise Avoidance of aggravating medications Avoiding supine sleep Alcohol avoidance Upper airway surgery
Restless legs syndrome	Iron replacement Avoidance of aggravating medications Pharmacotherapy	Behavioral approaches
Delayed sleep phase disorder	Behavioral modification Timed morning light therapy	Timed evening melatonin Pharmacotherapy
REM behavior disorder	Avoidance of aggravating medications Pharmacotherapy	Safe sleep environment to prevent injury
Narcolepsy	Pharmacotherapy	Sleep hygiene

BBT-I, brief behavioral therapy for insomnia; CBT-I, cognitive behavioral therapy for insomnia; PAP, positive airway pressure; REM, rapid eye movement.

sleep restriction, whereby time allowed for sleep is temporarily reduced to increase sleep efficiency and quality and then slowly increased back to a targeted goal duration. Additional components include promoting good sleep habits, relaxation, and cognitive therapy aimed at addressing misconceptions about sleep, resetting expectations about sleep, and reducing assumptions that the worst will happen if sleep goals are not achieved. Because the lack of clinicians trained in CBT-I has prevented widespread implementation of this treatment, simpler strategies have been developed that can be more readily incorporated into clinical practice. These include brief behavioral therapy that can be administered by nonexpert clinicians in one or two sessions and internet-based CBT-I. Randomized trials have demonstrated the utility of both of these options.[159,160]

COMORBID ILLNESSES

Many diseases are exacerbated at night due to circadian, behavioral, or positional factors. These include asthma, gastroesophageal reflux disease, heart failure, neuromuscular disorders affecting respiration, and chronic pain syndromes. Asthma has a circadian pattern, with increased airway responsiveness at nighttime. Nocturnal wheezing is identified as a marker of poor asthma control and a cause of nocturnal awakening. Control of nocturnal asthma symptoms can improve sleep quality and aid in control of daytime asthma symptoms.[161] Nocturnal gastroesophageal reflux disease is worsened by certain foods, such as spicy or highly acidic foods, and by large meals close to bedtime. Nocturnal reflux symptoms result in poor sleep quality and sleep fragmentation due to discomfort and have been implicated as a possible risk factor for OSA.[162] Classic heart failure symptoms, including orthopnea and dyspnea, are a result of the supine positioning during sleep and the redistribution of circulating blood volume from the periphery into the pulmonary circulation. This pulmonary vascular congestion predisposes to increased pulmonary edema, nocturnal dyspnea, and central sleep apnea (as described in Chapter 121) and, if not adequately controlled at night, will disrupt sleep, resulting in reduced pain threshold and result in a vicious cycle perpetuating chronic pain syndromes.

Many medications, particularly psychiatric, neurologic, cardiovascular, and pulmonary medications, have side effects that can include sedation and/or insomnia. Other medications, such as diuretics, can fragment sleep if taken at night. Opiate medications may be prescribed to control pain but may also worsen sleep disorders such as OSA. It is important therefore to ask patients about the timing of all medications and ensure timing is aligned with optimization of healthy sleep.

Acknowledgments

We thank Dr. Maria Antonelli, Dr. J. Daryl Thornton, and Dr. Edward Warren for their editorial comments.

Key Points

- Healthy sleep has the following dimensions: (1) optimal regularity of sleep over many days, (2) satisfaction with sleep quality, (3) daytime alertness (i.e., restorative capacity), (4) proper timing (i.e., aligned with one's circadian rhythm), (5) high efficiency (i.e., a low number of awakenings and time spent awake after falling asleep), and (6) sufficient duration.
- Sleep disruption has pervasive health consequences, including neurocognitive, psychiatric, cardiovascular, immunologic, metabolic, and oncologic derangements.
- Health consequences can disrupt the sensitive system required to initiate and maintain sleep, resulting in a potentially vicious feedback loop.
- Critically ill patients who experience sleep disruption during illness may be at higher risk for higher acuity illness, delirium, longer lengths of stay, and repercussions after discharge from the hospital.
- An emphasis on healthy sleep and correction of conditions that cause sleep disruption may play a pivotal role in promotion of overall health.

Asthma
KEY POINTS

INTRODUCTION

Sleep medicine is a field focused on the evaluation of disorders affecting nocturnal breathing, movements, behaviors, sleep-wake cycles, and the daytime consequences of disrupted sleep. It encompasses a broad range of disorders in which nocturnal ventilation, oxygenation, patency of the upper airway, and sleep-wake centers are highly relevant to caring for pulmonary patients in both inpatient and outpatient settings. Sleep disorders are germane to a multitude of different medical and surgical specialties, including those for which pulmonary consultants are commonly called to lend expertise in guiding care. An adequate fund of knowledge in sleep medicine is even more relevant to subspecialties within pulmonary medicine, such as asthma, COPD, interstitial lung disease, the intensive care unit, and chronic respiratory failure secondary to chest wall disorders and neuromuscular disease. This chapter presents an approach to thinking about sleep disorders, unifying concepts within Section O and Chapter 45, and reviews common clinical scenarios during which the impact of sleep should be considered. In-depth reviews of *obstructive sleep apnea* (OSA), central sleep apnea, hypoventilation, sleep disruption, and control of breathing are covered in other chapters.

THINKING LIKE A SLEEP PULMONOLOGIST

THE GOLDEN 8 HOURS

Sleep accounts on average for 30% of our adult lives. In an ideal undisturbed state, sleep restores physical and mental wellness and is critical to consolidation of learning and executive function.[1–5] When sleep disorders are present, the opposite is true, exposing affected individuals to pathologic states of intermittent or sustained hypoxemia, hypercapnia, inflammation, oxidative stress, cardiopulmonary mechanical stress, and/or sleep deprivation (see Figs. 118.2 and 120.5). Sleep affords a golden 8 hours during which we have a physiologic reset to promote healthy metabolic and cognitive function.

Although sleep medicine encompasses more than *sleep-disordered breathing* (SDB), mastering an understanding of respiratory physiology during sleep increases the aptitude of the astute pulmonary clinician to expand the differential diagnosis of clinical presentations, recommend and tailor personalized therapies, and educate other learners on the basis of sound physiologic principles. Indeed, a primary goal of this chapter is to increase awareness of the impact of SDB on common comorbidities frequently encountered by the pulmonary consultant or intensivist.

VENTILATION, OXYGENATION, AND MECHANICS DURING SLEEP

Considering the time spent asleep each night, consequences of SDB, such as hypoxemia and hypercapnia, are likely to be more clinically significant than initially recognized, especially in patients with underlying pulmonary disease. Frequently only the awake, upright oxygen saturation of medically stable pulmonary patients measured during outpatient visits is factored into assessments, differential diagnoses, and medical decision making. However, many factors affecting nocturnal oxygenation and ventilation must be considered when evaluating a patient with suspected SDB or an associated comorbidity (eTable 119.1). Recognizing all forms of SDB, including OSA, hypoventilation syndromes,

eTable 119.1 Factors Influencing Sleep-Disordered Breathing

ALTERATIONS IN VENTILATORY CONTROL

- Change in chemoreceptor set point for $Paco_2$
- Change in central ventilatory drive
  - Sedative hypnotics
  - Centrally acting non-sleep medications (i.e., opioids, benzodiazepines)
- REM-related reduction in ventilation

MECHANICAL CHANGES

- Reduced FRC
- Collapsibility of the upper airway
- Chest wall restriction
- Rostral fluid redistribution

UNDERLYING OBSTRUCTIVE VENTILATORY DEFECTS

- Increased dead space, reduced alveolar ventilation
- Hyperinflation and flattening of the diaphragm
- Circadian influence on bronchoconstriction
- Reduced oxygenation and ventilation during REM

UNDERLYING RESTRICTIVE VENTILATORY DEFECTS

- Neuromuscular disease (neuromuscular junction, myopathy, innervation)
- Skeletal abnormalities (pectus excavatum, kyphoscoliosis)
- Parenchymal disease (interstitial lung disease)
- Reduced oxygenation during REM and NREM

PULMONARY VASCULAR DISEASE

OBESITY-RELATED CHANGES

- Reduced FRC, ERV, small airway closure, expiratory flow limitation
- Ventilation-perfusion inequality
- Neurohormonal changes
- Excessive carbon dioxide production
- Obstructive sleep apnea
- Increased work of breathing
- Reduced central respiratory drive
- Obesity hypoventilation syndrome

ERV, expiratory reserve volume; FRC, functional residual capacity; NREM, non-rapid eye movement; $Paco_2$, arterial partial pressure of carbon dioxide; REM, rapid eye movement.

and hypoxemia, enables an understanding of downstream consequences such as *pulmonary hypertension* (PH), arrhythmias, and cognitive impairment.

Patients whose oxygen saturation is near the steep part of the oxyhemoglobin dissociation curve may maintain oxygenation while awake and upright but frequently desaturate once in a recumbent position and even further once asleep. Patients desaturate because of (1) increased ventilation-perfusion mismatch with increased perfusion to areas of decreased ventilation, (2) elimination of behavioral input into ventilation at sleep onset, (3) decreased chemosensitivity to both oxygen and carbon dioxide leading to mild hypoventilation,[6,7] (4) an upward shift in the ventilatory set point for *arterial partial pressure of carbon dioxide* (P_{CO_2}) by 2 to 3 mm Hg,[8] and (5) alterations in respiratory mechanics, including reduced functional residual capacity and restricted chest wall expansion (limited expansion in the posterior and downward dimensions when supine).[9–11] The effects of respiratory mechanics are more pronounced in individuals with central obesity and in those with underlying parenchymal disease (see also Chapters 10 and 11). OSA, especially when severe, may exacerbate hypoxemia and hypercapnia through repetitive occlusion of the upper airway leading to cyclic desaturation without recovery to normoxia or baseline between apneas. It is important to keep in mind that not all SDB is OSA and that patients can experience hypoventilation or hypoxemia in the absence of OSA.

IDENTIFYING PULMONARY PATIENTS AT RISK FOR COMORBID SLEEP DISORDERS

All patients with evidence of daytime hypoxemia or hypercapnia should be screened for SDB, particularly if nocturnal symptoms and daytime dysfunction (i.e., excessive daytime sleepiness) are present (Table 119.1). The association between OSA and pulmonary diseases such as COPD, asthma, interstitial lung disease, and even cystic fibrosis is increasingly recognized[12] (see the sections on COPD and asthma later and Chapter 120). Although OSA is not implicated in the pathogenesis of these pulmonary diseases, whether treatment of comorbid OSA leads to improved morbidity and mortality is an active area of research. Routine screening for OSA in asymptomatic adults without risk factors is not indicated.[13]

TAKING A RELEVANT SLEEP HISTORY

As with any specialty evaluation, there are unique aspects to taking a sleep history and performing a targeted physical examination. The purpose of the history is to elucidate the reason the patient perceives he or she has been referred to a sleep specialist, solicit symptoms that support or refute differential diagnoses, determine the most appropriate diagnostic workup, and gauge interest and ability to comply with recommended treatments. Not every referral for OSA will result in a diagnosis of OSA. In many cases, more than one sleep disorder is present, or the symptoms are nonspecific and attributable to another diagnosis, such as insomnia, circadian rhythm disorders, or movement disorders. It is of utmost importance to maintain the perspective that patients are often referred for symptoms, even when the referral asks to "rule out sleep apnea," and that not every sleep disorder seen by a pulmonologist will be sleep apnea. That said, OSA is highly prevalent, and treatment of OSA may very well resolve the initial complaint of nonrefreshing sleep, poor sleep quality, or nocturia. Patients are also referred to sleep specialists to evaluate for the presence of OSA suspected of complicating another comorbidity (i.e., before cardioversion for atrial fibrillation), even if the patient lacks perceived sleep disruption or sleep-related symptoms. In the absence of symptoms, negotiating a care plan that involves nightly adherence to a treatment for an asymptomatic disease becomes challenging. Motivational interviewing and identifying goals of care may be helpful in these cases. Table 119.2 summarizes the key components of a sleep history and targeted physical examination to generate a differential diagnosis for sleep complaints and to determine next steps in the evaluation process. Pulmonary consultants should consider the impact of SDB and sleep disruption on every patient, understand when screening questionnaires are indicated and when full sleep histories should be taken, and know the indications for sleep testing (Fig. 119.1) so they may reach the most accurate diagnoses and provide the most comprehensive recommendations possible.

Table 119.1 Signs, Symptoms, and Comorbidities Suggestive of Sleep-Disordered Breathing

SIGNS
Chronic compensated respiratory acidosis
Arterial P_{CO_2} >45 mm Hg
Serum bicarbonate >27 mEq/L
Resting awake, upright Sp_{O_2} <94%
DAYTIME SYMPTOMS
Excessive daytime sleepiness
Nonrefreshing sleep quality
Morning headaches
Morning confusion or fogginess
Impaired cognitive function
Difficulty with memory or concentration
NOCTURNAL SYMPTOMS
Snoring or witnessed apneas
Nocturnal wheezing, dyspnea, cough
Nocturia
Concern about breathing from bed partner
Excessive movements noted by bed partner
Orthopnea
Repetitive awakenings for unclear reasons
COMORBIDITIES
Obesity
Arrhythmia
Ischemic heart disease
Stroke
Gastroesophageal reflux disease
Interstitial lung disease
COPD
Asthma
Neuromuscular disease

P_{CO_2}, partial pressure of carbon dioxide; Sp_{O_2}, oxygen saturation as measured by pulse oximetry.

QUESTIONNAIRES

Several validated questionnaires are currently used to screen for SDB (STOP [*snoring, tiredness, observed apnea, high blood pressure*],[14] STOP-Bang [*STOP plus body mass index, age, neck*

Table 119.2 Components of a Sleep History and Physical Examination

Sleep history	■ Symptoms ■ Duration ■ Exacerbating and alleviating factors ■ Known triggers for sleep disruption or behaviors (i.e., nightmares, alcohol, choking or gasping) ■ Use of sleeping medications ■ Circadian preference (natural time to go to sleep and wake up) ■ Restless leg symptoms ■ Bed partner perspective/input ■ Witnesses apneas, snoring ■ Abnormal behaviors (dream enactment, vocalizations)
Sleep schedule	■ Time of lights out ■ Sleep latency ■ Number and cause of awakenings ■ Latency to return to sleep ■ Time of final morning awakening
Morning symptoms	■ Sleep quality ■ Perceived sleep duration ■ Morning headaches, dry mouth, sore throat
Social history	■ Shift work ■ Caffeine consumption: quantity and time of day of last caffeinated beverage ■ Alcohol use: quantity, time of consumption, whether alcohol is used to induce sleep ■ Nicotine use: quantity and timing ■ Exercise: duration and timing (i.e., within 3 hr of target bedtime)
Family history	■ Known sleep disorders (OSA, insomnia) ■ Neuromuscular disease (when relevant)
Sleep-specific physical examination	■ Obesity ■ Body habitus (pear vs. apple) ■ Neck circumference ■ Mallampati classification ■ Tonsillar hypertrophy ■ Palatal shape (i.e., high arch) ■ Nasal septal deviation, turbinate hypertrophy, polyps ■ Nasal valve collapse ■ Patency of nasal airflow ■ Presence and health of dentition ■ Occlusion (i.e., retrognathia) ■ Scalloping of tongue (due to imprint of teeth on edges of enlarged tongue)

OSA, obstructive sleep apnea.

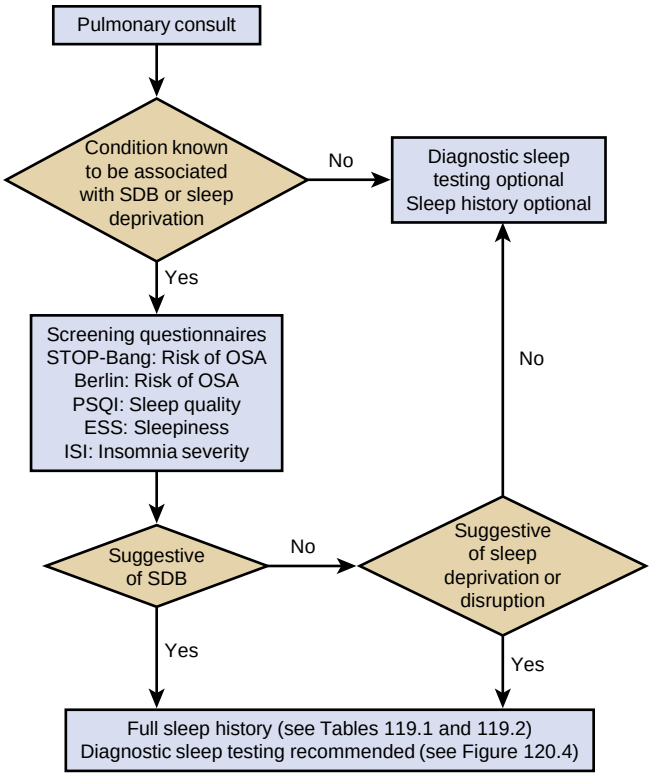

Figure 119.1 Approach to identifying sleep disorders in patients seen by the consulting pulmonologist. Familiarity with comorbidities associated with *sleep-disordered breathing* (SDB) or sleep disruption is essential to identifying patients at risk of nocturnal hypoxemia, hypercapnia, and *obstructive sleep apnea* (OSA). Once identified, patients can be screened using validated questionnaires to determine whether referral to a sleep specialist is warranted and whether further diagnostic testing is indicated. ESS, Epworth Sleepiness Scale; ISI, Insomnia Severity Index; PSQI, Pittsburgh Sleep Quality Index; STOP-Bang, snoring, tiredness, observed apnea, high blood pressure, body mass index, age, neck circumference, and male sex.

circumference, and male gender],[14] Berlin Questionnaire[15,16]), evaluate sleep quality and daytime symptoms (Pittsburgh Sleep Quality Index,[17] Functional Outcomes of Sleep Questionnaire,[18] Epworth Sleepiness Scale[19]), and identify other primary sleep disorders such as restless leg syndrome, insomnia, circadian rhythm abnormalities, and parasomnias. Sensitivity and specificity of each questionnaire in detecting sleep disorders depend on the population. The STOP-Bang[20] questionnaire, based on three reported symptoms (snoring, feeling tired, having witnessed apneas) and five physical characteristics (hypertension, obesity, age, enlarged neck circumference, and male gender) is one of the most widely used screening questionnaires for OSA in both medical and surgical populations. The addition of pulse oximetry,[21] serum bicarbonate levels,[22] and body shape[23] (apple vs. pear) to the STOP-Bang questionnaire has been evaluated for improved prediction models of patients at risk of OSA.

There is a paucity of literature validating traditional sleep screening questionnaires in patients with pulmonary disease. Most studies have evaluated the Berlin Questionnaire, Epworth Sleepiness Scale, Sleep Apnea Clinical Questionnaire, and STOP-Bang Questionnaire only in patients with COPD.[24–27] Few investigators have sought to validate sleep questionnaires in patients with interstitial lung disease, cystic fibrosis, or other pulmonary disorders. Growing interest in the overlap of SDB and COPD has led to the development of newer questionnaires such as the Manchester Respiratory-Related Sleep Symptom Questionnaire,[28] focused on the assessment of sleep symptoms and on patient-reported outcome measures in patients with COPD.

DIAGNOSTIC SLEEP TESTING

Sleep testing using *home sleep apnea testing* (HSAT) or in-laboratory *polysomnography* (PSG) evaluates for OSA, nocturnal hypoventilation, and nocturnal hypoxemia. All three should remain in the initial differential diagnosis of SDB given that treatment may include *continuous positive airway pressure* (CPAP), *bilevel positive airway pressure therapy* (BPAP), supplemental oxygen, or a combination thereof. Currently, sleep testing is required to establish a

diagnosis of OSA but is not necessary to fulfill requirements for qualifying patients for home oxygen therapy, which is based on nocturnal pulse oximetry or arterial blood gas. A sleep study demonstrating a minimum apnea-hypopnea index of at least five events per hour is needed to diagnose OSA and qualify the patient for treatment.[29,30] Patients with hypoventilation syndromes or hypoxemia must meet specific objective criteria demonstrating hypoxemia, hypercapnia, or a combination of both to qualify for noninvasive ventilation or home oxygen therapy.[31,32] In-laboratory sleep studies can demonstrate hypoventilation through the use of transcutaneous or end-tidal carbon dioxide monitoring, assist with determining optimal pressures for noninvasive ventilation, and enable education about and acclimation to positive airway pressure therapy by the sleep technologist during the study.

Overnight oximetry may identify patients who would benefit from further sleep testing, but it rarely suffices as a diagnostic tool on its own because it uses only a single-channel measurement and is thus considered insufficient to establish a diagnosis of OSA. Oximetry is, however, a useful tool in the assessment of efficacy of treatment; it is frequently used to ensure normalization of oxygen saturation during CPAP, noninvasive ventilation, or supplemental oxygen therapy. Severely reduced oxygen indices on overnight oximetry should prompt consideration of sleep apnea, hypoventilation, nocturnal hypoxemia, or a combination thereof.

HSAT and PSG are both validated methods of establishing a diagnosis of sleep apnea (see also Chapter 120 and Fig. 120.4). PSG has long been considered the gold standard and requires a patient to spend the night in a sleep laboratory. PSG entails monitoring of sleep (electroencephalography), respiratory effort (respiratory inductance plethysmography), nasal-oral airflow (pressure transducer recording), oxygen saturation (pulse oximetry), movements of the eyes (electrooculography) and the masseter and tibialis muscles (electromyelography), heart rate and rhythm (electrocardiography), snoring (microphone recording), and position (actigraphy). HSAT uses far fewer channels and is generally performed in a patient's home or inpatient setting, unattended by a technologist. HSAT devices may measure peripheral arterial tonometry and cardiorespiratory parameters (pulse oximetry, respiratory effort, nasal or nasal-oral airflow, and heart rate), as well as position, snoring, limb movements, and, in some cases, sleep (electroencephalogram). Determining which method of diagnostic sleep testing should be performed is based on current clinical guidelines,[29] patients' characteristics (i.e., cognitive function), availability of testing, payer coverage, and patient and provider preference.

NAVIGATING DEVICES AND TECHNOLOGIES

There is an increasing number of wearable, in-bed, and noncontact devices available that monitor sleeping patterns and physiologic parameters, including movement (by accelerometry), snoring, heart rate variability, skin temperature, and skin conductance (measurement of electrical conductance based on moisture of the skin, a marker of sympathetic nervous system activity). These devices often connect to cloud-based storage, enabling incorporation into digital health platforms. These data, along with data from traditional medical devices (diagnostic and therapeutic) and the electronic health record (health outcomes and measures), provide an enriched source of data through which we will learn more about population health, predictive analytics (i.e., identifying those at risk for SDB), and behavioral interventions to improve compliance with prescribed therapies. Wearable devices that track sleep are not yet accepted in lieu of PSG or HSAT, but there is widespread agreement that these devices do increase consumer and patient awareness of sleep and may support care plans involving biofeedback and self-management.[33,34] A discussion on devices used to treat SDB can be found in Chapter 122.

COMMON CLINICAL SCENARIOS TO CONSIDER SLEEP-DISORDERED BREATHING

There are some clinical conditions in both the inpatient and outpatient settings where sleep is highly relevant. Thinking about how the nocturnal sleeping period affects these conditions is important and will lead to a greater understanding about the role of sleep-related hypoxemia, hypoventilation, and apnea in the incidence or progression of the underlying disease, as well as how pulmonary diseases can affect sleep quality. Identifying sleep disorders in these conditions provides the opportunity to implement interventions and potentially mitigate poor outcomes.

ARRHYTHMIAS

Epidemiologic evidence supports an independent link between OSA and arrhythmias.[35–38] Both atrial and ventricular arrhythmias are strongly associated with OSA, particularly atrial fibrillation,[39,40] ventricular arrhythmias,[41] and sudden cardiac death.[42,43] Most of the studies focus on treatment of sleep apnea and its impact on the risk of recurrence of atrial fibrillation.[44–48] There is an overall paucity of studies investigating the impact of treatment of sleep apnea on non–atrial fibrillation arrhythmias.[49]

Prevalence of Arrhythmias in Obstructive Sleep Apnea

The prevalence of arrhythmias in individuals with OSA has been reported in the Sleep Heart Health Study,[50] the first population-based cohort study, consisting of 6441 participants (age ≥40 years) and designed to investigate the link between OSA and cardiovascular disease, including arrhythmias. In the 4 to 7 years following baseline enrollment, 3295 participants underwent repeat overnight PSG. Age-, race- or ethnicity-, and body mass index–matched samples with severe OSA (n = 228; respiratory disturbance index of 30 or more events per hour of sleep) and without OSA (n = 338; respiratory disturbance index <5 per hour of sleep) were obtained. All ventricular and supraventricular arrhythmias were more frequent during PSG in participants with OSA compared with participants without OSA (Fig. 119.2). Notably, atrial fibrillation was four times more common in participants with OSA than in those without OSA (4.8% vs. 0.9%; $P = .003$).[35] After adjusting for

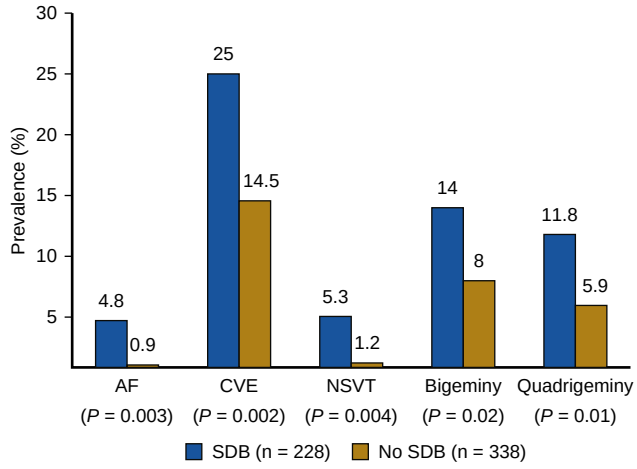

Figure 119.2 Arrhythmia prevalence in the Sleep Heart Health Study. Arrhythmia prevalence (%) according to *sleep-disordered breathing* (SDB) status. AF, atrial fibrillation; CVE, complex ventricular ectopy; NSVT, nonsustained ventricular tachycardia. (From Mehra R, Benjamin EJ, Shahar E, et al. Association of nocturnal arrhythmias with sleep-disordered breathing: the Sleep Heart Health Study. *Am J Respir Crit Care Med.* 2006;173:910-916.)

confounding variables, OSA was found to be independently associated with atrial fibrillation (*odds ratio* [OR], 4.0; *95% confidence interval* [CI], 1.0 to 15.7), complex ventricular ectopy (OR, 1.7; CI, 1.1 to 2.7), and nonsustained ventricular tachycardia (OR, 3.4; CI, 1.0 to 11.2). Conduction delay arrhythmias were also common among participants with sleep apnea. Findings from this cross-sectional study demonstrate a robust association between OSA and cardiac arrhythmias.[35] However, because OSA was not associated with new-onset atrial fibrillation (OR, 0.97; CI, 0.91 to 1.03), data from this study cannot be used to counsel patients on the risk of developing atrial fibrillation as a consequence of untreated OSA.[51] Other studies since then have demonstrated a strong association between OSA and new-onset atrial fibrillation,[52] but this is likely the result of referral and selection bias (i.e., enrollment from cardiology clinics or based on referrals to a sleep specialist).[51,52] Of note, in the Sleep Heart Health Study, central sleep apnea was independently associated with new-onset atrial fibrillation (OR, 3.0; CI, 1.4 to 6.4), discussed later.

Fatal cardiac arrhythmias have also been linked with OSA. The association between OSA and sudden cardiac death was prospectively investigated in 10,701 adults referred for overnight PSG at the Mayo Clinic Sleep Disorders Center between 1987 and 2003.[43] During an average follow-up period of 5.3 years (up to 15 years), 142 patients had sudden cardiac death (either resuscitated or fatal). In multivariate analysis, sudden cardiac death was predicted by an apnea-hypopnea index greater than 20 (*hazard ratio* [HR], 1.6; CI, 1.1 to 2.2), mean nocturnal oxygen saturation less than 93% (HR, 2.9; CI, 2.0 to 4.3), and lowest nocturnal oxygen saturation less than 78% (HR, 2.6; CI, 1.9 to 3.7).[43] On the basis of these data, the European Society of Cardiology[53] recommended that the aforementioned parameters of SDB be considered as important risk factors for sudden cardiac death; however, definitive evidence on the link between OSA and sudden cardiac death in individuals free of underlying cardiovascular disease is lacking. Similarly, no study to date has examined the impact of treating sleep apnea on reducing the risk of sudden cardiac death.[54]

Contributing Mechanisms

The potential mechanisms that link OSA to arrhythmias include (1) intermittent hypoxemia and hypercapnia, (2) elevations in sympathetic tone, (3) autonomic dysfunction, (4) increased transmural pressure on the atrial and ventricular walls as a consequence of wide variation in intrathoracic pressure during airway occlusion, (5) reduction of the atrial effective refractory period due to enhanced vagal tone, (6) surges in blood pressure resulting in increased cardiac oxygen demand and afterload, (7) QT prolongation that can trigger ventricular arrhythmias, and (8) elevated vagal tone contributing to bradyarrhythmias (see also Chapter 120).[55,56]

Impact of Obstructive Sleep Apnea Treatment on Arrhythmia

Whether treatment of OSA reduces the frequency of cardiac arrhythmias is not clear because of a lack of *randomized controlled trials* (RCTs). However, numerous observational studies suggest that treatment of OSA with CPAP reduces the risk for atrial fibrillation recurrence. A meta-analysis[47] of seven prospective cohort studies assessed the overall impact of CPAP on atrial fibrillation recurrence risk (n = 1087), and CPAP was associated with a marked reduction in atrial fibrillation recurrence (relative risk, 0.58; CI, 0.51 to 0.67). The benefit of CPAP was noted both in patients who were medically managed for their atrial fibrillation and in patients who underwent catheter ablation with pulmonary vein isolation. Therefore, in nonrandomized controlled studies, CPAP therapy is significantly associated with a reduced risk of atrial fibrillation recurrence regardless of the treatment pathway for atrial fibrillation.

In the largest RCT (n = 2717) evaluating cardiovascular end points[57] in patients with OSA who were treated with CPAP compared with patients without CPAP, new-onset atrial fibrillation was similar between the groups. Atrial fibrillation was not a prespecified end point in this study, and therefore the study may have been underpowered. Thus, more studies are needed to clarify whether sleep apnea treatment reduces the risk of new-onset and recurrent atrial fibrillation.

CPAP appears to reduce the risk of nocturnal arrhythmias in observational studies but, similar to atrial fibrillation, data from larger RCTs are lacking. In a prospective study of 23 patients with OSA and implanted loop recorders to monitor heart rhythm, 6 months of CPAP therapy abolished nocturnal ventricular bradycardia or asystole.[58] In a similar RCT of patients with heart failure and OSA,[59] patients using CPAP had a 58% reduction in premature ventricular beats compared with patients without CPAP. However, once again, RCTs are lacking to determine whether ventricular arrhythmias are reduced with sleep apnea treatment.

In summary, observational data suggest a strong and independent link between OSA and cardiac arrhythmias, particularly atrial fibrillation and fatal ventricular arrhythmias. However, for risk of recurrent or new-onset atrial fibrillation or sudden cardiac death, definitive data from RCTs are limited and not suggestive of benefit.

STROKE

Epidemiology of Obstructive Sleep Apnea and Central Sleep Apnea in Stroke

Both OSA and central sleep apnea are prevalent in patients who have had a stroke. A systematic review[60] of nearly 30 studies of 2342 patients with stroke or transient ischemic event reported an overall prevalence of any sleep apnea of 72% (apnea hypopnea index >5 events per hour); central sleep apnea predominance was observed in only 7% of the patients. Whereas central events typically resolved 3 months after stroke or transient ischemic attack, obstructive events persisted.[61] In addition to being commonly found in patients with stroke, OSA is also recognized as an independent risk factor for stroke. A meta-analysis of 10 observational cohort studies demonstrated that OSA increases the risk of stroke by more than twofold (eFig. 119.1).[62] This association also holds true in population-based cohorts,[63] a finding suggesting that referral bias is less likely to play a major role in this association.

Contributing Mechanisms

Multiple mechanisms have been implicated in the increased risk of stroke associated with OSA, including heightened sympathetic activity[64] with a resultant catecholamine surge[65] and development of hypertension,[66] which is a strong risk factor for stroke. Furthermore, intermittent hypoxemia results in vascular dysfunction and atherosclerosis[67,68] through oxidative stress, vascular inflammation, and immune activation. Furthermore, OSA may be an independent risk factor for stroke through its enhanced risk of atrial fibrillation,[39] a known risk factor for stroke (Fig. 119.3).

Impact of Continuous Positive Airway Pressure on Stroke Risk

Two of the largest RCTs to date, the *Randomized Intervention With CPAP in Coronary Artery Disease and Sleep Apnea* (RICCADSA)[69] and *Sleep Apnea Cardiovascular Endpoints* (SAVE)[57] trials, failed to show that treatment of OSA with CPAP reduces the risk of recurrent or new-onset cardiovascular events, including stroke. RICCADSA[69] determined the effects of CPAP on a composite of cerebrovascular and myocardial infarction outcomes in non-sleepy patients with a history of coronary artery disease. In the intention-to-treat analysis, OSA treatment did not significantly reduce the risk for recurrent major cardiovascular disease, including stroke. Similarly, SAVE[57] found no overall improvement in the risk of incident stroke or myocardial infarction in patients with OSA who were randomized to receive CPAP or no CPAP treatment. However, a prespecified propensity score–matched analysis in SAVE revealed that CPAP was beneficial in preventing recurrent stroke, but not myocardial infarction. eFigure 119.2 shows intention-to-treat and adherence analysis results summarized from the three major RCTs[57,69,70] designed to assess the impact of CPAP on cardiovascular outcomes. This figure is adapted[71] to demonstrate the impact of sleep apnea treatment on stroke in individuals compliant with CPAP for 4 or more hours a day.

Most recently, a systematic review and meta-analysis[72] (10 clinical trials; N = 7266) concluded that the use of CPAP compared with no treatment or sham treatment was not associated with a reduced risk of cardiovascular events (including stroke) or death in patients with OSA. An accompanying editorial[73] pointed out that the estimated risk reduction with CPAP for cardiovascular events, although not statistically significant, was sizeable (23%). The editorial attributed the lack of statistical significance of CPAP's impact on cardiovascular events to (1) poor adherence (mean CPAP use slightly more than 3 hours per night), (2) use of therapies known to reduce the background rate of cardiovascular disease events (e.g., statins), and (3) lack of better risk stratification of patients with OSA to predict those who would most benefit from CPAP.

In summary, definitive recommendations to treat OSA to reduce recurrent stroke risk cannot be made on the basis of existing evidence, although, of all cardiovascular outcomes, stroke risk reduction with sleep apnea treatment is the most promising according to available data. Further studies are

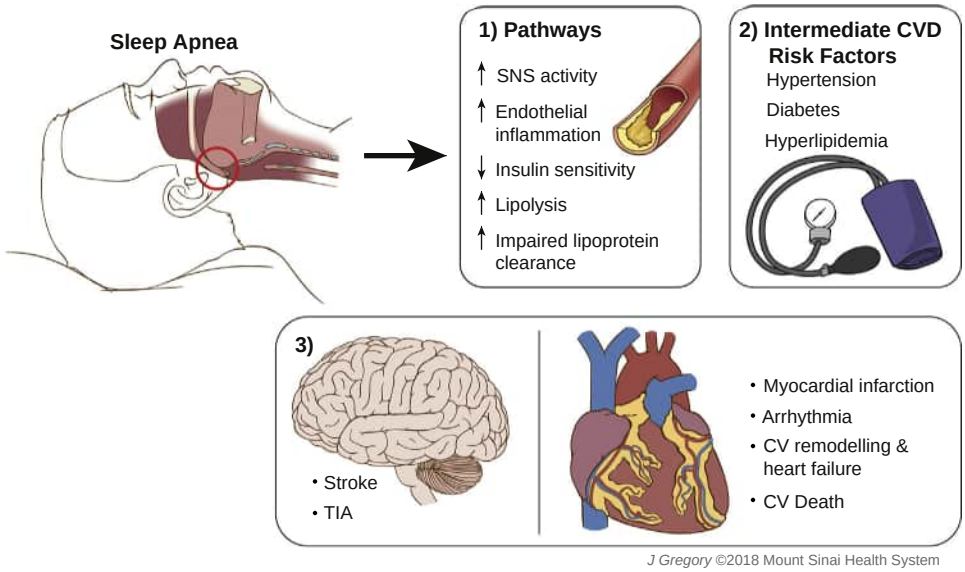

Figure 119.3 Mechanisms contributing to cerebrovascular and cardiovascular outcomes. *Obstructive sleep apnea* (OSA) is associated with several mechanistic pathways that influence the development of disease states such as hypertension, diabetes and hyperlipidemia, known to be risk factors for cerebrovascular and *cardiovascular disease* (CVD). The end result is an overall increased risk of stroke, transient ischemic attack (TIA), myocardial infarction, arrhythmia, cardiac remodeling, heart failure, and *cardiovascular* (CV) death. SNS, sympathetic nervous system. (Illustration by Jill Gregory. Copyright 2018 Mount Sinai Health System.)

needed to clarify the impact of OSA treatment on primary and secondary stroke risk reduction.

Impact of Continuous Positive Airway Pressure on Neurologic Outcomes After Stroke

Limited evidence suggests that treatment of sleep apnea may improve functional neurologic recovery after stroke. Most of the evidence comes from small clinical trials and prospective cohort studies.[74,75] A systematic review and meta-analysis[74] of 10 RCTs assessed the impact of CPAP on neurologic recovery in stroke patients with sleep apnea. Findings from this meta-analysis demonstrated improvement in neurofunctional scales (i.e., National Institutes of Health Stroke Scale and Canadian Neurological Scale) with CPAP, although there was significant variability across trials. Although CPAP appears to improve short-term functional recovery after stroke, it is not as clear whether CPAP alters long-term outcomes. Larger homogenous studies are needed to ascertain whether CPAP improves long-term outcomes, including mortality, after stroke.

PULMONARY HYPERTENSION

The prevalence of PH in patients with OSA without concomitant lung disease or left ventricular dysfunction is approximately 30%. When PH is present, it is often mild.[76] However, the independent link between OSA and PH in not clear. Similarly, treatment of sleep apnea with CPAP has been shown to reduce pulmonary arterial systolic pressures.[77,78] However, evidence demonstrating survival benefit with CPAP therapy in patients with sleep apnea and PH is lacking.

INPATIENT AND INTENSIVE CARE UNIT PATIENTS

Sleep serves a fundamental role for normal cognition, cardiovascular function, immune function, metabolism, and recovery from illness. Acutely ill hospitalized patients particularly benefit from sleep's restorative effects, but they are among the most at-risk populations for frequent nocturnal interruptions and poor sleep quality.[79] Whereas the literature on the sleep architecture of inpatients is scant because of the difficulty of measuring sleep in the hospital setting, available studies demonstrate consistent reductions in slow-wave and rapid eye movement sleep and marked increases in wakefulness after sleep onset, findings consistent with sleep fragmentation and nonrestorative sleep.[80] In certain groups of patients, such as those with critical illness, sleep is so abnormal that standard sleep staging may not even be possible.[81] Lack of the normal diurnal variation of melatonin suggests loss of normal circadian patterns and may in part explain why sleep in hospitalized patients is scattered throughout the 24-hour day.[80,82] These disruptions may be amplified in older patients who, at baseline, already have alterations in sleep architecture, such as reduced slow-wave sleep, decreased sleep efficiency, and altered circadian rhythms.[79] Whereas sleep surveys completed by patients generally corroborate these findings of poor sleep quality, provider-derived assessments overestimate both sleep time and sleep quality.[81] In fact, poor sleep quality is consistently reported by patients as one of the most disturbing experiences during their hospitalization.

There are many reasons for disrupted sleep in hospitalized patients. Poor sleep quality may be related to the acute illness necessitating hospitalization, an underlying preexisting medical condition or sleep disorder, or a combination thereof. External factors, including high noise levels, elevated nighttime ambient light levels, disruptive roommates, and patient care interactions such as wound care and phlebotomy, all contribute to sleep disruption.[82] Both the introduction and the withdrawal of medications can also affect sleep quality.

The physiologic effects of sleep deprivation are well known (see also Chapter 118). Sleep deprivation in healthy patients modulates immune function, disrupts neuroendocrine control systems (i.e., hippocampal-pituitary-adrenal axis), increases insulin resistance, decreases respiratory muscle strength, increases risks of falls, and increases the likelihood of poor cardiovascular outcomes. How these factors affect hospitalized patients is less well known because of the challenge of studying such populations and controlling for confounders. A growing literature suggests that acute sleep loss in hospitalized patients is associated with a variety of poor patient outcomes.[79] Importantly, sleep disruption persists for many patients long after their hospitalization.

Guidelines advise a multifaceted approach to address modifiable disrupters of sleep in the inpatient setting.[83] Such interventions include earplugs, eye masks, music therapy, relaxation techniques, bright light exposure during daytime hours, and scheduling nursing workflow to decrease nighttime interruptions. Such interventions appear to improve sleep quality and seem to be of low risk, although barriers such as mixed buy-in from staff and patients exist.[82] Pharmacologic interventions are frequently prescribed for hospitalized patients.[84] In general, hypnotic agents should not be used in inpatients because many of these drugs are associated with delirium, have significant side effects, interact with other medications, and contribute to polypharmacy. If a pharmacologic sleep aid is deemed to be absolutely necessary, it should be tailored to the individual patient profile. Melatonin has generated increased interest given its tolerability and low risk of side effects. In small, randomized trials, melatonin appears to improve sleep quality and duration.[85,86]

OSA is often considered an outpatient problem, and an inpatient diagnostic workup may be deferred for a variety of reasons, including decompensated cardiopulmonary disease and lack of availability of and reimbursement for testing. Inpatient testing is not recommended by current guidelines despite evidence that it is feasible and reliable in a variety of patient populations.[29,87] Home CPAP is also frequently discontinued in hospitalized patients,[88] thus representing lost opportunities to engage patients in teachable moments about *positive airway pressure* (PAP) therapy and to identify and address barriers to adherence. A diagnosis of OSA carries important implications for admitted patients because they are at increased risk of having complications and poor outcomes compared with patients without OSA, both during hospitalization and following discharge.[82] For example, in patients with heart failure with reduced ejection fraction, initiating CPAP before hospital discharge reduces readmission rates, improves ejection fraction, and

increases transplant-free survival.[89,90] Similarly, early initiation of CPAP in acute poststroke patients improves neurologic recovery.[91] Benefit from early initiation of CPAP or BPAP during or immediately following hospitalization has also been shown in patients admitted with acute exacerbations of COPD, decompensated obesity hypoventilation syndrome, and pneumonia.[92]

PERIOPERATIVE EVALUATION

Given its high prevalence in the general population,[93,94] it is not surprising that OSA is a common comorbidity in patients undergoing surgical procedures. This prevalence appears to be increasing in concert with rising rates of obesity[95] and with greater awareness of the need to screen surgical candidates in the preoperative period. Nonetheless, most patients remain undiagnosed before surgery.[96] In certain at-risk populations, such as those undergoing bariatric surgery, the rate of OSA may be as high as 90%.[97] OSA is associated with an increased incidence of respiratory complications, postoperative cardiac events, impaired wound healing, a longer hospital stay, and possibly mortality.[98,99] Screening for OSA in patients undergoing surgery is now routinely recommended.[100]

In addition to general pulmonary considerations, the consulting pulmonologist should include an assessment of OSA risk as part of the evaluation. Identifying patients at risk for or with known OSA frequently affects surgical and anesthetic approaches, as well as plans for postoperative monitoring to mitigate the increased risk of complications. Questionnaires have been developed that provide a simple, practical, and reliable method for identification and triage of patients at high risk for OSA. The most validated and widely used questionnaire in surgical patients is the STOP-Bang tool[101] (eFig. 119.3). A score of 0 to 2 (out of a possible 8) suggests that the patient is at low risk for OSA, whereas a score of 3 or more has a high sensitivity for moderate to severe OSA. Higher values on the STOP-Bang tool directly correlate with an increased probability of severe OSA.[102] Other screening tests of comparable accuracy in the surgical population include the perioperative sleep apnea prediction score, Berlin questionnaire, and American Society of Anesthesiologists checklist.[103] Other routine tests are not usually indicated but may be available. These tests include the serum bicarbonate level, which, if higher than 28 mmol/L, may increase the specificity of the STOP-Bang questionnaire[22] and identify patients at risk for obesity hypoventilation syndrome. The presence of suspected OSA may also prompt further workup for other associated conditions, such as PH.[103]

Identification of an increased risk for OSA in the preoperative setting raises a dilemma for the treatment team in deciding whether to cancel or delay surgery to pursue further evaluation and treatment. Formal testing may not be possible because of time and resource constraints. Conversely, proceeding without treatment may place the patient at an increased risk of complications. Suspected or known OSA should be incorporated into decision making regarding scheduling of surgery on an ambulatory basis, with particular attention paid to higher-risk procedures involving the upper airway or those requiring high doses of analgesic agents. Routine admission of patients with OSA to the intensive care unit is not necessary.[97] Patients and providers should be informed that the effects of surgery and postoperative analgesia on sleep architecture and SDB may persist for several days after surgery, or longer if narcotics are used.[104]

There is considerable uncertainty regarding the appropriate way to manage such patients, and decision making should include the patient, surgeon, and anesthesiologist. Although most patients will not experience any major perioperative complications related to OSA, complications can be catastrophic. Thus, efforts to optimize cardiopulmonary status, including treatment of OSA, are recommended. This includes using regional anesthesia when feasible, anticipating a difficult airway, and achieving high levels of consciousness in patients before extubation. Postoperative strategies include use of the upright, semiupright, or lateral positioning; minimization of respiratory depressants in the postoperative period; use of opioid-sparing analgesia; and close monitoring of oxygenation and ventilation.[105]

For patients with a known diagnosis of OSA, a preoperative workup should include a review of the patient's sleep studies, adherence to current therapy, and residual symptoms.[103] Patients whose OSA is well controlled with home PAP therapy should continue with treatment in the perioperative period. Continuation of PAP therapy has been shown to reduce unplanned intensive care unit transfers, hospital length of stay, cardiovascular complications, and pulmonary complications.[99,106] Unfortunately, fewer than two-thirds of patients using home CPAP therapy continue to receive it in the postoperative setting.[107,108] The pressure required to maintain a patent upper airway may be higher in the postoperative setting in response to fluid shifts, the effects of medications, or swelling from upper airway manipulation during anesthesia or surgery itself.[109] Empirical preoperative PAP in patients with suspected OSA is feasible, especially with auto-adjusting CPAP devices that automatically adjust pressures to maintain an unobstructed airway.[108] Despite studies demonstrating improvements in certain outcomes, empirical preoperative PAP is not routinely recommended in guidelines,[103] except for the particularly high-risk patient. Nonetheless, there should be a low threshold to start PAP therapy if there is hypoxemia, obstruction of the upper airway (i.e., witnessed apneas), or hypoventilation in the patient at risk for OSA. Use of CPAP can be continued after most operations, including bariatric surgery, without increasing the risk of anastomotic leak.[110] Patients undergoing transsphenoidal surgery or who have other anterior skull base defects are at risk for developing pneumocephalus with the application of PAP; in these patients, PAP should be avoided in the immediate postoperative period.[111]

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Respiratory abnormalities of COPD can disrupt sleep. The degree of sleep disruption correlates with the severity of airway obstruction (forced expiratory volume in 1 second).[112] In addition, sleep disturbances can affect COPD and may comprise an independent risk factor for exacerbations and mortality.[113] The physiologic changes of sleep well tolerated by healthy individuals are a significant challenge for the COPD patient with impaired pulmonary mechanics and baseline gas-exchange abnormalities. Pulmonologists, however, must not assume that poor sleep and nocturnal

hypoxemia are normal for their patients with COPD, and failure to identify the coexistence of SDB may place the patient at future risk.

The coexistence of COPD and OSA is often described as the overlap syndrome,[114] although the term has also been applied to patients with OSA and PH and to patients with OSA and asthma. It is prudent therefore to specify the specific overlap syndrome being discussed. Since it was first described in the 1980s, the *OSA-COPD overlap syndrome* has received the most attention in the literature. Nonetheless, it is not yet established whether OSA is more common in patients with COPD than in the general population and vice versa, and this uncertainty may result in part from the heterogeneity of COPD phenotypes as well as from varying definitions of OSA. The "pink-puffer," for example, with relatively preserved gas exchange, lower body mass index, and lung hyperinflation, may well be protected against OSA, whereas the "blue bloater," with a higher body mass index, lower respiratory drive, and peripheral fluid retention, could be at higher risk. Other pathophysiologic mechanisms that link OSA and COPD include increased upper airway inflammation and skeletal myopathy in patients with COPD, thus leading to greater collapsibility of the upper airway, and the potential for OSA to exacerbate lower airway inflammation in patients with COPD. Furthermore, medications used for COPD may be beneficial (e.g., theophylline) or harmful (e.g., inhaled corticosteroids) for patients with OSA.[114] On the basis of conservative estimates of 10% prevalence for each, at least 1% of the population may have an OSA-COPD overlap syndrome.[115,116] Patients with more severe obstruction appear to be at higher risk for OSA.[117]

Patients with OSA-COPD overlap syndrome may present with clinical features of either or both, depending on the severity of each. They are at high risk for hypercapnia, hypoxemia, and PH and thus may manifest signs and symptoms of those conditions at an earlier stage than expected given the degree of airway obstruction.[114] As in the general population, the diagnosis of OSA requires a sleep study. Patients with COPD not requiring supplemental oxygen may be candidates for HSAT. Use of in-laboratory PSG with carbon dioxide monitoring is preferred when moderate to severe obstructive lung disease, hypercapnia, or significant hypoxemia is anticipated. Monitoring of carbon dioxide levels may be particularly helpful for PAP titration studies to determine efficacy of ventilatory support because PAP parameters are adjusted throughout the night. Regardless of the modality used, conventional SDB metrics that help define severity (i.e., apnea hypopnea index) may not be as applicable in patients with COPD as in patients without COPD.[118] Nocturnal oximetry has limited utility as a diagnostic tool for OSA in patients with COPD because it cannot differentiate the relative contribution of each to the nocturnal hypoxemia observed.[119] Unless the baseline awake saturation is less than 88%, PSG is usually performed without supplemental oxygen. This allows for characterization of hypopneas, which may otherwise be missed.[118] Because of sleep-associated hypoventilation and reductions of functional residual capacity resulting in ventilation-perfusion mismatching, patients with COPD often experience significant hypoxemia, even when daytime saturations are normal.[120] Different patterns of oxygen desaturation are recognized in patients with OSA, COPD, and OSA-COPD overlap syndrome. Patients with OSA and normal underlying lung function have a normal baseline oxygen saturation with cyclical intermittent episodes of desaturation from a non-hypoxemic baseline saturation and often return to normal between apneic or hypopneic events. Patients with COPD, particularly those with advanced disease, have a lower baseline oxygen saturation with intermittent desaturation that can be sustained and profound during rapid eye movement sleep because of loss of accessory muscle use for breathing (atonia) characteristic of rapid eye movement sleep. Patients with OSA-COPD overlap demonstrate a combination of the two profiles, with intermittent desaturation from baseline hypoxemia and severe desaturation during rapid eye movement sleep (Fig. 119.4).[114] Patients with OSA-COPD overlap have more severe nocturnal hypoxemia parameters than patients with either OSA or COPD alone.[112,114,121] Additional PSG features specific to COPD include expiratory flow limitation and air trapping.[118]

A systematic review (n = 29,341) estimated the prevalence of OSA-COPD overlap syndrome to be 1–3.6% in the general population, 7.6–55.7% in patients with OSA, and 2.9–65.9% in patients with COPD.[121] OSA-COPD overlap syndrome is associated with several deleterious outcomes, including worse quality of life, increased health care use and cost, and increased cardiovascular morbidity compared with patients with COPD alone.[121] Patients with OSA-COPD overlap syndrome can have daytime hypercapnia with relatively preserved lung function if their ability to hyperventilate between apneic events is diminished, thus resulting in retention of carbon dioxide and progressive desensitization of the respiratory system to hypercapnia.[122] Hypoxemia is also more common, and the combination of hypoxemia and hypercapnia contributes to the increased incidence of PH in patients with OSA-COPD overlap.[123,124]

COPD and OSA are independently associated with an increased risk of cardiovascular disease, and this risk is amplified in patients with OSA-COPD overlap syndrome. Measures of inflammation (e.g., inflammatory molecules, oxidative stress, endothelial dysfunction) are elevated in both OSA and COPD.[114] In addition to PH, atrial fibrillation appears to be more common in patients with OSA-COPD overlap[125] than in either condition alone. In the overlap syndrome, nonrandomized trials suggest that all-cause cardiovascular mortality is increased,[126] with one study finding a synergistic effect only in women.[126]

Patients with COPD and nocturnal hypoxemia (without OSA) benefit from standard long-acting β-agonist and anticholinergic inhaled therapy, which independently increases nocturnal oxygen saturation compared with placebo[127,128] (see also Chapter 64). Other measures to optimize the underlying condition, such as smoking cessation and pulmonary rehabilitation, can be expected to improve breathing during sleep. Controversy exists regarding the clinical importance of "fixing" gas-exchange abnormalities that arise during rapid eye movement sleep in patients with COPD, but the profound derangements occasionally seen provide a rationale for therapy.[118] Supplemental oxygen may be indicated if significant nocturnal oxygen desaturations persists despite optimal pharmacotherapy. Oxygen should be carefully titrated to bring the saturation into the region of 90–92%.[112] Supplemental oxygen does not appear to be associated with significant additional risk of hypercapnia, but there is also limited evidence of improved survival, an issue that is being investigated in a large clinical trial.[129,130]

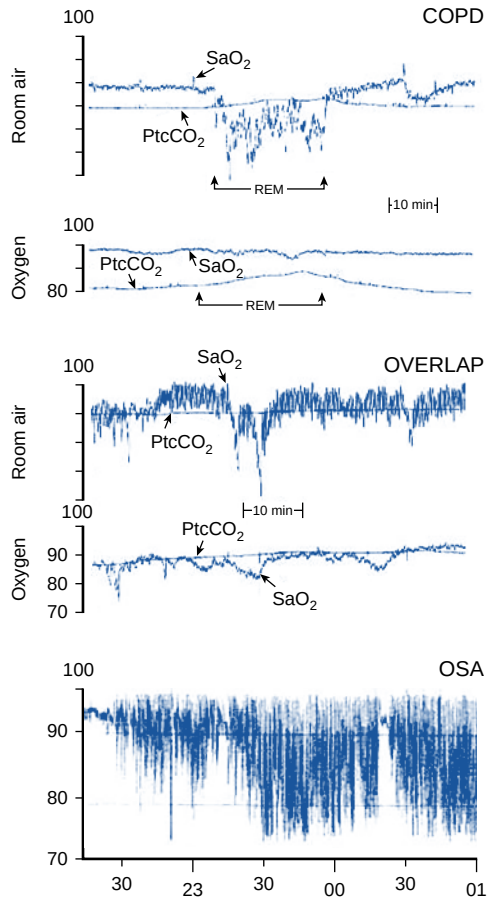

Figure 119.4 Different patterns of oxygen desaturation during sleep. Patients with COPD, overlap syndrome, and *obstructive sleep apnea* (OSA). Patients with moderate to severe COPD alone (*top*) desaturate during *rapid eye movement sleep* (REM) from associated REM atonia of respiratory accessory muscles, showing sustained, rather than cyclical, desaturation. Patients with overlap syndrome (*middle*) have lower baseline arterial oxygen saturation (Sa_{O_2}) and oxygen saturation as measured by pulse oximetry (Sp_{O_2}) while asleep and have greater cyclic variation in saturation correlating with OSA. The differences between arterial oxygen saturation and transcutaneous carbon dioxide levels are demonstrated in overlap patients on room air versus with supplemental oxygen. Although less desaturation is observed during use of supplemental oxygen, a greater increase in transcutaneous carbon dioxide tension (Ptc_{O_2}) levels is observed. Patients with OSA alone (*bottom*) demonstrate intermittent cyclical desaturation to varying degrees. (From McNicholas WT. Chronic obstructive pulmonary disease and obstructive sleep apnoea: the overlap syndrome. *J Thorac Dis.* 2016;8:236–242.)

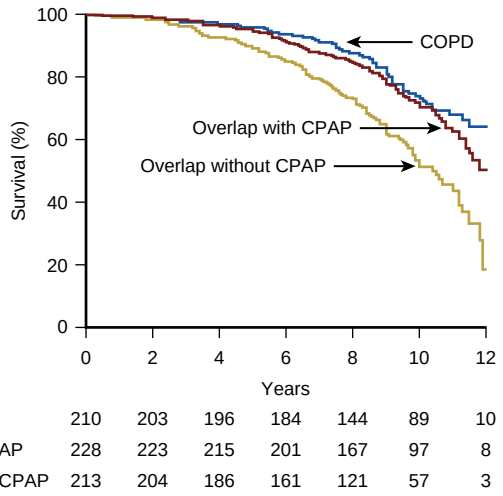

No. at risk							
COPD	210	203	196	184	144	89	10
Overlap with CPAP	228	223	215	201	167	97	8
Overlap without CPAP	213	204	186	161	121	57	3

Figure 119.5 Outcomes in patients with COPD and overlap syndrome with and without *continuous positive airway pressure* (CPAP). Kaplan-Meier survival curves for outcomes among chronic obstructive pulmonary disease patients without obstructive sleep apnea (OSA) (COPD group), patients with overlap syndrome treated with CPAP since enrollment (overlap with continuous PAP group), and patients with COPD and coexisting OSA not treated (overlap without CPAP group). The difference in survival among patients with COPD only and those with overlap with CPAP are statistically significant from the patients with COPD and overlap without CPAP ($P < 0.001$). A similar significant difference was also seen in exacerbations (not shown). (From Marin JM, Soriano JB, Carrizo SJ, Boldova A, Celli BR. Outcomes in patients with chronic obstructive pulmonary disease and obstructive sleep apnea: the overlap syndrome. *Am J Respir Crit Care Med.* 2010;182:325–331.)

In patients who have OSA-COPD overlap, PAP is the optimal therapy. Two large observational cohorts demonstrated significant mortality benefit with the use of CPAP in OSA-COPD overlap syndrome after adjusting for confounders (Fig. 119.5).[131,132] Patients with severe COPD or gas-exchange abnormalities should be titrated in the laboratory setting by the most skilled sleep technician available. BPAP or noninvasive ventilation is indicated when there is significant hypoventilation and COPD-related hypercapnic respiratory insufficiency. There are several mechanisms by which BPAP could benefit patients with OSA-COPD overlap, including resting chronically fatigued respiratory muscles, reversing atelectasis, resetting the chemoreceptor drive to breathe, and improving gas-exchange variables. A large meta-analysis and systematic review[133]of the role of home noninvasive ventilation in 51,085 patients using either BPAP or home mechanical ventilation showed a lower risk of mortality in those patients who used BPAP versus no device (22.3% vs. 28.6%; CI, −10.3% to −0.8%; OR, 0.66; $P = 0.003$), fewer all-cause hospital admissions (39.7% vs. 75%; CI, −49.4% to −21.1%; OR, 0.22; $P < 0.001$), and less need for intubation (5.3% vs. 14.7%; CI, −14.8 to −1.3%; OR, 0.34; $P = 0.02$). A similar reduction in all-cause hospital readmissions but not mortality was observed with home mechanical ventilation.[133] Supplemental oxygen in addition to CPAP or BPAP may at times be necessary if gas exchange parameters do not resolve with PAP alone.[134] Given the frequent sleep symptoms in patients with OSA-COPD overlap syndrome and COPD, the question of hypnotic agents frequently arises. Benzodiazepines should be avoided given their adverse effects on ventilation. The nonbenzodiazepine hypnotic agents, such as zolpidem, appear safer but should also be avoided if possible.[135] Newer agents such as melatonin receptor agonists or receptor antagonists to orexin (a neuropeptide involved in wakefulness) may improve sleep parameters without affecting respiratory parameters.[112,136] Cognitive behavioral therapy is the preferred therapy for insomnia in patients with COPD and has been shown to be effective.[137,138]

ASTHMA

Sleep disturbances in asthmatic patients are common.[139] Poorly controlled asthma leads to disrupted sleep and impaired cognitive performance, which has been shown to be reversible with effective daytime asthma treatment.[140,141] Nocturnal asthma symptoms are markers of poor asthma control and are frequently assessed in asthma

questionnaires. In addition to poor asthma control, other reasons for impaired sleep include coexisting rhinosinusitis, gastroesophageal reflux disease, anxiety, and depression, all of which are more common in asthmatic patients.[139,142] Not surprisingly, daytime sleepiness is also common.[143]

The prevalence and incidence of OSA are increased in asthmatic patients compared with the general population[144-146] (see Chapter 61). OSA has become an increasingly recognized comorbid condition in asthma, and both OSA and asthma are associated with obesity. Obese asthmatic patients are at risk for OSA and represent an asthma phenotype particularly difficult to control.[147] The presence of OSA in asthmatic patients appears to be associated with worse outcomes.[143,148,149] Severe exacerbations are more common and directly correlate with the apnea-hypopnea index.[150] The mechanisms of OSA contribution to these poor outcomes are being investigated. Sleep fragmentation, intermittent airway occlusion, and hypoxemia induced by OSA may lead to increased oxidative stress and inflammation, resulting in bronchoconstriction, increased airway resistance, and poorer asthma control.[151] Upper airway closure may trigger vagally mediated bronchoconstriction.[152,153] Asthma may also contribute to OSA. Asthmatic patients have greater reductions in lung volumes during sleep compared with persons without asthma, and this change may lead to a more collapsible upper airway. Asthma-associated systemic inflammation may impair the strength of respiratory muscles, including the upper airway dilators. Systemic corticosteroids used to treat acute exacerbations of asthma can lead to weight gain and cause myopathy of the pharyngeal dilator muscles, which may increase the risk of OSA.[145]

The nocturnal symptoms of OSA and asthma may be difficult to distinguish by history alone. PSG or HSAT should be considered when SDB is suspected or when nocturnal symptoms persist despite otherwise seemingly good asthma control. In asthmatic patients with significant OSA, CPAP remains the standard of therapy to improve daytime symptoms and nocturnal sleep. CPAP improves asthma quality of life measures, reduces the frequency of exacerbations, and reduces the use of bronchodilators, although the effect on objective lung function is equivocal.[149,154] In addition to maintaining upper airway patency, CPAP improves reflux symptoms, another trigger for nocturnal symptoms in asthmatic patients. CPAP is not a recommended treatment for asthmatic patients without OSA. The effects of second-line treatments for OSA, such as mandibular repositioning devices, have not been studied. The effects of asthma medications on OSA outcomes have also not been studied. At this time, there are no guidelines to manage the patient with both asthma and OSA, and the patient should be treated optimally according to standard asthma and OSA guidelines. Larger trials are urgently needed given the high prevalence of these two conditions and evidence suggesting that CPAP may increase bronchial hyperresponsiveness in patients without asthma and degrade sleep architecture in asthmatic patients without OSA.[146]

Key Points

- Patients with arterial P_{O_2} near the steep portion of the oxyhemoglobin dissociation curve may maintain oxygenation while upright and awake but frequently desaturate when recumbent and asleep.
- Not all sleep-disordered breathing is sleep apnea, and the absence of sleep apnea does not exclude the presence of hypoventilation or hypoxemia.
- Obstructive sleep apnea has a strong and independent association with cardiac arrhythmias, particularly with atrial fibrillation and fatal ventricular arrhythmias. Further randomized controlled trials evaluating the impact of positive airway pressure therapy on new-onset or recurrent arrhythmias are needed.
- Treatment of obstructive sleep apnea following acute stroke improves neurologic recovery, although the role of CPAP in improving long-term outcomes after stroke has not been shown.
- Screening for obstructive sleep apnea in patients undergoing surgery is now routinely recommended.
- In patients with COPD and hypercapnia, use of home bilevel positive airway pressure reduces all-cause hospital admission and intubation and improves survival.
- Patients with asthma who have nocturnal symptoms should be screened for obstructive sleep apnea. Treatment with positive airway pressure improves symptoms attributable to obstructive sleep apnea, improves asthma symptoms and quality of life, and reduces exacerbations.

SNORING? Do you **snore loudly** (louder than talking or loud enough to be heard through closed doors)?	Yes	No
TIRED? Do you often feel **tired, fatigued, or sleepy** during the daytime?	Yes	No
OBSERVED? Has anyone **observed** you **stop breathing** during your sleep?	Yes	No
PRESSURE? Do you have or are you being treated for **high blood pressure?**	Yes	No
BODY MASS INDEX more than 35 kg/m^2?	Yes	No
AGE older than 50 years?	Yes	No
NECK circumference? Neck circumference greater than 40 cm?	Yes	No
Gender=male?	Yes	No

eFigure 119.3 The STOP-Bang questionnaire. Low risk for obstructive sleep apnea = yes to 0 to 2 questions. High risk for obstructive sleep apnea = yes to 3 or more questions. STOP-Bang, snoring, tiredness, observed apnea, high blood pressure, body mass index, age, neck circumference, and male gender. (From Chung F, Yegneswaran B, Liao P, et al. STOP questionnaire: a tool to screen patients for obstructive sleep apnea. Anesthesiology 2008;108:812–21.)

INTRODUCTION AND DEFINITIONS

Sleep-disordered breathing (SDB) is characterized by discrete episodes of absent (apnea) or reduced (hypopnea) breathing, and/or by sustained reductions in breathing during sleep (hypoventilation) compared with wakefulness. The most common form of SDB results from closure of the upper airway during sleep and is called *obstructive sleep apnea* (OSA). SDB is diagnosed by *polysomnography* (PSG), which is a comprehensive multichannel sleep study, or by limited-channel home sleep apnea testing devices (see "Diagnosis" section later). In obstructive apneas, there are sustained respiratory efforts during the event, often identified using thoracic and abdominal respiratory inductance plethysmography bands, which demonstrate paradoxical thoracoabdominal motion (Fig. 120.1). In contrast, during central apneas, there is transient loss of respiratory drive output from the central respiratory controller, with absence of respiratory effort during the event. Mixed apneas are events that begin as central apneas but become obstructive.

In adults, an *apnea* is defined as a cessation of breathing longer than 10 seconds.[1,2] *Hypopneas* are associated with a reduction in airflow rather than complete cessation of airflow. These events are associated with a fall in oxygen saturation or a brief arousal from sleep (microarousal). Whereas the definition of apneas is well standardized, various criteria have been used to identify hypopneas based on the extent of flow reduction, oxygen desaturation, and microarousals.[1–3] Currently, the *American Academy of Sleep Medicine* (AASM) recognizes two alternative definitions of hypopnea[1,2] (Table 120.1). Another type of event is termed a *respiratory effort–related arousal* (RERA). These are episodes of mild upper airway narrowing during sleep, typically identified as flattening of the airflow signal from the nasal pressure cannula, with a reduction in flow amplitude not large enough to be scored as hypopnea,[4] terminating with a microarousal[1,2] (Fig. 120.2). The scoring criteria for respiratory events recommended by the AASM are shown in Table 120.1.

The standard metric for OSA severity is the *apnea-hypopnea index* (AHI), which is calculated as the number of apneas and hypopneas during sleep divided by total sleep time, represented in events per hour. OSA severity is graded as follows: normal (no OSA): AHI less than 5; mild sleep apnea: AHI 5 or greater but less than 15; moderate sleep apnea: AHI 15 or greater but less than 30; and severe sleep apnea: AHI of 30 or greater. Current AASM criteria for PSG analysis also define the *respiratory disturbance index* as the number of apneas, hypopneas, and RERAs per hour of sleep.[2]

Several factors can influence the AHI value derived from polysomnographic recordings.[1,5–8] For example, the technology used to assess airflow has evolved from reliance on oronasal thermistors to include the addition of the nasal pressure signal, which is more sensitive for obstruction and detection of mild reductions in airflow.[5] Prevalence estimates for OSA derived from studies that used thermistor technology only[9,10] are lower than from recent studies that also recorded nasal pressure.[11,12] Differences in hypopnea definitions (extent of flow reduction with associated O_2 desaturation and/or microarousal) can also lead to sizeable differences[6] in assessments of OSA severity and prevalence, as demonstrated by recent studies evaluating the differences between previous and current AASM-recommended scoring criteria.[7,8,13–15] Thus, it is

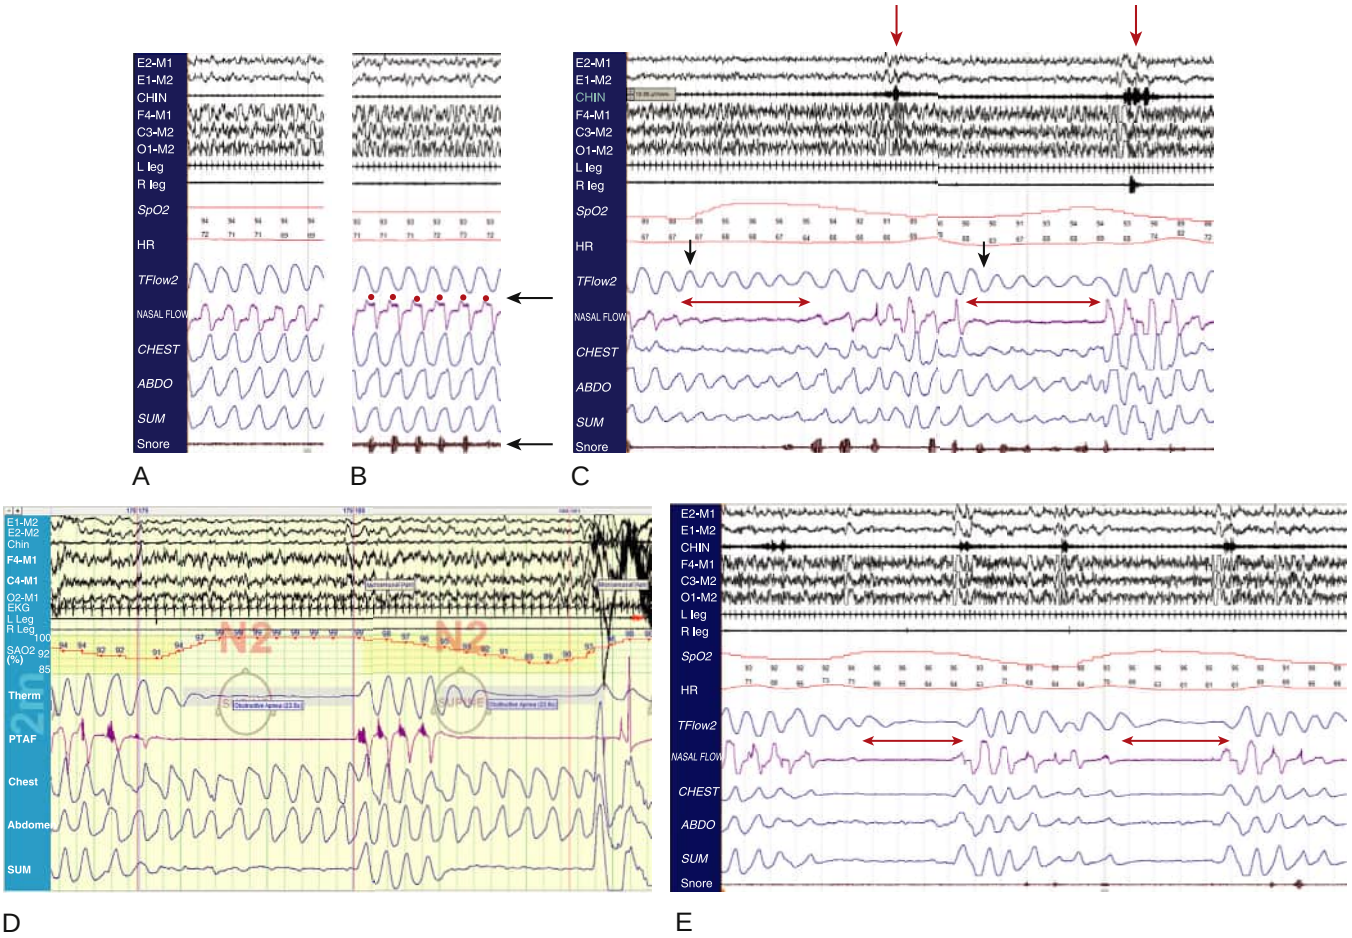

Figure 120.1 Polysomnographic tracings. Tracings illustrate stable breathing (A), simple snoring (B), obstructive hypopneas (*red arrows*, C), obstructive apneas (*blue markers*, D), and central apneas (*red arrows*, E). Note in panel B that the snores are shown as a microphone signal (snore) along with an inspiratory flattening on the nasal pressure flow signal *(red dots)*. Note in panel C that there is evidence of persistent airflow during events on the thermistor (Tflow2) signal while the nasal pressure signal shows no flow. The event is therefore scored as a hypopnea because flow must be absent on both signals to score an apnea (as in D and E). The events in panels C and D are considered obstructive because there is persistent effort during the event with paradoxical inward motion of the ribcage on the thoracic effort channel (Chest). In panel D, the events are apneas because of absent flow on both the thermistor (Therm) and nasal pressure (PTAF) channels. In addition, the paradoxical movement of the chest and abdomen result in no signal on the sum of these two channels (SUM) because the upper airway is completely obstructed and airflow is completely absent. The apneas in panel E are considered central because the absence of airflow is accompanied by an absence of effort (Chest, Abdomen).

essential in interpreting clinical reports of polysomnographic studies, or published research data, that the criteria for scoring respiratory events be stated clearly and considered when interpreting the findings.

Not all patients with OSA have symptoms related to respiratory disturbance. The term *sleep apnea syndrome* refers to the concurrence of OSA with symptoms, classically excessive daytime sleepiness.[16] The latter is often identified by the Epworth Sleepiness Scale,[17] in which the respondent indicates the likelihood of dozing (scale from 0 to 3) in eight common circumstances (Table 120.2). A score of 11 or greater is commonly accepted as indicating excessive sleepiness.[17] Currently, the *International Classification of Sleep Disorders* (third edition) identifies a diagnosis of adult OSA as an AHI of 5 or greater with symptoms, or an AHI of 15 or greater regardless of symptoms[16] (eTable 120.1).

Sleep-associated hypoventilation is defined as a sustained reduction in breathing associated with an increase in arterial P_{CO_2}. The *International Classification of Sleep Disorders* (third edition) threshold values are an arterial P_{CO_2} greater than 55 mm Hg for more than 10 minutes of recording or a value of greater than 50 mm Hg, which is more than 10 mm Hg above waking values, for more than 10 minutes of the PSG recording. Sleep-associated hypoxemia is identified when CO_2 monitoring is not recorded or CO_2 values for hypoventilation are not achieved, but there is a sustained reduction in arterial S_{O_2} less than 88% for more than 5 minutes of the night.[16] Various conditions are associated with hypoventilation during sleep. One of the most common is seen in obese individuals, which can progress to chronic hypercapnic respiratory failure and *obesity hypoventilation syndrome* (OHS). OHS is diagnosed in obese individuals (body mass index >30 kg/m^2) with SDB and elevated daytime arterial P_{CO_2} (>45 mm Hg) without other identifiable causes.[16] Elevated serum bicarbonate levels can point to the diagnosis, but measurement of CO_2 levels may be needed for the diagnosis. OHS is associated with OSA in 90% of cases and with severe OSA in 70%. In those with OSA, the risk for OHS increases with higher body mass index and lower lung function.[18] Patients often present with excessive daytime sleepiness and may be hypoxemic with signs of pulmonary hypertension and right heart failure (e.g., lower extremity edema); in up to 40% of cases, they may present with acute hypercapnic respiratory failure[19,20] (see Chapter 45).

eTable 120.1 Definition of Adult Obstructive Sleep Apnea

OSA is present when A and B or C are present:

A. AT LEAST ONE APPLIES:

- The patient reports daytime sleepiness, unrefreshing sleep, fatigue, or insomnia
- The patient wakens with breath holding, gasping, or choking
- The bed partner reports habitual snoring, breathing interruptions, or both during the patient's sleep
- The patient has been diagnosed with hypertension, mood disorder, cognitive dysfunction, coronary artery disease, congestive heart failure, stroke, atrial fibrillation, or type 2 diabetes

and

B. SLEEP RECORDING* SHOWS:

- Five or more predominantly obstructive respiratory events (obstructive or mixed apneas, hypopneas, or RERAs) per hour

or

C. SLEEP RECORDING* SHOWS:

- Fifteen or more predominantly obstructive respiratory events (obstructive or mixed apneas, hypopneas, or RERAs) per hour

*Sleep recording may be either laboratory *polysomnography* (PSG), or out-of-laboratory portable testing which typically does not record signals to allow sleep staging. Respiratory event numbers are expressed per hour of sleep for PSG and per hour of recording for portable monitors. Portable monitors tend to underestimate event indices as compared with PSG because patients typically are not asleep for an entire recording period. Hypopneas associated with arousals and RERAs cannot be scored from portable monitors without sleep staging capability because arousals cannot be identified.

OSA, obstructive sleep apnea; RERA, respiratory effort–related arousal.

Modified from American Academy of Sleep Medicine. *International Classification of Sleep Disorders* 3rd ed. Darien, IL: American Academy of Sleep Medicine; 2014.

Table 120.1 Definitions of Respiratory Events for Diagnostic Polysomnography

APNEA

- An event lasting ≥10 sec characterized by ≥90% reduction from pre-event baseline in oronasal thermistor airflow. An apnea is scored as:
  - Obstructive, if there is continued or increasing respiratory effort throughout the event
  - Central, if effort is absent throughout the entire event
  - Mixed, if effort is initially absent, then resumes in the latter part of the event
- There is no minimum desaturation or microarousal requirement for scoring of an apnea.

HYPOPNEA

- An event lasting ≥10 sec characterized by a ≥30% reduction from pre-event baseline in peak nasal pressure inspiratory airflow which is associated with:
  - Definition 1A: either a ≥3% reduction in arterial So_2 pre-event baseline or a microarousal
  - Definition 1B: a ≥4% reduction in arterial So_2 from pre-event baseline value
- The hypopnea is scored as *obstructive* if during the event there is any snoring, inspiratory airflow limitation, or paradoxical thoracoabdominal motion not present during pre-event breathing.
- The hypopnea is scored as *central* if none of the events described earlier is present.

RERA

- A sequence of breaths lasting ≥10 sec that does not meet criteria for apnea or hypopnea, which is characterized by increasing respiratory effort or inspiratory flattening of the nasal pressure flow signal leading to a microarousal.

HYPOVENTILATION

- An increase in arterial Pco_2 to >55 mm Hg for ≥10 min or an increase in arterial Pco_2 ≥10 mm Hg above awake supine values to >50 mm Hg for ≥10 min

RERA, respiratory effort–related arousal.
Modified from Berry RB, Abreu AR, Bibbs ML, et al. *The AASM Manual for the Scoring of Sleep and Associated Events*. Version 2.6 ed. Darien, IL: American Academy of Sleep Medicine; 2020; and American Academy of Sleep Medicine. *International Classification of Sleep Disorders* 3rd ed. Darien, IL: American Academy of Sleep Medicine; 2014.

PATHOGENESIS

The pathogenesis of OSA involves a complex interaction of factors including altered upper airway anatomy, tissue characteristics, neuromuscular function, sleep-related decrements in upper airway dilator muscle activity, attenuated protective reflexes, and altered ventilatory and arousal responses to chemical and other respiratory stimuli (Fig. 120.3). Different factors may predominate in different individuals, yielding different OSA phenotypes. Because the upper airway in OSA closes only during sleep, sleep-dependent

Table 120.2 Epworth Sleepiness Scale

Situation	Chance of Dozing (Score 0–3)
Sitting and reading	
Watching television	
Sitting inactive in a public place (such as a theater or meeting)	
Riding as a passenger in a car for an hour without a break	
Lying down in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after a lunch without alcohol	
In a car, while stopped for a few minutes in traffic	
	Total score (normal <11)

Instructions to patient: "What is the chance that you would doze off or fall asleep (not just "feel tired") in each of the following situations? Rate the chance for each situation. If you are never or rarely in the situation, please give your best guess for that situation."
Chance of dozing: 0, never; 1, slight chance; 2, moderate chance; 3, high chance. The individual scores are summed.

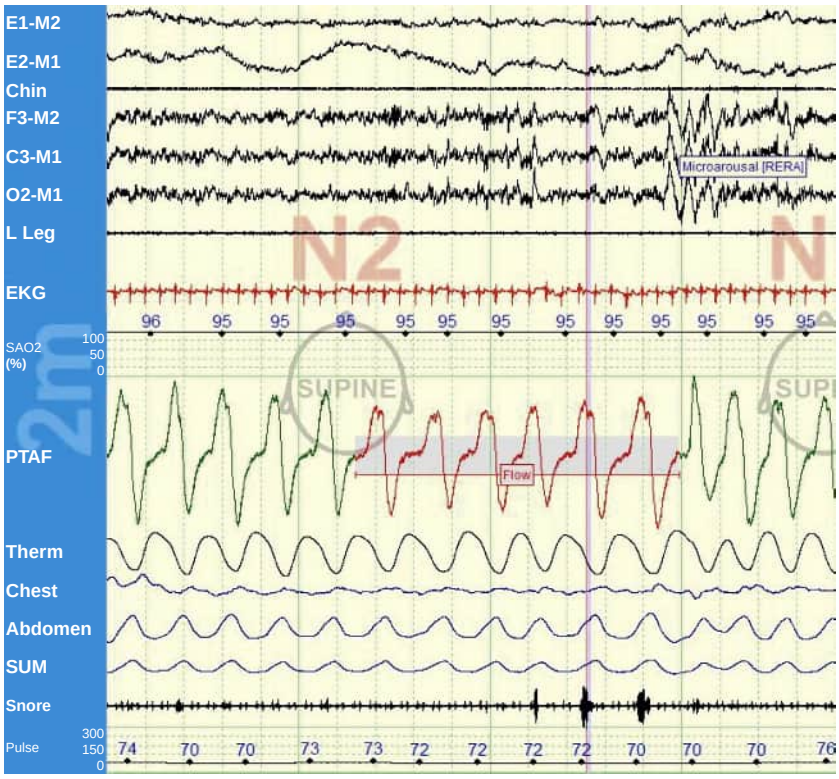

Figure 120.2 Polysomnographic tracing illustrating a respiratory effort-related arousal. The red-highlighted breaths on the nasal pressure flow signal (PTAF) show inspiratory flattening (flow limitation) reflective of upper airway narrowing. Flow is not reduced sufficiently to meet hypopnea criteria and there is no change in arterial So_2, but the electroencephalographic channels above demonstrate microarousal (label) at the termination of the respiratory effort–related arousal (RERA) event.

Factors affecting upper airway patency	Patency	Collapse
		Anatomic configuration (bony structure, soft tissue, fat)	Normal	Reduced dimensions
Lung volume	Normal lung volume: traction on upper airway	Lower lung volume: less traction
Lining fluid surface tension	Normal	Increased
Intraluminal pressure	Less negative	More negative
Extraluminal tissue pressure	Less positive	More positive
Airway collapsibility (P_{crit})	Lower	Higher
Sleep-related decrements in muscle activity	Normal, mild compared with wakefulness	Marked compared with heightened compensatory levels during wakefulness
Chemosensitivity	Normal	Blunted or heightened
Negative pressure reflexes	Mild sleep-related decrement	Blunted (latency, amplitude)
Chronic dilator muscle activation	Adaptation	Injury, dysfunction
Denervation (sensory, motor)	Absent	Present: neural and muscular dysfunction
Edema: inflammation; nocturnal fluid shift	Absent	Present: altered airway caliber and tissue characteristics

Figure 120.3 Schema illustrating factors that favor upper airway collapse during sleep in obstructive sleep apnea. (Modified from Kimoff R. The upper airway. In: Hamid QS, Martin JG, eds. *The Physiologic Basis of Respiratory Disease*. Hamilton, Canada: BC Dekker; 2005.)

changes in output to upper airway dilator muscles must be fundamental. The airway collapses when dilator muscle activity and compensatory reflexes are no longer sufficient to maintain patency of the compromised airway. The key elements of sleep-related influences on respiratory motor output and current approaches to pathophysiologic endotyping of OSA are discussed in detail in Chapter 117. This section focuses on structural and functional changes in the upper airway predisposing to airway closure.[21–23]

UPPER AIRWAY DIMENSIONS

A variety of imaging methods have shown that upper airway dimensions are reduced in OSA.[24] Airway size may be compromised by alterations in bony structures such as a small retrognathic mandible,[25] or by increased volume of soft tissues (tongue, lateral walls).[26] In addition to a reduction in the cross-sectional dimensions, airway length may also be increased, with increased length predisposing to collapse.[27,28] Upper airway caliber is also influenced by the effect of lung volume on tracheal traction, so that reductions in lung volume (e.g., in recumbency) lead to less tracheal traction and reduced upper airway patency.[29,30]

UPPER AIRWAY COLLAPSIBILITY

Due to a lack of rigid supporting structures, much of the human upper airway is a collapsible tube. Pressure-flow relationships in the airway have been modeled using the Starling resistor model, in which collapsibility is expressed as the *critical closing pressure* (P_{crit}). P_{crit} is measured during sleep by decreasing the intraluminal pressure (e.g., lowering *continuous positive airway pressure* [CPAP] level in an OSA patient or applying negative pressure in a normal subject) and assessing flow reductions. A more negative P_{crit} denotes a less collapsible airway. Studies have shown a continuum of upper airway collapsibility in subjects with normal breathing ($P_{crit} < -10$ cm H_2O), nonapneic snoring (P_{crit} range, -10 to -5 cm H_2O), obstructive hypopnea (P_{crit} range, -5 to 0 cm H_2O), and obstructive apnea ($P_{crit} > 0$ cm H_2O).[31–33] These values are for passive P_{crit}, which reflects the passive mechanical properties of the airway. Techniques are also available to measure active P_{crit}, which reflects active neuromuscular compensation for reduced intraluminal pressure, which is significantly impaired in some OSA patients.[23,33,34]

NEUROMUSCULAR FACTORS

In addition to the attenuation of protective reflexes during sleep discussed in Chapter 117, several factors may contribute to impaired neuromuscular upper airway function in OSA.[35–38] Loading of the upper airway dilators leads to myoadaptive changes (fiber type shifts) so that, whereas contractility appears preserved in most patients, the muscles are more fatigable.[38,39] In some patients with severe OSA, muscles may be injured, leading to reduced contractility, as described in the English bulldog model of OSA.[40] Changes in mechanical coupling due to connective tissue alterations[41] and fat deposition may also alter the efficacy of muscle activation. There is also evidence for upper airway neuropathy in OSA, with both sensory/afferent impairment[38,42,43] and efferent neuropathy in the form of muscle denervation,[37,44] both of which could impair neuromuscular compensatory responses.[21]

UPPER AIRWAY INFLAMMATION

There is increased inflammation in upper airway tissues in OSA, which may contribute to the pathogenesis of OSA.[41,45] Tissue trauma from snoring and apneas, oxidative stress, acid-pepsin reflux, smoking, and alcohol could all lead to inflammation. Increased inflammation, in turn, may produce edema and airway narrowing, lead to changes in soft tissue composition (e.g., increased collagen deposition) and mechanics, impair muscle contractility,

and contribute to upper airway afferent and efferent neuropathy.[21,41] Few studies to date have assessed the effects of anti-inflammatory therapy on OSA, though inhaled nasal steroids have been shown to improve mild OSA.[46]

FLUID SHIFT

There is growing evidence that spontaneous shifts in fluid volume from the legs to the neck during recumbency or sleep play a role in the pathophysiology of OSA.[47,48] In OSA, the extent of spontaneous overnight fluid shift correlates with AHI,[47,49] and interventions to reduce fluid shift may improve OSA severity in some patient subgroups.[48,50,51] Compression stockings to prevent daytime fluid accumulation reduced nocturnal fluid shift and AHI,[52,53] as did increased physical activity in sedentary patients.[48] Diuresis may improve AHI, particularly in hypertensive patients,[48,51] and increased dialysis/ultrafiltration improves fluid shift and sleep apnea severity in patients with end-stage renal disease.[48,50]

PREDISPOSING FACTORS

OBESITY

There are strong links between obesity and OSA.[54,55] Approximately 58% of moderate to severe OSA patients are obese.[54] Obesity may reduce upper airway caliber due to adipose tissue deposition as well as through a lung volume–dependent effect.[30] A change in weight is also associated with changes in AHI. In the Wisconsin cohort over 8 years of follow-up, a 10% increase in body weight was associated with a 32% increase in AHI and a sixfold increase in risk of developing an AHI of 15 or greater. A 10% weight loss was associated with a 26% reduction in AHI.[56] Weight-related changes in AHI are more marked in men than in women.[54,55] Despite the strong links between OSA and obesity, many obese individuals do not have OSA, and up to one-third of OSA patients are not obese.

UPPER AIRWAY ANATOMIC ABNORMALITIES

Abnormalities that may predispose to OSA include marked craniofacial disproportion, as is seen in Pierre-Robin syndrome,[57] benign tonsillar hypertrophy, macroglossia, and acromegaly.[58] Nasal obstruction may contribute to OSA[59] by increasing negative inspiratory driving pressure to maintain airflow, which may contribute to dynamic oropharyngeal collapse. However, surgical correction of mechanical nasal obstruction alone typically has minimal effects on OSA severity.[60,61] Several case series have reported a high incidence of OSA in patients with head and neck cancers,[62–64] related either to anatomic narrowing by tumor mass or surgical- or radiation-induced airway changes.[63,64]

GRAVITY/BODY POSITION

The frequency of OSA events is often higher in the supine position compared with the lateral decubitus position due to the effects of gravity on upper airway size and shape. Positional OSA is commonly defined as a supine AHI at least twice as high as that in the lateral position.[65–67] The duration of obstructive events and extent of associated oxygen desaturation may also worsen in the supine position.[68] Prevalence estimates vary depending on PSG recording and scoring techniques[66,69] and the patient population under study. Positional OSA was identified in 49.5% of mild (AHI 5 to 15), 19.4% of moderate (AHI 15 to 30), and 6.5% of severe (AHI ≥30) OSA patients in one study.[70] In the recent HypnoLAUS population study, positional OSA was present in 42% of women and 31% of men with AHI of 5 or greater and in 52% of women and 41% of men with AHI of 15 or greater.[69]

GENETIC FACTORS

Studies in diverse populations have demonstrated a familial propensity for OSA. The relative risk for OSA in a first-degree relative of an affected patient is approximately 2.0.[71–73] Obesity is a major OSA risk factor, which also has a genetic basis; it is estimated that approximately 40% of the genetic variance in AHI is shared with pathways that mediate obesity.[74,75] The remainder of heritability likely resides in genes controlling craniofacial structure, ventilatory control, sleep-wake patterns, and inflammation.[73,76–78] Candidate gene, genome-wide linkage, and genome-wide association studies have revealed gene loci and/or polymorphisms associated with OSA risk, severity, and complications, with findings in some cases differing between sex and ethnicities. Work is ongoing to translate these findings into clinical predictive and therapeutic strategies.[73,76–78]

ENDOCRINE DISTURBANCES

OSA has been reported in 25–35% of patients with untreated hypothyroidism.[79–81] Predisposition to OSA may be due to increased mucopolysaccharide and protein deposition in upper airway tissues. Altered central respiratory control or neuropathic changes in upper airway muscles may also play a role. Thyroid replacement therapy improves OSA in many patients, though there may be residual sleep-disordered breathing requiring continued standard treatment.[79,80] A clinical history suggesting hypothyroidism should be sought during evaluation of OSA patients, but routine biochemical screening of all potential OSA patients is not warranted.[82]

Sleep-disordered breathing is found in approximately 70% of patients with acromegaly.[81,83,84] While OSA predominates, central sleep apnea may also be observed. Upper airway dimensions are reduced due to both soft tissue (glycosaminoglycan and collagen deposition, edema) and bony changes.[58] Upper airway myopathy may also play a role. Correction of the endocrine disturbances in acromegaly results in variable improvements in OSA; continued treatment with CPAP is often required.[80]

OSA is found in up to 70% of women with polycystic ovarian syndrome.[85,86] Potential mechanisms include hormonal changes (relative androgen excess) and increased central adiposity. Polycystic ovarian syndrome is associated with a high rate of metabolic dysfunction. OSA may worsen metabolic function, and OSA treatment may improve metabolic parameters in these patients.[86,87]

SMOKING

Cigarette smoking has been linked to snoring and OSA in some epidemiologic studies,[88,89] with one analysis showing a significant positive dose-response relationship between cigarette smoking and OSA severity.[90] Possible mechanisms include worsening of upper airway inflammation

and sleep-disruptive effects of nicotine producing respiratory instability.

ALCOHOL, DRUGS

Alcohol is known to worsen snoring and OSA. This may be due to direct effects on upper airway motor activity or to a deepening of sleep and impairment of arousal responses.[91,92] Other drugs with similar effects include muscle relaxants, sedative-hypnotics, and opioids, although the latter may also produce central and/or complex sleep apnea. Drug effects on upper airway function remain an active area of study.[92–94]

EPIDEMIOLOGY

PREVALENCE

The original Wisconsin Sleep Cohort study in 1993 reported the prevalence of OSA syndrome (AHI ≥5 with daytime sleepiness) as 4% in men and 2% in women,[95] and the prevalence of AHI 15 or greater regardless of symptoms as 9% in men and 4% in women. Since this estimate, obesity has increased markedly in the United States and elsewhere,[96] and the Wisconsin Cohort investigators updated their estimates of OSA prevalence in 2013,[97] with OSA syndrome (AHI ≥5 with Epworth Sleepiness score ≥11) now estimated at 14% in men and 5% in women. Prevalence estimates from other studies vary based on differences in recruitment, ethnicity, airflow recording technology, definitions of hypopnea, and symptoms included for OSA syndrome.[98,99] However, these studies all confirm a high prevalence of OSA in the general population. Recently, Benjafield et al.[12] reported that 936 million individuals have mild to severe OSA (AHI ≥5) while 425 million have moderate to severe OSA (AHI ≥15) worldwide.

SEX DIFFERENCES

OSA is two to three times more prevalent among men than women. Several factors account for this, including differences in body fat distribution, upper airway anatomy (cross-sectional area, length) and collapsibility, ventilatory control, and other genetic factors. OSA is approximately three times more prevalent among postmenopausal than premenopausal women, pointing to a role for sex hormones.[100,101] Hormone replacement therapy may have a protective effect,[102,103] but appears to have little impact on OSA once present.[104] The clinical presentation of OSA may also differ, with complaints of insomnia, fatigue, and depressive symptoms being more common in women than men, while heavy snoring and nocturnal choking may be less prominent.[101,105,106]

ETHNICITY

Overall OSA prevalence is similar among African Americans and whites,[107] although it is comparatively higher among African Americans younger than 25 years[108] or older than 65 years.[109] Symptoms of OSA[110,111] and PSG-based prevalence are slightly higher among Hispanics than whites, with some ancestries more prominently affected than others.[77,112,113] OSA prevalence among Asians is comparable to that in whites, despite a lower prevalence of obesity among Asians.[77,113,114] While obesity remains an important risk factor, craniofacial structure may play a more prominent role in OSA pathogenesis among Asians.[113,114] Studies on ethnicity may be confounded by socioeconomic factors. Low socioeconomic status is linked to OSA risk among children.[115,116] Living in poor neighborhoods is associated with shorter sleep time and increased sleep disruption; air quality may also be worse, which could worsen OSA through increased airway inflammation.[117] CPAP compliance is reportedly lower in African Americans, which may be related to socioeconomic status[118] and shorter sleep duration.[119]

AGING

The prevalence of OSA increases with age. The updated Wisconsin Sleep cohort prevalence of OSA (AHI ≥5, Epworth Sleepiness score ≥11) among men was 12% for ages 30 to 49 years versus 18% for ages 50 to 70 years, and among women was 3% for ages 30 to 49 years and 8% for ages 50 to 70 years.[97] Studies in individuals older than 65 years have reported a high incidence of OSA (50–60%).[120–122] OSA is often underrecognized in elderly patients but may be associated with daytime sleepiness, neurocognitive dysfunction, depressive symptoms, falls, and adverse cardiovascular outcomes.[121,123–125] Recent *randomized controlled trials* (RCTs) in patients older than 65 years have shown improvements with CPAP in sleepiness and neurocognitive outcomes. Findings varied between studies, but improvements were greater in patients with more severe OSA and better CPAP compliance.[125–128]

PREGNANCY

OSA may develop or worsen over the course of pregnancy, with an estimated 17–45% of women affected by their third trimester.[129,130] A recent large cohort study of over 2500 nulliparous women (NuMom2b) found an OSA prevalence of 3.6% and 8.3% in early and mid-pregnancy, respectively, based on less sensitive level 3 sleep recordings (e.g., similar to home-based tests; see later).[131] Standard clinical prediction indices are not highly accurate, whereas incorporation of anthropometric factors (age, body mass index, chronic hypertension) improves accuracy.[132,133] Observational studies demonstrate links between maternal OSA and gestational hypertension/preeclampsia and gestational diabetes and, in some studies, low infant birth weight.[130,134] Two large registry studies also showed links to serious outcomes, including maternal cardiomyopathy, congestive heart failure requiring intensive care admission, and maternal death.[135,136] Data on the effects of CPAP or other OSA treatments during pregnancy are currently limited, though small, short-term studies suggest benefits in lowering blood pressure[130] and, in one study, in achieving better glycemic control.[130] Clinically, CPAP treatment during pregnancy can be challenging but may provide symptomatic benefit. However, large-scale trials are still required to evaluate the impact on maternal and fetal pregnancy outcomes.

CLINICAL EVALUATION

CLINICAL PRESENTATION

The patient with OSA classically presents with a history of heavy habitual snoring and *excessive daytime sleepiness*

(EDS). However, OSA is a heterogenous condition and may present with a variety of manifestations, and some patients with even moderate to severe OSA have few if any symptoms. Different symptom clusters have been identified in OSA that may include predominantly nocturnal symptoms with insomnia and disturbed sleep, predominantly EDS, or few if any symptoms.[137,138] OSA symptoms typically develop over many years in association with aging, weight gain, or onset of menopause, and may be underappreciated by the patient. Conversely, EDS may be the manifestation of a number of conditions other than OSA. A comprehensive sleep history should be obtained in evaluating patients, to assess not only features of OSA but also the impact of sleep habits and other potential sleep disorders on clinical symptoms.

ELEMENTS OF A COMPLETE SLEEP HISTORY

The chief complaint and the patient's main concerns should be elicited. The spouse or bed partner's observations can be invaluable with respect both to the manifestations during sleep and any impact on daytime functioning. It is also important to obtain the occupational history because of the potential risks related to EDS or impaired attention (e.g., commercial truck driver), and impact on daily functioning. Shift work is also associated with impaired sleep quality and EDS.[139]

The history should include medications taken. Benzodiazepines and other sedative-hypnotics, antidepressants, antipsychotics, lithium, anticonvulsants, opioids, stimulants, β-blockers and other cardiovascular medications, antihistamines, and other classes of drugs can affect sleep architecture, risk of OSA, or daytime functioning.[92] Similarly, other substance use should be elicited (nicotine, caffeine, alcohol, cannabis, illicit substances), including recent discontinuation, which could account for possible withdrawal symptoms.

A family history of sleep-disordered breathing can be helpful for diagnosis, whereas other conditions may affect treatment decisions (e.g., early cardiovascular disease).

OSA patients may manifest a number of nocturnal symptoms (Table 120.3). Loud, disruptive snoring is often present, which may lead the spouse to sleep in a separate room.

Table 120.3 Symptoms of Obstructive Sleep Apnea

NOCTURNAL
Heavy, habitual snoring
Apneas witnessed by bed partner
Nocturnal choking
Nocturia
Restless sleep
Sweating
Erectile dysfunction
Gastroesophageal reflux
Unrefreshing sleep
Headache upon awakening
Insomnia
Violent/jerking movements
DAYTIME
Excessive daytime sleepiness
Difficulty concentrating
Memory loss/cognitive changes
Irritability, personality change
Depressive symptoms
Fatigue
Lightheadedness

Snoring is not a specific symptom for OSA and has a high prevalence in the general population. An important finding is a report by the bed partner of witnessed apneas. Whereas the frequency or duration of events reported may not be accurate, a description of episodes during which breathing stops, followed by loud gasping or snoring, is highly suggestive of OSA. Patients themselves are often unaware of apneic episodes, and it is surprisingly uncommon for patients to report nocturnal choking or shortness of breath upon awakening. The differential diagnosis for nocturnal choking includes paroxysmal nocturnal dyspnea related to heart failure and Cheyne-Stokes respiration, nocturnal asthma, laryngospasm (idiopathic or due to acid-pepsin reflux), orthopnea due to diaphragm dysfunction, or insular seizures.[140] Other nocturnal symptoms of OSA include restless sleep, diaphoresis, and palpitations. Patients may report dry mouth upon awakening, a feeling of awakening unrefreshed, or morning headache.

The cardinal daytime symptom of OSA is EDS,[141] defined as a propensity to fall asleep in unwanted situations during normal waking hours. Patients should be asked whether they have experienced drowsiness while driving or have fallen asleep at the wheel because OSA increases the risk for crashes or near-crashes.[142,143] Patients may also describe symptoms of fatigue or lack of energy.[144] Other symptoms of OSA include cognitive impairment such as difficulty with concentration or memory loss, mood disturbances such as irritability or depression, and impaired quality of life. OSA may also be associated with nocturia, enuresis (in severe cases), reduced libido, and impotence.[145]

Although EDS is a common symptom of OSA, it is important to consider other potential causes of sleepiness (eTable 120.2). Many medical conditions may be associated with sleep disruption, resulting in excessive sleepiness and/or predisposing to OSA. A complete medical history and review of systems should assess for weight gain, menopause, endocrine disorders (hypothyroidism, acromegaly, Cushing disease), respiratory and cardiac history (e.g., with nocturnal cough or dyspnea), allergic rhinitis, nasal or oropharyngeal trauma or surgery, gastroesophageal reflux disease, neuropathic or chronic pain, and genetic syndromes. Psychiatric disorders such as depression may present with excessive sleepiness or insomnia. Anxiety, panic disorder, and posttraumatic stress disorder may affect sleep. Neurologic disorders, including head trauma, prior stroke, and neurodegenerative diseases, can impact EDS, sleep architecture, and sleep-disordered breathing.

The sleep history should include the habitual sleep schedule, including any daytime naps, and details of the patient's usual bedtime, time to fall asleep, number and duration of nocturnal awakenings, usual waking time, and whether wakening is spontaneous or requires one or more alarms. The regularity and timing of work and sleep schedules should also be ascertained. Short sleep duration during the week, with recovery sleep time on weekends, is often a sign of insufficient sleep. When habitually present for 3 months or more, this is termed *insufficient sleep syndrome*.[16] Patients should be questioned about light exposure and use of electronic devices before bedtime and in bed, given the impact of blue light on sleep and circadian rhythms.[146,147]

Symptoms of other sleep disorders should be elicited. The most common of these are narcolepsy, idiopathic

hypersomnolence, restless legs syndrome, and various *rapid eye movement* (REM) and non-REM *parasomnias* (i.e., complex movements, behaviors, or experiences during sleep).[16]

Additional descriptions of disorders of hypersomnolence, movement disorders, circadian sleep-wake disorders, and parasomnias are provided at ExpertConsult.com.

MEASUREMENT OF SLEEPINESS

The most commonly used questionnaire to quantify daytime sleepiness is the Epworth Sleepiness Scale described earlier (see Table 120.2).[17] Values of 11 or greater indicate excessive sleepiness. The Stanford Sleepiness Scale[178] asks subjects to rate their degree of sleepiness at a single moment in time. This scale has been used more commonly in research, and normative values have not been established, limiting its clinical applicability. Objective measurements can be made in the sleep laboratory during a series of scheduled daytime nap sessions to measure either physiologic sleepiness (Multiple Sleep Latency Test) or the ability to remain awake (Maintenance of Wakefulness Test).[179,180] The Oxford Sleep Resistance Test (OSLER Test), a more accessible behavioral test that does not require PSG recording, has been found to approximate findings on Maintenance of Wakefulness Test.[181,182]

DIAGNOSIS

QUESTIONNAIRES/PREDICTION EQUATIONS

Clinical prediction models that incorporate symptoms and anthropomorphic measurements (e.g., body mass index, neck circumference) have been developed to grade OSA risk.[183–187] These models tend to be relatively sensitive (76–96%) but not very specific (13–54%) when compared with PSG.[188] Several questionnaires such as the Berlin Sleep,[189] STOP-Bang,[190] and more recently the NoSAS[191] and GOAL questionnaires[192] have been developed, with slightly improved specificity. However, whereas questionnaires or prediction models are useful for screening or estimating pretest probability, objective sleep recording is required to establish a diagnosis of OSA and determine its severity.[193]

LABORATORY POLYSOMNOGRAPHY

The gold standard test for OSA has long been considered to be in-laboratory, technologist-attended complete overnight PSG, referred to as level 1 sleep testing. Standards for the performance and analysis of full PSG have been established by the AASM.[194] Level 1 recordings include monitoring of electroencephalography, electro-oculography, chin electromyography, electrocardiography, oronasal airflow and snoring, pulse oximetry, thoracic and abdominal movement, body position, and tibialis anterior electromyography for scoring periodic leg movements (see Fig. 120.1). Transcutaneous CO_2 is monitored in some laboratories to detect sleep-related hypoventilation. Infrared video monitoring is also used to record complex behaviors and movements to diagnose parasomnias. Sleep-wake state is scored using electroencephalography, electro-oculography, and electrocardiography signals. Respiratory events are scored based on airflow, thoracoabdominal motion, and oximetry signals using the criteria described in Table 120.1. PSG records may be autoscored or manually scored by trained technologists according to standard criteria[194] and summary data on sleep, respiratory, and other associated events generated in tabular and graphic summary format (eFig. 120.1).

UNATTENDED SLEEP STUDIES

Although complete in-laboratory PSG is the gold standard for OSA diagnosis, there is limited access to this resource in many locations.[195,196] There are now "out-of-center" or home sleep apnea testing options available, which are adequate for diagnosis of OSA in many instances. In addition to level 1 sleep testing (in-laboratory PSG), three other levels of sleep testing are defined by the AASM based on number of channels recorded. Level 2 testing involves a full PSG performed in an unattended, nonlaboratory setting; this has been used in population-based studies[10] and has clinical utility when full PSG recording is desirable but the patient cannot come to the sleep laboratory (e.g., intensive care unit or disabled patients). Level 3 home sleep apnea testing devices acquire respiratory airflow (nasal pressure and/or oronasal thermistor), respiratory effort, oximetry, and often snoring and body position (eFig. 120.2). Level 3 devices are increasingly being used for the diagnosis and management of OSA. Level 4 devices record oximetry and sometimes one other signal such as airflow, thus yielding less information than level 3 monitors. Recent guidelines recommend use of portable monitoring for evaluation of moderate- to high-pretest probability patients[193] (Fig. 120.4). A positive test in such patients will rule in a diagnosis of OSA, whereas a negative test does not exclude more subtle forms of disease, and full PSG should then be performed. Current guidelines do not recommend the use of portable monitoring for OSA diagnosis in the presence of major medical comorbidities or for diagnosis of sleep hypoventilation or central sleep apnea. However, for moderate to severe OSA patients, recent data show that the use of portable monitors in ambulatory-based clinical management algorithms results in similar treatment adherence and clinical outcomes as conventional level 1–based approaches[196–198] (see "Disease Management Strategies" section).

IN-HOSPITAL DIAGNOSIS

Patients with OSA and OHS have increased hospitalization rates and adverse outcomes.[199–201] In hospitalized patients, SDB is highly prevalent but underdiagnosed. In patients presenting with acute cardiac disease, OSA not previously diagnosed has been found in up to 78%.[202–204] Among patients hospitalized on internal medicine wards with a body mass index of 35 kg/m^2 or greater, 31% met criteria for OHS.[201]

Hospitalization presents an opportunity to detect and treat SDB because treatment appears to improve outcomes during current[201,202] and future hospitalizations[205] and reduces rehospitalization rates.[202] Access to level 1 PSG is limited for hospitalized patients. Protocols using level 3 testing and *auto-positive airway pressure* (APAP) titration can facilitate diagnosis and rapid treatment initiation. Level 3 studies in

Insufficient sleep (behaviorally induced)
Circadian rhythm disorders
Delayed sleep-wake phase syndrome ▪ Advanced sleep-wake phase syndrome ▪ Irregular sleep-wake rhythm disorder ▪ Non–24-h sleep-wake rhythm disorder ▪ Shift work disorder
Sleep-related breathing disorders ▪ Obstructive sleep apnea ▪ Central sleep apnea ▪ Sleep-related hypoventilation
Hypersomnia of central origin ▪ Narcolepsy type 1 ▪ Narcolepsy type 2 ▪ Idiopathic hypersomnia ▪ Periodic hypersomnia (e.g., Kleine-Levin syndrome)
Insufficient sleep syndrome
Sleep-related movement disorders ▪ Restless legs syndrome ▪ Periodic limb movement disorder
Parasomnias ▪ REM sleep behavior disorder ▪ Sleepwalking ▪ Confusional arousals
Sleep-related eating disorder
Sleepiness due to medical disorders, medication, and other conditions

REM, rapid eye movement.

DIFFERENTIAL DIAGNOSIS

HYPERSOMNIAS OF CENTRAL ORIGIN

The most common disorder is narcolepsy, which typically presents in the second or third decade of life and is characterized by a tetrad of symptoms including daytime sleepiness, cataplexy, hypnagogic or hypnopompic hallucinations (hallucinations that take place in the transition between wakefulness and sleep), and sleep paralysis.[148,149] Narcolepsy is a disorder of REM sleep with an "unpackaging" of REM phenomena so that aspects of REM sleep become apparent during wakefulness. Cataplexy is the sudden loss of muscle tone, as takes place in REM sleep, which is precipitated by emotion (laughter, anger, surprise) during wakefulness. It starts in facial muscles and can be partial and limited to the face or total and diffuse, leading to collapse, mimicking syncope, though there is no true loss of consciousness. Cataplexy is associated with objective transient areflexia. Cataplexy is highly specific to narcolepsy and is a virtually pathognomonic symptom, although narcolepsy can be seen without cataplexy (narcolepsy type 2).[16] Hypnagogic or hypnopompic hallucinations are vivid dreams typically with a strong visual component that are experienced either at sleep onset or when awakening from sleep. Individuals with sleep paralysis wake up from sleep unable to move because they are emerging from REM sleep and the REM-associated atonia has not been switched off.[148,149] Although particularly common in narcolepsy, sleep paralysis may also be experienced by otherwise healthy individuals. The diagnosis of narcolepsy is confirmed with cerebrospinal fluid hypocretin-1 deficiency or a Multiple Sleep Latency Test showing reduced mean sleep latency and sleep-onset REM periods in at least two naps, in the absence of other causative factors.

Excessive sleepiness in narcolepsy is commonly treated with stimulant medication.[150,151] Modafinil is the drug of choice due to a better side-effect profile and lesser potential for abuse than for other stimulants. When modafinil is ineffective, alternative stimulants are methylphenidate or amphetamine preparations.[150] The stimulant solriamfetol[152] and the histamine H_3 receptor agonist pitolisant[153] are novel treatment options for EDS in narcolepsy. Residual EDS in OSA may also be treated with modafinil, solriamfetol, or pitolisant, when other contributing factors have been carefully excluded.[154] Improvements in EDS with stimulant therapy in narcolepsy can be associated with improvement in other symptoms such as cataplexy and sleep paralysis, though specific medication may be required. Cataplexy is commonly treated with antidepressants (tricyclic, selective serotonin-noradrenalin reuptake, and monoamine oxidase inhibitor classes).[150,151] The central nervous system depressant sodium oxybate (Xyrem) is approved for treatment of cataplexy and may also improve nocturnal sleep quality and excessive daytime sleepiness. Its use is limited by cost and potential side effects such as headache, mood swings, nausea, enuresis, sleepwalking, and others, including potential need to retitrate CPAP in those with OSA, which raises concerns about respiratory depression.[155–157] Pitolisant also appears to reduce cataplexy but it is not currently approved for this indication.[158]

Periodic Hypersomnia

Kleine-Levin syndrome is a rare cause of EDS, which usually presents in adolescence and is characterized by intermittent episodes of intense hypersomnia with normal intervening sleep and alertness.[16,151] Episodes of extreme hypersomnia may last for days and patients may sleep for up to 20 hours each day. Episodes are associated with behavioral abnormalities, including binge eating and hypersexuality. Treatment is usually supportive during the episodes, with a limited role for stimulants; lithium may be effective in some cases.[151]

Idiopathic Hypersomnia

This disorder is a diagnosis of exclusion and is characterized by persistent marked excessive sleepiness despite documented adequate sleep duration and hygiene, frequent daytime napping that is typically unrefreshing, unlike in narcolepsy,[159] subjectively uninterrupted nocturnal sleep, and normal nocturnal PSG recording, without symptoms of another sleep disorder or medical cause for hypersomnolence.[16] Although most patients have prolonged nocturnal sleep, some may not. The current *International Classification of Sleep Disorders* does not distinguish between these two variants.[16] Pathophysiology is not well understood, but patients have a high prevalence of autonomic symptoms (e.g., vasomotor, secretomotor, orthostatic intolerance).[160] Management is similar to narcolepsy, although symptoms may be more difficult to control.[150,151]

MOVEMENT DISORDERS DURING SLEEP

Movement disorders during sleep may cause sleep disruption and EDS. The most common is the *restless legs syndrome* (RLS),[16] which is characterized by an urge to move the legs, usually accompanied by uncomfortable or unpleasant sensations in the legs that (1) get worse with periods

of physical inactivity or rest, (2) are partially or totally relieved by movement such as walking or stretching, and (3) are worse or are felt only in the evening or night. The timing of symptom onset is such that the patient has difficulty falling asleep until the uncomfortable sensations ease and the urge to move subsides, which may take 2 to 3 hours after bedtime. Several factors can precipitate or exacerbate RLS, the most common of which is iron deficiency. Serum iron and ferritin levels should be checked in all RLS patients. Caffeine, stimulants, and other medications may exacerbate RLS. RLS is common in renal dialysis and congestive heart failure patients and in patients with neuropathic disorders and may emerge or worsen during pregnancy.[161] Familial RLS has been described, and genetic studies have identified several loci linked to RLS, though to date these have not led to major insights into etiology, prevention, or treatment.[162]

Treatment of RLS[163,164] first involves avoidance of precipitating factors and correction of potential precipitating factors. Oral iron replacement is recommended when serum ferritin levels are 75 μg/L or less. Intravenous preparations can be used if oral replacement fails, but some formulations are associated with anaphylactic reactions.[164,165] Pharmacologic treatment of RLS includes dopamine agonists such as pramipexole , ropinirole, or the rotigotine patch.[163,164] They can be used intermittently for occasional symptoms or regularly for persistent symptoms but are associated with impulse control disorders such as pathologic gambling and the augmentation phenomenon (worsening of symptoms, including earlier onset, increased intensity, or spread of symptoms to the arms). For patients with chronic persistent symptoms, α2δ ligands can be used, including gabapentin, enacarbil, and pregabalin.[163,164,166] They may be preferred in those with a predominant painful component and those with insomnia. There is, however, a concern about potential respiratory depression, especially when combined with other central nervous system depressant medication, in those with respiratory conditions, and in the elderly.[167] In those with resistant symptoms, oxycodone, alone or in combination with naloxone, has been found to be efficacious and safe.[164]

CIRCADIAN RHYTHM DISORDERS

This set of clinical disorders is characterized by disturbances of the internal "biological clock"[168] so that sleep is usually normal but takes place at abnormal times.[169] The most common disturbance is delayed sleep-wake phase disorder.[16,169] Affected individuals may present with complaints of difficulty initiating sleep and inability to awaken on time in the mornings. The natural bedtime preference of someone with delayed sleep-wake phase disorder is during the early morning hours (commonly 2 AM or later), and rise time preference is late morning or mid-day. Because sleep is otherwise normal, patients with delayed sleep-wake phase disorder report few daytime symptoms so long as they are able to follow their natural sleep schedule. However, when work or school imposes a conflicting schedule, sleep time is restricted, and daytime sleepiness ensues. Management of delayed sleep-wake phase disorder includes interventions to shift the biological clock, such as administration of melatonin in the evening and exposure to bright light in the morning.[169–171] While changes in sleep schedule can be achieved, the effects may not be dramatic, and patients tend to revert easily to a delayed schedule if circadian measures are not rigorously maintained. Some patients choose occupations or work schedules that are compatible with their delayed phase.

Other circadian disorders include *advanced sleep-wake phase disorder*, in which sleep begins in the early evening and terminates in the early morning.[16] When social or work schedules conflict with this schedule, treatment with bright light exposure in the early evenings can be instituted to delay sleep onset.[170,171] *Jet lag disorder* results from circadian misalignment due to travel across time zones with subsequent sleep disruption and daytime symptoms.[172] Management includes sleep scheduling, appropriately timed light therapy, and possible use of melatonin.[169,170] *Shift work disorder* is characterized by more than 1 month of excessive sleepiness during scheduled work time, and insomnia during scheduled sleep times in the context of nonconventional and/or rotating work schedules.[16] Management includes optimizing the sleep environment and sleep schedule, preshift napping, bright light exposure during night shifts, and avoidance of bright light during the return trip home in the morning. Evidence supports the use of melatonin and judicious use of hypnotics to promote sleep, and modafinil and caffeine to promote wakefulness during work.[170]

PARASOMNIAS

Parasomnias are complex movements, behaviors, or experiences happening during sleep, and can be divided into REM and non–REM-related parasomnias. Non–REM-related parasomnias are disorders of arousal and include confusional arousals, sleepwalking, sleep terrors, sleep-related eating disorder, and sexsomnia.[16] Typically, patients will have recurrent episodes of abnormal behaviors with incomplete awakening and limited memory of the events. The most common REM parasomnias are *REM sleep behavior disorder* (RBD) and nightmare disorder. RBD manifests as movements or vocalizations related to dream content. Behaviors can be violent, endangering both the patient and bed partner. RBD results from loss of normal REM atonia, which normally prevents dream enactment, and can be confirmed on PSG. RBD is associated with certain antidepressant medications and with α-synucleinopathies (e.g., Parkinson disease).[173] Nightmare disorder is characterized by recurrent highly unpleasant dreams that result in significant distress. Nightmare disorder should be differentiated from other causes of nightmares, such as nightmares secondary to posttraumatic stress disorder. Stereotyped behaviors or dystonic posturing suggest nocturnal seizures.[174]

Management of parasomnia starts with optimizing lifestyle and sleep hygiene and avoiding triggers such as sleep deprivation. Causative medications (e.g., some antidepressants) or substances (e.g., alcohol) should be discontinued if possible. Safety measures should be taken to avoid injury to the patient or their bed partner. Patients should be evaluated and treated for OSA, which can exacerbate parasomnias, presumably by increasing propensity for arousal. Clonazepam has been used with reasonable efficacy in the management of non-REM parasomnias[175] as well as RBD. Due to safety concerns with long-term use of clonazepam, especially in older individuals, melatonin is now the preferred treatment for RBD.[176] Second-line options include ramelteon, a melatonin receptor agonist.[177]

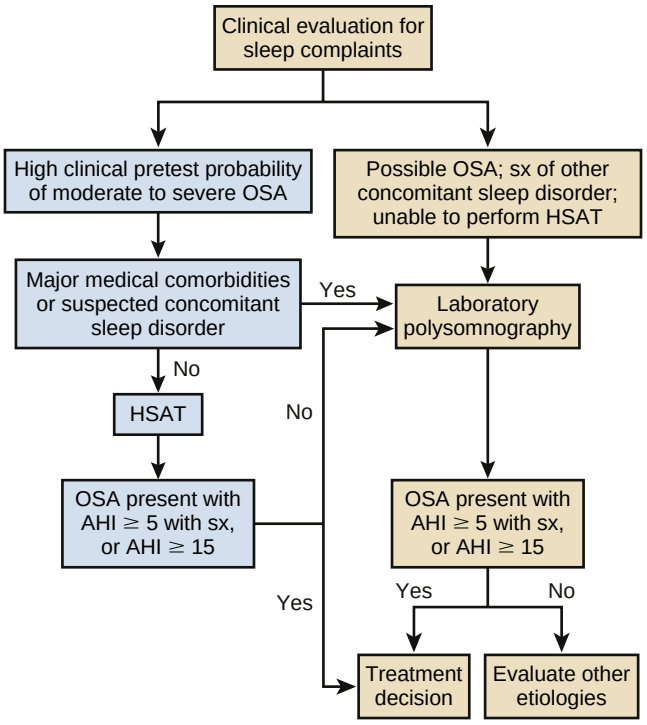

Figure 120.4 Schema illustrating an approach to the diagnosis of *obstructive sleep apnea* (OSA). An ambulatory pathway for patients with symptomatic moderate to severe OSA without other major comorbidities is shown in blue. Patients with a lower pretest probability of OSA or who are suspected of having another sleep disorder are recommended for evaluation in the laboratory-based pathway in orange. AHI, apnea-hypopnea index; HSAT, home sleep apnea testing; sx, symptoms.

hospitalized patients have acceptable technical success rates in patients with comorbidities[202,206] and satisfactory accuracy.[203,207,208] Results can be used to optimize management and initiate in-hospital positive airway pressure therapy as appropriate.[202,206] However, physiologic changes after the hospitalization may change the diagnosis.[209] Medical management should be optimized and the patient reevaluated, particularly when central sleep apnea is detected.[202,206]

OSA is found in 10–20% of surgical patients and up to 70% of those presenting for bariatric surgery.[19] OSA predisposes to perioperative complications,[210,211] including cardiovascular events.[212] OHS is associated with particularly high complication rates.[213] Life-threatening perioperative events are rare,[210] but potentially catastrophic and preventable. Hence, screening for SDB may allow appropriate precautions, interventions, and monitoring to reduce complications. Questionnaires (e.g., STOP-Bang) have been used as a screening method in this context and can predict increased complication rates, but specificity is low (i.e., high false-positive rates).[211] Serum bicarbonate measurement in addition to STOP-Bang may help identify patients with OHS at highest risk.[214] Overnight pulse oximetry is a relatively simple screening test and, when used for preoperative detection of OSA, was found to reduce perioperative hypoxemia but not complication rates, length of stay, intensive care unit transfers, or mortality.[215] The feasibility of full sleep testing preoperatively has not been well studied.[210] Hence, it is generally accepted that OSA and particularly OHS may increase perioperative risk and that screening should be performed prior to surgery. However, evidence is currently insufficient to guide screening and optimization of OSA and OHS in this context, notably regarding which patients are at greatest risk of complications and which interventions are effective[210] (see also Chapter 122).

PATHOPHYSIOLOGY OF CONSEQUENCES

NEUROCOGNITIVE SEQUELAE

A majority of apnea and hypopnea events terminate with an arousal (see Fig. 120.1). Thus, recurrent respiratory events and their associated arousals lead to sleep fragmentation and marked disruption of sleep continuity. Furthermore, OSA is also typically associated with a reduction in the duration of deeper, more "restorative" sleep, including Stage N3 (slow wave) and REM sleep, which contribute to excessive daytime sleepiness and other neurocognitive sequelae of OSA. Application of CPAP to treat OSA aims to restore sleep continuity and may be associated acutely with a rebound increase in N3 and REM sleep, which patients perceive as improved sleep quality.[216]

Although respiratory-related sleep fragmentation alone without oxygen desaturation can produce EDS, in studies of moderate to severe OSA, sleepiness and other neurocognitive sequelae correlate more closely with OSA-associated hypoxemia than with measures of sleep disruption.[22,141,217] Studies in mice that were exposed to intermittent hypoxia mimicking OSA showed that severe hypoxia can produce excessive sleepiness, which persists up to 6 months following return to normoxia.[218] Neuronal injury in these mice was identified in specific wake-promoting areas (monoaminergic neurons in the locus coeruleus, periaqueductal gray), with evidence that injury is mediated by nicotinamide adenine dinucleotide phosphate hydrogen oxidase–dependent oxidative mechanisms.[218,219] Intermittent hypoxia in mice also induces deficits in learning and memory, with the hippocampus being a particular site of neuronal injury.[220] Neuroimaging studies in OSA patients have demonstrated changes in the hippocampal region and in other areas subserving cognitive functions known to be impaired in OSA.[221,222] It is therefore likely the hypoxia-reoxygenation associated with human OSA may produce sleepiness and other neurocognitive changes through similar pathways to those identified in experimental animals. Intermittent hypoxia in mice has also been shown to induce arousals and significant changes in sleep architecture.[223] When animals were asleep, the 30-second intermittent hypoxia exposure produced an arousal response 100% of the time, concomitant with the nadir of hypoxia. REM sleep was nearly eliminated in these mice after intermittent hypoxia exposure when compared to nonhypoxic sleep fragmentation. Thus, these findings suggest that intermittent hypoxia exposure may have greater negative impacts on sleep architecture compared to nonhypoxic arousals. Debate continues concerning the relative roles of sleep fragmentation and hypoxic-mediated injury in producing OSA-related neurocognitive deficits.[224,225]

Excessive sleepiness in OSA patients may also be influenced by factors other than those directly related to OSA

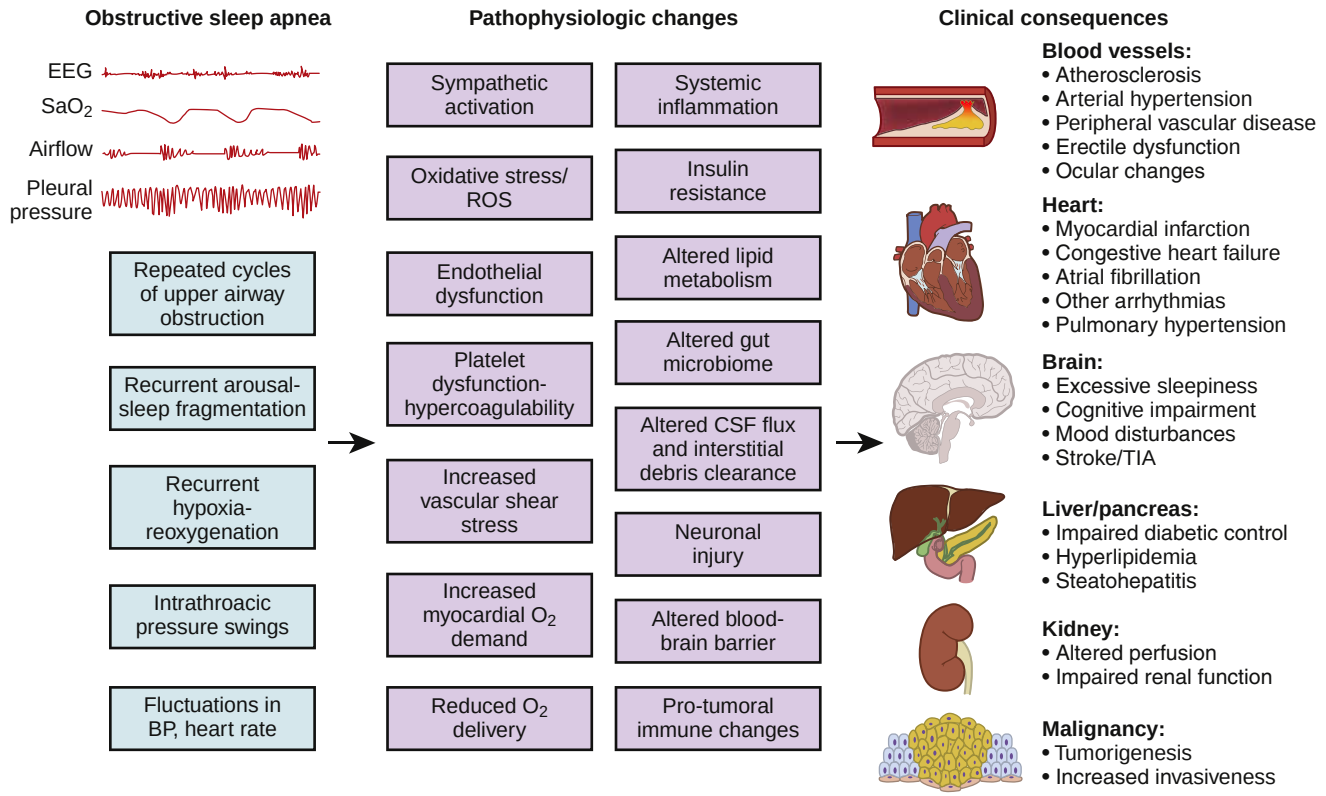

Figure 120.5 Schema depicting the pathophysiologic changes resulting from obstructive sleep apnea, which in turn lead to a diversity of clinical sequelae. See text for detailed discussion. itself. For example, sleep schedule, obesity per se, and depression may all contribute to symptoms of sleepiness in OSA patients.[226,227]

CARDIOMETABOLIC SEQUELAE

The intermittent hypoxia, negative intrathoracic pressure swings, and microarousals from obstructive apneas and hypopneas trigger a cascade of acute hemodynamic, autonomic, biochemical, inflammatory, and metabolic effects that can produce both acute and long-term changes in cardiovascular function[228–230] (Fig. 120.5). Autonomic tone is altered during apneas, with acute sympathetic-mediated increases in blood pressure and heart rate observed at airway reopening[231] (Fig. 120.6). In OSA, the persistent increase in sympathetic drive during sleep abolishes the physiologic blood pressure dipping that is important for cardiovascular health.[232,233] The increased sympathetic neural activity during apneas may persist into wakefulness, long after the immediate effects of apneas and hypopneas have subsided, contributing to sustained hypertension.[231] This ultimately leads to increased vascular resistance and vascular remodeling, contributing to the observed increase in blood pressure.[234] Blood vessel shear stress is also increased due to hypertension and hemodynamic surges. The negative intrathoracic pressures generated during obstructed inspiratory efforts increase left ventricular transmural pressure and, therefore, afterload, a stimulus for ventricular hypertrophy and an excessive load for a compromised ventricle.[229] OSA-associated hypoxia-reoxygenation has analogous biologic effects to ischemia-reperfusion, leading to generation of reactive oxygen species.[235] This oxidative stress activates nuclear transcription factors, including hypoxia inducible factor-1α and nuclear factor-κB, which activate a diverse number of proinflammatory pathways.[235,236] Inflammatory mediators, in turn, may lead to endothelial cell dysfunction,[237] promote atherogenesis,[238] and have antifibrinolytic/prothrombotic effects that could contribute to acute vascular events. These effects, in concert with increased sympathetic activity and increased insulin resistance, likely further contribute to the elevated cardiovascular risk associated with OSA.[239,240]

Both human and animal studies have demonstrated that intermittent hypoxia[241–246] and sleep fragmentation[239,247,248] are associated with abnormal glucose homeostasis, including increased insulin resistance and elevated glucose levels. A CPAP withdrawal study with recurrence of OSA was associated with dynamic increases in nocturnal glucose levels, cortisol, and free fatty acids, in parallel with respiratory obstructive events.[249] Over time, these disturbances may lead to the development of type 2 diabetes. Animal studies also indicate that intermittent hypoxia can adversely affect lipid metabolism, further contributing to the pro-atherogenic effects of OSA.[238] There is growing evidence, on the basis of these pathophysiologic mechanisms, that OSA has important clinical effects on cardiometabolic morbidity and mortality.

There are emerging studies suggesting that intermittent hypoxia resulting from OSA may protect the myocardium during ischemic periods by reducing infarct size, a concept referred to as ischemic preconditioning.[230,250–252] Two clinical studies showed lower troponin-I[253] and troponin-T levels[254] as markers of myocardial infarct size in patients with OSA and acute myocardial infarction. OSA has been shown to increase coronary collateral vessel development, and therefore an alternative source of blood flow in patients with total coronary occlusion.[255] In the setting of myocardial infarction, there are increased numbers of endothelial progenitor cells with heightened proliferative and angiogenic properties, indicating compensatory angiogenesis in patients with OSA compared to patients without OSA.[256] Thus, while intermittent hypoxia is known to be associated with adverse cardiovascular sequelae, recent literature also suggests that intermittent hypoxia may evoke a variety of adaptive cardioprotective pathways. Further research is therefore required to understand the mechanisms determining the balance of adaptive versus maladaptive effects of intermittent hypoxia.

There is tremendous heterogeneity between OSA patients in their risk for developing adverse neurocognitive and cardiometabolic sequelae. While genetic and environmental factors play an important role, alterations in the gut microbiome have also been shown to account for some of this phenotypic variation. Growing literature has identified the importance of the gut microbiome composition in obesity and metabolic disease.[257,258] In children with OSA, insulin resistance was associated with gut endotoxemia.[259] Sleep fragmentation in mice induced significant changes in the gut microbiome and metabolomic profile.[259] Similarly, alterations in gut microbiota have also been observed after intermittent hypoxia,[260,261] and some of these were irreversible after a period of normoxic recovery.[261] One animal study demonstrated that alterations in gut microbiota may have a causal role in contributing to hypertension in patients with OSA.[262] Future studies are needed to understand whether manipulation of gut flora plays a role in the management of hypertension in patients with OSA.

CONSEQUENCES/COMPLICATIONS OF OSA

NEUROBEHAVIORAL COMPLICATIONS OF OSA

Excessive Sleepiness and Motor Vehicle Operation

EDS is the most common symptom of OSA. It can have profound adverse effects on quality of life, social relationships, and professional safety and performance. Patients with untreated OSA and daytime sleepiness are at significantly increased risk for motor vehicle crashes. Meta-analyses[142,263] have identified a two- to threefold increase in risk of vehicular crashes among patients with untreated OSA (e.g., *odds ratio* [OR], 2.4; 95% *confidence interval* (CI), 1.2 to 4.9).[142] CPAP therapy was found to reduce the number of near-accidents and accidents in OSA patients in parallel with reduced subjective EDS.[264] Meta-analyses found that treatment with positive airway pressure for severe OSA decreased the risk ratio for motor vehicle crashes to 0.3 (95% CI, 0.2 to 0.4),[265,266] translating into a reduction of 65–78% in crash rates with OSA treatment.

There are important public safety and medicolegal implications of OSA for the practicing physician. Practice guidelines on OSA, sleepiness, and crash risk have recently been published.[143,267] Whereas the prediction of crash risk in individual OSA patients is imprecise, it is important to identify high-risk patients who have symptoms of excessive sleepiness while driving and have a history of a previous crash or near-miss due to sleepiness.[268] Such individuals should be warned of the dangers of driving prior to treatment, undergo diagnostic sleep testing within 1 month, and be promptly initiated on CPAP treatment following a positive diagnostic test.[143] Clinicians should also familiarize themselves thoroughly with legal requirements in their jurisdiction for reporting of OSA and the consequent driving restrictions.

One area of particular concern is the increased rate of motor vehicle crashes among commercial drivers.[267,269,270] Several studies have shown a high prevalence of OSA among commercial drivers.[271–273] OSA was found to increase accident rates specifically among commercial drivers who are nonadherent to CPAP therapy.[274] Screening for OSA is recommended as part of the general medical evaluation for commercial drivers.[269] However, such screening relies heavily on self-reporting of sleepiness and OSA symptoms by drivers, who are known to under-report due to concerns about work restrictions.[273] Drivers may be more likely to report symptoms if they can do so anonymously online.[275] However, an employer-mandated program of OSA screening and treatment can successfully reduce accidents and be cost-effective.[276] Several entities have proposed recommendations concerning OSA screening of commercial vehicle operators including rail workers, assessment of fitness for duty, and evaluation for return to work following OSA treatment.[267]

Fatigue

Rather than sleepiness, some patients with OSA will complain of fatigue, lack of energy, or tiredness.[144] This is more often found in women. Fatigue may be associated with greater dysfunction than EDS.[277,278] Hence, lack of EDS should not discount OSA as a possible underlying problem. Moreover, these symptoms have been found to improve with adherence to CPAP therapy.[279]

Mood Disturbances: Depression, Anxiety

Depressive symptoms are common in OSA patients and are more prevalent in women.[280] Although epidemiologic studies indicate that the presence of untreated OSA is a risk factor for developing depression,[281] the interaction between depression and OSA remains poorly understood.[280,282] Depression

may also worsen symptoms of sleepiness and fatigue in OSA.[227] A meta-analysis has found that OSA treatment with either CPAP or a mandibular advancement device resulted in improved depressive symptoms.[283] The prevalence of OSA among patients with clinical depression is not known,[280] but symptoms of OSA should be sought in all patients with depression, given the potential beneficial effects of OSA treatment. Conversely, depression may be a cause for residual sleepiness in treated OSA patients. Anxiety, which has not to date been extensively studied, also appears to interact with OSA. Treating OSA can help anxiety symptoms.[284]

Quality of Life

OSA can have a substantial negative impact on patients' overall quality of life. Disease-specific indices have been developed to assess the impact of OSA on quality of life, including the Functional Outcomes of Sleep Questionnaire,[285] Calgary Sleep Apnea Quality of Life Index,[286] and the Quebec Sleep Questionnaire.[287] Studies using these measures indicate that OSA-related impairment can be substantial and that OSA treatment can significantly improve quality of life,[288,289] particularly in women[290] and the elderly.[204]

Cognitive Impairment

OSA is associated with cognitive impairment.[222] OSA produces impairments in attention and vigilance, visuospatial construction abilities, verbal episodic and visuospatial memory, and subdomains of executive function.[291–293] Treatment of OSA can improve global cognitive function, attention/vigilance, verbal and visual memory, and executive function.[291,293] However, results have been inconsistent.[266] The multicenter trial, APPLES (Apnea Positive Pressure Long-term Efficacy Study), assessed domains of cognitive function in OSA after 2 and 6 months of effective versus sham CPAP treatment[294] and did not demonstrate sustained improvements in cognition. However, baseline function was high in study participants. It has become clear that individuals have different propensities for the cognitive effects of OSA, related to genetic factors, premorbid cognitive functioning, and comorbidities.[295] Patients with OSA and comorbid insomnia may have more marked cognitive impairment.[296] The elderly appear to be particularly vulnerable. CPAP treatment of OSA in the elderly may improve function in several cognitive domains over a period of a few months, particularly in severe OSA.[126,204,297]

OSA has also been associated with falls and gait disturbances,[298] which are affected by cognitive function.[299] EDS is associated with fall risk in older women.[300] Preliminary data suggest gait can improve with CPAP therapy,[279,301] though it remains unknown if risk of falls can be reduced by treating OSA in older individuals.

Neurodegenerative Disease and Dementia

OSA in the elderly is thought to be different from that in middle-aged individuals with respect to presentation, evolution, and outcomes.[128] Though older individuals are less prone to adverse OSA-related cardiovascular outcomes and mortality compared with middle-aged individuals,[302,303] OSA in the elderly has been associated with an increased risk of neurodegenerative processes. First, there is an association between OSA and Alzheimer disease.[304] Additionally, several, but not all,[305] prospective studies and a meta-analysis have found that older individuals with OSA, cognitively intact at baseline, are at increased risk for future cognitive impairment or dementia.[306,307] Large database studies have also found that those with OSA have an increased risk of Parkinson disease.[308,309] Moreover, OSA is associated with reduced cognitive function in Parkinson disease.[310,311] A number of mechanisms resulting from intermittent hypoxia and sleep fragmentation (see "Pathophysiology of Consequences" section and Chapters 117 and 118) have been implicated in the relationship between OSA and neurodegeneration, including changes in synaptic plasticity, small and large vessel disease, neuroinflammation, changes in brain structure and network function, as well as abnormal clearance of metabolic debris from the brain.[312,313] Blood and CSF biomarkers hold promise for future studies on this topic.[314] In summary, although OSA appears to increase the risk of neurocognitive decline, some individuals are likely more prone than others, although the characteristics conferring this susceptibility are currently unknown.

CPAP therapy has been shown to reduce the risk of developing mild cognitive impairment in older individuals in a cohort study.[307] Unfortunately, adherence to CPAP therapy in the elderly is reported to decline with age,[315] and may be even more challenging in individuals with cognitive or physical impairment. This may explain the lack of positive findings in some trials.[127] Nevertheless, CPAP has been successfully used in selected patients with Alzheimer[316] and Parkinson disease.[317,318] In Alzheimer disease, CPAP was found to improve sleep architecture and reduce daytime sleepiness with short-term use.[319] Sustained use appeared to benefit sleep and mood, and reduce cognitive decline.[320] In Parkinson disease, CPAP reduced sleepiness.[317] In a 12-month observational study, CPAP improved nonmotor symptoms of Parkinson disease, including sleep quality and anxiety, as well as cognition.[318] However, others did not demonstrate cognitive improvement with CPAP.[311] Observational data suggest that CPAP may also help stabilize gait and motor function in Parkinson disease over 12 months,[321] though this also requires further study. Hence, while CPAP therapy may be a challenge for those with neurodegenerative disorders, a trial of treatment is likely warranted given the potential benefits.

CARDIOMETABOLIC COMPLICATIONS

Hypertension

The evidence linking OSA to cardiovascular complications is strongest for hypertension. Experimental studies have shown that repeated airway obstruction during sleep in dogs induces hypertension during wakefulness[322] and that intermittent hypoxia produces hypertension in rodents.[323] Cross-sectional studies demonstrate an independent association of OSA with hypertension after controlling for confounders.[324,325] Several studies have reported a high prevalence of OSA (50–60%) in patients with refractory hypertension, with OSA representing the most common cause of secondary hypertension in these patients.[326] Data from the Wisconsin Sleep Cohort showed dose-response relationships over 4 to 8 years of follow-up between OSA severity and odds of developing incident hypertension[327] and nondipping in nocturnal systolic blood pressure,[328] although findings from other longitudinal cohort studies have been discrepant.[329,330]

The strong weight of evidence from RCTs is that positive airway pressure treatment improves hypertension. Several meta-analyses have been published.[266,331–335] In the most recent,[335] positive airway pressure was associated with reductions of systolic and diastolic blood pressure compared to control (mean: −2.5 mm Hg systolic, −2.5 mm Hg diastolic). Although the observed reductions in blood pressure with CPAP are relatively small, they have significant implications for primary cardiovascular prevention at the population level.[336] The observed reductions may have been diminished by inclusion of normotensive/treated participants[337] and/or milder OSA. Indeed, patients younger than 60 years with uncontrolled baseline pressure and more severe OSA/oxygen desaturation have been found to have the greatest reductions in blood pressure on CPAP[334,335,338] (e.g., −7.1 mm Hg systolic and −4.3 mm Hg diastolic for uncontrolled hypertensives in one analysis).[338] There is also a significant positive correlation between the duration of CPAP use and decrease in blood pressure.[339–342]

Despite reduced efficacy of treatment, mandibular advancement devices have shown similar reductions in blood pressure compared to CPAP, possibly due to greater adherence.[343] Patients who use CPAP and also lose weight may experience greater reductions in blood pressure compared to CPAP or weight loss alone.[344]

Arrhythmias

OSA is associated with cardiac arrhythmias.[345,346] Bradyarrhythmias, including sinus pauses and atrioventricular block, are more common in severe OSA than in the general population. Although some data suggest that CPAP may improve bradyarrhythmias, RCT data are lacking.[345] Studies linking OSA to ventricular arrhythmias have produced conflicting results.[345] In one recent prospective cohort study, 3 months of CPAP was associated with a decrease in extrasystoles, atrial fibrillation, and nonsustained ventricular tachycardia.[347] There is growing evidence showing strong associations between OSA and atrial fibrillation.[345,346,348] Atrial fibrillation is more common in individuals with severe OSA than in those without OSA.[345,349] Untreated OSA is associated with a higher rate of recurrent atrial fibrillation after either cardioversion[350–352] or catheter ablation.[352,353] Among patients with atrial fibrillation, Holter monitoring showed reduced atrial and ventricular ectopy after 3 months of CPAP.[354] In a meta-analysis of seven prospective cohort studies including over 1000 patients, CPAP was associated with a significant reduction in recurrence of atrial fibrillation (RR, 0.6; 95% CI, 0.5 to 0.7).[355] In another meta-analysis, CPAP-treated patients had a lower risk (25%) of recurrent atrial fibrillation after catheter ablation compared to non-CPAP-treated (42%) groups.[356] CPAP also reduced the left atrial diameter and increased the left ventricular ejection fraction.[356] Although one randomized trial did not find any significant reduction with CPAP in recurrence of atrial fibrillation after electrical cardioversion in OSA,[357] this study was limited by small sample size (25 participants) and limited evaluation of atrial fibrillation.[358] Whereas larger RCTs are needed to confirm an effect of OSA treatment on control of atrial fibrillation, evaluation for OSA and, if present, institution of treatment should be considered in patients with atrial fibrillation (see also Chapter 119).

Myocardial Infarction

OSA is associated with ischemic heart disease. In the Sleep Heart Health study, there was a modest association of OSA with coronary heart disease (adjusted OR, 1.3; 95% CI, 1.0 to 1.6).[359] In a meta-analysis of four cohort studies, OSA was significantly associated with an increased risk of ischemic heart disease in men (OR, 1.9; 95% CI, 1.1 to 3.5),[360] whereas no significant association was observed in the one study of women.[303] However, OSA is prevalent among patients who have had an acute myocardial infarction[361] and, when present, OSA is associated with worse cardiovascular outcomes.[362–364] Patients with OSA also have a greater propensity to have myocardial infarction and sudden cardiac death between midnight and 6 AM,[365,366] indicating a diurnal variation in myocardial infarction in patients with OSA. Given that REM sleep is associated with increased myocardial demand and sympathetic activity, it follows that REM sleep–specific severe OSA (REM AHI >30, non-REM AHI <5) has been reported to be associated with worse cardiovascular outcomes in patients with prevalent cardiovascular disease when compared to individuals with no OSA.[367] In observational studies on OSA patients, compliance with OSA treatment has been associated with significantly reduced cardiovascular morbidity and mortality compared to refusal of treatment.[199,266,368,369] However, refusal of CPAP may be a marker of poor health behavior, which could also adversely affect outcomes.

More recently, prospective RCTs have been conducted to assess the effects of OSA treatment on cardiovascular outcomes.[266,370] The MOSAIC trial evaluated the effects of CPAP compared to control on reduction of a surrogate cardiovascular risk score in OSA and found that calculated risk was not significantly reduced.[371] However, CPAP significantly improved endothelial function in a subgroup of MOSAIC subjects,[372] and a 2-year follow-up of a subset of patients showed a small but significant reduction in overall vascular events with CPAP.[373] A Spanish collaborative group trial showed no significant difference over 7 years in incident cardiovascular events and hypertension in CPAP-treated compared to control groups.[339] However, there was a significant reduction in events for patients compliant with CPAP for at least 4 hours a night (incidence density ratio = 0.7 [95% CI, 0.5 to 0.9] compared with control). In the Sleep Apnea Cardiovascular Endpoints trial, 2717 patients with a history of coronary artery disease or cerebrovascular disease received either CPAP or usual care with a mean follow-up of 3.7 years.[374] CPAP did not show a reduction in a composite end point including death from a cardiovascular cause, myocardial infarction, stroke, hospitalization due to unstable angina, heart failure, or transient ischemic attack.[374] However, a major limitation to the study was the poor CPAP adherence at only 3.3 hours per night, which may have been an inadequate dose to prevent cardiovascular events.[375] A propensity-matched analysis showed a trend to benefit on the primary outcome in CPAP-adherent (>4 hours/night) participants.[374] The RICCADSA trial addressed whether CPAP reduced recurrent cardiovascular events in revascularized patients with coronary artery disease who were not sleepy but had OSA.[376] Although the study was negative, a subgroup analysis found significant risk reduction in patients who used CPAP more than 4 hours per night.[376] A meta-analysis of the latter three trials and a secondary prevention study in patients with OSA

and stroke[377] concluded that CPAP use was not associated with a reduced risk of major adverse cardiac events overall over 4 years, except in patients who used CPAP for more than 4 hours per night.[378] However, the recent ISAAC trial, which assessed patients who were admitted to hospital with acute coronary syndrome who were nonsleepy, did not show improvements in the composite cardiovascular end point with CPAP[379] even in CPAP-compliant subgroups. Potential reasons for the marked discrepancies between observational studies showing strong benefit of CPAP treatment[266] and these RCTs include, in addition to low CPAP compliance, the exclusion of very sleepy and severely hypoxemic patients, even though such patients are the most likely to be compliant in clinical practice.[370] In addition, as discussed earlier, OSA may provide a protective effect through ischemic preconditioning in some patients while leading to deleterious effects in others.[230,253,254] Further RCTs are needed to evaluate the effects of CPAP treatment with optimized compliance on cardiovascular outcomes in well-defined groups of both sleepy and nonsleepy patients with severe OSA.

Cerebrovascular Events

Cross-sectional and longitudinal epidemiologic studies show that OSA is associated with stroke,[380–382] with a recent meta-analysis showing a twofold increased risk of incident stroke.[383] Thus, OSA predisposes to stroke, though stroke may also, in turn, produce or worsen sleep-disordered breathing. However, studies suggest that in many cases OSA preceded the stroke.[384,385] Overall, OSA is highly prevalent among those with stroke and transient ischemic attacks, with a recent meta-analysis reporting a prevalence of 63% (95% CI, 58–68%) for AHI greater than 10 (data from 24 studies).[385] The presence of OSA after stroke appears to confer a worse prognosis for recurrent stroke and poststroke mortality.[386] Treatment of OSA with CPAP in stroke patients may be challenging and, whereas several studies suggested that OSA treatment may improve poststroke functional outcomes, the impact of treatment on stroke recurrence and mortality remain inconclusive.[386,387] In the Sleep Apnea Cardiovascular Endpoints trial discussed earlier, no difference in stroke incidence was noted between the CPAP and usual care group.[374] However, in the propensity-matched analysis including CPAP-adherent patients, there was a reduced cerebrovascular event rate with CPAP (hazard ratio, 0.5; 95% CI, 0.3 to 0.9; $P = 0.02$). A large trial of CPAP for stroke prevention (The Sleep for Stroke Management and Recovery Trial, NCT03812653) is currently underway[388] (see also Chapter 119).

Congestive Heart Failure

OSA was found to be associated with *congestive heart failure* (CHF) in the Sleep Heart Health study (OR of 2.4 for the highest category of OSA severity) in the initial cross-sectional analysis[359] and with development of new heart failure in longitudinal follow-up.[303] OSA has been identified in 11–53% of patients with stable chronic CHF (with central sleep apnea–Cheyne-Stokes respiration also being present in 11–35%, yielding an overall apnea prevalence of approximately 50% in CHF patients).[229,389] OSA may worsen left ventricular function. Experimentally induced severe OSA in a dog model produced changes in left ventricular dimensions and reduced systolic function after 8 weeks.[390] As of 2017, the American College of Cardiology/American Heart Association recommends screening for OSA in patients with New York Heart Association class II to IV heart failure.[391] However, RCTs are required to demonstrate long-term improvement in both cardiac function and outcomes with OSA treatment in patients with CHF. The ongoing ADVENT-HF trial (NCT01128816) will evaluate the impact of adaptive servoventilation on CHF patients with OSA.

Pulmonary Hypertension

The reported prevalence of pulmonary hypertension in OSA varies considerably between studies, ranging from 15–75%,[392–394] although pooled data from several studies yielded a 10% prevalence (mean pulmonary artery pressure > 25 mm Hg at cardiac catheterization).[389] Most OSA patients without major comorbidities have normal pulmonary artery pressures; pulmonary hypertension, when present, is mild.[389,394] More severe pulmonary hypertension, in some instances leading to right ventricular dysfunction and right heart failure, may develop in patients with underlying lung function abnormalities (COPD, obesity restriction, neuromuscular disease), many of whom will present with daytime hypoxemia and hypercapnia.[389,392,394–397] Early studies in patients with severe OSA showed that pulmonary artery pressure can improve substantially following tracheostomy but may not normalize.[398,399] Limited studies evaluating the effects of CPAP on pulmonary hypertension indicate that both pulmonary pressures and indices of right ventricular function may improve with CPAP therapy.[389,392,394,400,401] However, in the recent Pickwick study, improvements in pulmonary artery pressure and interventricular septal thickness were seen after 2 months treatment in OHS patients treated with bilevel positive airway pressure but not CPAP.[402] Long-term effects have not yet been evaluated.

Renal Perfusion/Dysfunction

Both OSA and central sleep apnea are prevalent in patients with chronic kidney disease[403,404] and are associated with a greater risk of cardiovascular disease and mortality.[405,406] OSA has been shown to worsen kidney function via mechanisms that include OSA-induced elevations in sympathetic activity and blood pressure.[407,408] Some studies suggest that chronic kidney disease itself may worsen OSA through mechanisms of hypervolemia and uremia-induced myopathy.[409] Early observations found that nocturnal hemodialysis in patients with chronic renal failure improved OSA.[410] In addition, treatment of OSA with CPAP has been shown to improve renal hemodynamics.[411,412] In the only RCT that has examined kidney function, the Sleep Apnea Cardiovascular Endpoints trial found no difference in the rate of decline in kidney function in the CPAP versus control group.[374] Further RCTs that are adequately powered to evaluate kidney function are needed to determine if CPAP can slow the progression of chronic kidney disease.

Metabolic Disturbances: Insulin Resistance, Dyslipidemia

In addition to compelling evidence that OSA alters metabolic function, OSA is strongly associated with glucose dysregulation, including prediabetes and type 2 diabetes.[413]

The prevalence of OSA among patients with type 2 diabetes is estimated to be approximately 60–85%,[413] and prospective cohort studies have shown that OSA is associated with incident type 2 diabetes.[414,415] However, questions remain about the relationship between OSA and metabolic dysfunction after RCTs with CPAP have shown mixed results.[416–423] Chronicity of the underlying metabolic disturbance (i.e., prediabetes versus type 2 diabetes),[424] varying use of antidiabetic medications, degree of obesity, presence/absence of excessive daytime sleepiness,[425] adherence to CPAP therapy,[420,423] and inconsistency in the metabolic outcome being measured (i.e., fasting glucose, hemoglobin A1c, 24-hour glucose, insulin sensitivity) may all contribute to the heterogeneity in RCT results.[413,420] Whereas it is still not clear whether CPAP improves glycemic outcomes, there should be a high level of clinical suspicion for OSA in patients with type 2 diabetes, and treatment of OSA in such patients may have a host of beneficial effects beyond improvement in glucose control.

A growing body of literature also supports an association between OSA and abnormal lipid metabolism. Intermittent hypoxia leads to hyperlipidemia and up-regulation of genes involved in lipid synthesis.[426,427] Decreases in triglycerides and high-density lipoprotein in association with OSA have been demonstrated in a number of clinical studies,[428–430] while others have shown no association between OSA and lipid profiles.[431,432] A meta-analysis that included over 18,000 patients demonstrated that OSA was associated with elevated triglycerides and total cholesterol concentrations and lower high-density lipoprotein.[433] However, in a meta-analysis of six RCTs examining the impact of CPAP on lipid profiles, reductions in total cholesterol were observed, without any changes in triglyceride, low-density, or high-density lipoprotein profiles.[434] Given the few RCTs done to date, with limitations of small sample sizes and variable adherence rates to CPAP, further studies are required to evaluate the relationship between OSA and dyslipidemia.

Hepatic Sequelae/Steatohepatitis

Emerging studies have shown that OSA is associated with nonalcoholic fatty liver disease,[435] even in nonobese individuals and children. Nonalcoholic fatty liver disease is part of the group of conditions called metabolic syndrome, and glucose metabolism and lipid abnormalities are key contributors in its development. Early animal models of intermittent hypoxia showed that genes of lipid biosynthesis in the liver were up-regulated after exposure to chronic intermittent hypoxia.[426] CPAP trials examining liver fibrosis as an outcome of treatment have been negative to date.[436,437]

Mortality

In keeping with the links between OSA and cardiometabolic dysfunction, OSA has been associated with increased mortality in large prospective cohort studies. The signal is strongest for severe OSA when compared with non-OSA cohort participants. Most of the increased mortality is cardiovascular and is seen largely in individuals with severe OSA, with an increase in mortality risk of 1.5- to 5-fold over follow-up periods of 8 to 20 years, compared with non-OSA cohort participants.[302,438–440] More recent data from 9 years of follow-up of Sleep Heart Health participants showed an increased mortality risk of 1.4 among patients with severe REM-isolated OSA.[367]

OTHER COMPLICATIONS

There is increasing evidence that OSA may interact with other medical conditions in addition to those discussed earlier.

A discussion of links between OSA and ocular disease (nonarteritic ischemic optic neuropathy, glaucoma, floppy eyelid syndrome, and other conditions), erectile dysfunction, and cancer incidence and mortality is provided at ExpertConsult.com.

DISEASE MANAGEMENT STRATEGIES

This chapter focuses on clinical and diagnostic aspects of OSA; OSA treatment is covered in Chapter 122. Clinical practice requires an integrated approach to OSA diagnosis and management to improve clinical outcomes. Given the high prevalence of OSA and the high costs and limited access in many countries to laboratory PSG,[195] alternative strategies to conventional PSG-based diagnosis and titration in highly specialized centers[476] are needed for management of OSA.[198,477,478] An initial study by Mulgrew et al.[479] demonstrated that ambulatory-based diagnosis of severe OSA (see Fig. 120.4) followed by titration using *automatic positive airway pressure* (APAP) and then treatment with fixed CPAP yielded equivalent clinical outcomes at 3 months compared with a conventional in-laboratory diagnostic and manual titration approach. A series of subsequent publications supported these findings, with later studies also including more moderate OSA.[197,480–483]

All of these studies, however, were conducted in specialty sleep centers and involved traditional interactions between patients and specialized sleep physicians. More recently, several groups have evaluated either specialist nurse–led or family physician/community nurse–led ambulatory management of moderate to severe OSA and compared outcomes with traditional PSG- and specialist physician–based management.[196,198] Improvements in sleepiness and other symptoms and CPAP compliance were in general similar for either the nurse-led[198,484] or family physician–led[198,485] strategies compared with specialist- and laboratory-based strategies. Telemedicine approaches may be complementary and provide improved access to care.[486] However, these studies have largely focused on symptomatic OSA patients with few comorbidities. Future studies will need to identify optimal approaches for matching patient needs with care providers, integrating broadly accessible community-based management with specialty center–based management for complex patients.

Recommendations for treatment of OHS have been provided by the American Thoracic Society.[19] For stable ambulatory OHS patients with severe OSA, CPAP therapy has been shown to be as effective as noninvasive bilevel ventilation for first-line treatment in terms of resolution of hypercapnia, need for oxygen supplementation, improvement in sleepiness and quality of life, and days in hospital.[19,487] However, those who are hospitalized for acute hypercapnic respiratory failure, those without significant OSA, as well as those who do not respond to CPAP should be managed with noninvasive ventilation[19] (see also Chapter 122).

OSA and Ocular Disease

OSA has been linked to a number of ocular conditions, including nonarteritic ischemic optic neuropathy, glaucoma, central retinal vein occlusion, central serous retinopathy, and floppy eyelid syndrome.[441,442] The hemodynamic sequelae, intermittent hypoxia, and sympathetic activation associated with OSA (see "Pathophysiology of Consequences") have been proposed to underlie the putative effects of OSA on ocular health. However, it remains unclear whether there is a direct causal effect of OSA in relation to these conditions. Nonarteritic ischemic optic neuropathy is the most common optic neuropathy in the population, typically presenting with sudden unilateral visual loss and for which there is no known treatment. Prospective studies have reported the presence of OSA in 55–89% of affected patients.[441,442] In one recent study, OSA patients who were adherent to CPAP treatment had a reduced risk of progression to involvement of the second eye.[443] However, larger, randomized trials are required to more clearly evaluate the role of OSA in this condition.

Numerous studies have evaluated potential links between OSA and glaucoma, which is the second leading cause of blindness worldwide.[441,442] OSA has been hypothesized to contribute to the optic nerve head damage and visual field impairment that characterize glaucoma either through ischemia-reperfusion and oxidative stress injury or by changes in intraocular and ocular perfusion pressure profiles.[441,442] Several meta-analyses have shown an increased risk of 1.4- to 2.5-fold for OSA among patients with open-angle or normal-pressure glaucoma. However, many of the studies included did not adjust for potential confounding effects of comorbidities known to increase glaucoma risk.[441,442] Three more recent large cohort studies with better characterization of participants did not demonstrate a significant association between OSA and glaucoma.[441] However, one 5-year prospective study of 1012 OSA patients showed a 1.7-fold increase in risk for development of incident glaucoma compared with controls.[444] The effect of CPAP treatment on the progression of glaucoma has not been well studied.[441] OSA may be associated with a reduction in the normal nocturnal increase in intraocular pressure and may be associated with increased diurnal intraocular pressure, though findings vary.[441] CPAP treatment can restore a normal nocturnal pattern,[445] but there are conflicting reports with respect to diurnal intraocular pressure.[441,442] Thus, the relationship between OSA and glaucoma is not yet firmly established, and there is no basis for recommending routine screening for OSA in patients diagnosed with glaucoma. The effect of OSA treatment with CPAP on outcomes in glaucoma patients requires further study; patients with glaucoma initiated on CPAP should have regular ophthalmologic follow-up.

Floppy eyelid syndrome (FES) is characterized by increased eyelid laxity, ptosis, tendency to easy lid eversion, and associated conjunctivitis and other corneal changes.[442,446,447] FES may be unilateral favoring the sleeping side or bilateral in 40%.[446] OSA has consistently been reported to be highly prevalent (85–90%) among patients with FES[446,447] and has been hypothesized to contribute to the pathogenesis of FES. Histopathologic studies of tarsal tissue demonstrate decreased elastic fiber content and increased matrix metalloproteinase 7 and 9 expression.[442,446] Matrix metalloproteinases are up-regulated in response to intermittent hypoxemia, and increased circulating matrix metalloproteinase 9 has been identified in both animal models and human OSA.[448] Furthermore, case reports and nonrandomized case series have reported improvement in FES manifestations following CPAP and, in one study surgical, treatment of OSA.[446,447] Whereas CPAP may also be associated with increased ocular symptoms in some FES patients, OSA treatment is currently recommended as a mainstay approach in FES management prior to considering ophthalmic surgical intervention.[446,447]

Erectile Dysfunction

OSA may be associated with erectile dysfunction,[449,450] which has been linked to nitric oxide and nicotinamide adenine dinucleotide phosphate hydrogen–related pathways in animal models[451,452] and endothelial dysfunction in humans[4,49] CPAP treatment of OSA has been shown to improve erectile function and sexual satisfaction,[453–455] and may provide additive benefits to exercise, lifestyle modification,[456] and pharmacotherapy.[453–455,457]

OSA and Cancer

There is growing evidence for a link between OSA and cancer incidence and mortality.[458–460] The Wisconsin Cohort investigators reported an increase in cancer-associated mortality with increasing OSA severity, with an adjusted OR of 4.8 for severe OSA (AHI >30) and an even stronger effect in relation to severity of OSA-related hypoxemia.[461] A Spanish cohort study also reported increased cancer-associated mortality associated with increasing severity of OSA-related hypoxemia, particularly in patients younger than 65 years.[462] However, a more recent study in 5.6 million members of a U.S. nationwide employee health database did not identify an increase in OSA-related cancer mortality.[463] The differences in findings may be related to the patient populations studied, methods used for OSA diagnosis, or other factors; further studies are required in this area.

Studies evaluating incident risk for specific cancers in relation to OSA have shown varying results. A meta-analysis of five studies evaluating the risk of incident cancer in 34,402 patients with OSA found a significant risk ratio of 1.4 for any incident cancer in OSA compared with controls, even after adjustment for traditional cancer risk factors.[460] The nationwide health database study cited earlier showed significant increases in adjusted risk for kidney and pancreas cancer and melanoma but not other cancers in OSA patients.[463] Another study including over 34,848 OSA patients showed significant increased risk for incidence of any cancer and for kidney, breast, and uterine cancers and melanoma compared to patients without OSA.[464] Results for breast[463–466] and lung[464,467–469] cancer have been conflicting between studies. The heterogeneity in findings likely reflects methodologic differences with respect to the patient populations studied, diagnostic strategies for both cancer and OSA, as well as variable accounting for confounders. Nonetheless, links between OSA and melanoma appear quite robust across studies, with evidence for increased incidence of melanoma as well as increased aggressivity of tumor markers and clinical behavior in relation to OSA.[470,471]

Mechanistic studies have identified several pathways by which OSA may promote tumorigenesis and cancer progression.[458,459,472,473] Intermittent hypoxia promotes tumor growth, invasiveness, and metastasis in experimental animals,[472] which, as illustrated in Figure 120.5, is related to oxidative stress, free radical generation, and inflammatory changes promoting DNA damage and tumorigenesis, and activation of hypoxia-inducible factor-1α and other transcription factors with diverse cellular effects, including production of angiogenic factors[474] and proangiogenic exosomes,[475] which promote tumor vascularization and growth.[458,473] Altered function of tumor-associated macrophages to a pro-tumoral phenotype has been shown in response to both intermittent hypoxia and sleep fragmentation.[458,473] Further discussion on the mechanisms by which sleep fragmentation impacts cancer biology is provided in Chapter 118. Further research is required to determine whether the association exists and, if so, whether treatment of OSA will improve cancer outcomes in specific cancer subtypes.

Key Points

- *Obstructive sleep apnea* (OSA) is a frequent health problem in the general population, estimated to affect 14% of men and 5% of women, with the risk increasing further in women after menopause.
- Pathogenic factors contributing to OSA may differ between individuals, and include reduced airway dimensions, sleep-associated decrements in upper airway muscle activity and protective reflexes, changes in upper airway tissue characteristics and neuromuscular function, nocturnal fluid shift, altered microbiome and altered chemosensitivity, and arousal responsiveness.
- Diagnosis of OSA syndrome rests on both clinical history and a diagnostic sleep recording objectively documenting the presence of obstructive events during sleep.
- Simplified, portable sleep recordings perform well for the diagnosis of moderate to severe OSA in patients without major comorbidities, improving access to diagnosis.
- OSA is associated with daytime sleepiness and increased motor vehicle accidents and may adversely affect cognitive function, mood, and quality of life.
- High-level evidence indicates that treatment of OSA improves daytime sleepiness and quality of life. Evidence also indicates that OSA treatment reduces motor vehicle accidents and may be associated with improved mood and cognitive function.
- OSA is linked to multiple other morbidities including hypertension, arrhythmias, vascular ischemic events, congestive heart failure, pulmonary hypertension, renal dysfunction, metabolic dysfunction (insulin resistance and dyslipidemia), steatohepatitis, cancer incidence and progression, and increased mortality.
- OSA patients compliant with CPAP therapy experience significant improvements in cardiovascular and metabolic outcomes, as shown in observational studies. Randomized controlled trials have thus far yielded less-compelling results. This may, in part, be related to limited CPAP adherence in these trials and the exclusion of severely somnolent and hypoxemic patients.
- Obesity-hypoventilation syndrome develops in a minority of OSA patients, presenting with awake hypercapnia, often with daytime sleepiness, pulmonary hypertension, right heart failure, and may present with acute hypercapnic respiratory failure. Full polysomnography with CO_2 monitoring is the recommended diagnostic test.
- For stable patients with obesity-hypoventilation syndrome and severe OSA, CPAP therapy is shown to be as effective as noninvasive bilevel ventilation in improving clinical outcomes; however, bilevel ventilation is required for management of acute respiratory failure.

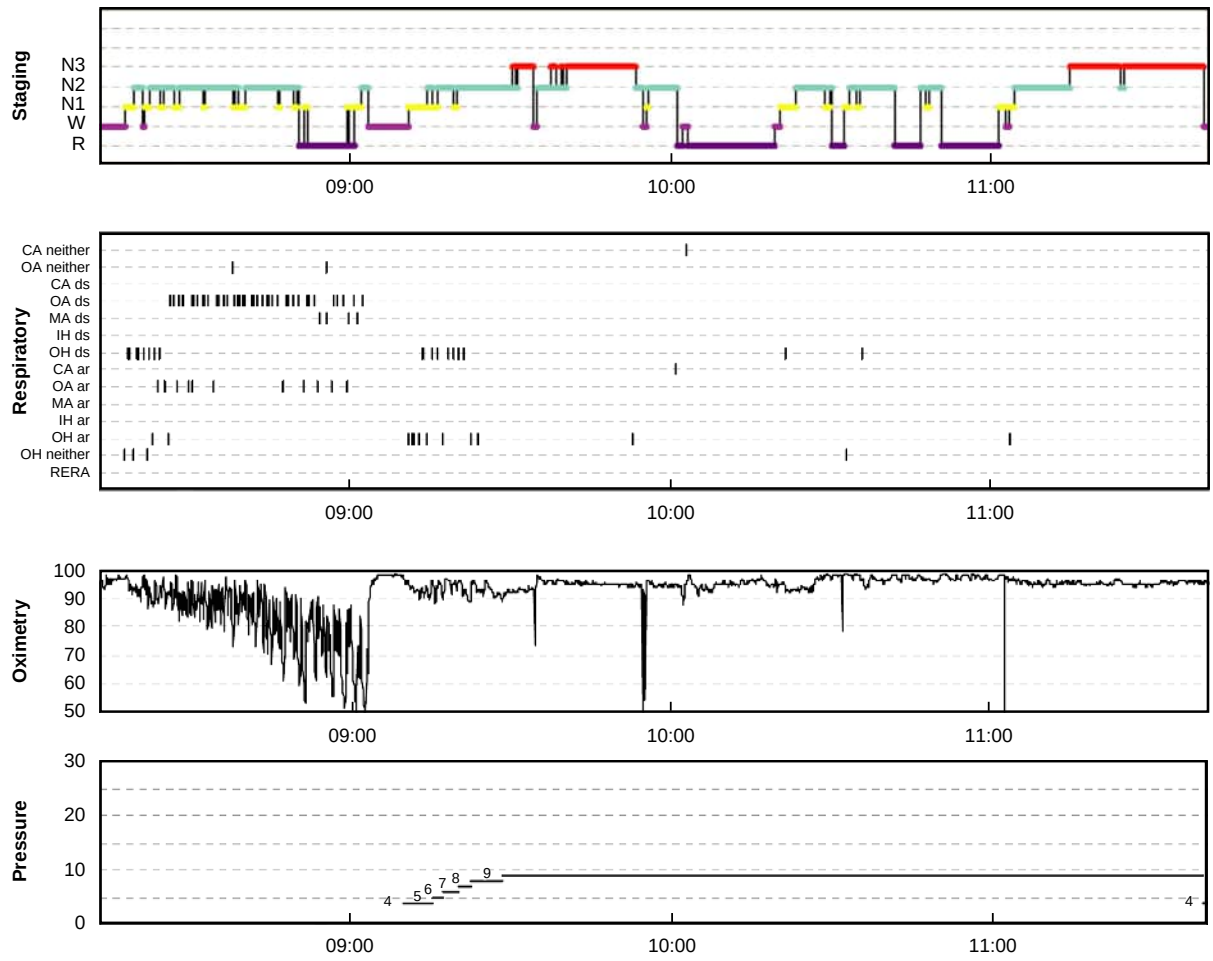
eFigure 120.1 Composite hypnograms generated by sleep analysis software after manual scoring of sleep-wake stages and respiratory events. (A) A typical report from a patient with *obstructive sleep apnea* (OSA). In this patient, apneas and hypopneas happen predominantly when the patient is sleeping supine; O_2 desaturation is more marked for events in supine *rapid eye movement* (REM) sleep (stage *R*; *red lines*) than in stages N (non-REM), which is often the case. (B) Sleep-associated hypoventilation, with a progressive rise in transcutaneous CO_2 ($TcCO_2$) over the night from an initial value of 54 mm Hg to a peak of 72 mm Hg, without apneas or hypopneas. There is worsening of hypoventilation during periods of stage R (REM) sleep when there are larger increases in CO_2 *(red arrows)* and falls in arterial So_2 *(blue arrows)*.



C

eFigure 120.1 cont'd (C) A composite hypnogram for a split diagnostic and therapeutic polysomnogram. This study was performed during the daytime in a patient with marked hypersomnolence. The initial diagnostic segment of the recording demonstrates severe OSA (apnea-hypopnea index of 98). Continuous positive airway pressure (Pressure) was applied beginning at approximately 9:10 AM and increased from 4 to 9 cm H_2O, resulting in resolution of apneas and hypopneas, normalization of arterial So_2, and prolonged periods of rebound stage N3 (non-REM) and R (REM) sleep. A, apnea; Ar, arousal; C, central; DS, desaturation ≥4%; H, hypopnea; M, mixed; neither, neither Ar or DS; O, obstructive.

KEY POINTS

INTRODUCTION

A central apnea during sleep results from a transient abolition of central respiratory drive to the respiratory muscles, leading to cessation of airflow, most often due to a fall in *arterial partial pressure of carbon dioxide* ($Paco_2$) below the threshold required to stimulate breathing. By convention, *apnea* in adults is defined as an absence or reduction of airflow to less than 90% of the baseline level for at least 10 seconds. In contrast to obstructive apneas, during which central drive and respiratory efforts continue throughout the apnea, causing deformation of the chest wall, during central apnea, there is no respiratory effort and therefore no movement of the chest wall. *Hypopneas* can also be central; in this case, airflow and tidal volume decrease by 30–90% compared to normal breathing for at least 10 seconds in association with oxygen desaturation and/or an arousal from sleep, but without evidence of airflow limitation due to upper airway obstruction. However, distinguishing central from obstructive hypopneas can be difficult depending on the type of instrumentation used to detect them.

A *central sleep apnea* (CSA) disorder is defined as recurrent central apneas and hypopneas during sleep. However, a clear threshold above which a CSA disorder can be said to exist has not been well defined owing to its relative rarity and its heterogeneous pathophysiology, clinical symptoms, and complications. Nevertheless, the following criteria have been proposed to define a CSA disorder: an *apnea-hypopnea index* (AHI) of 5 to 15 as mild, of 15 to 30 as moderate, and greater than 30 as severe, of which the majority of events are central. Similarly, criteria for a *CSA syndrome* have not been clearly defined but include the presence of a CSA disorder accompanied by symptoms, which may include habitual snoring, restless sleep, nocturnal awakenings, morning headaches, insomnia, or excessive daytime sleepiness (Table 121.1).[1,2]

DIAGNOSIS OF CENTRAL SLEEP APNEA

Full overnight polysomnography or home sleep apnea testing with instrumentation capable of detecting respiratory effort and airflow limitation is required for the diagnosis of CSA.[3,4] Respiratory effort is best determined noninvasively by respiratory inductance plethysmography.[5–8] Techniques such as piezo-electric crystal bands, oronasal thermistors, and nasal pressure are not reliable in detecting the presence or absence of respiratory effort and therefore of distinguishing central from obstructive events.[9–11] Although distinguishing central from obstructive apneas is not difficult with appropriate instrumentation, differentiation of central from obstructive hypopneas can be challenging due to the presence of some respiratory effort in both cases (eFigs. 121.1 to 121.3). Most laboratories do not differentiate between central and obstructive hypopneas, which is a problem because, in patients with *obstructive sleep apnea* (OSA) or CSA, most respiratory events are hypopneas. Thus, in many cases the classification of the type of sleep apnea disorder is made based on apneas, which constitute a minority of respiratory events. Central hypopneas are characterized by attenuated in-phase thoracoabdominal motion due to reduced respiratory drive without airflow limitation due to upper airway obstruction.[3] In some cases, more sensitive techniques may be required to detect the presence of respiratory effort or airflow limitation, such as measurement of intrapleural pressure by an esophageal catheter or diaphragm electromyographic activity.[8,12] The use of oxygen desaturation criteria for hypopneas is controversial because it has been shown that central events in patients with heart failure are accompanied by less oxygen desaturation than obstructive events of similar duration,[13] and it is unclear to what extent oxygen desaturation contributes to morbidity or mortality.[14]

CLASSIFICATION AND APPROACH TO CENTRAL SLEEP APNEA

Central sleep apnea is not a single disease entity but rather includes several heterogeneous disorders as outlined in Table 121.2. Common to all forms of CSA is a transient reduction in $Paco_2$ below the level required to stimulate breathing during sleep; that is, the apnea threshold as illustrated in Figure 121.1. Two distinct underlying

Table 121.1 Clinical Characteristics and Symptoms of Patients With Central Sleep Apnea

Characteristic	Hypercapnic	Nonhypercapnic
Sex distribution	Equal	Predominantly male
History of respiratory failure	Frequent	Not reported
Peripheral edema and right heart dysfunction	Frequent	Not reported
Polycythemia	Frequent	Not reported
Muscle weakness	Frequent	Not reported
Morning headaches	Common	Uncommon
Snoring	Common	Frequent
Nasal obstruction	Uncommon	Common
Hypertension	Uncommon	Common
Nocturnal choking	Uncommon	Common
Nocturnal awakenings and insomnia	Uncommon	Common
Daytime sleepiness	Frequent	Frequent
Restless sleep	Common	Common

From Bradley TD, Phillipson EA. Central sleep apnea. *Clin Chest Med.* 1992;13:493–505.

Table 121.2 Classification of Central Sleep Apnea

Hypercapnic (P_{CO_2} > 45)	Nonhypercapnic ($P_{CO_2} \leq 45$)
DECREASED RESPIRATORY DRIVE OR LIMITED MECHANICAL RESPONSE	**NORMAL OR INCREASED RESPIRATORY DRIVE**
Secondary ■ Developmental or degenerative diseases ■ Brainstem tumors ■ Cerebrovascular disease ■ Neuromuscular diseases Primary ■ Central alveolar hypoventilation syndrome	Secondary ■ Congestive heart failure (Cheyne-Stokes respiration) ■ Cerebrovascular disease ■ Atrial fibrillation ■ Renal failure ■ Acromegaly ■ High altitude ■ Opioid use ■ Complex sleep apnea Primary ■ Idiopathic CSA

CSA, central sleep apnea; P_{CO_2}, partial pressure of carbon dioxide.

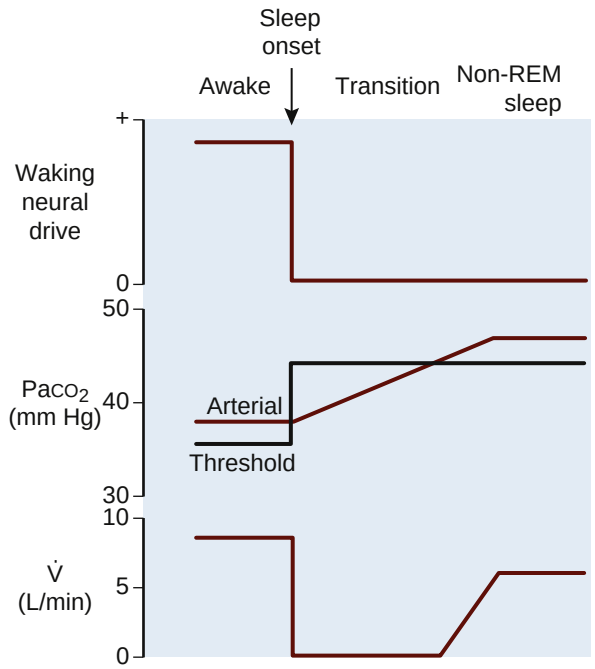

Figure 121.1 Schematic diagram showing a proposed mechanism underlying central sleep apnea at sleep onset. With the loss of the waking neural drive to breathing at sleep onset, there is an increase in the arterial partial pressure of carbon dioxide (P_{aCO_2}) threshold required to maintain respiratory rhythm. As a result, the P_{aCO_2} present during wakefulness may be below the threshold P_{aCO_2} for rhythm generation in sleep. Hence ventilation ($\dot{V}$) falls to zero and apnea ensues until P_{aCO_2} rises above the threshold level for rhythm generation in sleep, whereupon rhythmic breathing resumes. REM, rapid eye movement. (From Bradley TD, Phillipson EA. Central sleep apnea. *Clin Chest Med.* 1992;13:493–505.)

mechanisms can account for cessation of central respiratory output during sleep, causing either hypercapnic or nonhypercapnic CSA. An approach to evaluating a patient with CSA is outlined in Figure 121.2.

In *hypercapnic CSA*, there are outright defects in the respiratory control system or in the respiratory neuromuscular apparatus. Such defects generally result in suppressed respiratory drive and a chronic alveolar hypoventilation syndrome, manifested by some degree of daytime hypercapnia. However, the full impact of such defects becomes most apparent during sleep, when nonchemical waking neural drive to breathing is abolished and the stimulatory influence of behavioral, cortical, and reticular inputs to the brainstem respiratory neurons are reduced so that breathing becomes critically dependent on the defective metabolic respiratory control system, resulting in more pronounced hypercapnia during sleep than wakefulness.[15,16] This happens in conjunction with a markedly elevated P_{aCO_2} apneic threshold. Figure 121.3 illustrates a typical central apnea in a patient with hypercapnic CSA: as respiratory drive diminishes during sleep, there is a gradual reduction in tidal volume until cessation of breathing.

In contrast, in *nonhypercapnic CSA*, there are transient fluctuations or instabilities in an otherwise intact respiratory control system. These instabilities typically manifest during drowsiness and light *non–rapid eye movement* (NREM) sleep and, because there is no suppression of respiratory drive, P_{aCO_2} levels during wakefulness or sleep are normal or low. This type of CSA is typically triggered by a sudden increase in ventilation that causes P_{aCO_2} to fall below the apnea threshold, often due to an arousal from sleep, as illustrated in Figure 121.4A. This type of CSA is characteristically associated with periodic breathing, during which there are regularly recurring alternations in tidal volume between central apneas, hypopneas, and hyperpneas. Several theoretical and experimental models have been developed to account for such transient fluctuations in central respiratory drive. Common to all these models is a P_{aCO_2} level during sleep that falls transiently close to (hypopnea) or below (apnea) the critical threshold value required for maintenance of regular respiratory rhythm.

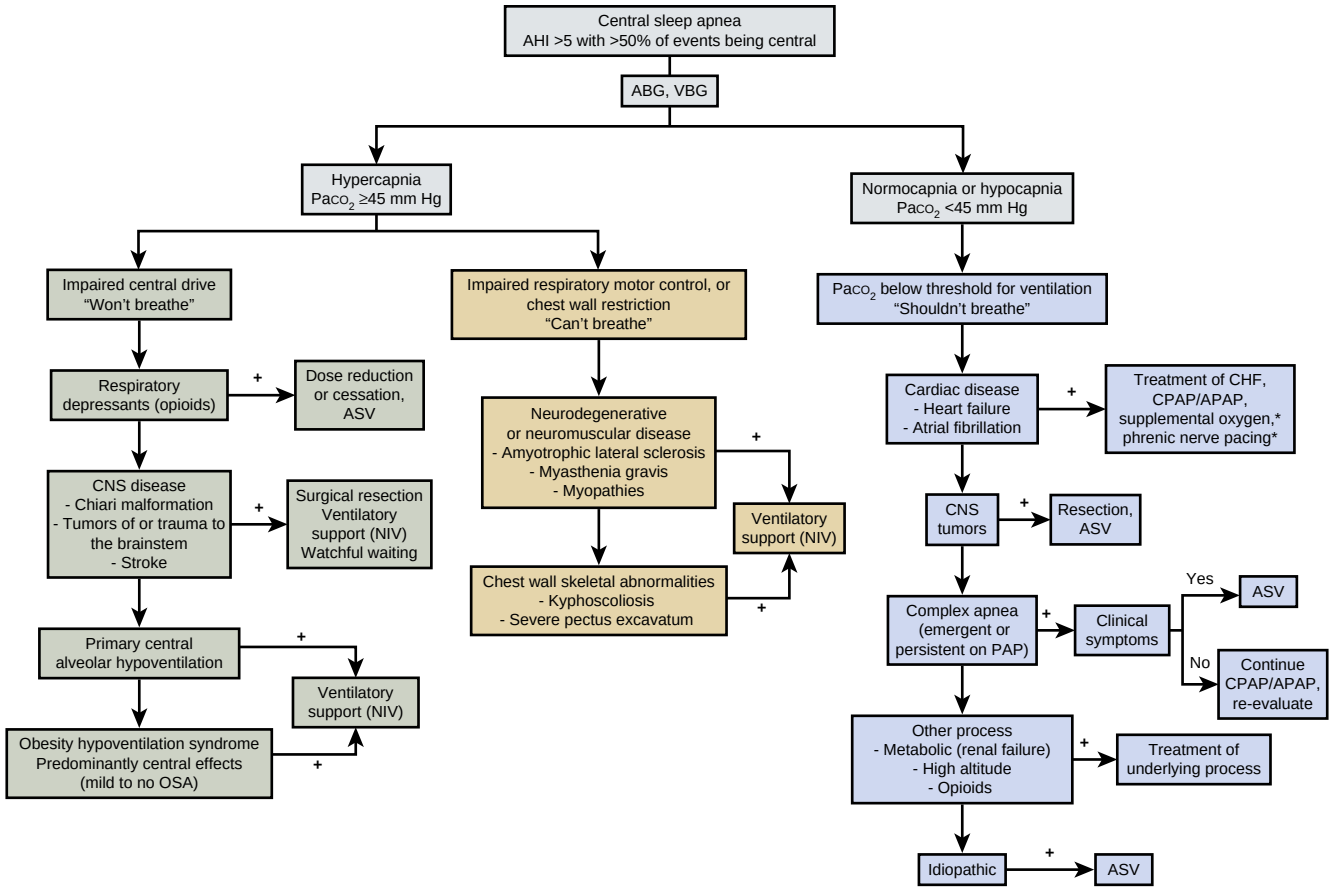

Figure 121.2 Algorithm demonstrating a diagnostic approach to central sleep apnea. *These treatments are under investigation. +, yes; –, no; ABG, arterial blood gas; APAP, auto-adjusting positive airway pressure, ASV, adaptive servoventilation; AHI, apnea–hypopnea index; CNS, central nervous system; CPAP, continuous positive airway pressure; OSA, obstructive sleep apnea; $Paco_2$, arterial partial pressure of carbon dioxide; PAP, positive airway pressure; VBG, venous blood gas.

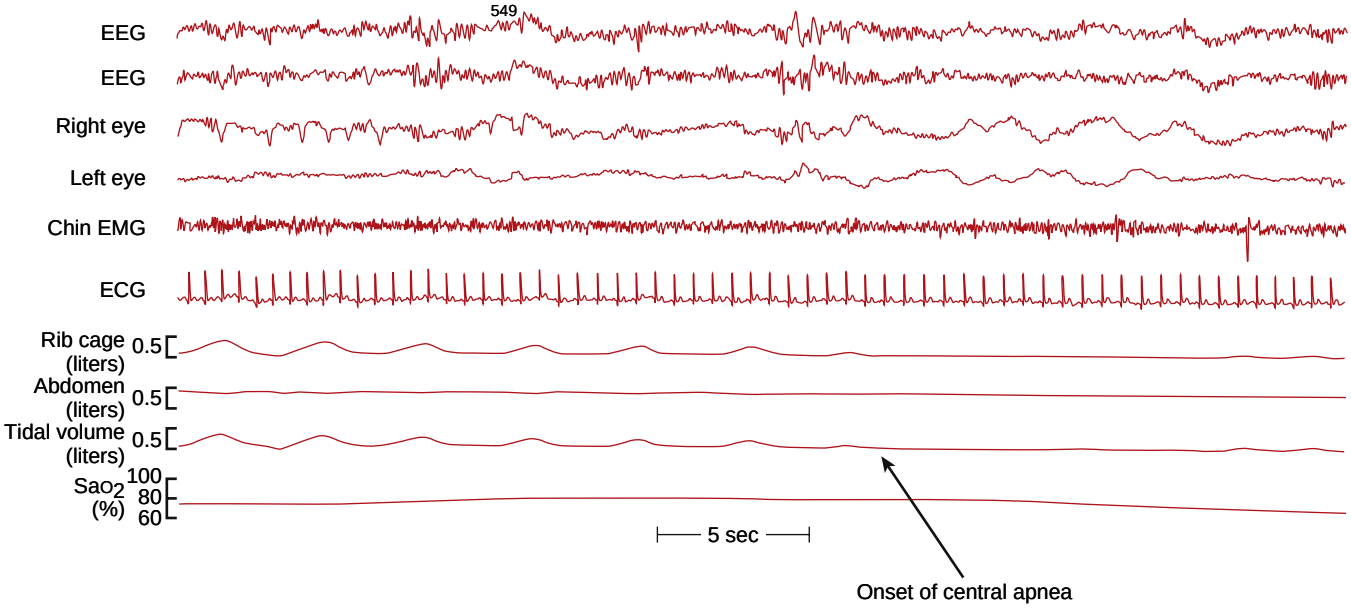

Figure 121.3 Hypercapnic central sleep apnea. Polysomnographic recording of a central apnea is from a patient with hypercapnic central sleep apnea due to primary central alveolar hypoventilation syndrome. Note the typical gradual reduction in tidal volume just before the onset of the central apnea and severe degree of hypoxemia with arterial oxygen saturation (Sao_2) below 80% throughout the recording. ECG, electrocardiogram; EEG, electroencephalogram; EMG, electromyogram.

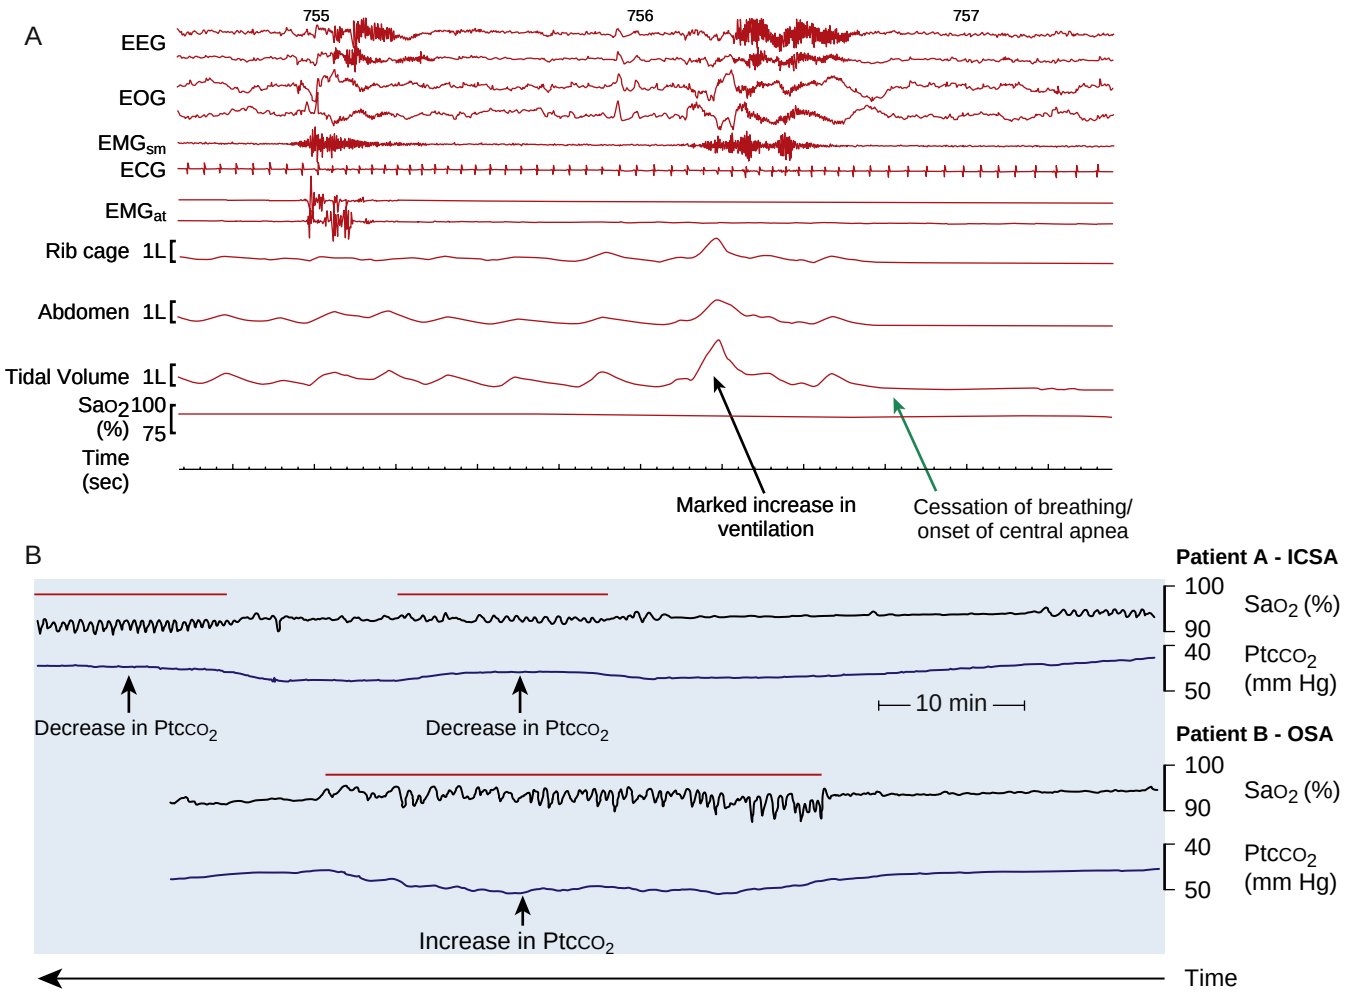

Figure 121.4 Nonhypercapnic central sleep apnea and comparison to obstructive sleep apnea. (A) Polysomnographic recording from a patient with nonhypercapnic central sleep apnea due to idiopathic central sleep apnea (ICSA). Note that, in contrast to the central apnea shown in Fig. 121.3, central apnea in this case follows an abrupt increase in ventilation triggered by an arousal, after which there is an abrupt decrease in ventilation to zero. In addition, note that in contrast to the recording shown in Fig. 121.3, arterial oxygen saturation (Sao_2) is within normal limits. (B) Note compressed records of nocturnal Sao_2 and transcutaneous $Paco_2$ ($Ptcco_2$) in a patient with ICSA (patient A), and in a patient with obstructive sleep apnea (patient B). Record reads from right to left. Note that in patient A the segments containing recurrent apneas (indicated by oscillations in Sao_2) are preceded by a small decrease in $Ptcco_2$. In contrast, in patient B the segment containing recurrent apneas is accompanied by a small increase in $Ptcco_2$. The *solid lines* indicate the apneic periods. Note also that in the $Ptcco_2$ scales an upward deflection of the signal indicates a fall in $Ptcco_2$, and vice versa. ECG, electrocardiogram; EEG, electroencephalogram; EMG_{at}, anterior tibialis electromyogram; EMG_{sm}, submental electromyogram; EOG, electrooculogram; $Paco_2$, arterial partial pressure of carbon dioxide. (A, From Xie A, Wong B, Phillipson EA, Slutsky AS, Bradley TD. Interaction of hyperventilation and arousal in the pathogenesis of idiopathic central sleep apnea. *Am J Respir Crit Care Med.* 1994;150:489–495. B, From Bradley TD, Phillipson EA. Central sleep apnea. *Clin Chest Med.* 1992;13:493–505.)

Such transient discrepancies in $Paco_2$ levels arise in several conditions, the most common of which is the transition from wakefulness to sleep. Because of the waking neural drive to breathe, ventilation is higher and $Paco_2$ levels are lower during wakefulness than during sleep.[16] Withdrawal of this drive at the transition from wakefulness to sleep results in a $Paco_2$ level that, although appropriate for wakefulness, is below the value appropriate for sleep (see Fig. 121.1). If this $Paco_2$ level of wakefulness is below the threshold value to stimulate ventilation during sleep, an outright apnea will ensue at sleep onset until $Paco_2$ rises to the critical threshold value when ventilation will resume. If sleep becomes firmly established at this point, regular breathing resumes without further apneas or hypopneas. However, in some individuals prone to periodic breathing, the transition from wakefulness to sleep is characterized by repeated fluctuations in central nervous system state between "awake" and "asleep." With each momentary arousal from sleep toward wakefulness, the $Paco_2$ levels that were present during sleep represent a hypercapnic stimulus during wakefulness, and ventilation therefore increases in accordance with the awake response to CO_2, resulting in an hyperpneic phase during which there is ventilatory overshoot causing $Paco_2$ to fall below the apnea threshold upon the transition to sleep. In this scheme, the magnitude of fluctuation in ventilation with changes in central nervous system state depends on the difference between the awake and sleeping values of $Paco_2$ and the steepness of the ventilatory response to CO_2 during wakefulness.[17] Any factor that magnifies these variables enhances the tendency to periodic breathing and CSA.

HYPERCAPNIC CENTRAL SLEEP APNEA

The automatic process of breathing originates from the central respiratory rhythm generator located in the pons and medulla. This central generator provides most of the input to spinal motoneurons responsible for activation of respiratory muscles. Hypercapnic CSA results from processes that damage the cerebral cortex, brainstem, spinal cord, muscles, or motor nerves. CSA arising in association with hypercapnia almost always presents as chronic respiratory failure with hypercapnia during wakefulness and sleep due mainly to a reduction in central respiratory drive. At the transition from wakefulness to sleep, the already reduced central drive is further reduced, causing a gradual reduction in ventilation until there is complete cessation of respiratory drive that leads to transient central apneas (see Fig. 121.3). Coincident with this reduction in ventilation, $Paco_2$ rises and Sao_2 falls. Apneas and hypopneas are more frequent during *rapid eye movement* (REM) sleep than *non-REM* (NREM) sleep owing to a further reduction in ventilator drive and partial paralysis of the respiratory muscles in REM sleep.[18]

Patients with hypercapnic CSA characteristically present with a clinical picture dominated by symptoms and sequelae of chronic respiratory failure with hypercapnia and hypoxemia that can include cyanosis, polycythemia, peripheral edema, and right heart dysfunction.[2] They may present at variable time points after the onset of the underlying disease. Symptoms suggestive of CSA may include snoring, restless sleep, morning headaches, excessive daytime sleepiness, and fatigue. However, some patients with hypercapnic CSA may not have symptoms suggestive of a sleep apnea syndrome.[2]

SECONDARY FORMS OF HYPERCAPNIC CENTRAL SLEEP APNEA

The brainstem includes the medulla, midbrain, and pons. Although the central respiratory controller is located predominantly in the medulla, it has projections to other areas of the brainstem. Diseases affecting the brainstem, such as Chiari malformations, tumors, cerebrovascular disease, and neurodegenerative diseases, may induce hypoventilation and CSA via a number of mechanisms, such as (1) physical compression of the brainstem resulting in damage to the respiratory center and reticular activating system, (2) stretching of the lower cranial nerves and damage to the peripheral chemoreceptors that carry inputs from the carotid bodies to the medulla, (3) depletion of medullary chemosensitive respiratory neurons,[19] or (4) degeneration of the central rhythm generator located in the dorsolateral pons.

Developmental and Degenerative Diseases

Chiari malformations are congenital abnormalities of the craniocervical junction with downward displacement of the cerebellar structures often in association with syringomyelia, myelomeningocele, hydrocephalus, and aqueductal stenosis. Other bony anatomic abnormalities associated with these Chiari malformations include platybasia, basilar invagination, Klippel-Feil anomaly (failure of segmentation of two of the seven cervical vertebrae), and scoliosis. Chiari malformations are classified into three types: type I, II, and III. These anatomic abnormalities can lead to degeneration of brainstem respiratory neurons with resulting hypoventilation and, in some cases, CSA.

In children with type I Chiari malformation, prospective studies show a prevalence of CSA of 9–15%, with an increased risk of CSA in those with hydrocephalus.[20,21] In adults with type I Chiari malformation, prospective studies report high rates of sleep-related breathing disorders (59–75%),[22] but the reported prevalence of CSA has varied widely from 1–59%.[23,24,25] In a small cross-sectional study of patients with Chiari malformation type II and associated myelomeningocele, the prevalence of CSA was higher at 63%.[26]

Congenital central hypoventilation syndrome (CCHS) is a rare genetic disease with an incidence of approximately 1 in 200,000 live births, caused by a mutation of the *PHOX2B* gene.[27–29] Most cases present in the neonatal period or early childhood with acute or chronic respiratory failure as a result of a loss of respiratory drive. However, it may present de novo in adults after a severe respiratory infection with combined CSA and OSA.[30–32] A diagnosis is considered only in those in whom metabolic, neurologic, pulmonary, and medication-induced disorders have been excluded. When CCHS is suspected, the *PHOX2B* gene screening test is recommended for purposes of genetic counseling.[33,34]

Neurodegenerative diseases of the brainstem, including multiple system atrophy, Leigh syndrome (or subacute necrotizing encephalomyelopathy), and Parkinson disease, can be accompanied by CSA.[35–37] Prevalence rates vary depending on the severity of the disease. In those with multiple system atrophy, CSA is reported to range from 9–20%.[38–40] In patients with multiple sclerosis, a demyelinating disease that can affect the brainstem and spinal cord, CSA may develop in those with medullary lesions affecting the respiratory neurons.[41,42] The prevalence of CSA in such patients is, however, unknown.

Brainstem Tumors

There have been fewer than a dozen documented cases of CSA associated with brainstem tumors, suggesting that tumors are a rare cause of hypoventilation with CSA.[43–49] Tumors such as gliomas, meningioma, astrocytoma, or neurofibromas have been implicated. The tumor type is probably less important than its location, which usually involves the medulla or pons. A retrospective study involving a series of children with brainstem tumors referred for assessment to a sleep clinic over an 8-year period found a prevalence of CSA of 14% (2 of 14).[45]

Cerebrovascular Disease

CSA can develop after stroke. The stroke location associated with hypercapnic CSA is usually the nucleus tractus solitarius region of the medulla responsible for neural output to the diaphragm.[50–53] Prevalence is probably low because there are only a small number of cases reported in the literature. Of interest, in Fabry disease, which is an X-linked recessive multisystem disease characterized

by vasculopathic changes and ischemia, CSA was reported in 22% of those with white matter lesions in the brainstem.[54,55]

Neuromuscular Diseases

Muscular dystrophies, myotonic dystrophy, and other types of inherited and acquired myopathies may result in hypoventilation and hypercapnic CSA. These diseases impair function of the inspiratory muscles, including the diaphragm, leading to alveolar hypoventilation. At the transition from wakefulness to sleep, the associated reduction in ventilatory response to CO_2 and hypoxemia, combined with the loss of respiratory muscle tone, can lead to apneas without respiratory effort (i.e., CSA).[56,18] Although some central output to the respiratory muscles may be present, and therefore, strictly speaking, events may not be central, the muscles are unable to respond; the reduced or absent muscle force generation leads to hypopneas and apneas, respectively, that have the appearance of central events. From the clinical viewpoint, it is reasonable to classify these as hypercapnic CSA because their treatment is similar to that for CSA arising from an absence of central drive.

Many of these disorders present in childhood. Although phenotypically variable, they are characterized by progressive muscular weakness and the development of hypoventilation over time. In addition to the high prevalence of hypoventilation, a significant proportion (20–60%) in adults and children develop CSA.[57–60] Nonhypercapnic Cheyne-Stokes respiration with CSA may also be seen in myotonic dystrophy or Duchenne muscular dystrophy when there is associated cardiomyopathy and heart failure.[61,62]

Diseases of the motor neurons include amyotrophic lateral sclerosis, spinal muscular atrophy, and postpolio syndrome. Due to varying degrees of degeneration of the respiratory motor neurons, hypoventilation and CSA can ensue. Recent studies in amyotrophic lateral sclerosis have reported either no CSA or a very low prevalence of 5%.[63,64] The prevalence of CSA is reported to be approximately 18% in amyotrophic lateral sclerosis[65] and approximately 5% in postpolio syndrome.[66] In one small study involving patients with traumatic spinal cord injury affecting the cervical spinal cord and resulting in tetraplegia, a high prevalence of CSA (60%) was reported.[67,68] Exaggerated sleep-related hypoventilation as a result of altered medullary motor output is thought to be the responsible mechanisms for the CSA.[69,70]

Myasthenia gravis is a disease of the postsynaptic neuromuscular junction. The reported prevalence of CSA in myasthenia gravis is highly variable (0–35%) and is probably dependent on disease severity.[58,71,72]

PRIMARY HYPERCAPNIC CENTRAL SLEEP APNEA

Central Alveolar Hypoventilation Syndrome

This is a rare syndrome that presents as chronic hypercapnic respiratory failure with normal respiratory mechanics, chest wall configuration, and muscle strength in the absence of any of the above secondary causes. The primary abnormality giving rise to hypoventilation is reduced sensitivity of the central and peripheral chemoreceptors.[73] In some cases, this may be due to CCHS.[74] Only a few cases of CSA have been described in association with primary central alveolar hypoventilation syndrome.[18,75] This diagnosis is made only after the exclusion of other causes of CSA and hypoventilation syndromes, including CCHS.

TREATMENT

The initial approach to treatment of hypercapnic CSA is to determine the underlying cause. In some cases, treatment of the underlying etiology will alleviate the CSA. For example, in those with tumors compressing the pons or medulla, resection may abolish CSA.[76] Surgical treatment of Chiari II malformations is dependent on the severity of the malformation and, despite posterior fossa decompression for the Chiari II malformation, CSA will often persist.[26] No specific intervention is usually required for patients with acute stroke and CSA because CSA may resolve with improvement of the stroke. However, if respiratory failure and CSA persist, specific therapy for these conditions may be indicated, as described later. For those with neuromuscular disease, pharmacologic therapies available for some inherited myopathies or myasthenia gravis may also alleviate CSA by improving muscle strength.[77]

In most patients, the management of CSA is the same as for chronic alveolar hypoventilation syndromes. However, few studies have specifically addressed the treatment of hypercapnic CSA. The main aim of treatment is to augment ventilation and thereby improve gas exchange and abolish CSA.

It is important that patients be cautioned against the use of sedative medications that can induce acute respiratory failure and aggravate CSA. In patients with CSA in association with central alveolar hypoventilation, a trial of the respiratory stimulant medroxyprogesterone can be given but is successful in only a minority of patients.[78] Supplemental nocturnal oxygen may alleviate hypoxia and CSA and may even lower $Paco_2$ if hypoxia caused central nervous system depression.[73,75] However, there is a potential for supplemental oxygen to abolish hypoxic respiratory drive and worsen CSA. Therefore, a trial of supplemental oxygen should be accompanied by careful monitoring of $Paco_2$, end-tidal CO_2 or transcutaneous CO_2, and either Po_2 or *arterial oxygen saturation* (Sao_2).

Where pharmacologic therapies are unavailable or are ineffective, noninvasive ventilation is often indicated, either via *bilevel positive airway pressure* (BPAP) support ventilation or volume-cycled ventilation.[79] The aim of noninvasive ventilation is to reduce $Paco_2$ below 45 mm Hg while awake and below 50 mm Hg while asleep and maintaining Sao_2 at or above 90%. This is best achieved by performing polysomnography during a trial of noninvasive ventilation in which transcutaneous $Paco_2$ or fraction of end-tidal CO_2 and Sao_2 are monitored. It is sometimes possible to maintain normal gas exchange during sleep and wakefulness by noninvasive ventilation only during sleep. If the underlying disease progresses despite the above measures, tracheotomy and invasive mechanical ventilation may be required. Unfortunately, there are no randomized trials or long-term observational studies that have determined the effects of noninvasive and invasive mechanical ventilation on morbidity, mortality, and quality of life in patients with hypercapnic CSA.

NONHYPERCAPNIC CENTRAL SLEEP APNEA

Nonhypercapnic CSA differs from that of hypercapnic CSA in that symptoms are mainly related to the sleep disturbance similar to that observed in OSA, but with insomnia being a more prominent feature. There are many causes of this type of CSA, and Table 121.1 is based mainly on symptoms related to idiopathic CSA. Nevertheless, symptoms related to secondary forms of nonhypercapnic CSA are, in general, similar.

SECONDARY FORMS OF NONHYPERCAPNIC CENTRAL SLEEP APNEA

Central Sleep Apnea in Association With Heart Failure: Cheyne-Stokes Respiration

Central sleep apnea in heart failure is manifest by a *Cheyne-Stokes respiration* (CSR) pattern. CSR can, however, happen during sleep and wakefulness. Because this chapter focuses on central apnea during sleep, CSR with central apneas during sleep is referred to as CSR-CSA. CSR-CSA is distinguished from other forms of CSA and periodic breathing by its characteristic crescendo-decrescendo pattern of tidal volume in which hyperpneas are markedly prolonged compared to those in patients without heart failure owing to reduced cardiac output and prolonged lung-to-chemoreceptor circulation time (Fig. 121.5). Therefore, a finding of CSR-CSA on a polysomnogram is highly suggestive of low cardiac output; it is seen most often in patients with reduced ejection fractions (i.e., *heart failure with reduced ejection fraction* [HFrEF]) and rarely affects the non–heart failure population.[80] Mechanisms that mediate CSR-CSA remain incompletely understood. However, as in all other forms of nonhypercapnic CSA, central to the process is respiratory control instability resulting from the dependence of the sleep state on metabolic control of ventilation, especially $Paco_2$.[2] A proposed pathophysiologic scheme for CSR-CSA is illustrated in Figure 121.6.

In heart failure, a key factor destabilizing the respiratory control system and predisposing to CSR-CSA is the presence of chronic hyperventilation that lowers $Paco_2$ during wakefulness and sleep and maintains it close to the apnea threshold (see also Chapter 117). Because $Paco_2$ is closer to the apnea threshold than normal, small perturbations, such as arousals from sleep that augment ventilation, may be enough to drive $Paco_2$ below the apnea threshold and trigger central apneas. The main factor contributing to this instability and hyperventilation is increased loop gain. Loop gain is an engineering term first used when a mathematical model was developed to explain factors involved in the instability within the respiratory control system in patients with CSR-CSA.[81] Simply put, *loop gain* is the ratio of ventilatory output to a given stimulus. Ventilation becomes unstable when loop gain is elevated so that the ventilatory output for a given stimulus is higher than normal. Thus, if central sensitivity to CO_2 is augmented, any given increase in $Paco_2$ will cause a greater-than-normal increase in ventilation that can then drive $Paco_2$ close to, or below, the apnea threshold. Several factors interact to increase the tendency to respiratory instability and hyperventilation. These include:

1. Increased peripheral and central chemoresponsiveness.[82,83]
2. Elevated pulmonary capillary wedge pressure that causes pulmonary congestion and activation of the pulmonary juxtacapillary irritant receptors that augment central drive and ventilation.[84]
3. Impaired cerebral vascular reactivity and blood flow responses to changes in the $Paco_2$, leading to instability of breathing.[85–87] Whereas this has been proposed as a mechanism for ventilator instability, it requires a differential effect of $Paco_2$ on the cerebral arterial and venous vessels that has not been fully demonstrated or explained. In consequence, this potential mechanism remains controversial and not fully established.
4. Sleep state instability in which arousals from sleep during the hyperpneic phase of CSR-CSA cause a transient awakening with an associated engagement of the wakefulness drive to breathe, increased chemosensitivity, and a lower $Paco_2$ apnea threshold.[88,89] Unlike OSA, where arousals take place at apnea termination and contribute to airway opening and resumption of airflow, arousals after central apnea generally take place several seconds after resumption of airflow but before the peak of hyperventilation.[90,91] Thus, they appear not to have the same protective role as they do in OSA. Although recurrent arousals during the ventilatory phase have been shown to trigger and propagate CSR-CSA,[88,92] the absence of arousals in 27% of central events suggests that they are not a critical factor.[91]
5. The response of the lungs (as assessed by the change in $Paco_2$ or arterial partial pressure of oxygen (Pao_2) per unit change in ventilation, that is, *plant gain*) is a predictor of CSR-CSA during nighttime and daytime. Plant gain is higher in those with heart failure and CSR-CSA compared to those without CSR-CSA.[83]

CSR-CSA typically arises during NREM sleep and resolves or becomes less prominent in REM sleep.[2,88] There are several reasons for this. First, breathing is predominantly under metabolic control during NREM sleep and is therefore highly dependent on $Paco_2$. Thus, reductions in $Paco_2$ below the apnea threshold will invariably give rise to central apneas. However, breathing is largely independent of metabolic control during REM sleep so that breathing is not nearly as dependent on $Paco_2$ as in NREM sleep. Second, ventilatory responses to CO_2 and hypoxemia are brisker in NREM than in REM sleep, so the potential to hyperventilate is greater in the former state than in the latter. Third, arousal thresholds for $Paco_2$ and Pao_2 are significantly lower in NREM than in REM sleep. Thus, people are more arousable and therefore more prone to respiratory control system instability in NREM than in REM sleep. Fourth, the respiratory muscles, save for the diaphragm, are essentially paralyzed in REM but not in NREM sleep. Thus, for any given chemical (e.g., $Paco_2$) or nonchemical (e.g., arousal) stimulus, the augmentation in ventilation will be greater in NREM than in REM sleep, making hyperventilation more likely in the former state.

Regarding the role of low cardiac output and prolonged circulation time in the pathogenesis of CSR-CSA, it appears that these are not crucial to the pathogenesis of the central

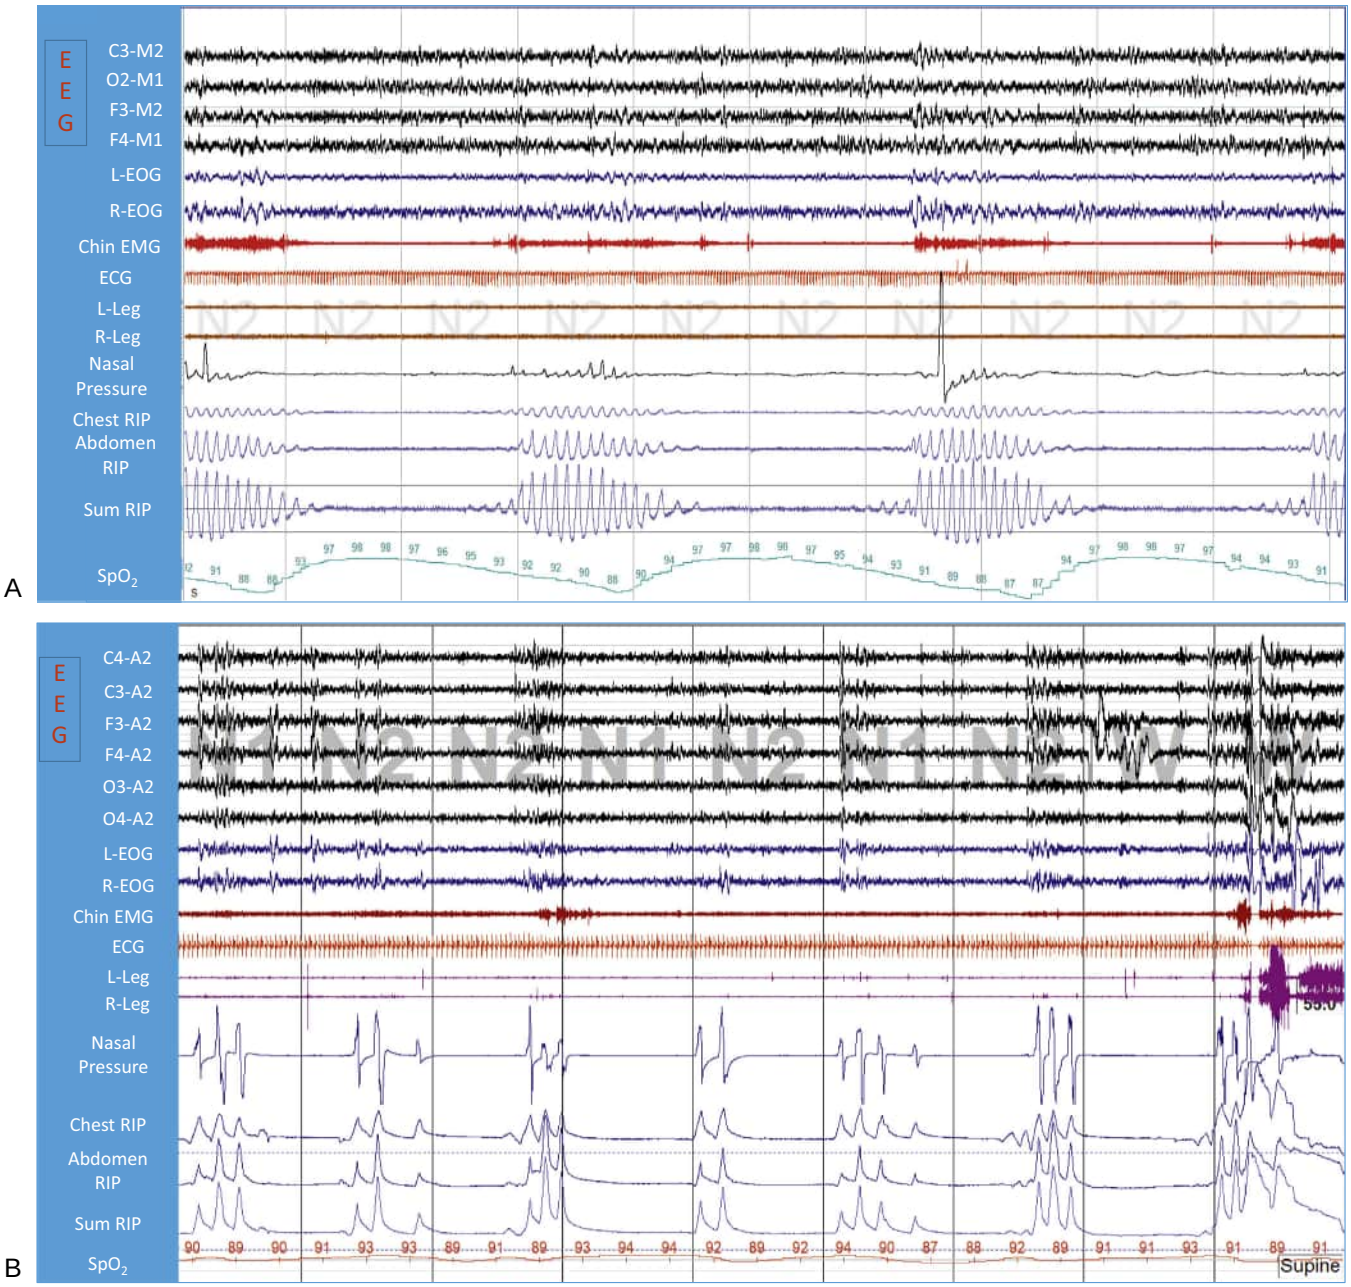

Figure 121.5 Central sleep apnea polysomnographic recordings. (A) Polysomnographic recording of Cheyne-Stokes respiration with central sleep apnea pattern (CSR-CSA) during stage N2 sleep. There is an absence of rib cage (chest RIP) and abdominal (abdominal RIP) motion as illustrated by the chest, abdominal, and SUM Respitrace recordings. There is no airflow as illustrated by the nasal pressure transducer recording. Note the typical long apnea-hyperpnea cycle duration (i.e., 90–100 seconds) with prolonged crescendo-decrescendo pattern of hyperpnea. Apneas are accompanied by cyclical mild oxygen desaturations. This is a 5-minute recording. (B) Polysomnographic recording of central apneas during stage N1/N2 sleep from a patient with opioid-induced central sleep apnea. There is no airflow as illustrated by the nasal pressure transducer recording and an absence of rib cage (chest RIP) and abdominal (abdominal RIP) motion. Note the typical short apnea-hyperpnea cycle duration (i.e., 30–35 seconds) with cyclical mild oxygen desaturations that contrasts with the long cycle duration in CSR-CSA. ECG, electrocardiogram; EEG, electroencephalogram; EMG, electromyogram; EOG, electrooculogram; RIP, respiratory inductance plethysmography; Spo_2, pulse oxygen saturation.

apneas because there is evidence that cardiac output in heart failure patients with CSR-CSA does not differ significantly from that in heart failure patients without CSR-CSA.[93] Moreover, experimentally induced prolongation of lung-to–carotid body circulation time in dogs only precipitated periodic breathing in a minority of experiments and then only when circulation times approached 1 minute or longer, a time far exceeding that observed in human heart failure.[94] However, these factors play a role in sculpting the crescendo-decrescendo pattern of hyperpnea[83] because the rate of rise of tidal volume and the duration of the hyperpnea are directly proportional to lung-to-chemoreceptor circulation time and indirectly proportional to cardiac output.[95] In consequence, in patients with heart failure, cardiac output is lower, and lung-to-chemoreceptor circulation time, hyperpnea, and periodic breathing cycle duration of CSR-CSA are longer than they are in CSA in patients without heart failure.[95] Figure 121.5A also shows the latency from

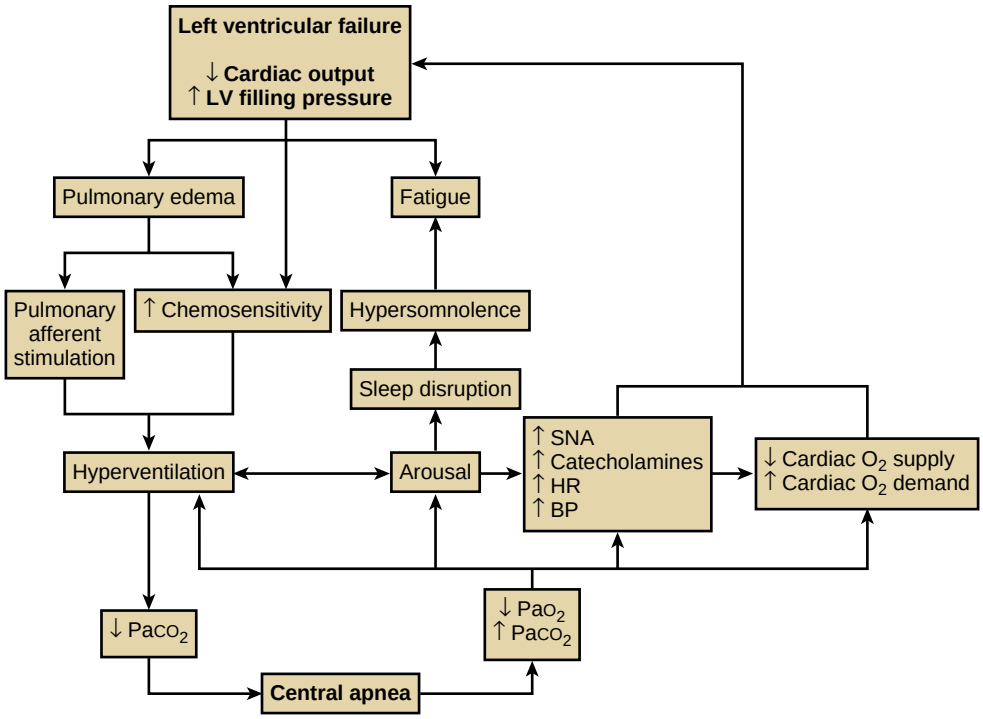

Figure 121.6 Pathophysiologic scheme of Cheyne-Stokes respiration with central sleep apnea. Left ventricular failure leads to reduced cardiac output and increased filling pressure that cause pulmonary edema and stimulation of pulmonary vagal irritant receptors that then, together with increased chemosensitivity, provoke hyperventilation and hypocapnia. A fall in $Paco_2$ below the apnea threshold triggers central apnea, during which Po_2 falls and $Paco_2$ rises, eventually leading to resumption of ventilation and arousals that provoke further hyperventilation and central apneas. The combination of hypoxia and arousals from sleep augment sympathetic nervous system activity that provokes rises in heart rate and blood pressure and, in turn, increases cardiac oxygen demand in face of reduced supply. The combination of oxygen demand/supply mismatch and sympathetic overactivation could lead to worsening left ventricle failure. In addition, sleep fragmentation due to recurrent arousals could contribute to fatigue and, in a minority, hypersomnolence. BP, blood pressure; HR, heart rate; LV, left ventricular; $Paco_2$, arterial partial pressure of carbon dioxide; Pao_2, arterial partial pressure of oxygen; SNA, sympathetic nervous system activity. the termination of a central apnea to arousal in the patient with CSR-CSA (panel A), but an arousal is seen immediately upon central apnea termination in the patient with opioid-induced CSA (panel B).

Heart failure is a prevalent condition affecting approximately 1.5% of the general population.[96] Among patients with symptomatic heart failure, earlier studies involving only men reported a prevalence of CSR-CSA of approximately 40%.[97] However, more recent epidemiologic studies involving both men and women have shown a substantially lower prevalence of CSR-CSA in those with optimally treated heart failure of 15–26%,[98–101] probably because CSR-CSA is very uncommon in women.[102] CSR-CSA also appears to be common in patients with asymptomatic left ventricular systolic dysfunction.[103] Risk factors for CSR-CSA include older age (>60 years); male sex; atrial fibrillation; awake hypocapnia ($Paco_2 \leq 38$ mm Hg); diuretic use; more severe heart failure, defined by lower *left ventricular ejection fraction* (LVEF); higher New York Heart Association functional class; higher brain natriuretic peptide level; and higher pulmonary capillary wedge pressure[84] and left ventricular end-diastolic volume.[97–99,101,104]

OSA and CSA can coexist in patients with heart failure. In a significant minority of patients, a shift between these two types of sleep apnea may happen overnight or over longer periods.[93,105–107] Predominantly obstructive events may shift to central events in association with reductions in the $Paco_2$ and prolongation of circulation time and the hyperpnea phase.[106,107] This suggests deterioration in cardiac output and elevation in left ventricular filling pressure as a result of the adverse hemodynamic effects of OSA.[108,109] Conversely, the shift from CSA to OSA is associated with improvements in LVEF and shortening of circulation time.[105] These observations suggest a pathophysiologic interaction between heart failure and sleep apnea, indicating that sleep apnea can influence cardiac function, whereas heart function can influence sleep apnea type. Thus, in some heart failure patients, OSA and CSA may be part of a spectrum of sleep-related breathing disorders that can shift according to underlying cardiovascular function.

One factor that may contribute to the pathogenesis of OSA and CSR-CSA, and to shifts in predominant apnea type over time in patients with heart failure, is fluid retention in the legs during the day and its overnight rostral redistribution during the night (eFig. 121.4). Strong relationships between the amount of fluid displaced from the legs due to gravity overnight and the AHI have been described in patients with heart failure and either OSA or CSA.[110] In the case of OSA, the fluid shift was accompanied by an overnight increase in neck circumference that correlated strongly with the AHI. These observations suggest that fluid accumulation in the neck was contributing to severity of OSA, likely by increasing peripharyngeal tissue pressure[111] and thereby increasing its collapsibility.[112] In the case of CSA, the fluid shift correlated inversely with nocturnal $Paco_2$, suggesting

that some of the fluid was redistributed into the lungs, where it stimulated pulmonary irritant receptors, causing hyperventilation and reductions in the $Paco_2$ close to or below the apneic threshold.[110,113] In addition, the magnitude of the fluid shift from the legs was greater in those with CSA than in those with OSA. Thus, it is possible that varying degrees of rostral fluid shift could lead to changes in predominant apnea type over time. The degree of nocturnal rostral fluid shift is related directly to time spent sitting in the day and inversely to physical fitness. Thus, fluid accumulation in the legs during the daytime results largely from the heart failure state itself, as well as inactivity with passive gravitational collection of fluid in the legs that also moves rostrally due to gravity when lying down at night.

Clinical Features of Cheyne-Stokes Respiration–Central Sleep Apnea. Although symptoms of heart failure, including orthopnea, paroxysmal nocturnal dyspnea, witnessed apnea, fatigue, and insomnia are common in those with CSR-CSA,[114] no specific constellation of symptoms has been identified in association with CSR-CSA. For example, patients with CSR-CSA do not usually have snoring or excessive daytime sleepiness.[98,115,116] Nor is there clear evidence that CSR-CSA has an adverse impact on quality of life.[116]

It is still a matter of debate whether CSR-CSA is merely a manifestation of elevated left ventricular filling pressures and poor cardiac function, or whether it has an adverse effect on cardiac function and prognosis independently of other risk factors. The balance of the evidence suggests that CSR-CSA has an adverse effect on prognosis. Most, but not all, single-center observational studies have reported a twofold to threefold increased risk of death or cardiac transplantation in association with CSR-CSA.[99,117–123] Caution is recommended in interpreting these studies because patient populations were generally small, and definitions and quantification of CSR-CSA were inconsistent. Because several of these studies were reported before widespread treatment of heart failure with β-blockers, implantable cardiac defibrillators, and cardiac resynchronization therapy, their findings may no longer be applicable to the present environment.[120–123]

One factor that might contribute to poor prognosis in CSR-CSA is elevated sympathetic nervous system activity, which is known to have a deleterious effect on the prognosis of patients with heart failure.[124] There is evidence that CSR-CSA increases sympathetic nervous activity during sleep and wakefulness,[125] probably via intermittent apnea-related hypoxia and arousals from sleep.[126–128] High sympathetic nervous activity induces activation of the aldosterone-renin pathway and reduces myocardial contractility over time due to abnormalities in calcium handling with precipitation of cardiac arrhythmias.[103] This combination of autonomic dysfunction and propensity to arrhythmogenesis and sudden death are the presumed mechanisms by which CSR-CSA contributes to increased mortality in heart failure.[98,129,130] This is supported by evidence of a 50% higher rate of appropriate implantable-defibrillator discharges in those with CSR-CSA compared to those without sleep-disordered breathing.[131]

On the other hand, there is evidence that CSR-CSA does not cause adverse hemodynamic effects in patients with heart failure. A recent study demonstrated that, in contrast to obstructive apneas during which stroke volume and cardiac output decrease, during central apneas, stroke volume and cardiac output actually increase slightly but fall slightly during hyperpnea.[108] Phenotyping of CSR-CSA–related features has suggested patterns that may aid in stratification of those most at risk of adverse outcomes. These include (1) measurement of the cycle length, lung-to-periphery circulation time, and time to peak flow, whereby a longer CSR cycle length, circulation time, and time to peak flow are associated with adverse outcomes in heart failure[132] and (2) identification of the pattern of the hyperpnea phase. Two separate patterns of hyperpnea during CSA-CSR have been identified: a positive pattern, in which the end-expiratory lung volume is at or above the functional residual capacity and a negative pattern in which the end-expiratory lung volume falls below the functional residual capacity (Fig. 121.7).[133] The negative CSR-CSA pattern is associated with poorer cardiac function. End-expiratory lung volume can only fall below functional residual capacity through activation of the expiratory muscles that would generate a greater degree of positive intrathoracic pressure than would be the case if end-expiratory lung volume was at or above functional residual capacity. Such pressure could have a compressing effect on the heart with augmentation of stroke volume similar to external chest compressions during cardiopulmonary resuscitation.[133] The observation that, in comparison to the positive, the negative CSR-CSA pattern is associated with smaller relative reductions in stroke volume and reduced myocardial workload during hyperpnea is supportive of this possibility. This raises the possibility that CSR-CSA with the negative hyperpnea pattern could be a form of autoresuscitation that acts as a compensatory mechanism to maintain stroke volume in those with severe heart failure.[134] Thus, under certain circumstances, CSR-CSA may provide some compensatory effect for low cardiac output and may not be entirely detrimental to cardiovascular function.[135]

Treatment of Cheyne-Stokes Respiration. Because few symptoms have been attributed to CSR-CSA, symptomatic targets for therapy are difficult to identify. However, because CSR-CSA is associated with increased risk of morbidity and mortality, a logical goal in treating CSR-CSA would be to reduce morbidity or mortality. Nevertheless, no treatments have been shown to affect these outcomes in randomized trials. Thus, because there are no clear-cut indications for treating CSR-CSA, a decision to treat CSR-CSA rests on clinical judgment, and the following possibilities can be considered with the proviso that therapies that reduce the severity of CSR-CSA may not lead to improvements in patient symptoms, quality of life, or long-term outcomes. All interventions in current use for CSR-CSA require further study to assess their long-term effectiveness and safety.

Treatment of Heart Failure. Because CSR-CSA arises as a consequence of heart failure, it would be reasonable to optimize pharmacologic and device treatments for the underlying heart failure to manage CSR-CSA. A few nonrandomized observational studies suggest that angiotensin-converting enzyme inhibitors,[136] β-blockers,[137] and cardiac

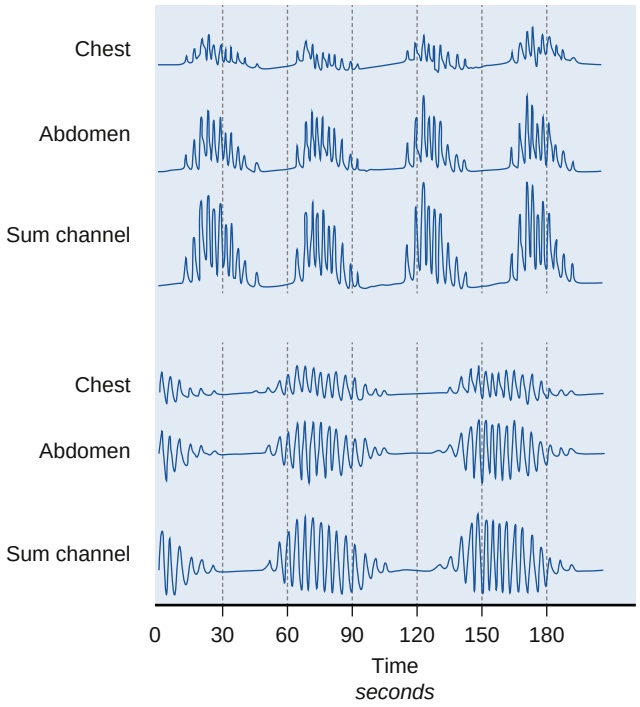

Figure 121.7 Different patterns of hyperpnea during Cheyne-Stokes respiration. Raw data tracing of chest, abdomen, and sum channels of the respiratory inductance plethysmograph demonstrating two patterns of hyperpnea during Cheyne-Stokes respiration with central sleep apnea. The upper tracings show a positive pattern in which end-expiratory lung volume remains at or above functional residual capacity, and the lower tracings show a negative pattern in which end-expiratory lung volume falls below functional residual capacity. (From Perger E, Inami T, Lyons OD, et al. Distinct patterns of hyperpnea during Cheyne-Stokes respiration: implication for cardiac function in patients with heart failure. *J Clin Sleep Med.* 2017;13:1235–1241.)

resynchronization therapy[138] may reduce severity of CSR-CSA in chronic heart failure. However, these findings have not been confirmed in randomized trials, and one large epidemiologic study showed no reduction in frequency or severity of CSR-CSA with institution of β-blockers.[98] In one study, atrial overdrive pacing led to a reduction in the AHI in patients with bradyarrhythmias and CSA but without heart failure.[139] However, these findings have not been reproduced. In another small study, it was reported that cardiac transplantation for end-stage heart failure reduced severity of CSR-CSA.[140] Although consideration can be given to the implementation of one or more of the above approaches for therapy of CSR-CSA, none of them is specifically indicated for therapy of CSR-CSA, and their use should be reserved to treat the underlying heart failure as required.

Positive Airway Pressure

Continuous Positive Airway Pressure. The effects of *Continuous positive airway pressure* (CPAP) have been studied extensively in patients with heart failure and CSR-CSA. Its acute application in patients with heart failure increases intrathoracic pressure, thereby reducing right and left ventricular volumes (i.e., preload), left ventricular transmural pressure (i.e., afterload), and the work of breathing by unloading the inspiratory muscles.[125,141] It also augments stroke volume and cardiac output in those with elevated left ventricular filling pressures but has the opposite effect in those with normal or reduced left ventricular filling pressures.[142]

Several small randomized trials in heart failure patients with CSR-CSA lasting 1 to 3 months have demonstrated that CPAP reduces the AHI by 50–60%.[125,143] The means by which it reduces the AHI is not well understood but may include (1) raising lung volume, thereby increasing the lung O_2 reservoir, which can stabilize breathing by dampening fluctuations in Pa_{O_2}, and (2) reducing lung water, thereby reducing pulmonary irritant receptor stimulation, reducing ventilation, and allowing Pa_{CO_2} to rise above the apnea threshold.[125] Other small randomized trials in heart failure patients with CSR-CSA also demonstrated that CPAP increases LVEF, reduces mitral regurgitation, and decreases sympathetic nervous system activity.[125,144]

The largest randomized trial involving CPAP was the *Canadian Positive Airway Pressure for Patients with Central Sleep Apnea and Heart Failure* (CANPAP), which involved 258 patients over a mean and maximum follow-up of 24 and 64 months, respectively.[145] CPAP reduced the AHI by approximately 55%, improved LVEF and 6-minute walking distance, and reduced sympathetic nervous system activity. However, it had no effect on the primary outcome, which was heart-transplant–free survival. Therefore, it cannot be recommended for routine use as therapy for CSR-CSA. However, in a post hoc analysis of the trial, it was observed that, among patients in whom CPAP reduced the AHI to less than 15, heart-transplant–free survival was significantly better than in the control group and in the CPAP subgroup in which the AHI remained above 15.[146] These results suggest that a trial of CPAP may be given to heart failure patients with CSR-CSA and, if their AHI is reduced to below 15, CPAP can be continued because of its potential to reduce morbidity and mortality. However, if the AHI remains above 15, discontinuation of CPAP could be considered because of the potential for harm.[146]

Adaptive Servoventilation. *Adaptive servoventilation* (ASV) is a form of positive airway pressure specifically designed to alleviate CSA with or without CSR. For CSR-CSA, ASV is analogous to a cardiac pacemaker: When it detects a central apnea, it provides intermittent pressure support ventilation on top of expiratory positive airway pressure; when it detects that the patient is breathing spontaneously, the inspiratory assist is turned off. In heart failure patients with CSR-CSA, it causes a greater fall in the AHI than CPAP, BPAP, and supplemental O_2.[147–149]

The *minute-ventilation–targeted ASV* (ASVmv) device, whose algorithm targets minute ventilation to alleviate CSA, has been assessed in the multicenter international randomized controlled *Treatment of Sleep-Disordered Breathing with Predominant Central Sleep Apnea by Adaptive Servo Ventilation in Patients with Heart Failure* (SERVE-HF) trial.[102] It enrolled 1325 patients with heart failure and reduced ejection fraction of 45% or less (HFrEF) on optimal heart failure therapy and with an AHI of 15 or more events per hour. For those who were randomized to usual care or usual care plus ASVmv, ASVmv reduced the AHI from 31.2 at baseline to 6.6, indicating reasonably good control of CSA. However, over the median 31 months of follow-up, adherence to ASVmv was only 3.7 hours per night, and the dropout rate from ASVmv was high (29%), whereas 16% of patients in the control group crossed over

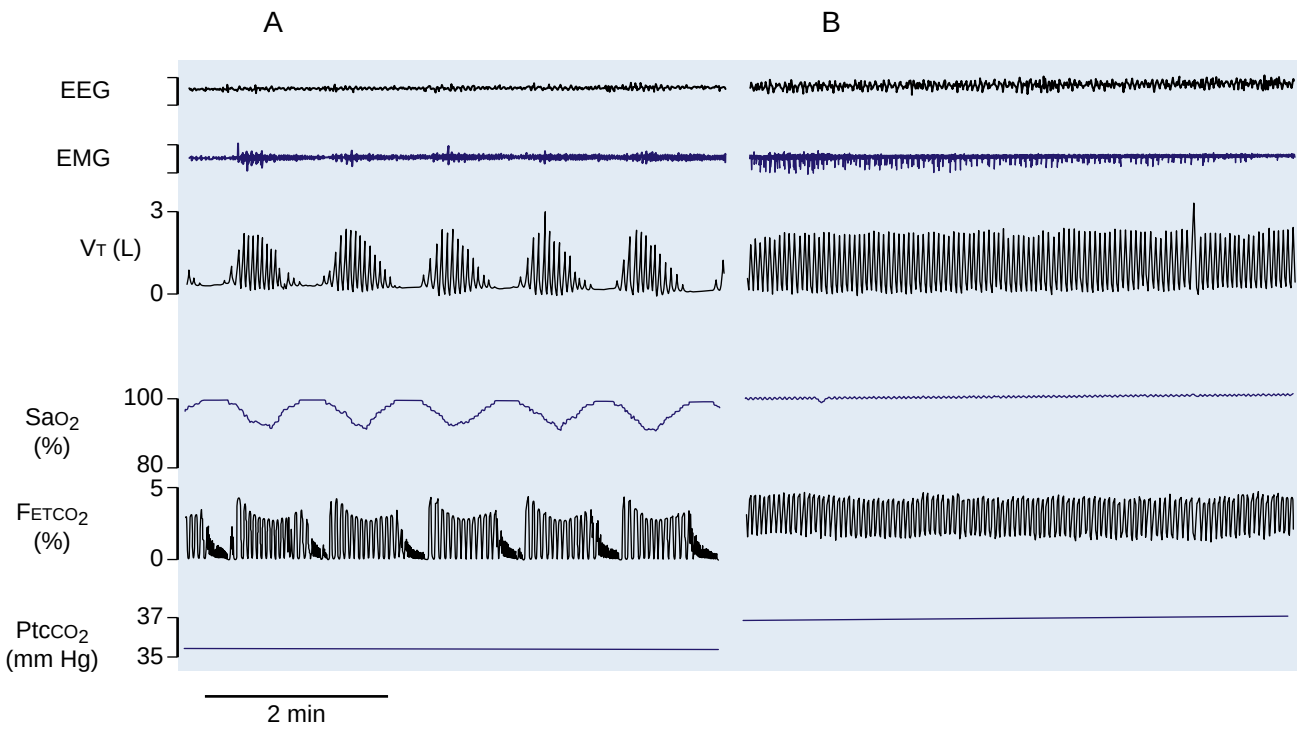

Figure 121.8 Inhaled carbon dioxide abolishes Cheyne-Stokes respiration. Polysomnographic recordings are shown from a patient with recurrent central apneas associated with Cheyne-Stokes respiration during stage 2 sleep while breathing air (A) and 1% carbon dioxide in air (B). Note abolition of both central apneas on the tidal volume (VT) trace and of recurrent decreases in arterial oxygen saturation (Sao_2) during carbon dioxide inhalation, in association with an increase in transcutaneous $Paco_2$ ($Ptcco_2$) of 1.6 mm Hg. EEG, electroencephalogram; EMG, submental electromyogram; FETCO, end-tidal carbon dioxide concentration. (From Lorenzi-Filho G, Rankin F, Bies I, et al. Effects of inhaled carbon dioxide and oxygen on Cheyne-Stokes respiration in patients with heart failure. *Am J Respir Crit Care Med.* 1999159:1490–1498.)

to some form of positive airway pressure therapy. The intention-to-treat analysis revealed no difference between the two groups in the composite primary outcome of all-cause mortality, cardiac transplantation, implantation of a ventricular assist device, resuscitation after sudden cardiac death, lifesaving shock, or unplanned hospitalizations for worsening heart failure (hazard ratio for the ASVmv group of 1.1; 95% confidence interval [CI], 1.0 to 1.3; $P = 0.10$). However, more concerning were the 28% and 34% increased all-cause and cardiovascular death rates in the ASVmv group (hazard ratio of 1.3; 95% CI, 1.1 to 1.6; $P = 0.01$; and hazard ratio of 1.3; 95% CI, 1.1 to 1.7; $P = 0.006$, respectively).

The cause of the excessive death rate in the ASVmv group was sudden cardiac death. The greatest risk for death in the ASVmv group was observed in those with a lower LVEF of 30% or less and those with a higher proportion of CSR related to their CSA. However, the cause of this increased rate of sudden death has not been identified.[150] Possibilities include that CSA is compensatory in heart failure and its reversal is harmful,[135] that positive intrathoracic pressure generated by ASVmv may have compromised cardiac output due to reduced preload, or that inspiratory pressure support generated by ASVmv may have induced hyperventilation, hypocapnia, alkalosis, and hypokalemia with an increased propensity for arrhythmias, particularly in those taking diuretics. Because of relatively poor adherence to the study protocol, a subsequent on-treatment analysis was performed and confirmed that use of ASVmv was associated with a higher cardiovascular death rate.[151] These trial results indicate that ASVmv is contraindicated to treat CSA in patients with HFrEF.

In a subsequent ancillary study of SERVE-HF involving a subset of 312 patients, several secondary physiologic outcomes were examined. These included echocardiographic measures of LVEF, LV diastolic function and dimensions, right ventricular dimensions, and biomarkers, including N-terminal pro–brain natriuretic peptide, troponins T and I, C-reactive protein, tumor necrosis factor-α, and creatinine. ASVmv had no significant effect on any of these secondary outcome variables compared to the control group.[102]

A second randomized trial of usual care versus usual care plus ASVmv, the *Cardiovascular Outcomes with ASV Therapy in Heart Failure* (CAT-HF) trial, was performed in patients hospitalized with acute decompensated heart failure on optimal therapy and sleep-disordered breathing with an AHI of 15 or greater.[152] It included patients with heart failure and either reduced or preserved ejection fraction and did not distinguish between CSA and OSA. The primary end point was the global rank composite of death, cardiovascular hospitalizations, and 6-minute walking distance. However, this study was halted prematurely after publication of the SERVE-HF trial results because the same ASVmv device was being tested, and there was overlap in the study populations. At that time, only 126 patients had been enrolled and, during the 6-month follow-up period, adherence to ASVmv was relatively poor at 2.7 hours per night. There was no difference in the primary end point between

the control and ASVmv groups. In accordance, these data do not support the use of ASVmv to treat CSA in patients with acute decompensated heart failure with either reduced or preserved ejection fraction.

Supplemental Oxygen. Supplemental oxygen reduces central apnea–related dips in Pa_{O_2}, thereby reducing peripheral chemoreceptor stimulation. Reduced chemoreceptor responsiveness decreases loop gain and lessens the chance of ventilatory overshoot and dips in Pa_{CO_2} below the apnea threshold.[153] Where Pa_{CO_2} has been measured during supplemental oxygen administration, Pa_{CO_2} was reported to increase when the AHI was markedly reduced[154] but did not change when the AHI only decreased marginally,[155] indicating that one of the mechanisms through which oxygen attenuates CSR-CSA is via dampening ventilation and raising Pa_{CO_2} above the apnea threshold.

Small randomized trials, from one night to 1 month in duration, have demonstrated that nocturnal oxygen reduces the AHI by approximately 50% in heart failure patients with CSR-CSA.[154,156–158] However, the effects of oxygen on physiologic and clinical outcomes have been inconsistent. Staniforth and colleagues[157] found that supplemental oxygen for 1 month reduced overnight urinary norepinephrine excretion but had no effect on daytime plasma norepinephrine, brain natriuretic peptide, neurocognitive function, sleepiness, or quality of life. In another randomized trial, Andreas and colleagues[156] reported that administration of nocturnal oxygen for 7 days to 22 heart failure patients improved peak oxygen consumption and ventilatory efficiency but had no effect on quality of life. Arzt and colleagues[159] allocated 10 consecutive patients to nocturnal oxygen and the next 16 consecutive patients to CPAP at 8 to 10 cm H_2O for 3 months. Both CPAP and oxygen reduced the AHI by 67%, but only CPAP improved ventilatory efficiency and LVEF. Neither intervention had any effect on peak exercise oxygen consumption. The Home Oxygen Trial[160] randomized 51 patients to receive or not to receive supplemental oxygen over 1 year. Those who received oxygen had a significant reduction in severity of CSR-CSA and a significant improvement in quality of life as measured by the specific activity scale compared to the control group. However, there was no difference in cardiac event rates between the groups.

Although oxygen attenuates CSR-CSA in patients with heart failure and can reduce nocturnal sympathetic activity, there is no consistent evidence that it improves cardiovascular function or clinical outcomes in such patients.[161] Moreover, administration of supplemental oxygen to patients with heart failure could cause hyperoxia and, by doing so, induce oxidative stress that can exert adverse hemodynamic effects, such as raising vascular resistance, blood pressure and left ventricular filling pressure, and lowering cardiac output.[162–164] Therefore, there is insufficient evidence to support the use of oxygen to treat CSR-CSA in patients with heart failure. In consequence, larger long-term trials are required to determine whether oxygen improves clinical outcomes in patients with heart failure and CSR-CSA.

Respiratory Stimulants. Acetazolamide is a carbonic anhydrase inhibitor that causes a metabolic acidosis that induces a constant stimulus to breathe, thereby raising ventilation and lowering the Pa_{CO_2} apneic threshold.[165] Two small 6-day randomized trials demonstrated modest (from 38–50%) reductions in the AHI in heart failure patients with CSR-CSA in association with reductions in daytime sleepiness and fatigue.[166,167] However, there are concerns regarding acetazolamide related to the promotion of transient elevations in sympathetic nervous activity from the metabolic acidosis, hyperventilation contributing to increased fatiguability, and hypokalemia that could predispose to cardiac arrhythmias.[168] Theophylline is an adenosine antagonist that stimulates central respiratory drive and augments cardiac contractility. In a 5-day randomized trial involving 15 patients with heart failure and CSR-CSA, theophylline reduced the AHI but did not improve LVEF.[169–171] However, although once used widely for therapy of acute heart failure, theophylline is no longer used for this purpose because it increases the risk of cardiac arrhythmias and sudden death.[172,173] In consequence, neither of these agents can be recommended for therapy of CSR-CSA because their long-term safety and efficacy remain to be demonstrated.

Carbon Dioxide. Increasing Pa_{CO_2} above the apnea threshold either by inhalation of CO_2 or the addition of dead space abolishes CSR-CSA instantaneously in patients with heart failure, as illustrated in Fig. 121.8.[174] However, there is no evidence that raising Pa_{CO_2} through these means provides any clinical benefits. Moreover, because CO_2 increases sympathetic nervous activity and disrupts sleep[175] and, because no long-term studies have demonstrated its safety or clinical efficacy, it cannot be recommended for therapy of CSR-CSA.

Transvenous Phrenic Nerve Pacing. Modulation of ventilation by unilateral transvenous phrenic nerve stimulation via the superior vena cava is under investigation as a treatment for CSR-CSA on the premise that activation of the diaphragm during central apneas will improve cardiac function. A 3-year open-label, multicenter, randomized controlled trial was designed to explore the therapeutic efficacy and safety profile over a 24-month period of overnight intermittent phrenic nerve stimulation. Efficacy was defined as a 50% or greater reduction in the AHI, which was achieved in 93% of the treatment group at 24 months.[176] The actual change in AHI was from 47 per hour at baseline to approximately 16 per hour at 24 months, indicating that a significant proportion of subjects had residual CSA. Ten percent of subjects sustained serious adverse events related to the phrenic stimulator, which included mainly complications from the implantation procedure. All these events resolved readily, and therefore the device was deemed to have an acceptable safety profile. Further studies will be necessary to evaluate whether such an intervention improves clinically important outcomes.

Central Sleep Apnea Associated With Cerebrovascular Disease

Nonhypercapnic CSA has been observed in patients with cerebrovascular accident, where its prevalence is approximately 10–15%.[177,178] Its pathogenesis and clinical features have not been well described. However, several studies have found no relationship between the vascular territory or type of stroke and the presence of CSA.[177–179] In some patients, CSA appears in a CSR-CSA pattern. In

such cases, CSR-CSA is associated with left ventricular systolic dysfunction[180] or left atrial enlargement, bilateral hemispheric involvement, or greater neurologic disability.[179] These observations strongly suggest that CSR-CSA in patients with stroke is related to either underlying occult cardiac dysfunction or preexisting cerebrovascular disease. A therapeutic approach to CSA in patients with stroke has not been studied in any depth, although a small observational study demonstrated short-term efficacy of ASV in alleviating CSA.[181] Thus, the implications of finding CSR-CSA in patients after stroke is that one should investigate for evidence of left ventricular systolic dysfunction to evaluate candidacy for ASV. However, there is currently insufficient evidence to recommend a therapeutic approach to CSR-CSA or to CSA of any kind in patients after a stroke.

Central Sleep Apnea Associated With Atrial Fibrillation

Among patients with heart failure, atrial fibrillation is associated with increased odds of having CSR-CSA.[98] Among patients with CSA but without heart failure, cerebrovascular disease, or renal disease, atrial fibrillation was observed in 27%.[182] Both CSR-CSA and CSA are predictors of incident atrial fibrillation risk in older men (>65 years) without heart failure.[183] The reason for the strong association between CSA and atrial fibrillation was not identified. However, the most likely possibility is that atrial fibrillation predisposes to CSA by mechanisms similar to those that predispose patients with heart failure to CSR-CSA: atrial fibrillation lowers cardiac output and raises pulmonary venous pressure that could trigger hyperventilation and hypocapnia through stimulation of pulmonary vagal irritant receptors.

Central Sleep Apnea Associated With Renal Failure

CSA has also been described in those with end-stage renal disease.[184,185] Prevalence rates are difficult to estimate because many of the studies are small. In earlier studies, the prevalence of CSA was reported to be 7–75%.[184–187] In a more recent study of 89 patients with stage 4 or 5 chronic kidney disease and 75 with end-stage renal disease on hemodialysis, CSA was uncommon, and the median central apnea index was 0 to 0.7 per hour.[188] However, the combination of obstructive, central, and mixed events is frequently reported in hemodialyzed patients with end-stage renal disease.[186,187,189] Predictors for CSA include atrial fibrillation, an increased cardiothoracic ratio on a chest radiograph, and low $Paco_2$, all of which suggest mechanisms for CSA in renal disease similar to those in heart failure and atrial fibrillation, including fluid overload.[185]

With respect to fluid overload, in end-stage renal failure, greater total-body extracellular fluid and neck, thorax, and leg fluid volumes were demonstrated in those with sleep apnea compared to those without.[190] Nonrandomized studies showed that one night of CPAP alleviated CSA in 6 patients with end-stage renal disease[187] and that conversion from conventional thrice-weekly hemodialysis to more intense 7 days per week of nocturnal hemodialysis in 14 patients with a mixture of obstructive and central respiratory events reduced all types of events in association with an increase in $Paco_2$.[186] In addition, among 15 patients with end-stage renal failure on thrice-weekly hemodialysis, fluid removal by ultrafiltration on a nondialysis day attenuated OSA and CSA with a 36% overall reduction in AHI. The improvement was not associated with any changes in blood urea concentration or venous $Paco_2$, indicating that this effect was due to fluid removal per se and not to a change in degree of uremia. Furthermore, the reduction in the AHI correlated with reductions in total-body extracellular fluid and neck and thorax fluid.[191] This suggests that greater fluid removal during nocturnal hemodialysis compared with conventional hemodialysis contributed to alleviation of OSA and CSA through reductions in overnight fluid shifts into the neck, in the case of OSA, and into the lungs, in the case of CSA.[110,186,192]

Central Sleep Apnea Associated With Acromegaly

Acromegaly is associated with OSA and CSA. The prevalence of CSA in small studies has ranged from 5–20% of patients with acromegaly.[193–195] In one small study, the $Paco_2$ was either low or normal and was associated with increased ventilator responsiveness to CO_2 and hypoxia, as well as to higher growth hormone and insulin-like growth factor-1 levels compared to patients with OSA or no sleep apnea. Slopes of the hypercapnic ventilator responses were related to growth hormone and insulin-like growth factor-1 levels, suggesting that these substances have effects on breathing control. Moreover, the severity of CSA was directly related to the level of insulin-like growth factor-1and to CO_2 responsiveness.[195] Thus, the pathogenesis of CSA in acromegaly appears similar to other forms of nonhypercapnic CSA.

Clinical features of CSA in acromegaly have not been well characterized but appear to be similar to symptoms of OSA, including loud snoring and excessive daytime sleepiness.[195] In small nonrandomized studies involving patients with acromegaly and sleep apnea, medical treatment of acromegaly by hormonal control was associated with reductions in the AHI that involved central and obstructive events.[193,196] Similarly, in another nonrandomized study involving six patients with acromegaly and a mixture of OSA and CSA, treatment of acromegaly by transsphenoidal adenomectomy alleviated OSA and CSA, but effects on symptoms of sleep apnea were not assessed.[197] These results suggest a causative role of acromegaly for CSA and OSA.

Central Sleep Apnea Associated With High Altitude (See Chapter 105)

At high altitude, hypobaric hypoxia provokes hyperventilation that causes $Paco_2$ to fall recurrently below the apnea threshold during sleep.[198] Although high-altitude CSA is observed in natives of high and low altitudes, not everyone is susceptible.[199] Alterations in cerebral blood flow and cerebrovascular reactivity to $Paco_2$ are likely to be important pathophysiologic mechanisms in high-altitude CSA.[200,201] Men are more likely to develop CSA at high altitude than women for unknown reasons, just as they are more prone to other forms of nonhypercapnic CSA.[202]

In lowlanders, there is a progressive increase in the frequency of central events and a reduction in the periodic breathing cycle length with increasing altitude from 2400 to 7546 m.[203–205] The progressive reduction in cycle length

is probably due to increasing cardiac output and therefore reduced lung-to-chemoreceptor circulation time. Over time, as individuals acclimatize to high altitude, CSA attenuates.[206,207] This is due mainly to metabolic compensation for respiratory alkalosis; over 2 to 3 days, bicarbonate moves out of the cerebrospinal fluid and is excreted by the kidneys in association with renal retention of H^+ ions, acidifying the arterial blood and cerebrospinal fluid, causing pH to move toward normal. As a consequence, the difference between $Paco_2$ and the apnea threshold increases, causing periodic breathing to dampen over time.[165] Complaints related to CSA at high altitude include poor quality sleep, nocturnal dyspnea, morning headaches, and impaired cognition.[208–211]

Return to low altitude quickly reverses high-altitude CSA. Specific therapies for high-altitude CSA include supplemental oxygen that causes $Paco_2$ to rise above the apnea threshold with immediate reversal of CSA and subjective improvement in sleep quality.[210] Respiratory stimulants can alleviate high-altitude CSA. For example, a randomized trial involving 30 subjects with high-altitude CSA demonstrated virtual elimination of CSA by either acetazolamide or theophylline. However, 60% of subjects on acetazolamide reported paresthesias and altered taste, and 70% of subjects receiving theophylline complained of palpitations.[212] In a randomized trial involving 33 subjects at high altitude, the sedative medication temazepam caused a modest reduction in severity of CSA.[213] Although no data on mechanism of action were provided, the proposed mechanism of action of this sedative is that, by reducing the frequency of arousals from sleep, it prevents abrupt hyperventilation and consequent fall in $Paco_2$ below the apnea threshold.

A comparative study of ASVmv versus supplemental oxygen or no treatment was performed in 18 nonacclimatized subjects with high-altitude CSA at 3800 m. Oxygen eliminated CSA, whereas the effect of ASVmv on CSA did not differ from no treatment.[214] The likely reason for this is that ASVmv requires several seconds to adjust and implement pressure support, which works well in CSR-CSA, where the cycle length is long, but not as well in high-altitude CSA, where the cycle length is shorter. In a recent randomized double-blind sham controlled cross-over study in 19 subjects with high-altitude CSA, a portable expiratory resistance mask containing a small amount of dead space designed to elevate the $Paco_2$ achieved a 49% reduction in the AHI.[215] At present, although firm recommendations cannot be given regarding the pharmacologic treatment of high-altitude CSA, it seems most logical to use supplemental oxygen and/or acetazolamide because they are routinely used at high altitude to correct hypoxemia and to prevent acute mountain sickness and high-altitude pulmonary edema, respectively.

Central Sleep Apnea Associated With Opioid Use

Both OSA and CSA have been described in patients using opioids.[216–218] Unfortunately, little is known about the pathophysiology of opioid-induced CSA. There are at least two physiologic effects of opioids that could predispose to CSA. First, opioids activate endogenous opioid receptors in areas of the brain that inhibit inspiratory drive and cause respiratory depression, particularly in the pre-Botzinger complex of the medulla.[219] Exaggeration of such inspiratory depression at the onset of sleep could therefore cause central apneas and hypopneas. If so, then one would expect it to happen in the presence of hypercapnia. However, when arterial blood gas analyses have been performed in awake subjects with methadone-related CSA, $Paco_2$ has generally been within normal limits and bore no relationship to the presence or severity of CSA.[217,220–222] In consequence, opiate-induced CSA appears not to be associated with hypercapnia and respiratory depression per se but, rather, appears to fall into the nonhypercapnic category.

Second, opioids also cause arterial and venous dilation in the pulmonary and systemic circulation via stimulation of histamine receptors.[223,224] This venous dilating effect causes peripheral venous pooling and, in patients with acute cardiogenic pulmonary edema, this reduces left ventricular filling pressure and pulmonary congestion.[225] It is therefore possible that chronic opioid use could cause chronic venous pooling in the capacitance vessels of the splanchnic circulation and legs. If so, there may be substantial rostral fluid shift upon lying down at night that could accumulate in the lungs and stimulate vagal irritant receptors that would provoke hyperventilation and a fall in $Paco_2$ toward the apnea threshold similar to that described in patients with heart failure and CSA.[110,226] However, such a mechanism remains speculative.

The severity of CSA in those on narcotics may vary from night to night depending on the dosage: The higher the dose is, the higher the AHI.[217,227,228] The prevalence of CSA among opioid users remains uncertain because of a lack of prospective studies. In retrospective studies of opioid users referred to sleep clinics, the prevalence of isolated CSA ranged from 14–30%.[217,227,229,230]

Central nervous system symptoms of opioids include dizziness, nausea, neurocognitive impairment, and hypersomnolence.[231] The extent to which these symptoms are due to opioid use or to CSA is difficult to determine. Chronic opioid use can increase the risk of sudden death, possibly due to cardiac arrhythmias, but there is no evidence to date that this is related to CSA or other sleep-related breathing disorders.[232]

In patients with opioid-induced CSA, opioid withdrawal resolves or reduces the severity of CSA and daytime hypersomnolence.[233,234] However, opioid withdrawal is often not feasible because of addiction or chronic pain. CPAP, BPAP, and ASV have been tested for therapy of opioid-induced CSA. A systematic review has shown CPAP to be largely ineffective and BPAP with or without supplemental oxygen to be effective in 62% of patients.[235] ASV has been evaluated in two small prospective studies. In the first study, ASV was assessed over a single night and was highly effective (AHI 50.3 ± 22.2 to 2.5 ± 3.5 events/hr).[236] In the second study, performed over a 3-month period, ASV was also effective in reducing the median AHI from 32.5 to 5.8 events per hour, although the longer-term adherence was poor at 49%.[237] Because of the paucity of data on effectiveness of various interventions, randomized trials are needed to determine the impact of treatments on opioid-induced CSA and related symptoms.

Complex Sleep Apnea

Complex sleep apnea was originally described as the emergence of CSA in patients with OSA during or after

initiation of CPAP therapy (i.e., CPAP-emergent CSA). Subsequently, the emergence of CSA in patients with OSA has also been described after maxillomandibular advancement surgery,[238,239] application of mandibular advancement devices,[240] tracheostomy,[241] and nasal surgery[242] (i.e., *treatment-emergent CSA*). There is, however, controversy as to the definition of complex sleep apnea and whether it is a distinct entity. The term complex sleep apnea has also been used to describe persistence of only central events after treatment of a combination of CSA, mixed, and OSA (i.e., *treatment-persistent CSA*). Therefore, a clear definition of complex sleep apnea has yet to emerge.[243,244] For the purposes of this chapter, the term complex sleep apnea includes treatment-emergent and treatment-persistent CSA.

The main postulated mechanism of CSA emergence upon initiation of CPAP and the other therapies mentioned above in patients with OSA is that relief of upper airway obstruction in someone with a high central respiratory drive facilitates augmented ventilation that reduces $Paco_2$ below the apneic threshold.[243,245]

During CPAP titration in patients with OSA with and without heart failure, the prevalence of treatment-emergent CSA ranges from 5–20%.[245–250] After 2 to 3 months of acclimatization to CPAP, treatment-emergent CSA dissipates in greater than 50% of subjects without heart failure.[246,248] A gradual reduction in treatment-emergent CSA has also been described over 6 months posttracheostomy.[251]

In unselected sleep cohorts, risk factors identified for the development of treatment-emergent CSA were poorer sleep efficiency, hypertension, coronary artery disease, heart failure, opioid use, and more severe OSA.[246,248,252] In the heart failure population, predictors for development of treatment-emergent CSA included older age, lower $Paco_2$, poorer New York Heart Association class, less diuretic therapy, and increased ventilatory responsiveness to CO_2.[250] However, up to one-third of those with treatment-emergent CSA do not have any of these risk factors.[253]

In most patients, no specific treatment is necessary for treatment-emergent CSA because these events may dissipate over 2 to 3 months with ongoing CPAP use. Furthermore, even in those with persistent treatment-emergent CSA, daytime sleepiness is usually alleviated.[246] For those in whom complex CSA persists despite CPAP or other therapies, there is no available information on long-term consequences.

Treatments for persistent treatment-emergent CSA include BPAP, ASV, oxygen, and addition of dead space. In most studies, decisions to treat complex CSA were not based on patient symptoms. Studies with BPAP are conflicting, with one study demonstrating an improvement[254] and two studies demonstrating no improvement in CSA.[255,256] A retrospective study evaluating the addition of 50 to 200 mL of dead space via a nonvented mask to a standard CPAP unit reported abolition of CSA.[257] In retrospective studies, ASV was reported to abolish treatment-emergent CSA in 79–100% of patients on titration studies.[258–260] In small prospective randomized trials, treatment of treatment-emergent CSA was abolished by ASV in 97–100% of patients after between 6 and 12 weeks.[250,252,261]

PRIMARY NONHYPERCAPNIC CENTRAL SLEEP APNEA

Idiopathic Central Sleep Apnea

Idiopathic CSA (ICSA) is a form of CSA in which there are central apneas and hypopneas without evidence of cardiovascular diseases or other lesions that might explain their presence. Two large epidemiologic studies reported a prevalence of CSA of 0.4% in men[262] but essentially 0% in women.[263] Because these populations were considered healthy, one can assume that most cases of CSA identified were ICSA. In accordance, ICSA appears to be rare.

Patients with ICSA hyperventilate with low $Paco_2$ during wakefulness and sleep. The tendency to hyperventilate is related to increased responsiveness of the peripheral and central chemoreceptors that increase loop gain and lead to respiratory instability.[89,264,265] Episodes of central apneas and hypopneas during sleep are typically precipitated by an abrupt increase in ventilation usually triggered by an arousal, after which $Paco_2$ drops below the apnea threshold. Their dependence on hypocapnia is illustrated by the observation that increasing the $Paco_2$ either by inhalation of a small concentration of CO_2 or by addition of dead space immediately abolishes this breathing disorder.[266] As in CSR-CSA, central events happen predominantly during NREM sleep with a reduction in frequency or complete cessation of events during REM sleep. Compared to heart failure patients with CSR-CSA, the durations of the hyperpnea and periodic breathing cycle are much shorter due to shorter lung-to-chemoreceptor circulation time and higher stroke volume and cardiac output (see Fig. 121.4).[95]

In some respects, the clinical presentation of ICSA resembles that of OSA. Patients are usually middle-aged or older men who are overweight and report snoring, restless sleep, and possibly excessive daytime sleepiness but more often complain of insomnia. There are no studies on the natural history of this disorder, so its overall clinical significance is difficult to assess. Treatments assessed include the respiratory stimulant acetazolamide,[212,267] which provides a constant stimulus to breathe and therefore reduces fluctuations in ventilation. Studies evaluating acetazolamide have been nonrandomized and produced inconsistent results without careful evaluation of clinical outcomes. Therefore, acetazolamide cannot be recommended as chronic treatment for this disorder at this time.

Because increased arousals and sleep instability can precipitate CSA, sedative medications have been tested to reduce arousability and thereby alleviate ICSA. In a nonrandomized, open-label, 9-week trial of the nonbenzodiazepine gamma-aminobutyric acid receptor agonist zolpidem,[268] the AHI fell by 55% in association with a reduction in arousal frequency and subjective daytime sleepiness. In a one-night randomized trial, the benzodiazepine hypnotic triazolam[269] was also reported to reduce the AHI modestly in association with a reduction in arousal frequency. Because these studies included only small numbers of subjects, much larger randomized studies will be required before more evidence-based treatment recommendations can be made. There are no published studies evaluating the effects of positive airway pressure devices in ICSA.

Key Points

- *Central sleep apnea* (CSA) is characterized by a reduction (hypopnea) or cessation (apnea) of airflow in the face of reduced or absent respiratory effort, respectively. Hypopneas and apneas are caused by reductions in *arterial partial pressure of carbon* dioxide ($Paco_2$) close to (hypopnea) or below (apnea) the apnea threshold during sleep, either because the $Paco_2$ falls or the apnea threshold rises.
- CSA is a heterogeneous disorder, and classification is based on the presence or absence of hypercapnia. There are two major types, hypercapnic and nonhypercapnic.
- Hypercapnic CSA is associated with hypercapnia arising from impaired central respiratory drive or neuromuscular weakness affecting the respiratory muscles, which is exacerbated during the transition from wakefulness to sleep by the withdrawal of the waking drive to breathe and is most prominent in *rapid eye movement* (REM) sleep.
- Nonhypercapnic CSA is associated with normocapnia or hypocapnia that is often associated with augmented central respiratory drive that predisposes to alternating periods of hyperventilation that drive $Paco_2$ recurrently down toward or below the apnea threshold. It is most prominent in non-REM sleep.
- Cheyne-Stokes respiration with CSA, a form of nonhypercapnic CSA most commonly associated with heart failure, is characterized by a waxing and waning pattern of respiration during hyperpnea typically seen during non-REM sleep and is associated with increased mortality risk.
- Complex sleep apnea is a form of CSA that *arises* after treatment of obstructive sleep apnea by continuous positive airway pressure or other interventions (i.e., treatment-emergent CSA) or *persists* after treatment of a combination of central, mixed, and obstructive sleep apnea (i.e., treatment-persistent CSA).
- Treatment of CSA varies depending on the underlying etiology. First-line therapy should target the underlying disorder (e.g., reduce opioid medication or initiate appropriate pharmacotherapies for heart failure). If CSA persists and is associated with symptoms, noninvasive bilevel positive airway pressure should be considered in hypercapnic CSA. In those with nonhypercapnic CSA, positive airway pressure therapies, including adaptive servoventilation, may be effective.

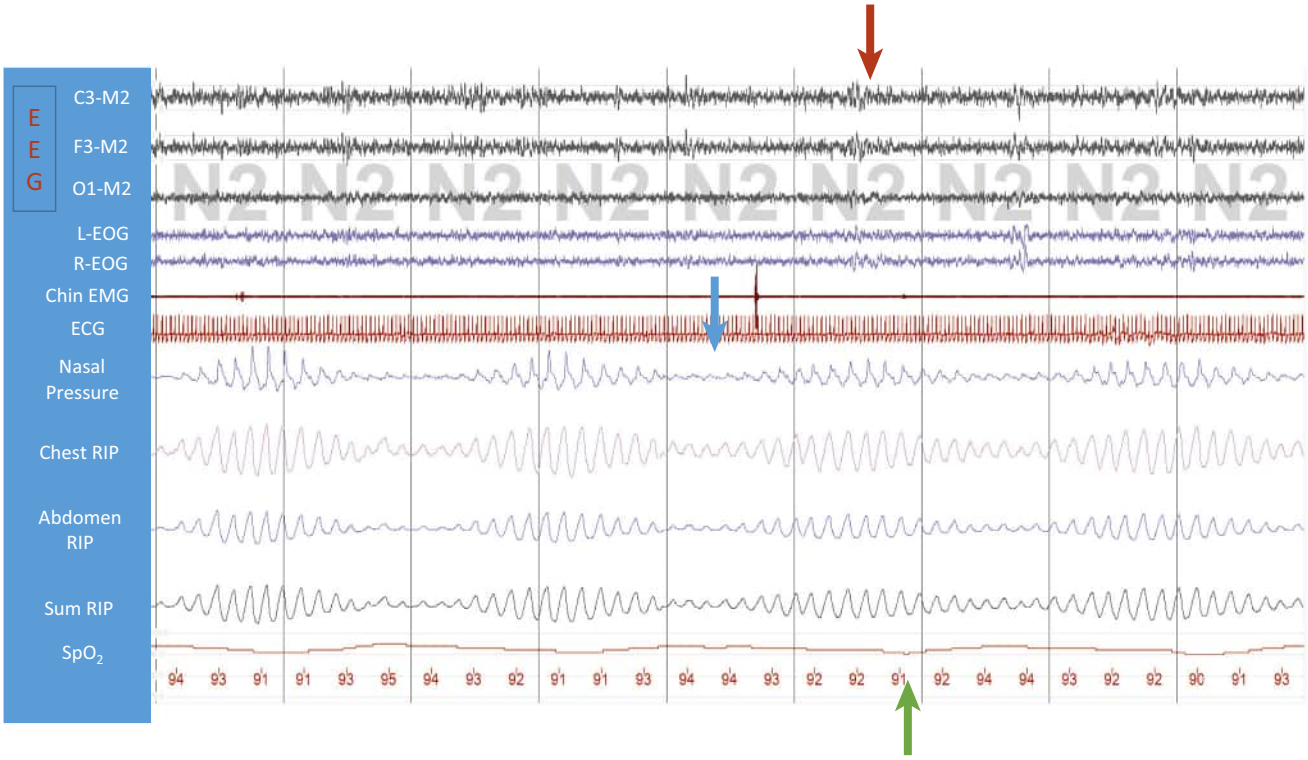
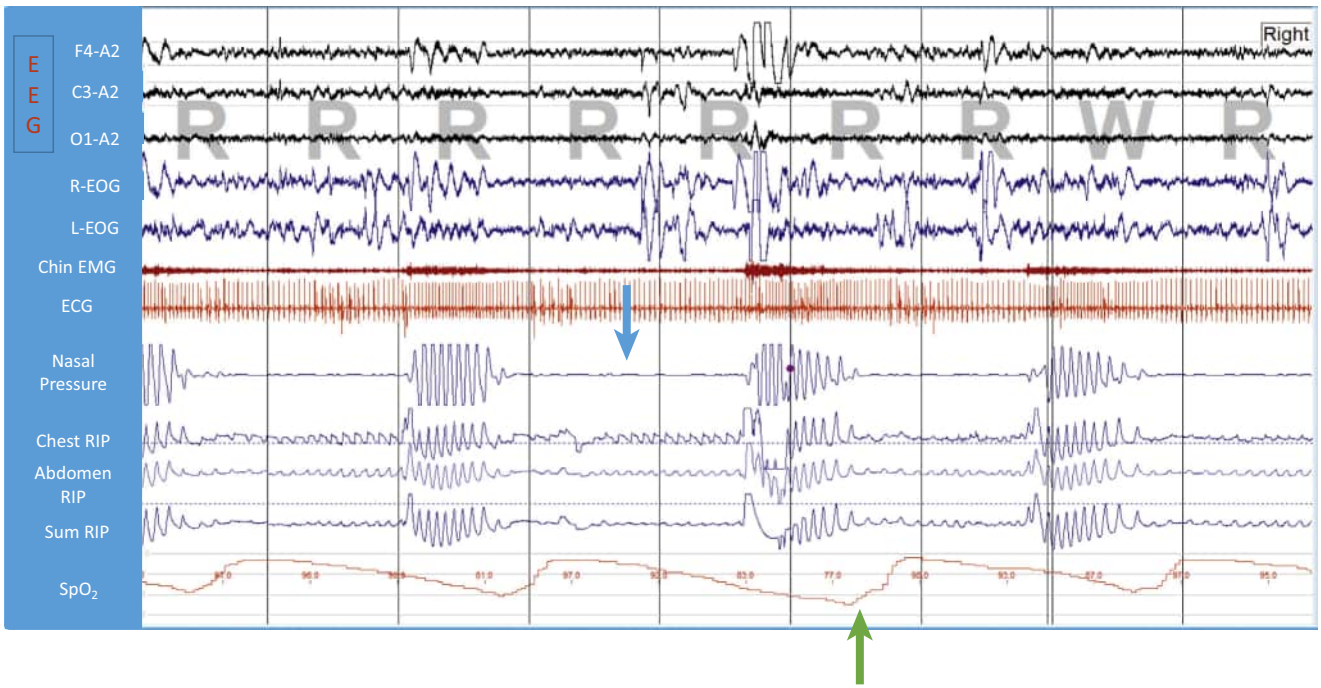
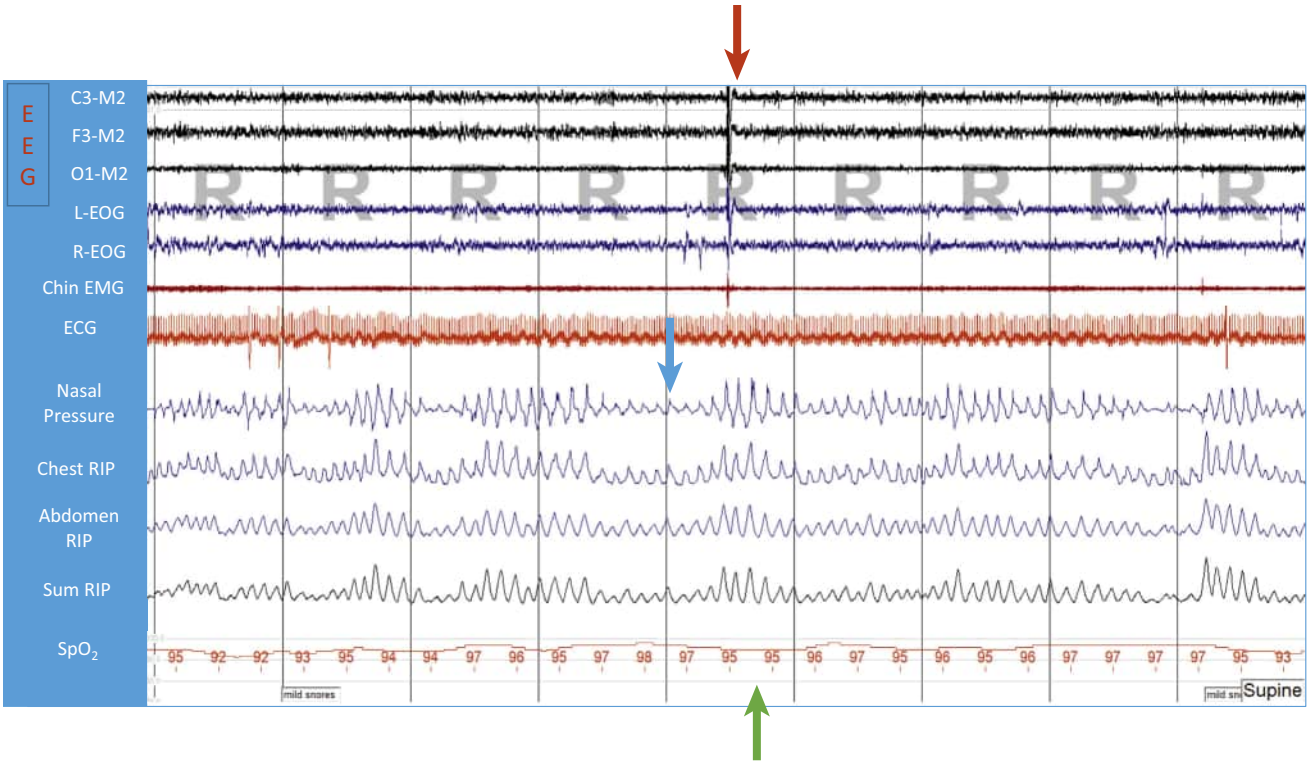
eFIGURE IMAGE GALLERY



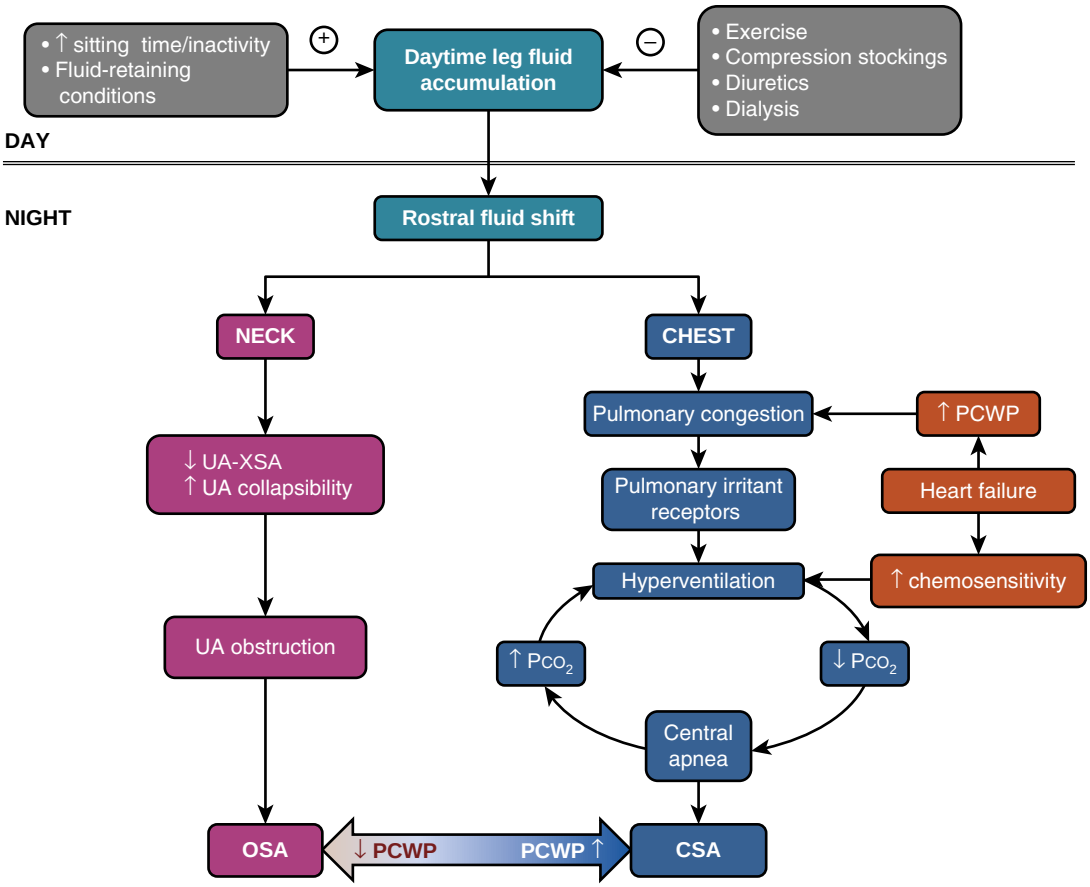
eFigure 121.1 Polysomnographic 5-minute recording of central hypopneas during stage N2 sleep in a Cheyne-Stokes respiration–central sleep apnea pattern. There are peak signal excursion drops of 30% or greater of pre-event baseline as illustrated by the nasal pressure, and there are in-phase motions of the rib cage and abdomen and reduced airflow (*blue arrow*). There is a 3% oxygen desaturation (*green arrow*) and an associated arousal on the electroencephalogram (*red arrow*). ECG, electrocardiogram; EEG, electroencephalogram; EMG, electromyogram; EOG, electrooculogram; RIP, respiratory inductance plethysmography; Spo_2, pulse oxygen saturation.



eFigure 121.2 Polysomnographic 5-minute recording of obstructive apneas during rapid eye movement sleep. There is an absence of airflow as illustrated by the nasal pressure transducer recording (*blue arrow*). There is paradoxical rib cage and abdominal motion. There is associated severe oxygen desaturation with the events (*green arrow*). ECG, electrocardiogram; EEG, electroencephalogram; EMG, electromyogram; EOG, electrooculogram; RIP, respiratory inductance plethysmography; Spo_2, pulse oxygen saturation.



eFigure 121.3 Polysomnographic 5-minute recording of obstructive hypopneas during rapid eye movement sleep. There are peak signal excursion drops of greater than or equal to 30% of pre-event baseline as illustrated by nasal pressure (*blue arrow*). There is paradoxical rib cage and abdominal motion. There is associated oxygen desaturation (*green arrow*) and arousal on the EEG (*red arrow*). ECG, electrocardiogram; EEG, electroencephalogram; EMG, electromyogram; EOG, electrooculogram; RIP, respiratory inductance plethysmography; Spo_2, pulse oxygen saturation.



eFigure 121.4 The role of overnight rostral fluid shift in the pathogenesis of obstructive and central sleep apnea (OSA and CSA). Overnight fluid shift from the legs to the neck can affect upper airway mechanics and lead to OSA, whereas fluid shift to the lungs can provoke hyperventilation, hypocapnia, and CSA. In addition, the type of apnea can shift from one type to another according to fluid status. Pco_2, partial pressure of carbon dioxide; PCWP, pulmonary capillary wedge pressure; UA, upper airway; UA-XSA, upper airway cross-sectional area. (From White LH, Bradley TD, Logan AG. Pathogenesis of obstructive sleep apnoea in hypertensive patients: role of fluid retention and nocturnal rostral fluid shift. *J Human Hypertens.* 2015;29:342–350.)

INTRODUCTION

Sleep-disordered breathing comprises several entities: *obstructive sleep apnea* (OSA), *central sleep apnea* (CSA), CSA Cheyne-Stokes breathing, and sleep-related hypoventilation, each with specific pathophysiology and therefore specific treatment. OSA treatment is evolving in such a way that identification of endophenotypes of critical closing pressure, loop gain, arousal threshold, and muscle recruitment can be used to develop targeted, personalized therapeutic approaches. The chapter is mainly focused on the options for treatment of OSA.

CSA is characterized by temporary failure of breathing rhythm generation (from levels of arterial *partial pressure of carbon dioxide* [P_{CO_2}] falling to less than the apneic threshold) or lack of respiratory effort during cessation of air flow. CSA treatment is targeted by reducing the delta gap and stabilizing a high loop gain system. CSA, including treatment, is covered in depth in Chapter 121. Finally, sleep-related hypoventilation comprises a group of disorders resulting in hypercapnia and hypoxemia during sleep resulting from alveolar hypoventilation, neuromuscular disease, and/or primary pulmonary disease, with therapies aimed at addressing sleep-related hypercapnia and hypoxemia (see also Chapter 45).

An understanding of the physiologic basis of sleep breathing disorders is only one aspect of a more global understanding of which therapy is best suited for a given individual; patient preference, motivations to engage in treatment, social determinants of health (i.e., spousal support, stable housing, occupation requiring frequent travel), and history of compliance are also important considerations in selecting the most effective therapy.

OBSTRUCTIVE SLEEP APNEA

The most common sleep disorder the pulmonologist will be asked to evaluate in the outpatient setting is suspected OSA. Objective sleep testing should be obtained before initiation of any therapy for OSA to facilitate decision making about the most appropriate treatment option for an individual, which may include alternatives to *positive airway pressure* (PAP).[1] Discussions with patients with a new diagnosis of sleep apnea should include education about pathophysiology relevant to their comorbidities (i.e., sympathetic activation and the association with hypertension), symptoms (i.e., nocturia or daytime sleepiness), consequences of not engaging in treatment (i.e., risk of major adverse cardiac events), and treatment options available. For providers, a primary goal is to identify the therapeutic option the patient is most likely to engage with long term, to facilitate a shared decision-making process with patients when multiple therapies are appropriate, and to educate patients on the importance of behavioral changes in their success with chronic disease management.

Machine learning is gaining traction in the realm of predictive analytics for sleep medicine. The ability to identify patients who are most likely to adhere to any given therapy and those least likely to comply (i.e., refill a medication or apply a *continuous positive airway pressure* [CPAP] mask nightly) is critically important; one will require lesser resource intensity to achieve adherence with treatment, and the other will require greater engagement or should be considered for definitive treatment (i.e., maxillomandibular advancement). Data sources for deep learning models include electronic health records (e.g., comorbidities, medication refill records, demographics, health care use rates), nonmedical wearable devices (e.g., activity trackers or other applications with patient-generated data), sleep testing databases to identify patterns of upper airway obstruction and sleep disruption, genetic databases, and therapeutic databases (i.e., PAP manufacturers).

Selection of an initial therapy to treat OSA should be viewed as nonbinding. When one approach fails, others are often possible. Combination therapy is not uncommon (e.g., simultaneous use of a PAP device and an oral appliance), and most therapy options are not mutually

exclusive (e.g., surgical treatment does not preclude the use of PAP). Multiple therapies may be acceptable first-line treatments, and this approach should be tailored to the individual patient as much as possible. One such approach to thinking about therapeutic options is outlined in Figure 122.1.

NONSURGICAL OPTIONS

Numerous nonsurgical therapies are available for consideration in the treatment of OSA (Fig. 122.2), although treatment should be personalized as much as possible. Not all treatment options are appropriate for all patients with OSA. Factors to consider in the selection of treatments include severity of sleep apnea, patient preference (with emphasis on long-term adherence), urgency of the intervention (CPAP is immediate vs. 3 months to complete oral appliance evaluation, fabrication, and adjustments), presence and condition of dentition, patency of nasal air flow, comorbidities (e.g., reduced ejection fraction heart failure), medications (i.e., opioids or other medications that suppress ventilatory drive), and likelihood of engaging in chronic disease management (i.e., will they be able to make behavioral modifications to adhere to prescribed nightly treatment). Understanding the physiologic basis of the patient's sleep-disordered breathing will guide treatment decisions.

Weight Loss

Weight loss interventions through dietary approaches and/or exercise are strongly recommended to be included in the treatment approach of OSA by the American

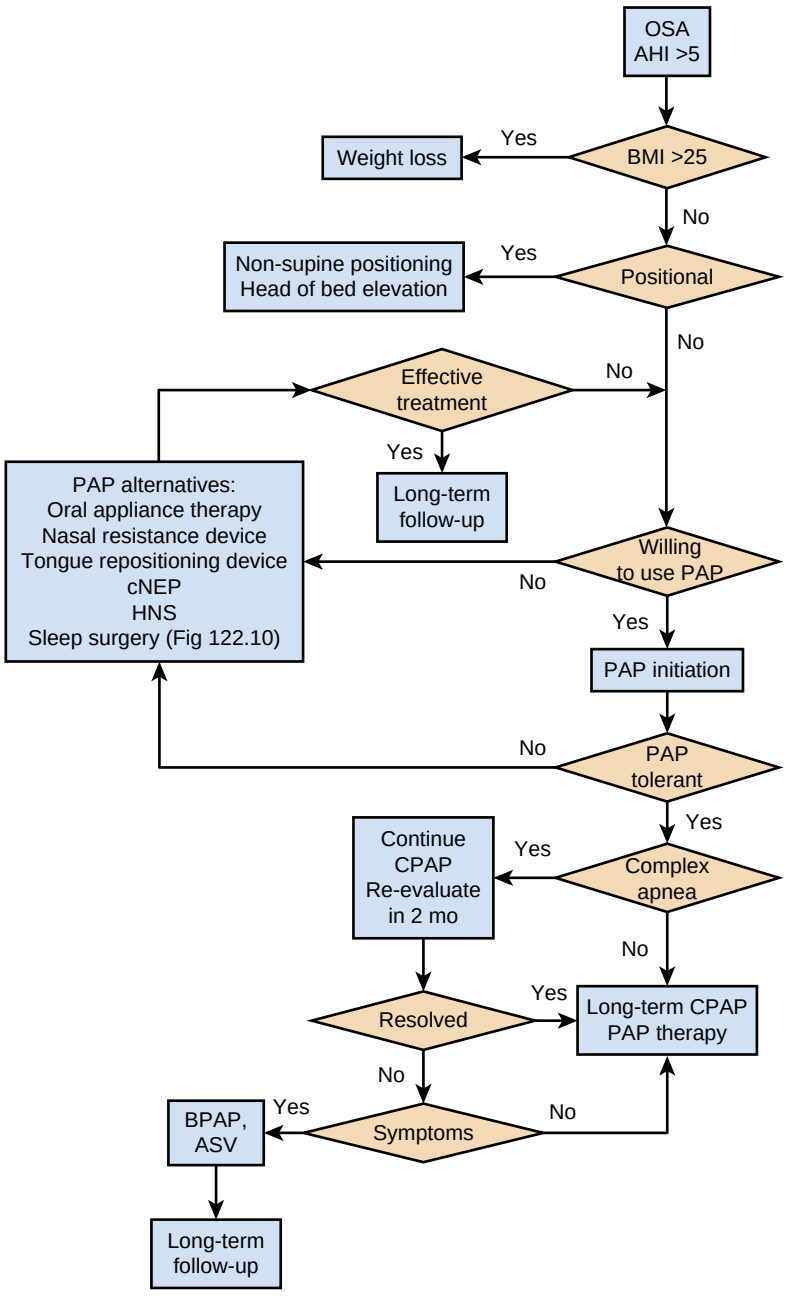

Figure 122.1 Algorithm for selecting appropriate therapies for the treatment of sleep-disordered breathing. An approach to understanding appropriate treatment options for *obstructive sleep apnea* (OSA). Weight loss is always recommended for patients who are overweight or obese. For those with sleep apnea only when supine, positional therapy may be sufficient as a stand-alone intervention. Both weight loss and positional therapy can be recommended in combination with any other treatment for obstructive sleep apnea. *Positive airway pressure* (PAP) remains the most common treatment, and the decision to proceed with PAP versus an alternative is based on a patient's preference. Evaluation of residual events following initiation of therapy facilitates identifying treatment-emergent central events (complex apnea). When these events persist and are associated with symptoms, the PAP mode can be changed to target resolution of these events. When PAP is not accepted or tolerated, treatment alternatives are considered. Some alternatives may be used in combination with any other therapies (i.e., *continuous positive airway pressure* [CPAP] and oral appliance, nasal resistance device and positional therapy). AHI, apnea-hypopnea index; ASV, adaptive servoventilation; BMI, body mass index; BPAP, bilevel positive airway pressure; cNEP, continuous negative external pressure; HNS, hypoglossal nerve stimulation.

Academy of Sleep Medicine,[2] particularly because the *body mass index* (BMI) of patients with OSA in sleep clinics is typically 30 to 40 kg/m^2.[3] At least nine randomized clinical trials support the utility of comprehensive lifestyle intervention compared with no intervention in patients with moderate to severe OSA for overweight and obese persons leading to improvement in the *apnea-hypopnea index* (AHI) and sleepiness symptoms. As such, a program including a reduced-calorie diet, exercise or increased physical activity, and behavioral counseling is strongly endorsed by existing guidelines.[4] Upper airway imaging data suggest that intensive lifestyle intervention or bariatric surgery–related weight loss may exert benefit on OSA pathophysiology by reducing volumes of upper airway soft tissue, including tongue fat.[5,6] Even modest weight loss of 10% observed in epidemiologic studies has been shown to reduce the AHI by 26%.[7] Dose-response relationships are present, so that the effect on AHI reduction is even more pronounced with more substantial weight loss.[8,9] Changes in AHI secondary to weight loss are accentuated in men compared with women.[10,11] Although the etiology of sex-specific differences in weight loss in OSA severity is unclear, a higher proportion of central adiposity in men, including visceral adiposity or hormonal influences on upper airway tone, is a plausible explanation. All lifestyle interventions (diet, exercise, and the combination) reduce the severity of OSA as defined by the AHI by similar magnitudes.[12] Anti-obesity pharmacologic therapy modestly improves OSA symptoms and severity, but benefits should be balanced with risks of these medications.[13] Gastric banding and lifestyle modification provide similar benefit of improving OSA severity and sleep symptoms. However, OSA-specific trials have not been performed to assess the impact of bariatric procedures resulting in greater weight loss, such as gastric bypass and sleeve gastrectomy, on OSA severity, although these surgical procedures may improve glycemic control and quality of life.[13]

Positional Therapy

Positional OSA (POSA) is characterized by breathing events happening exclusively or the majority of time when in the supine posture. Three classification systems are used for POSA: Cartwright, Bignold, and *Amsterdam Positional OSA Classification* (APOC). The Cartwright definition stipulates that POSA requires a 50% or more AHI difference between supine and nonsupine positions.[14] The Bignold criteria require "an overall AHI ≥15, supine AHI at least twice the nonsupine AHI; ≥20 min of sleep in supine and non-supine postures and non-supine AHI <15."[15] The APOC criteria focus on likelihood of benefit from positional therapy by defining three classes of POSA severity dependent on the relationship between the best and worst sleep position (on the basis of the AHI). All APOC classifications require at least 10% of sleep time in the best and worst sleep positions.[16] Patients classified as APOC I have an AHI lower than 5 in their best sleep position. APOC II allows for an AHI of 5 or more in the best sleep position, which should be in a lower AHI severity category than the overall AHI. APOC III is defined by an overall AHI higher than 40 and a 25% decrease from the overall AHI in the best sleep position.[16]

Population-based epidemiologic studies suggest a prevalence of POSA of 75% in middle-aged and older adults with OSA, and exclusively (sleep apnea present in *only* the supine position) in slightly more than one-third of patients with OSA, findings highlighting the importance of this entity.[17] Although POSA can be treated with PAP or oral appliances, positional therapy is effective and an excellent first-line treatment. Adherence to positional therapy has historically been unmeasurable and presumed to be low because of the challenge of remaining nonsupine during

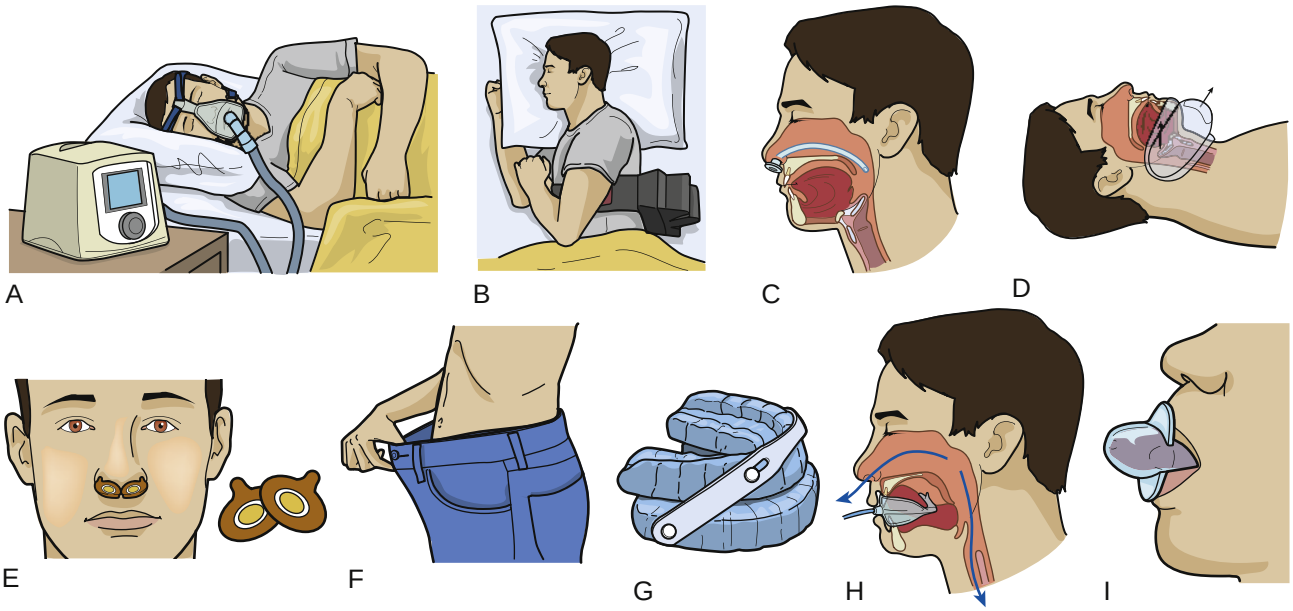

Figure 122.2 Noninvasive methods for treating obstructive sleep apnea. (A) Positive airway pressure, (B) positional devices, (C) nasal bypass, (D) continuous negative external pressure therapy, (E) nasal resistance device, (F) weight loss, (G) mandibular advancement device, (H) oral pressure therapy, and (I) tongue-retaining device.

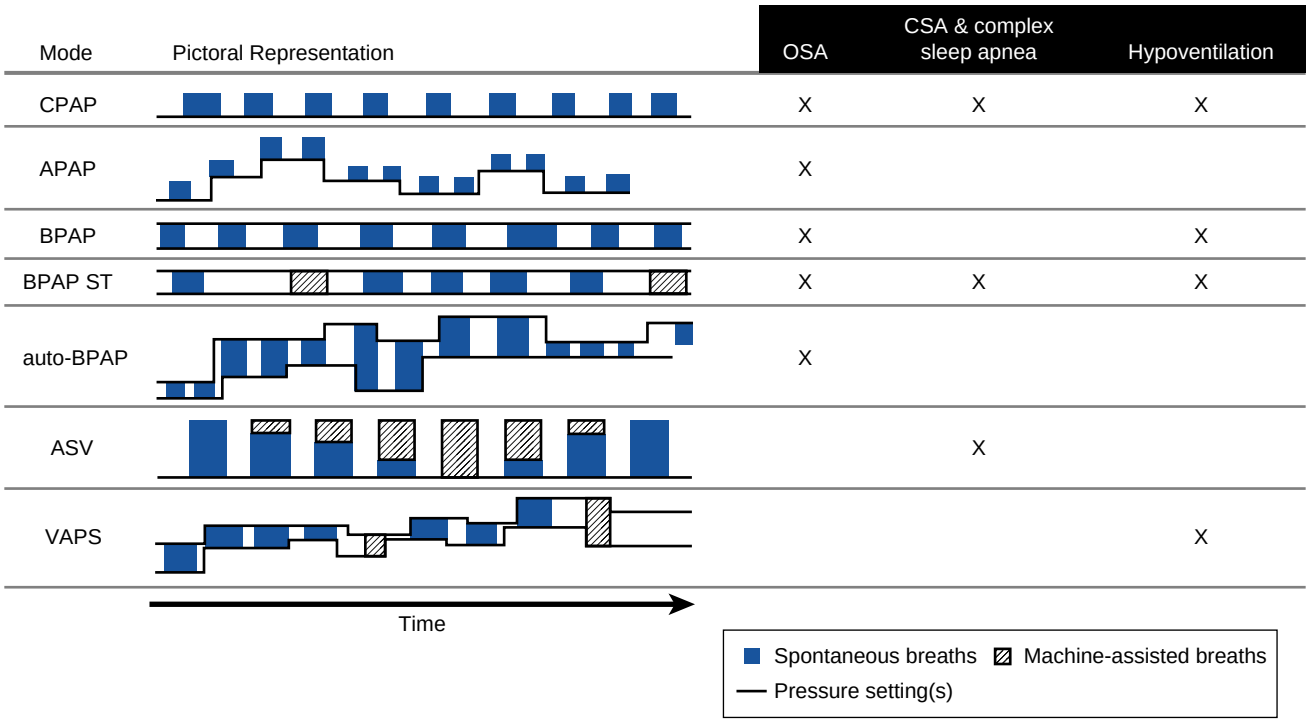

Figure 122.3 Positive airway pressure modes. Representation of different modes of positive airway pressure from simple to more complex, with the x-axis representing time and y-axis pressure. *Blue rectangles* represent patient-initiated breaths, and *black hatched rectangles* represent machine-initiated or assisted breaths. Which modes are appropriate for the three broad categories of sleep-disordered breathing are noted by an X. Continuous positive airway pressure is appropriate for obesity hypoventilation syndrome when moderate to severe obstructive sleep apnea is also present. Pressures are not drawn to scale. APAP, autotitrating positive airway pressure; Auto-BPAP, autotitrating bilevel positive airway pressure; ASV, adaptive servoventilation; BPAP, bilevel positive airway pressure; ST, spontaneous timed; VAPS, volume-assured pressure support. (From Cleveland Clinic Center for Medical Art & Photography © 2020. All rights reserved.)

the unconscious state of sleep; adherence is improved with more recent innovations to create low-profile, comfortable devices that alert users to undesirable positioning.[18] Newer-generation approaches involve attaching a small device to the neck or chest that delivers a subtle vibrating stimulus to serve as negative reinforcement for supine positioning. These devices are associated with high short-term adherence compared with 10% self-reported adherence with the traditional approach of tennis balls sewn into the back of a shirt or use of bulky attachments that prevent rolling onto the back.[18] In addition to nonsupine sleeping, even modest (7.5-degree) head-of-bed elevation is another positional therapy that may result in mild improvements in the AHI irrespective of lateral, prone, or supine position.[19] Head-of-bed elevation may also alleviate gastroesophageal reflux disease symptoms and thereby improve sleep architecture.

Positive Airway Pressure

CPAP serves as a pneumatic splint for the upper airway throughout the respiratory cycle, thus preventing collapse of the soft tissues in the upper airway and improving sleep architecture.[20] Proprietary algorithms have been developed by PAP manufacturers to adjust pressures dynamically according to continuous feedback from these devices. Autoadjusting devices such as *automatic PAP* (APAP) and *auto-bilevel PAP* (auto-BPAP) devices sense changes in flow and resistance in the circuit and, when flow is absent, send test air or sound pulses to determine whether lack of flow is the result of an obstructive or nonobstructive event. Detection of respiratory events guides these autoadjusting devices to increase or decrease the pressure being delivered (Fig. 122.3). The Centers for Medicare & Medicaid Services allow coverage of PAP therapy on the basis of an AHI or respiratory disturbance index of 15 or greater regardless of symptoms or comorbidities, or an AHI (or respiratory disturbance index) of 5 or higher if accompanied by other symptoms or complications, including history of stroke.[21]

Once a decision is made to initiate PAP therapy, a mode must be selected. PAP devices can be started following in-laboratory titration or by recommending empirical settings on an autoadjusting device such as APAP (Table 122.1). CPAP or APAP is generally recommended as initial therapy for OSA when treatment needs to be instituted immediately and when sleep apnea is severe.[1] Remote monitoring of PAP usage and efficacy can be performed through telehealth because most PAP devices are now equipped with modems to transmit data about usage (e.g., when the devices are turned on and how long they are used) and treatment outcomes (e.g., residual apneas and mean pressures required to achieve this) (Fig. 122.4). Use of remote monitoring is considered standard of care and facilitates delivery of sleep care through telephone and video chat visits (telemedicine).[1] There are entire care pathways engaging patients solely through telehealth, even for initiation of PAP, including mask fittings. Regardless of whether care is delivered in person or by telehealth, longitudinal follow-up by sleep medicine providers should be provided to ensure ongoing adherence to and tolerance of OSA therapy.[1]

Table 122.1 Settings Available for Each Mode of Positive Airway Pressure Devices (in cm H_2O)*

Mode	EPAP	$EPAP_{min}$	$EPAP_{max}$	IPAP	PS_{min}	PS_{max}	P_{max}	RR	VT (mL)
CPAP	4–20								
APAP		4	20						
BPAP-S	4–25			4–25					
BPAP-ST	4–25 or 30 (manufacturer dependent)			4–25				1–30/auto	
Auto-BPAP		4–25	25		0–8	PS_{min}+8	25		
ASV	4–25				0–3	0–21	25	4–30/auto	
VAPS	4–25				0–20	0–20	25	1–30/auto	200–1500 mL (6–8 mL PBW)

*Settings are informed by in-laboratory titration, empirically (i.e., APAP initiation), or by device download (i.e., Fig. 122.4). Pressures <5 cm H_2O are generally ineffective for obstructive sleep apnea. Higher pressure requirements correlate with higher apnea-hypopnea index and body mass index, particularly when weight is distributed centrally. The EPAP setting targets elimination of apneas, and IPAP targets resolution of hypopneas. All pressures can be adjusted based on review of efficacy data from the device. When ventilation is the goal, an IPAP-EPAP difference of at least 4 cm H_2O should be targeted. CPAP = EPAP = PEEP; PS = IPAP − EPAP; $P_{max} = EPAP_{max} + PS_{max} = IPAP_{max}$; VT based on patient-predicted body weight and disorder.

APAP, autotitrating positive airway pressure; ASV, adaptive servoventilation; auto-BPAP, autotitrating bilevel positive airway pressure; BPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure; EPAP, expiratory positive airway pressure; IPAP, inspiratory positive airway pressure; P_{max}, maximum pressure; PBW, predicted body weight; PS, pressure support; RR, respiratory rate; S, spontaneous; ST; spontaneous timed; VAPS, volume-assured pressure support; VT, tidal volume.

Continuous Positive Airway Pressure. CPAP, the most commonly used modality for OSA treatment, provides the same fixed pressure on both inspiration and expiration and has no set respiratory rate (see Fig. 122.3).[1] This expiratory PAP is analogous to positive end-expiratory pressure during mechanical ventilation, although pressure is transmitted largely to the upper airway. CPAP devices can be programmed with any pressure between 4 and 20 cm H_2O (see Table 122.1). Randomized clinical trials of CPAP therapy in OSA have shown consistent modest reduction in high blood pressure, improvement in sleepiness, and improvement in quality of life.[22–25] Some CPAP and APAP devices have an expiratory pressure relief setting triggered at the end of the inspiratory cycle that allows brief lowering of the pressure during exhalation. This setting is a comfort feature and is commonly used in patients who report difficulty exhaling against a constant pressure (pressure intolerance), but it has not been shown to improve adherence in patients without this symptom.[1]

Automatic Positive Airway Pressure. APAP is a mode very similar to CPAP in that only one pressure is delivered both for inspiration and expiration; however, this pressure can change throughout the night according to an algorithm sensing obstructive respiratory events (see Fig. 122.4). APAP settings require a range of pressures (e.g., 5 to 12 cm H_2O); if there is no range set (e.g., 5 to 5 cm H_2O), then the machine becomes equivalent to CPAP because it provides a single pressure on inspiration and expiration without adjustment throughout the period of use (see Table 122.1 and Fig. 122.3). APAP can either be used for an initial time-limited home titration, which guides selection of a fixed CPAP pressure,[26] or as long-term therapy. APAP can be initiated in patients with OSA without significant comorbidities, but it has not been systematically studied in other subgroups, particularly patients with chronic cardiac or respiratory failure.[26] For example, patients with heart failure who begin APAP should be closely monitored because standard APAP algorithms may perpetuate central and mixed events in this predisposed group, thereby posing a theoretical risk.[26,27]

APAP and CPAP adherence and patient preference are similar in adults. APAP may also be a reasonable alternative for patients experiencing aerophagia with CPAP because, with APAP, the pressure is continually adjusted throughout the night and often leads to a lower mean pressure on any given night than with CPAP, which is generally fixed at the highest pressure most effective at eliminating apneas during rapid eye movement or supine sleep.[28] That said, emerging data suggest that APAP may result in sleep disruption, somewhat offsetting the advantage conferred by CPAP therapy on outcomes such as improved blood pressure and renal function.[29–34] More data are needed to elucidate these APAP-specific influences more clearly. APAP is used only for OSA, not CSA, because the algorithms respond primarily to upper airway respiratory events. Inappropriate increases in pressure from APAP may result in periodic breathing or *treatment-emergent CSA* (i.e., emergence of central respiratory events as a result of PAP therapy, also referred to as complex sleep apnea).[35] However, treatment-emergent CSA can be seen with both CPAP and APAP modes. Often, treatment-emergent CSA is transient, resolving within 90 days (55%).[36] Treatment-emergent CSA can be persistent in 25% of patients and can be effectively treated with BPAP or adaptive servoventilation if clinically indicated.[36]

Bilevel Positive Airway Pressure. BPAP delivers two set pressures: a higher inspiratory pressure and a lower expiratory pressure (see Fig. 122.3). *Spontaneous mode BPAP* (BPAP-S) provides only patient-initiated breaths

Figure 122.4 A one-night positive airway pressure download. *Top box (purple):* The pressure curve throughout the night. *Middle box (blue):* Detected respiratory events, including periodic breathing (PB), clear airways (central) apneas (CA), obstructive apneas (OA), hypopneas (H), flow limitation (FL), vibratory snore (VS), and respiratory event-related arousals (RE). *Bottom box (yellow):* Information on unintentional leak throughout the night. Summary statistics are provided at right in each box. This download shows a high leak associated with increased respiratory events; the patient-mask interface should be assessed and adjusted as needed to improve device performance. AHI, apnea-hypopnea index; CPAP, continuous positive airway pressure; LPM, liters per minute; max, maximum; min, minimum.

compared with a BPAP-*spontaneous and timed* (ST) BPAP mode, which involves a device-delivered breath if a patient-initiated breath is not sensed in a prespecified time period (Table 122.2). For patients reporting pressure intolerance or aerophagia without benefit from expiratory relief on APAP, BPAP is a reasonable alternative, given the lower expiratory pressure level delivered. BPAP devices also offer the flexibility to increase inspiratory pressure to greater than 20 cm H_2O when higher pressure is needed.

Auto-BPAP is a mode where the *expiratory PAP* (EPAP) and pressure support, which jointly determine the *inspiratory PAP*, can each vary within a limited range. The set values are the EPAP range, pressure support range, and inspiratory PAP maximum (see Fig. 122.3 and Table 122.1). The range of pressure support varies by the device manufacturer, with most using a flow trigger to determine inspiratory PAP. Auto-BPAP is appropriate for treating OSA but not CSA.

Adherence to Therapy

PAP therapy is typically quite effective in reversing OSA pathophysiology; however, when adherence is suboptimal, symptom-related and health benefits are not realized.[37–40] Increasing age, early PAP adherence, self-reported daytime somnolence, treatment-emergent CSA, and psychological traits have most consistently been identified as both positive and negative predictors of long-term PAP adherence.[36,40] Psychological associations with low PAP adherence include depression, hypochondriac personality, avoidant coping strategies, and low self-efficacy (belief in one's ability to execute behaviors to attain treatment goals).[41] Numerous factors can compromise tolerance of or willingness to use PAP (Table 122.3). Key strategies to optimize adherence

Table 122.2 Modes of Ventilation

Modes of Ventilation	Interpretation
Spontaneous (S)	1. Breaths are patient triggered, pressure limited, and flow cycled. 2. Breaths are triggered by patient effort. Breathing frequency is determined by the patient. The effort needed to start a breath is either determined by software or set by the clinician. Devices of different manufacturers trigger differently. 3. Breaths arc flow cycled from inhalation to exhalation. This can be determined by the software or the clinician. Devices of different manufacturers cycle differently.
Pressure control (PC)	1. Breaths are patient or time triggered, pressure limited, and time cycled. 2. Breaths are triggered by the patient or by the ventilator if the patient becomes apneic. 3. Breaths are cycled by the set inspiratory time.
Spontaneous timed (ST)	Combination of above: 1. Breaths are triggered by the ventilator when the patient's breathing rate falls below the backup rate. 2. Breaths are pressure supported if triggered by the patient or pressure controlled if triggered by the ventilator.

From Sahni AS, Wolfe L. Respiratory care in neuromuscular diseases. *Respir Care*. 2018;63(5):601–608.

include disease education, discussion of treatment goals, establishing a patient support network (including peer-to-peer support), and early and consistent follow-up.[42] Motivational interviewing, cognitive-behavioral therapy–based interventions and, in the PAP NAP study, an abbreviated sleep study to facilitate PAP desensitization and acclimatization, have proven to be beneficial in optimizing PAP adherence.[43,44]

Negative External Pressure Therapy

Continuous negative external pressure (cNEP) therapy is still in trial phases for home use in the United States. The basis of cNEP is similar to the concept of iron lung ventilation, in which negative extrathoracic pressure rather than PAP is applied to facilitate ventilation. Patients with OSA have higher critical closing pressures (a measurement of upper airway collapsibility) than patients without OSA. In patients with OSA, the critical closing pressure is close to atmospheric pressure, whereas the pressure in patients without OSA is markedly negative.[45] cNEP involves applying negative external pressure to the neck, thereby decreasing the critical closing pressure toward normal. As negative pressure is created within a soft silicone collar, which is fitted across the anterior neck surface connected to a vacuum pump, the soft tissue structures comprising the pharyngeal airway are pulled anteriorly, mitigating airway collapsibility. The cNEP device reduces obstructive apneas in patients undergoing mild to moderate sedation and has been approved for use in procedural settings (i.e., same-day surgery, colonoscopy) to maintain upper airway patency in patients

Table 122.3 Troubleshooting Common Issues for Positive Airway Pressure Treatment That May Affect Adherence

Issue	Possible Solutions
Hesitancy about trying therapy or difficulty maintaining therapy	■ Education ■ Motivational interviewing ■ Early and consistent follow-up ■ Peer support group ■ PAP buddies (pairing an experienced and adherent peer coach with new PAP user) ■ PAP nap (short supervised nap in a sleep laboratory to address barriers and provide reassurance)
Nasal congestion	■ Increasing humidification ■ Checking for mask leak ■ Checking for mouth breathing ■ Nasal steroids ■ Oral antihistamines ■ Nasal saline rinse ■ Otolaryngology referral
Air leaks	■ Assessment of mask fit ■ Change of mask for improved cushion seal ■ Change of mask for hose location (e.g., to the top of head for frequent turners) ■ Chinstrap if mouth breathing with nasal or nasal pillow mask ■ Adjustment of hose placement to reduce traction on mask ■ Shaving of facial hair
Claustrophobia	■ Desensitization ■ Low-profile mask ■ Helmet mask
Aerophagia	■ Elevation of head of bed ■ Expiratory pressure relief ■ Transition from CPAP to APAP ■ Transition from CPAP/APAP to BPAP ■ Increase in ramp time and decrease in ramp pressure ■ Treatment of underlying GERD ■ Consideration of metoclopramide to increase lower esophageal sphincter tone
Pressure too low: suffocation	■ Increase in CPAP pressure ■ Increase in IPAP on BPAP ■ Increase in minimum pressure for APAP or EPAP for BPAP, ASV, or VAPS
Pressure too high	■ Enabling of ramp feature to lower pressures temporarily for up to 45 min or to match the patient's sleep latency ■ Decrease in maximum APAP pressure to 2 cm H_2O above 90th or 95th percentile pressure use on PAP download ■ Switch from CPAP to APAP ■ Expiratory pressure relief ■ Transition from CPAP/APAP to BPAP ■ In BPAP modes, decrease in EPAP and, if needed to treat resulting residual hypopneas, increase in pressure support

APAP, autotitrating positive airway pressure; ASV, adaptive servo-ventilation; BPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure; EPAP, expiratory positive airway pressure; GERD, gastroesophageal reflux disease; IPAP, inspiratory positive airway pressure; PAP, positive airway pressure; PAP nap, abbreviated sleep study to facilitate positive airway pressure desensitization and acclimatization; VAPS, volume-assured pressure support.

with OSA.[46] cNEP therapy has been found to be effective with few side effects and appears to be safe and effective for short-term OSA treatment.[47] However, larger trials are needed to document efficacy and adherence to this therapy before large-scale adoption.

Nasal Therapies

The nasal end-expiratory PAP devices create a back-pressure in the oropharynx by using the patient's own breathing to create increased resistance during expiration (see Fig. 122.2). The oropharyngeal back-pressure created during expiration prevents collapse of the upper airway and increases functional residual capacity, thereby treating OSA. This is the same mechanism as PAP; however, these are either disposable or multiple-use devices that do not require any electricity, tubing, or water instillation. Instead, a device attaches to and occludes the nares. Therefore, this option is advantageous to patients who do not have access to electricity (e.g., while camping) or are intolerant of PAP therapy secondary to claustrophobia. Nasal end-expiratory PAP reduces the AHI and oxygen desaturation index by 40–50% and improves the lowest oxygen desaturation.[48]

Therapies targeting improved air flow through nasal passages, including nasal corticosteroids, montelukast, and internal or external dilators, can improve snoring but have not been shown to be effective in controlling moderate to severe sleep apnea in adults.[49–51] Internal dilators are effective in the treatment of nasal valve collapse, which improves nasal air flow, but effectiveness in treatment of mild sleep apnea remains unclear.[52] For patients with OSA and nasal congestion, nasal steroids and similar therapies are recommended before starting PAP to decrease the PAP pressure needed to control respiratory events and to improve adherence.[53,54]

Oral Appliances

Mandibular Advancement Device. *Mandibular advancement devices* (MADs) are oral appliances that have shown benefit for some indications (see Fig. 122.2). Although PAP remains the mainstay of therapy for OSA, according to the most recent American Academy of Sleep Medicine and American Academy of Dental Sleep Medicine clinical guidelines,[55] MADs are recommended for use in primary snoring and as a first-line alternative to CPAP for mild to moderate OSA.[56,57] MADs can also be an adjunct to PAP therapy to decrease the pressure needed for effective therapy.[56,57] Custom oral appliances are tightly fitted on both upper and lower dental arches and are connected through a variety of mechanisms (i.e., hooks, rubber or plastic bands, or they are fixed in place), and lower and advance the jaw in a protruded state, thereby increasing both the posterior pharyngeal space and the critical closing pressure.[58] Candidates should have at least eight supporting teeth per arch, healthy periodontal tissue, a protrusion range of more than 5 mm, mandibular bone loss of less than 50%, and evenly distributed occlusal tooth contact.[55] Compared with PAP devices, MADs are considered more comfortable by many patients, are more portable, and require less maintenance. Short-term side effects include excessive salivation or dryness, tooth pain, gum soreness, gingival irritation, and myofascial pain. Custom, titratable devices made by qualified dentists with expertise in MAD therapy are preferred over other commercially available boil-and-bite devices.[56] MAD adherence is often greater than for CPAP, albeit with attenuated improvement in AHI and hypoxemia indices and comparable improvement in degree of subjective sleepiness symptoms.[59] There is also evidence that a MAD improves 24-hour ambulatory blood pressure measures and markers of inflammation.[57]

Tongue-Repositioning Devices. Several devices reposition the tongue to prevent it from occluding the upper airway (see Fig. 122.2). Devices may be applied directly to the tongue itself (anterior displacement), or they may use negative intraoral pressure through active continuous suction to draw oropharyngeal soft tissue, particularly the tongue, anteriorly and superiorly toward the hard palate.[60] Reported success rates varied widely from 23–71% on the basis of the definition of successful treatment; however, when the definition of success was a decrease of AHI of at least 50% *and* a reduction of AHI to less than 10, success rates were 25–37%.[61]

Nocturnal Supplemental Oxygen

Nocturnal supplemental oxygen (NSO) in OSA can address obstructive respiratory event–related hypoxemia; however, except for a small proportion of patients with high loop gain and modest airway collapsibility, NSO does not directly address the obstructive airway events of OSA.[62] Practically, because associated hypoxemia is inherent in scoring of hypopnea events, NSO can mask identification of hypopnea events, thereby leading to underestimation of the true degree of OSA. Sympathetic nervous system activation, large swings in intrathoracic pressure, and sleep fragmentation are consequences of upper airway collapse that will persist in most patients with isolated supplemental oxygen administration.[63] NSO has minimal impact on sleep architecture and neurobehavioral OSA consequences.[64–66] Although intermittent hypoxemia increases blood pressure in experimental animal models, NSO has not been shown to reduce blood pressure profiles in clinical trials. This finding suggests that other nonhypoxemic mechanisms such as microarousals and/or sleep fragmentation likely contribute to blood pressure elevation in OSA.[24,67] However, a more recent clinical trial using higher-flow NSO rates (5 L/min vs. 2 to 3 L/min used in previously published studies) did show an effect on blood pressure.[68] This crossover trial consisted of participants with moderate to severe OSA. Participants were taken off their CPAP therapy (CPAP withdrawal) and randomized to either NSO or room air for 14 nights. Participants had a 14-night washout period on their usual CPAP settings followed by 14 nights of the other trial condition (room air or NSO). The investigators found that NSO prevented morning blood pressure elevation seen in the control (room air) condition as well as reversal of hypoxemia but without improvement in sleepiness between the groups.[68] NSO in this trial abolished the morning rise in blood pressure after CPAP withdrawal.[68] Although these data suggest a potential favorable role for NSO in OSA on blood pressure, additional well-conducted trials are needed to verify these findings. Of note, NSO is also used as an adjunct to

PAP therapy when sleep-related hypoxemia persists after obstructive respiratory events are eliminated by PAP, as is often seen in patients with underlying cardiopulmonary disease who are on the steep portion of the oxyhemoglobin dissociation curve. However, hypoventilation as a cause of hypoxemia in these patients should be ruled out before initiation of NSO.

Pharmacologic Therapy

Tidal volume and respiratory rate are attenuated during sleep compared with wakefulness. In patients with a low arousal threshold, sleep is disrupted more easily. These disruptions may trigger changes in ventilation, thus leading to vacillations between high and low minute ventilation. This predisposes to cyclic respiratory events such as periodic breathing as well as postarousal central apneas. Medications promoting sleep and sedation can both increase the arousal threshold and reduce ventilatory instability by altering loop gain (see also Chapter 117).

When used in reference to ventilation, *loop gain* describes the stability of the respiratory system and is characterized as being high or low. Physiologically, loop gain reflects the degree of compensation in ventilation triggered by a given disturbance (i.e., an arousal). High loop gain promotes unstable breathing by triggering an overcompensation in ventilatory response to a given stimulus. This hyperventilation may, in turn, become the perpetuating stimulus for further disordered breathing events. Several small studies have shown that short-term (1 night) administration of medications such as acetazolamide attenuate loop gain and improve the AHI.[69–71]

Although there are no approved drug therapies to reduce apnea severity, a crossover trial of atomoxetine (a selective norepinephrine reuptake inhibitor) and oxybutynin (an antimuscarinic agent) decreased AHI by 63% (mean, 28.5 to 7.5).[72] Atomoxetine alone improved Epworth sleepiness scores and global quality of life measures, but it did not produce a significant change in AHI.[73] However, larger trials over a longer follow-up period are lacking.

Psychostimulant pharmacologic therapy in patients with OSA and residual hypersomnia despite optimal PAP adherence and sufficient sleep with no other identifiable somnogenic contributing factors (i.e., another organic sleep disorders such as periodic limb movement disorder) consists of Food and Drug Administration schedule IV drugs (i.e., with a low potential for abuse or dependence). Residual hypersomnia after adequate OSA treatment is reported in 10–60% of patients,[74,75] and it is putatively attributable to long-term intermittent hypoxemic exposure and sleep fragmentation, leading to injury of the wake-promoting neurons.[76,77] Improvement in overall functioning with the use of modafinil, a psychoactive drug that increases wakefulness by unknown mechanisms, was 61–68%, respectively, compared with 38% in the placebo arm.[78] Armodafinil, the r-enantiomer of modafinil, is also effective for improving sleepiness, fatigue, and overall clinical condition.[79] Solriamfetol, a selective dopamine and norepinephrine reuptake inhibitor, improves sleepiness measured both objectively and subjectively.[80] Other stimulants can also be used, including methylphenidate, amphetamine salts, and dexamphetamine. However, there is little published evidence on the safety and efficacy of these medications for this purpose.

SURGICAL OPTIONS: ANATOMIC TARGETS (See Chapter 70)

How to Think About Upper Airway Surgery for Obstructive Sleep Apnea

Upper airway surgery has become an important option in the care of patients with OSA. Sleep surgery is part of a continuum of care for OSA that involves medical, pharmacologic, and behavioral therapy. The main purpose of upper airway surgery for OSA is not necessarily to achieve "cure" based on the AHI alone. The chronic nature of OSA means that ongoing management will always be required. However, an effective reduction in AHI from surgery allows patients more options for treatment.

Upper airway surgery for OSA may not alter arousal threshold, loop gain, or muscle tone. It can, however, significantly change the critical closing pressure.[81] This is the same mechanism of action as PAP or MADs. The aim of surgery for OSA is restoration of function rather than mere reconstruction of anatomy.[82]

Sleep surgery has historically been viewed as having a phased approach.[83] Phase 1 involves soft tissue surgery such as tonsillectomy, uvulopalatal flap, septoplasty and turbinate reduction, uvulopalatopharyngoplasty, hyoid suspension, or genioglossus advancement, or a combination of these (expanded descriptions later).[83,84] Phase 2 operations include skeletal surgery such as maxillomandibular advancement.

Nasal Procedures

Every effort is made to establish nasal breathing, instead of mouth breathing, for all patients. Assessment should involve endoscopic examination to identify all possible anatomic and functional causes of nasal obstruction.[85] Whereas there is only modest correlation between the severity of disease and grading of airway collapse during Mueller's maneuver, the negative pressure maneuver is a quick method to assess upper airway collapsibility.[86] A mandibular protrusion maneuver can be performed at the same time to visualize the degree of lateral pharyngeal wall dilation and tongue base advancement. Of note, dynamic airway assessment has been augmented with examination under *drug-induced sedation (sleep) endoscopy* (DISE)[87,88] (Video 122.1).

In the office, nasal examination is not limited to the nose. Long-term nasal obstruction leads to facial changes, most often in the appearance of a long midface, open bite, and retruded mandible. Intraoral examination tends to show narrow, high-arch maxilla with the appearance of a relatively large tongue and redundant soft palatal tissue. This is the classic adenoid facies associated with chronic mouth breathing.[89–91]

The internal nasal valve, the most restrictive location of nasal air flow, is a key area for intervention. The internal nasal valve includes the septum, the inferior turbinates, the upper lateral cartilage, and the nasal floor. Patients can undergo procedures to address each of the indicated areas. Whereas operations addressing the septum (septoplasty), nasal valve collapse (valve reconstruction or stabilization

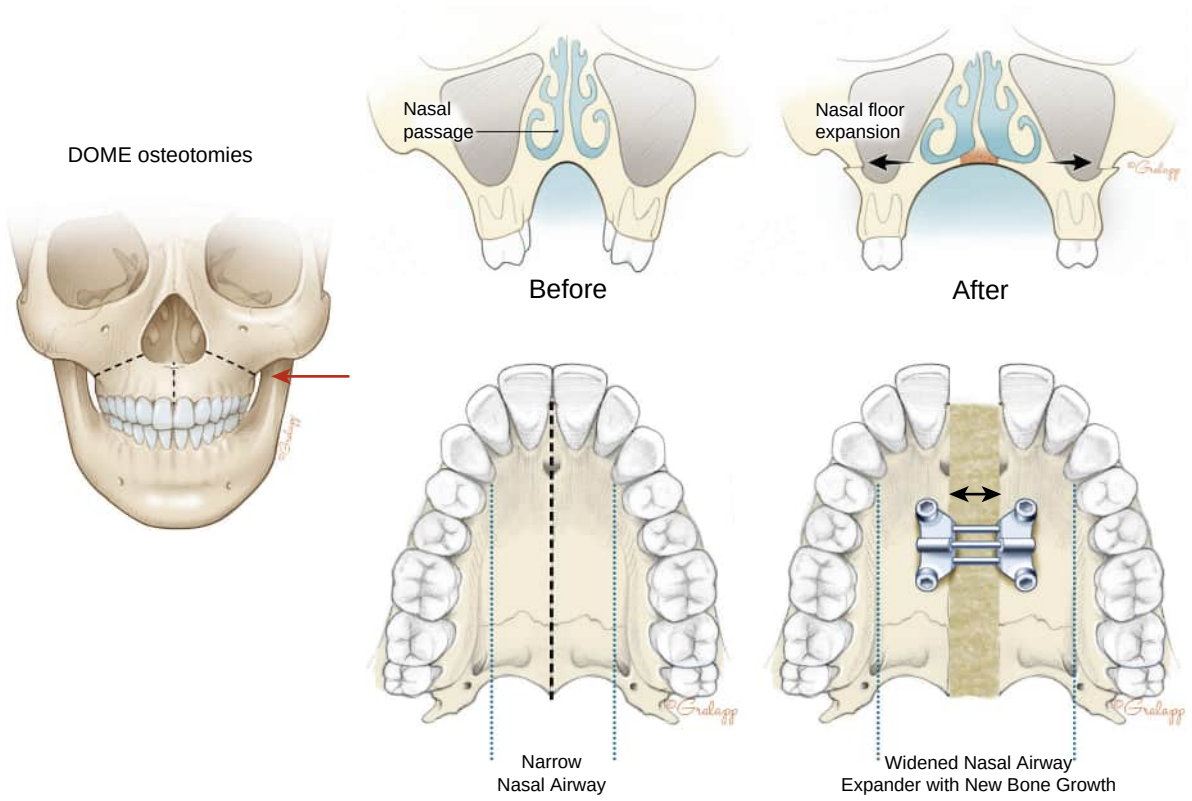

Figure 122.5 Expansion of the nasal floor and palatal roof with *distraction osteogenesis with maxillary expansion* (DOME). Conceptually similar to pediatric rapid maxillary expansion, DOME effectively addresses the same anatomic phenotype in adults. The procedure involves osteotomy only at the Lefort 1 level (*red arrow*), followed by splitting of the midpalatal suture. The goal of DOME is to transform a narrow, arch-shaped palate into a wider, dome-shaped palate, thereby creating greater intraoral and nasal airway volumes. The nasal floor at the internal nasal valve can expand 8 to 10 mm within 1 to 2 months. Orthodontic treatment is required to restore occlusion. (Copyright 2017 Chris Gralapp. Courtesy Christine Gralapp, CMI/chrisgralapp.com.)

procedures), and inferior turbinate reduction (submucosal procedures using various modalities) are well known, expansion of the nasal floor for adults is described more recently. This is particularly helpful with a phenotype of patients with OSA who present with a narrow and high-arch maxilla.[91] They tend to struggle with both nasal obstruction and lack of intraoral volume for the tongue during sleep. For this subgroup, intranasal surgery may not be adequate, and *distraction osteogenesis with maxillary expansion* (DOME) has shown promising results.[92–95] Minimally invasive osteotomies can be made at the Lefort I level through an intranasal incision. A miniscrew-secured expander is placed at the roof of the maxilla. The patient turns the expander fairly rapidly at a rate of 0.025 mm a day, which generally results in 8 to 10 mm of widened nasal floor at the internal nasal valve in a month. Orthodontic treatment restores the occlusion. Conceptually similar to pediatric rapid maxillary expansion, DOME effectively addresses the same anatomic phenotype in adults.[95–99] (Fig. 122.5).

Soft Palate Procedures

Uvulopalatopharyngoplasty remains the most commonly performed sleep surgical procedure worldwide.[100] Most surgeons specialized in OSA have stopped performing earlier methods of uvulopalatopharyngoplasty, which tend to be ablative by including resection of the uvula. This is particularly true in procedures such as the laser-assisted uvulopalatopharyngoplasty, which worsened AHI in 44% of patients, according to meta-analysis.[101] Isolated soft palate surgery has the highest success rate in Friedman stage I patients who have enlarged tonsils but an otherwise uncrowded, unobstructed airway.[102] In clinical practice, various forms of uvulopalatopharyngoplasty are often performed as part of multilevel surgery to maximize surgical success.[83,103,104] In the classic phased protocol described earlier, a uvulopalatal flap is performed as part of multilevel surgery with genioglossus advancement during phase 1. The uvulopalatal flap was designed as a reversible soft palate procedure in the event of velopharyngeal (soft palate) insufficiency, which can lead to alterations in speech and nasal sounds.[84] Most forms of contemporary uvulopalatopharyngoplasty focus on palatal muscle expansion and stabilization with targeted vectors during suturing.[105–108] Another indication for isolated uvulopalatopharyngoplasty is part of a phased approach toward *hypoglossal nerve stimulation* (HNS). Because complete concentric collapse of the soft palate (velum) seen during DISE is an exclusion criterion for HNS, palatopharyngoplasty can reverse this collapse pattern and thereby increases candidacy for HNS[109] (Fig. 122.6).

Tongue Muscle Strengthening: Genioglossus Advancement

Genioglossus advancement is usually performed in conjunction with other procedures (uvulopalatopharyngoplasty,

maxillomandibular advancement).[110] The genioglossus muscle, one of the most powerful dilators of the upper airway, is attached to the genial tubercles (bony protuberances on the inside of the anterior mandible). By advancing the genial tubercles, contractility of the genioglossus muscle increases through muscle fiber remodeling, thus allowing greater tongue advancement during sleep.[111] With the wide availability of computed tomography, virtual surgical planning and cutting guides allow the contemporary genioglossus advancement to be considerably more precise.[112] Genioglossus advancement can often be performed in conjunction with genioplasty (chin advancement) to improve overall facial balance in retrognathic patients.[113] This combination also exerts strengthening effects on the suprahyoid muscles (Fig. 122.7).

Tongue Volume Reduction: Lingual Tonsillectomy

Reduction of the posterior tongue volume and lingual tonsillectomy can be accomplished by the use of laser, robotic assistance or coblation (i.e., controlled ablation, involving radiofrequency at a low temperature).[114–116] The removal of tissue in this area can be supplemented by an anterior anchorage of the epiglottis to the base of the tongue for treating epiglottis collapse. With high-quality optics for improved visualization and instrumentation, robotics have been adapted and introduced to target the posterior tongue.[116,117] Although transoral robotic surgery offers unparalleled visualization, the use of multiarmed robots originally designed for the abdominal cavity can be cumbersome for the upper airway. Results for the use of transoral robotic surgery as part of a multilevel surgical approach for OSA are promising for selected patients. However, the cost and morbidity may be greater than with other techniques, thereby offsetting its advantages in visualization and precision.[118] The advent of a single-port robot system designed for single-cavity operative sites is promising.[119] Augmented reality–assisted transoral robotic surgery using a single-port robot will reduce morbidity such as bleeding and increase precision in distinguishing fat from muscle.[120]

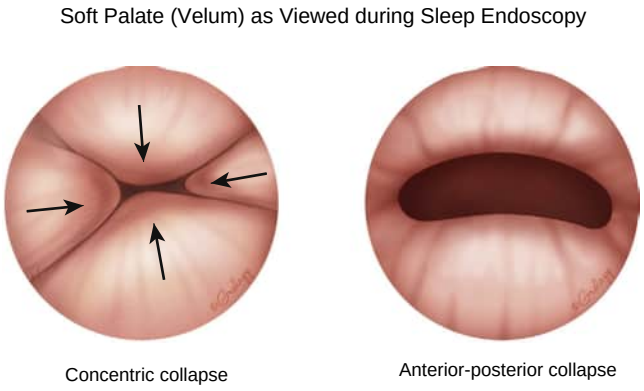

Figure 122.6 Change of concentric collapse at velum with palatopharyngoplasty. *Left*, Concentric collapse at the velum has been shown not to benefit from *hypoglossal nerve stimulation* (HNS) and is thus a contraindication. *Right*, Palatopharyngoplasty can be performed to alter this pattern so that now, with anterior-posterior collapse, patients become eligible for HNS. (Copyright 2017 Chris Gralapp. Courtesy Christine Gralapp, CMI/chrisgralapp.com.)

Hypoglossal Nerve Stimulation

HNS, a surgical treatment for OSA, targets reduced upper airway dilator muscle activity during sleep without altering the anatomy (Fig. 122.8). It generates a unilateral respiration-synchronized stimulation of the medial hypoglossal nerve branches and C1 nerve, leading to tongue stiffening and protrusion during sleep through the genioglossus and geniohyoid muscles (lowering critical closing pressure). The hypoglossal nerve (cranial nerve XII) innervates both the tongue protrusor (genioglossus) and retrusor (styloglossus and hyoglossus) muscles through its medial and lateral divisions. Selective stimulation of the protrusor muscles leads to anterior movement of the tongue and causes an increased air flow and reduced pharyngeal collapse during sleep.[121] Selective stimulation of the deep and horizontally oriented genioglossus fibers results in curling and stiffening of the tongue, thus further increasing patency of the upper airway[122] (Video 122.2).

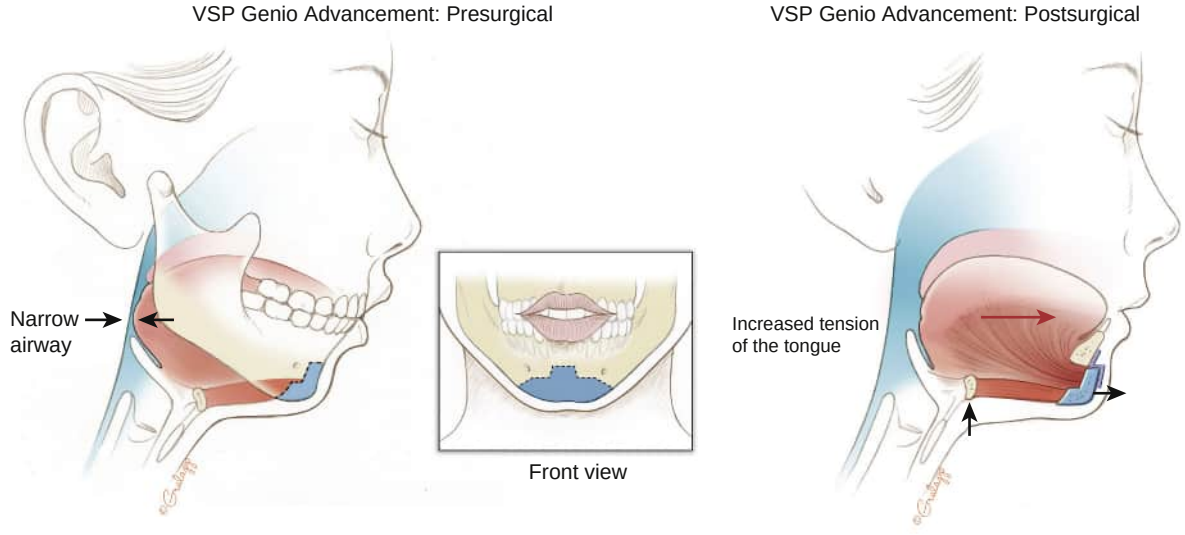

Figure 122.7 Contemporary genioglossus advancement and genioplasty (Genio). Virtual surgical planning (VSP) and cutting guides allow genioglossus advancement with or without genioplasty to be considerably more precise. The airway is widened by the anterior advancement of the genioglossus and the chin. (Copyright 2017 Chris Gralapp. Courtesy Christine Gralapp, CMI/chrisgralapp.com.)

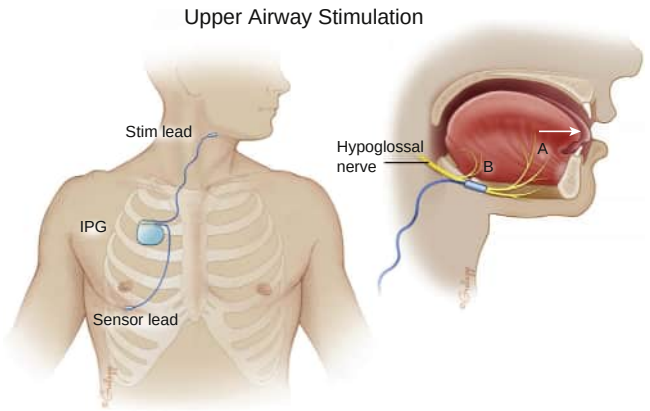

Figure 122.8 Hypoglossal nerve stimulation. The hypoglossal nerve (cranial nerve XII) innervates the tongue protrusor (genioglossus) and retrusor (styloglossus and hyoglossus) muscles through its medial and lateral divisions, respectively. Selective stimulation of the protrusor muscles leads to anterior movement of the tongue and results in increased air flow and reduced pharyngeal collapse during sleep. The stimulation lead is placed around the medial branches (protrusor, *B*), whereas the lateral branches (retrusor, *A*) are excluded. The sensing lead is placed between the internal and external intercostal muscles for timing the stimulation with breathing. The implantable pulse generator (IPG) receives input from the sensing lead and signals the stimulation lead to activate the hypoglossal nerve at the end of expiration. (Copyright 2017 Chris Gralapp. Courtesy Christine Gralapp, CMI/chrisgralapp.com.)

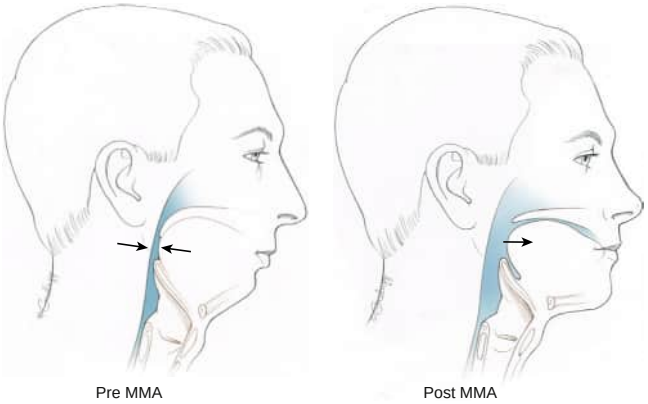

Figure 122.9 *Maxillomandibular advancement* (MMA). MMA involves osteotomies of the maxilla and mandible, followed by their advancement, which frequently incorporates counterclockwise rotation. This rotation allows the jaw complex to move forward and upward while maintaining facial balance. It remains one of the most effective surgical interventions for patients with obstructive sleep apnea. (Copyright 2017 Chris Gralapp. Courtesy Christine Gralapp, CMI/chrisgralapp.com.)

The Food and Drug Administration approved this therapy in 2014. The existing HNS system consists of a sensing lead, pressure sensor, implantable pulse generator, stimulation lead, and cuff electrode. The Stimulation Treatment for Apnea Reduction (STAR) trial, a multicenter prospective trial, enrolled patients with moderate to severe OSA (AHI ≥20); these investigators reported a reduction of AHI of 68%, from 29.3 to 9, and an oxygen desaturation index reduction of 70% from 25.4 to 7.4.[123] Clinical indication–based inclusion criteria consist of age older than 22 years, AHI of 20 to 65 with less than 25% central apneas, inability to use CPAP, and lack of complete concentric collapse of the velum on DISE. HNS is most effective in patients with a BMI less than 32 kg/m^2; however, a BMI of 32 to 35 kg/m^2 is acceptable. Predictors of effectiveness include increasing age, lower BMI, and female sex.[124] Approximately 2 months after implantation, patients undergo titration of HNS where voltage is adjusted to alleviate residual obstructive apneas and hypopneas. The therapy is turned on by the patient nightly by using a remote control. HNS is well-tolerated by patients,[123] and it improves subjective sleep quality, quality of life, and daytime sleepiness.[86] Evaluation of outcomes at 5 years in 71 patients showed that HNS is effective in achieving an AHI less than 5 in 44% and, by less stringent definitions, effective at reducing both the AHI by at least 50% and the residual AHI to less than 20 in 75% of patients.[125]

Maxillomandibular Advancement

Maxillomandibular advancement (MMA) was pioneered by Riley and Powell at Stanford Hospital in the late 1980s and addresses total upper airway collapse. It remains one of the most effective surgical interventions for patients with OSA and has compared favorably to CPAP in a variety of studies.[83,111,126–131] MMA involves osteotomies of the maxilla and mandible, followed by their advancement that is frequently accompanied with counterclockwise rotation[132,133] (Fig. 122.9). The rotation is intended to maximize advancement of the jaw complex without negative impact on overall facial balance. The net effect includes greater volume for intraoral soft tissue structures and, more importantly, stability of the upper airway dilator muscles[134–137] (Video 122.3). In general, indications for MMA are (1) moderate to severe OSA with or without a history of phase 1 surgery, (2) OSA of any severity if there is a comorbid dentofacial deformity, and (3) concentric and lateral pharyngeal wall collapse seen with DISE.[133,137–139] Age and severity of disease have not been shown to affect the technical aspects of MMA in a high-volume center.[140]

In a meta-analysis evaluating the treatment efficacy of MMA in 22 studies involving 627 patients who underwent MMA, the mean AHI decreased from 63.9 to 9.5. The investigators defined surgical success with the following criteria: a minimum of 50% reduction with a final AHI less than 20.[141] The surgical success rate was 86.0%, and the cure rate (AHI <5) was 43.2%. The predictive factors for surgical success were younger age, lower BMI, and greater degree of maxillary advancement.[142] The major and minor complication rates were 1.0% and 3.1%, respectively. This meta-analsysis was updated with 45 studies and 528 patients reporting success and cure rates of 85.5% and 38%, respectively.[143] In 40 patients who underwent MMA with average follow-up of 4.2 years (range, 1 to 12 years), 36 (90%) patients maintained a significant reduction in respiratory disturbance index (71.2 to 7.6) and improvement in daytime sleepiness.[142] In another study with mean follow-up of 12.5 years, surgical success rate remained 100% in patients who were both younger than 45 years and had a BMI less than 25.[144]

Beyond the AHI, MMA has shown normalization of sleep architecture as shown by an increase in rapid eye movement sleep and a decrease in wakefulness after sleep onset when compared with age-matched healthy controls. It has also shown improvements in multiple health-related and functional outcomes.[145]

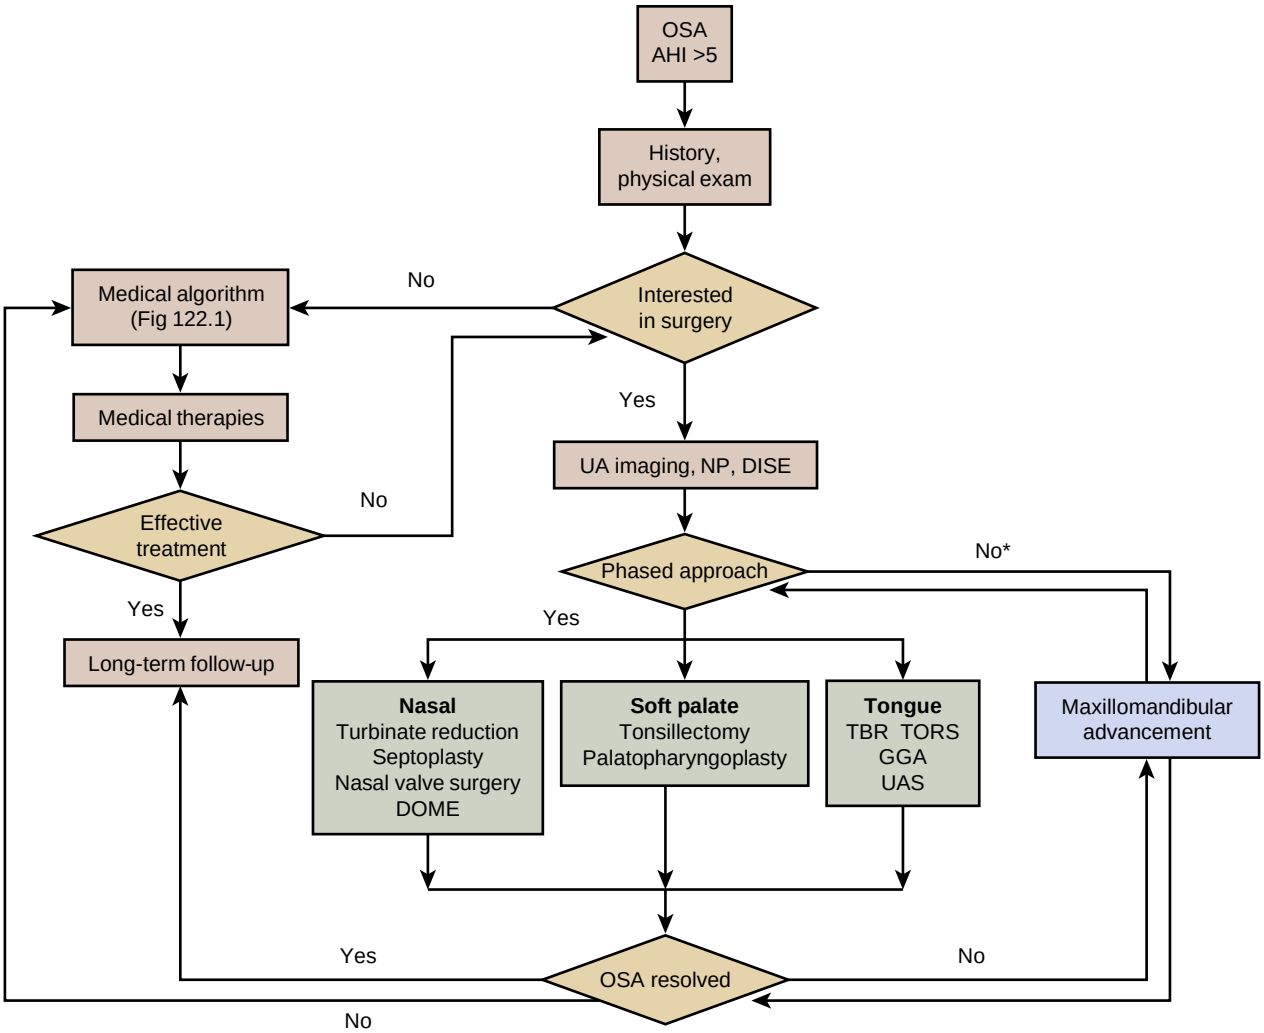

Figure 122.10 Updated sleep surgery algorithm. The updated algorithm places sleep surgery within the continuum of care and readily incorporates multimodal therapy. It improves precision in three key areas: (1) patient selection, (2) identification of unaddressed anatomic phenotypes, and (3) surgical techniques. Patients can flow between medical and surgical management strategies depending on the treatment preference of the patient as well as candidacy for interventions. For example, patients considered for surgical intervention may proceed to soft tissue surgery (e.g., nose, soft palate, or tongue) or directly to skeletal-based surgery with maxillomandibular advancement, depending on the degree of obstructive sleep apnea (OSA) severity, dentofacial deformity, and pattern of pharyngeal wall collapse on drug-induced sleep endoscopy (DISE). A classic phased approach includes soft tissue surgery first and then skeletal-based surgery. However, a phased approach may not be the best initial choice on the basis of the foregoing factors, and a phased approach does not have to be followed sequentially. If one approach does not resolve the obstructive sleep apnea, other surgical interventions may still be considered (i.e., maxillomandibular advancement may follow a uvulopalatopharyngoplasty, and vice versa). *Patients with a preexisting dentofacial deformity (e.g., maxillary and/or mandibular hypoplasia) and complete concentric and lateral pharyngeal wall collapse seen during DISE may be candidates for maxillomandibular advancement surgery first, rather than a phased approach. AHI, apnea-hypopnea index; DOME, distraction osteogenesis maxillary expansion; GGA, genioglossus and genioplasty advancement; LPW, lateral pharyngeal wall; NP, nasopharyngoscopy; TBR, tongue base reduction; TORS, transoral robotic surgery; UA, upper airway; UAS, upper airway stimulation.

APPLYING THESE CONCEPTS: AN ALGORITHM INCORPORATING SURGICAL AND NONSURGICAL TREATMENTS

An early Stanford protocol used for 3 decades suggested beginning with a multilevel phase 1 approach (tonsillectomy, uvulopalatal flap and genioglossus advancement), followed by phase 2 MMA in nonresponders.[130] This combined approach compares favorably with PAP therapy, especially with the inclusion of MMA.[128] The drawback to this approach is its unidirectional nature. It assumes that OSA does not recur if a cure, defined as AHI less than 5 events per hour, is achieved at one point. It also does not take into account patient preferences of these elective procedures and does not incorporate treatment such as PAP and MADs.

This phased approach has been replaced by an updated algorithm reflecting a more multidisciplinary and multimodal strategy for managing OSA[137–139] (Fig. 122.10). This updated algorithm places sleep surgery within a continuum of care, where medical management can precede or follow surgical interventions. It is characterized by improved precision in anatomic phenotyping, thereby facilitating the selection of the most appropriate patients for procedures such as DOME, HNS, and MMA.[123,135,136] It also adds greater precision to the way older procedures, such as genioglossus advancement and MMA, are performed.[94,112]

The algorithm begins with a thorough history, physical examination, review of sleep testing results, nasopharyngoscopy, and DISE. The indication for DISE is based on specific patient characteristics and needs. An initial decision is made regarding optimization of PAP, weight management, or oral appliance therapy. Nasal operations targeting resolution of nasal obstruction can be effective in improving adherence to PAP and may be considered an adjunct to PAP management. Weight is a key element determining successful outcomes with nearly all therapies other than PAP. The efficacy of upper airway surgery for OSA decreases as BMI increases. Thus, medical weight loss and bariatric surgical evaluation and treatment should precede upper airway surgery in selected candidates.

Nasopharyngoscopy and DISE results guide candidacy for both soft tissue and skeletal surgical procedures. DISE is currently required to rule out complete concentric collapse of the upper palate (velum) before considering HNS, because concentric collapse and lateral pharyngeal wall collapse seen on DISE are associated with a low success rate of soft tissue surgery.[146,147] MMA is reliable in reversing these collapse patterns.[135,136] MMA can also be a first-line consideration for patients with any degree of OSA with concurrent dentofacial deformity. Comorbidities (medical and psychiatric), likelihood of compliance with a therapy requiring daily initiation (HNS, CPAP, MAD), and patient preference are also considered when determining candidacy for these procedures.

The updated surgical algorithm adds precision in three areas: (1) patient selection, (2) identification of previously unaddressed anatomic phenotypes, and (3) surgical techniques.[137–139] Conceptually, whereas focus had been on individual surgical success, this algorithm provides a roadmap to overall treatment success. Because surgery is elective for patients with OSA, an effective algorithm accommodates the patient's personal preferences. Patients may elect to start with phase 1 procedures or with MMA and still remain candidates for other treatment regardless of their order. The key is to have surgeons experienced in sleep therapies and capable of performing the entire spectrum of procedures and counseling patients appropriately on chosen treatment paths.

Whereas this updated algorithm attempts to help guide the surgical care of patients with OSA, the most pressing need is its integration with physiologic phenotyping.[148] The combination of cutting-edge sleep surgery with advances in modulation of arousal threshold, loop gain, and muscle tone will truly redefine precision in OSA care.

Treatments for CSA, including CPAP, BPAP, supplemental oxygen, compression stockings and diuretic agents, and phrenic nerve stimulation, can be found at ExpertConsult.com and in Chapter 121.

SLEEP-RELATED HYPOVENTILATION SYNDROMES

Sleep-related hypoventilation syndromes primarily consist of those related to *obesity hypoventilation syndrome* (OHS), advanced obstructive lung disease, and restrictive lung disease caused by neuromuscular disease or intrinsic parenchymal or pulmonary vascular disease. These disorders often require *noninvasive ventilation* (NIV) with settings guided by the acuity and severity of disease and the patient's unique needs (see Figs. 122.1 and 122.3) (see also Chapter 136).

Not all hypoventilation syndromes require NIV. Some hypoventilation syndromes such as OSA-OHS respond well to alleviation of upper airway obstruction. Selection of a given mode of PAP (CPAP, APAP, BPAP-S, BPAP-ST, BPAP-PC, and VAPS add-on) requires an understanding of the underlying physiology of the respiratory disorders involved. Use of NIV in patients with neuromuscular disease and hypercapnic COPD reduces morbidity and mortality, as does use of CPAP in OSA-OHS and overlap syndrome.

OBESITY HYPOVENTILATION SYNDROME

OHS is defined by obesity (BMI >30 kg/m^2), daytime hypercapnia (arterial P_{CO_2} >45 mm Hg), and sleep-disordered breathing following exclusion of other causes of chronic alveolar hypoventilation (see also Chapters 45 and 120). For patients with a low to moderate probability of OHS, a rapid and sensitive screening test is serum bicarbonate.[162] A serum bicarbonate level lower than 27 dramatically decreases the probability of OHS.[162] However, arterial P_{CO_2} rather than serum bicarbonate is recommended in patients with OSA and a high pretest probability of OHS.[162] OHS is accompanied by OSA in 90% and by severe OSA in 70% of patients.[162] CPAP is effective at eliminating both OSA and OHS in 80% of patients, in whom upper airway obstruction rather than reduced drive to breathe is the primary cause.[163,164] Thus, CPAP is recommended as initial therapy for patients with severe OSA and OHS (eFig. 122.1). If sleep-related hypoventilation and hypoxemia persist despite effectively addressing upper airway obstruction with CPAP, then the BPAP-S mode can be tried. Although randomized clinical trials have been small, existing data suggest that CPAP and BPAP-S result in similar improvements in quality of life and adherence. BPAP-S has also been shown to improve sleep quality in the absence of severe nocturnal hypoxemia.[165] Resolution of hypoventilation with several weeks of treatment is evident in normalization of serum bicarbonate or arterial P_{CO_2} (see Chapter 136).

In some patients, BPAP-S therapy is not effective as a result of reduced respiratory drive. These patients can be identified by their low minute ventilation. Minute ventilation would be considered inadequate if there is either no change or worsening in carbon dioxide by surrogate monitoring during therapy. In these cases, bilevel modes with backup rates such as BPAP-ST or average volume-assured pressure support may be considered, the latter at 8 to 10 mL/kg ideal body weight with adjustments guided by carbon dioxide monitoring.[166] Selection of settings on BPAP-ST should include strategies to increase inhalation time favoring larger tidal volumes and improved gas exchange, such as increasing rise time, prolonging inspiratory time, or lowering cycle sensitivity.[166] The backup respiratory rate is usually set approximately two breaths below the patient's spontaneous frequency or auto-rate. End-expiratory PAP settings alleviate the obstructive component of sleep-disordered breathing, as well as oppose reduced respiratory system compliance from abdominal compression; the higher the AHI, and the greater the chest

CENTRAL SLEEP APNEA

Treatment of CSA with PAP devices, supplemental oxygen, compression stockings, and phrenic nerve stimulation is briefly covered in this chapter and discussed in depth in Chapter 121. Pharmacologic therapies are discussed exclusively in Chapter 121.

Continuous Positive Airway Pressure

Although CPAP mainly functions to maintain upper airway patency, it also confers advantages of reducing left ventricular afterload, improving ventilation-perfusion mismatch, and slightly increasing arterial P_{CO_2} which may help to stabilize ventilation in a high loop gain system.[149] The Canadian Continuous Positive Airway Pressure trial showed that whereas intermediate measures, including left ventricular ejection fraction and urinary catecholamines improved, no survival benefit was conferred by CPAP in CSA in patients with systolic heart failure.[150]

Bilevel Positive Airway Pressure With Backup Rate

Although BPAP with backup rate (BPAP-ST) has the potential to address both obstructive and central aspects of sleep-disordered breathing, few studies have reported the effectiveness of this therapeutic approach.[151] Treatment-emergent CSA is defined by the emergence of central respiratory events during PAP therapy, and it affects up to 20% of patients with OSA.[152,153] Indeed, patients with predominantly obstructive events on baseline sleep testing may have unmasking of central events during early exposure to PAP therapy. General recommendations are to treat with a trial of CPAP therapy while recognizing that central events will commonly resolve over the first 3 months of therapy.[152,153] If close follow-up reveals persistence of CSA on CPAP, the use of a BPAP (adaptive servoventilation or ST) mode is a reasonable next step. The addition of a backup rate may reduce transient cycling between hyperventilation and hypoventilation that causes or perpetuates central events.

Adaptive Servoventilation

Adaptive servoventilation adjusts breath-by-breath levels of inspiratory pressure support to counterbalance either overshooting or undershooting of ventilation; that is, it increases pressure support during apneas and hypopneas and reduces support during hyperventilation by analyzing the breathing pattern in a moving average and applying pressure support according to predefined parameters (see Fig. 122.3). Adaptive servoventilation devices can be programmed with either fixed or variable expiratory pressure to address obstructive respiratory events (similar in concept to CPAP and APAP). Adaptive servoventilation devices also have a nonadjustable (preprogrammed by the manufacturer) or adjustable backup rate to address central apneas. The use of adaptive servoventilation in treatment-emergent CSA, idiopathic CSA, and CSA associated with heart failure, opioids, and high altitude is covered in Chapter 121.

Supplemental Oxygen

NSO resulting in mild hyperoxia may reduce excessive chemoreceptor sensitivity, thereby reducing AHI. Randomized controlled trials with small sample sizes demonstrated improvement of CSA in patients with heart failure with use of NSO therapy by reduction of hypoxic ventilatory drive and reduced sympathetic activation, as well as improvement in quality of life measures.[154] However, multicenter clinical trial data suggested improvement in physical activity and quality of life measures with NSO therapy in non–CSA-predominant sleep-disordered breathing.[155] The definitive role of supplemental oxygen as an effective isolated treatment option needs further study. This is further discussed in Chapter 121.

Compression Stockings

Venous compression stockings have shown benefit in reducing fluid accumulation in the lower extremities that reduces redistribution of the edema to the neck during sleep, thereby addressing one mechanism contributing to the pathogenesis of both OSA and CSA. A direct relationship between the amount of fluid displaced from the legs and the AHI has been described in patients with heart failure and either OSA or CSA.[156] Fluid shifts correlated inversely with nocturnal arterial P_{CO_2}, a finding suggesting that some of the fluid was redistributed into the lungs, thus stimulating pulmonary irritant receptors and leading to hyperventilation and reductions in the arterial P_{CO_2} close to or below the apneic threshold.[156,157] In the case of OSA, this fluid shift decreases patency of the upper airway through accumulation of fluid in the neck and increased peripharyngeal soft tissue edema,[158] thereby increasing its collapsibility.[159] It is possible that varying degrees of rostral fluid shift could lead to changes in predominant apnea type over time. In fact, the magnitude of fluid shifts from the legs is greater in patients with CSA than in patients with OSA. Therefore, addressing both pulmonary edema and rostral neck edema beneficially affects both CSA and OSA sleep-disordered breathing.[160] Intensification of diuretic therapy also represents another strategy in the management of lower extremity edema.

Phrenic Nerve Stimulation

Transvenous phrenic nerve stimulation has emerged as an effective treatment for CSA (eFig. 122.2). One lead is implanted in the brachiocephalic or left pericardiophrenic vein to stimulate the phrenic nerve, and a second lead senses breathing for respiratory gating. The stimulation lead is attached to a pulse generator responsible for delivering low-energy stimulation to the phrenic nerve to alleviate central apneas. Initial outcomes show a 50% reduction in AHI and more than 90% reduction in the central apnea index. A subsequent multicenter randomized clinical trial confirmed these findings of a significant reduction in the severity of CSA of more than 50% at 6 months, as well as improvement in oxygenation and quality of life measures.[161]

wall restriction is, the higher the end-expiratory PAP will need to be set. Additionally, higher pressure support is often needed to ensure that adequate target tidal volumes are achieved. In general, compared with BPAP, volume-assured pressure support improves hypercapnia, hypoxemia, and sleep quality.[167,168] In unstable OHS (i.e., acute respiratory failure), NIV should be used during hospitalization and on discharge. NIV with empirical settings should be provided to the patient with expeditious follow-up (less than 3 months) for in-laboratory polysomnography, ideally with transcutaneous carbon dioxide surrogate monitoring, because end-tidal carbon dioxide values cannot be accurately obtained during PAP therapy as a result of washout. End-tidal capnography does not provide accurate data in the presence of obstructive lung disease, in cases where there is no end-expiratory plateau, there is an increase in dead space, or during use of either NIV or supplemental oxygen.[169–171] Adequacy of therapy can be assessed by monitoring for carbon dioxide normalization with serum bicarbonate or arterial P_{CO_2}.

NEUROMUSCULAR DISEASE

The goals of treatment for neuromuscular weakness are to reduce the load on the respiratory system, reduce physiologic dead space, and increase minute ventilation. For patients with neuromuscular disease and OSA with no evidence of hypoventilation, CPAP and close monitoring can be considered. Early initiation of NIV in amyotrophic lateral sclerosis is feasible and has been shown to improve quality of life, slow lung function decline, and improve survival.[172] Weighing the risks and benefits of NIV is crucial because patients with significant bulbar symptoms and sialorrhea may have poorer adherence and increased risk of aspiration. That said, early NIV has been shown to improve quality of life and survival in patients with bulbar symptoms, when tolerated. Another challenge is triggering NIV breaths in patients with diaphragmatic weakness. Indicators of diaphragm function include maximum inspiratory pressure, arterial P_{CO_2}, forced vital capacity in the upright and/or supine position, and overnight oximetry. Thus, initiation of NIV is based on impairment in any of these parameters, including forced vital capacity less than 50% of predicted, maximal inspiratory pressure 60 cm H_2O or lower, awake arterial P_{CO_2} greater than 45 mm Hg, or nocturnal desaturation of up to 88% for at least 5 minutes.[173] Symptoms, objective evidence of sleep-related hypoventilation, and the rate of disease progression should all be considered in the timing of ventilatory support.[166] Initiation of NIV for neuromuscular disease, including selection of initial device settings, is outlined in eFigure 122.3 and is based on the degree of impairment of respiratory function, as well as the presence of bulbar disease. NIV can be provided through either home mechanical ventilators, which include internal batteries but are larger and heavier, or BPAP respiratory assist devices, which are more portable but must be connected to an electrical outlet or an external power pack. Monitoring of NIV in patients can be done remotely through telehealth. BPAP devices allow data from the patient to be viewed and settings to be changed remotely. Home mechanical ventilators can send data from the patient to the provider for review but do not allow remote adjustments to settings, which must be done in person.

COPD

Mild hypoventilation at sleep onset is a normal phenomenon of non–rapid eye movement sleep. Rapid eye movement sleep is characterized by paralysis of accessory muscles of respiration, resulting in cyclic reductions in minute ventilation, hypercapnia, and hypoxemia in patients with advanced COPD. Patients perched on the cusp of the steep portion of the oxyhemoglobin dissociation curve who have awake, upright daytime measurements of oxygen saturation as measured by pulse oximetry lower than 94–95% should be considered for overnight oximetry or sleep testing to evaluate for sleep apnea, sleep-related hypoventilation, or sleep-related hypoxemia.

COPD and OSA frequently exist in the same patient, with up to 66% of patients with COPD also having a diagnosis of OSA.[163] Comorbid COPD and OSA, also known as overlap syndrome, is associated with an increased risk of hospitalization and death[174] from COPD exacerbations compared with patients who have COPD only. This increased risk is likely the result, in part, to greater nocturnal and daytime hypoxemia, as well as increased risk of pulmonary hypertension caused by chronic lung disease (see also Chapter 85). Currently, polysomnography rather than home sleep apnea testing is recommended to diagnose OSA, although the level of evidence for this recommendation is weak.[175]

Treatment goals are defined by the results of sleep testing, and they may include alleviation of OSA alone, treatment of isolated hypoventilation and/or hypoxemia, or a combination thereof. Given hypercapnia is a contributing factor of mortality, it follows that a reduction in arterial P_{CO_2} may improve overall prognosis. In patients with overlap syndrome, CPAP has shown improved survival and reduction of first-time hospitalization for COPD exacerbation.[164] When NIV is deemed a more appropriate therapy than CPAP (i.e., as a result of pressure intolerance or persistent hypercapnia), it can be initiated following in-laboratory polysomnography for stable outpatients or empirically on the basis of predischarge inpatient settings when criteria for NIV or home mechanical ventilation are met. Both inpatient observation and in-laboratory studies allow continuous monitoring of oxygen saturation and, where available, monitoring of transcutaneous, end-tidal carbon dioxide, or arterial blood gases.

Various strategies have been used in the treatment of hypoventilation caused by overlap syndrome or COPD. Initial studies using low-intensity BPAP (small delta between inspiratory and expiratory pressure settings) did not show a substantial difference in hospitalizations, exacerbations, quality of life, or even awake arterial P_{CO_2}.[176] Conversely, high-intensity BPAP in patients with severe stable hypercapnic COPD reduces hospitalization readmission and death.[177,178] Current European Respiratory Society guidelines support using NIV in chronic stable COPD with hypercapnia and after acute COPD exacerbation requiring NIV.[179] In further support of this, a meta-analysis of patients with chronic hypercapnic COPD concluded

that home ventilation with BPAP versus no device at all reduced all-cause mortality, all-cause hospitalizations, and intubation.[180]

Key Points

- Numerous options are available for treatment of sleep-disordered breathing. Patients' characteristics and preferences are key to initiating therapy that will be effective long term.
- Positive airway pressure is the primary therapy for obstructive sleep apnea, some forms of central sleep apnea, and hypoventilation syndromes. Understanding the physiologic basis of obstructive sleep apnea, central sleep apnea, and hypoventilation syndromes facilitates an understanding of how to select the most appropriate positive airway pressure mode for an individual patient or disease process.
- Oral appliances should be considered first-line therapy for mild to moderate obstructive sleep apnea, and they may be used in combination with positive airway pressure therapy to reduce the pressure required to achieve a therapeutic apnea-hypopnea index.
- Surgical interventions aim to restore function by promoting stability of the upper airway against collapse. Soft tissue and skeletal procedures can be used as primary therapies or to improve tolerance or response to treatments such as positive airway pressure and oral appliances.
- Drug-induced sedation (sleep) endoscopy has allowed more precise surgical decision making, particularly with the selection of responders to hypoglossal nerve stimulation and maxillomandibular advancement.
- Hypoglossal nerve stimulation and phrenic nerve stimulation are novel implantable neurostimulation therapies for obstructive sleep apnea and central sleep apnea, respectively.
- Continuous positive airway pressure or bilevel positive airway pressure use in obesity hypoventilation syndrome is determined by stability and severity of hypoventilation. Continuous positive airway pressure is effective in 80% of patients with combined obstructive sleep apnea and obesity hypoventilation syndrome.
- Noninvasive ventilation improves morbidity and mortality and should be instituted early in hypoventilation caused by progressive neuromuscular disease, such as amyotrophic lateral sclerosis.

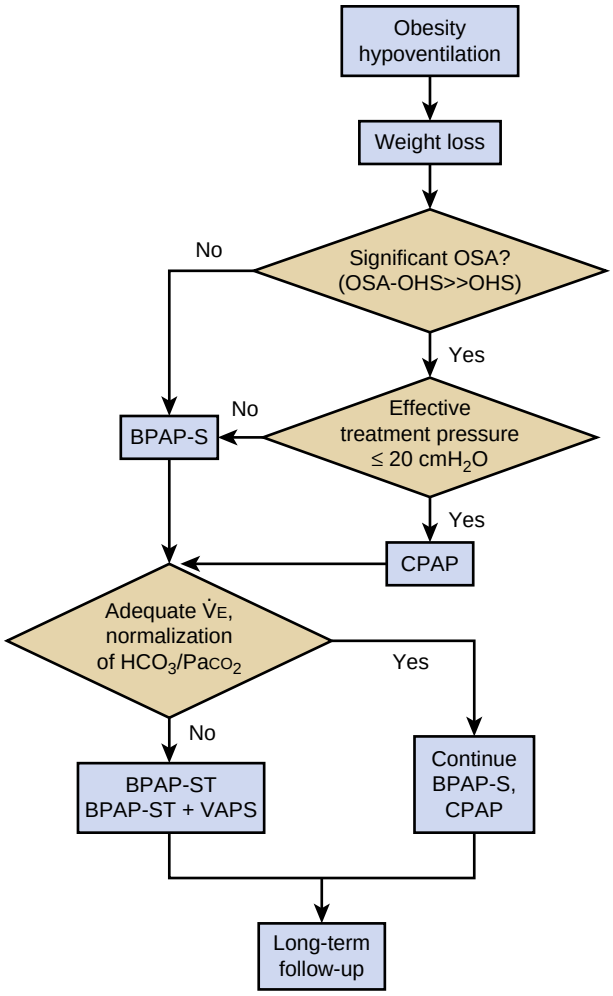
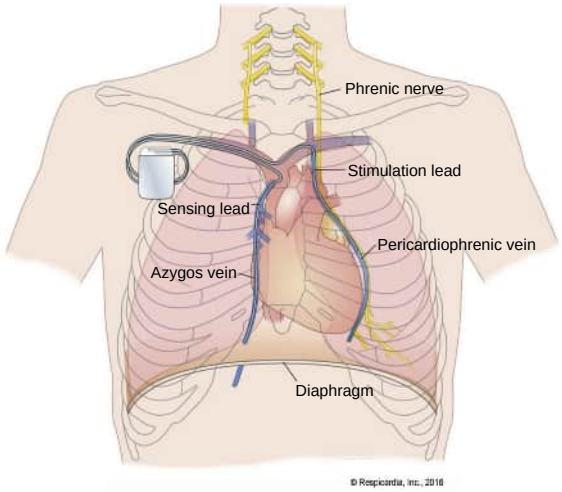
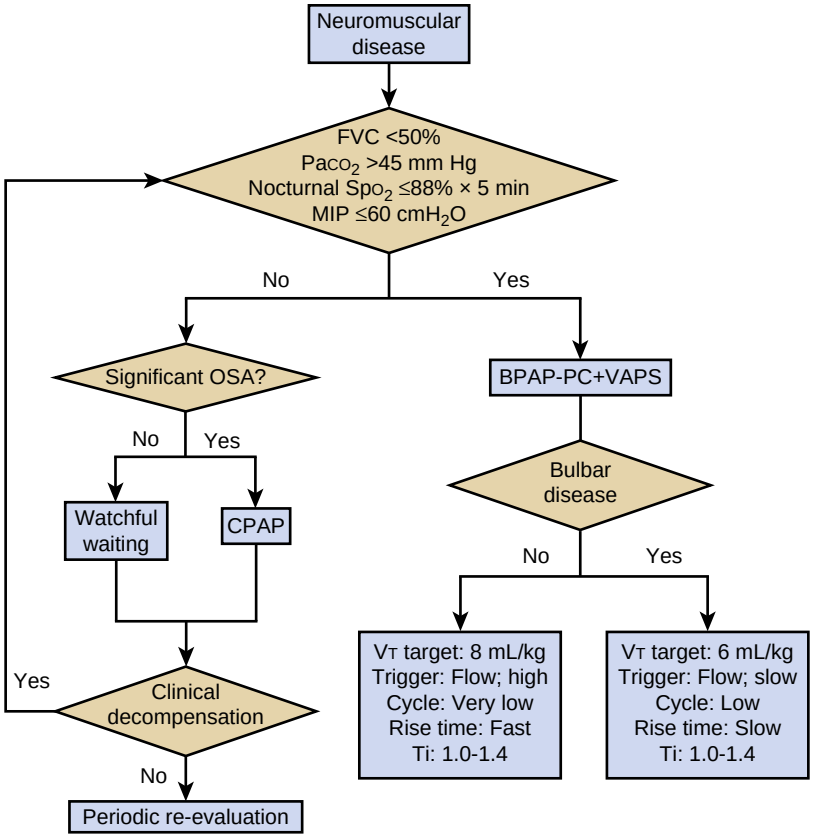
eFIGURE IMAGE GALLERY



eFigure 122.1 ***Obesity hypoventilation syndrome*** **(OHS) outpatient treatment algorithm.** Management of OHS in medically stable outpatients begins with weight loss but usually requires treatment with positive airway pressure therapy. When there is a significant degree of *obstructive sleep apnea* (OSA), *continuous positive airway pressure* (CPAP) is effective in alleviating upper airway obstruction, thereby facilitating improved ventilation. When there is mild or no OSA, initiation of bilevel therapy is indicated. Patients requiring pressures higher than 20 cm H_2O will also require bilevel treatment because all CPAP devices have a maximum possible pressure of 20 cm H_2O. If adequate ventilation is not achieved, adding a backup rate or volume-assured pressure support (VAPS) add-on is indicated. If sufficient weight loss is achieved, de-escalation of bilevel therapy to CPAP may be possible. BPAP, bilevel positive airway pressure; HCO_3, bicarbonate; $Paco_2$, arterial partial pressure of carbon dioxide; S, spontaneous; ST, spontaneous timed.



eFigure 122.2 Neurostimulation in central sleep apnea treatment. Phrenic nerve stimulation consists of a generator, implanted stimulating lead (located within the pericardiophrenic vein), and sensing lead (located within the azygos vein). The sensing lead detects respiratory effort. The device can be programmed to deliver timed pulses at a fixed rate (asynchronous mode), or it can be set to deliver a pulse only when the sensing lead detects a prolonged pause in breathing (synchronous mode). (Remed ē system. Courtesy Respicardia, Inc., Minnetonka, MN.)



eFigure 122.3 Neuromuscular disease treatment algorithm. Management of patients with neuromuscular disease is based on markers of ability to ventilate effectively. When the underlying disease is advanced and ineffective ventilation is evident, noninvasive ventilation should be instituted. Early in the underlying disease course when ventilation is preserved, patients may be offered continuous positive airway pressure (CPAP) or alternative treatments if obstructive sleep apnea (OSA) is diagnosed. If no sleep-disordered breathing is present, watchful waiting is acceptable. Initial settings for patients with and without bulbar disease are suggested, although therapy should be tailored at an individual level. BPAP-PC, bilevel positive airway pressure-pressure control; FVC, forced vital capacity; MIP, maximal inspiratory capacity; $Paco_2$, arterial partial pressure of carbon dioxide; Spo_2, oxygen saturation as measured by pulse oximetry; VAPS, volume-assured pressure support; V_T, tidal volume.

KEY POINTS

INTRODUCTION

Since the recognition of the first cases of *acquired immunodeficiency syndrome* (AIDS) in 1981, our understanding of *human immunodeficiency virus* (HIV) and its myriad infectious and noninfectious complications has markedly increased. The prognosis for persons infected with HIV has undergone dramatic change for those with access to effective combination *antiretroviral therapy* (ART) and medications for treatment and prevention of HIV-associated infectious complications. These advances have resulted in a dramatic decline in the incidence of new AIDS cases and the number of AIDS-associated deaths where this care is widely and consistently available.[1]

The lungs remain one of the chief target organs of HIV morbidity and mortality. The spectrum of pulmonary manifestations is broad and includes infectious and noninfectious complications (Table 123.1).[2] These complications include diseases that are AIDS defining (e.g., *Pneumocystis* pneumonia) or HIV associated (e.g., bacterial pneumonia), disorders that are not identified classically as HIV associated but appear to be more common in those with HIV infection (e.g., lung cancer, *pulmonary arterial hypertension* [PAH], and COPD), and conditions whose association with HIV is inconclusive or purely coincidental (e.g., sarcoidosis).

EPIDEMIOLOGY

Global estimates indicate that 38 million people were living with HIV in 2019.[3] Overall, approximately 0.7% of adults age 18 to 49 years are infected with HIV worldwide

in 2019. Eastern and sub-Saharan Africa have 54% of the global population living with HIV. After Eastern and sub-Saharan Africa, the regions with the highest burden are Asia and the Pacific, and Western and central Africa. The estimated prevalence of diagnosed HIV infection in the United States was 374.6 per 100,000 population in 2018.

New HIV infections have declined over the past 2 decades, from 3.4 million in 1996 to 1.7 million in 2019.[3] AIDS-related mortality has also declined by 39% since 2010.[3] Because survival has improved for HIV-infected patients since the introduction of ART, more people are living with HIV in the United States than ever before.[5] Furthermore, in the recent era, HIV-infected adults in clinical care in the United States are more likely to be prescribed ART, to have a suppressed HIV viral load, and to have a higher median $CD4^+$ T cell count.[6]

The gender and racial/ethnic demographics of HIV-infected populations vary worldwide. In sub-Saharan Africa, women account for the majority of people estimated to be living with HIV.[3] In the United States, women comprise approximately 24% of adult AIDS cases.[4] Although early in the epidemic HIV was predominantly seen among non-Hispanic white *men who have sex with men* (MSM), HIV increased disproportionately in minorities, especially Blacks and Hispanic/Latin Americans, and recently for Native Hawaiians/other Pacific Islanders.[4,7,8]

IMMUNOLOGIC ABNORMALITIES

Without ART, HIV causes a gradual and inexorable loss of host immunity characterized as a syndrome of immune dysregulation, dysfunction, and deficiency involving multiple components of the immune system. HIV is tropic for $CD4^+$ lymphocytes and monocytes.[9] After initial infection, HIV leads to massive depletion of $CD4^+$ effector-memory lymphocytes from mucosal-associated lymphoid tissue.[10] During the chronic phase of untreated HIV infection, there is generalized immune activation and ultimately a progressive decline in the naive and memory T cell pool that results in systemic $CD4^+$ lymphocyte depletion.[10,11] As well as being decreased in number, T cells are also dysfunctional and mount abnormal responses to antigens. HIV infection is also associated with B cell dysfunction, with polyclonal activation, hypergammaglobulinemia, and defective specific antibody responses. This combination of immune dysfunction, dysregulation, and depletion of $CD4^+$ lymphocytes results in increased risk of infections and other complications if HIV infection is untreated.

Among *people living with HIV* (PLWH) treated with ART,[10] chronic inflammation and immune activation decrease, although they can persist, particularly in those who began ART at lower $CD4^+$ cell counts or those whose treatment is interrupted.[12,13] Premature mortality and comorbidities, including pulmonary, cardiovascular, neurologic, renal, and liver disease, have been associated with residual inflammation and immunodeficiency despite ART.[14,15]

HIV infection alters several lines of host defense in the lung and respiratory tract that contribute to an increased risk for pulmonary infections.[16] Among other defenses, HIV alters mucociliary function and soluble defense molecules in respiratory secretions. Within the lung, innate and adaptive immune responses to pathogens may be impaired. For example, alveolar macrophages from HIV-infected individuals have deficiencies in pathogen recognition, including abnormalities in toll-like receptor 4 signaling.[17,18] *Bronchoalveolar lavage* (BAL) $CD4^+$ T cells from HIV-infected individuals display impaired responses

to respiratory pathogens, including influenza virus and *Mycobacterium tuberculosis*.[19] HIV can also result in chronic stimulation and activation of inflammatory cells within the alveolar space.[20] Studies in animal models suggest that certain HIV proteins disrupt the barrier function of the alveolar epithelium.[21]

Persistently increased inflammation and immune activation related to HIV have been linked to chronic lung complications. Within the alveolar space, HIV infection is associated with changes in the cellular profile[16]; however, the mucosal depletion of $CD4^+$ T cells that takes place in the gastrointestinal tract is not observed in the lung. Instead, BAL fluid from HIV-infected individuals has more $CD4^+$ T cells than does the terminal ileum.[22] Lung cells that can be infected with HIV include alveolar macrophages, T cells, and fibroblasts.[16] Alveolar macrophages and T cells may be reservoirs of HIV in the lung.[23] The clinical significance of the lung as a compartment for HIV-infected cells is incompletely understood.[24]

DIAGNOSTIC APPROACH

The evaluation of an HIV-infected patient with pulmonary disease is aimed at making a specific diagnosis. Although each pulmonary disease has characteristic clinical and radiographic features, these features often overlap. On occasion, the presenting features are atypical, or more than one pulmonary disease is present. Without appropriate therapy, patients with pneumonia can progress rapidly to respiratory failure and death. The therapies used to treat HIV-associated pulmonary diseases have substantial toxicities and interactions with other medications.

The evaluation should begin with the history and physical examination.[25] Laboratory testing should be performed and a chest radiograph obtained in patients with suspected pulmonary disease. Frequently, the results of this evaluation suggest a specific differential diagnosis and management plan. On occasion, additional studies such as *pulmonary function testing* (PFTs) or chest *computed tomography* (CT) are needed to narrow the differential diagnosis and to refine the management plan.

$CD4^+$ LYMPHOCYTE COUNT

The blood $CD4^+$ lymphocyte count is an indicator of an HIV-infected patient's risk for development of opportunistic infections or neoplasms. Many HIV-associated pulmonary diseases present at or below a characteristic $CD4^+$ lymphocyte count and are seldom seen at higher counts.[26] Exceptions are diseases that can present in persons without HIV infection, such as bacterial pneumonia, *tuberculosis* (TB), and *non-Hodgkin lymphoma* (NHL). In HIV-infected persons, these diseases can present at any $CD4^+$ lymphocyte count, although their incidence increases and their characteristic presentation changes as the $CD4^+$ lymphocyte count declines.

The risk of opportunistic infections is best reflected by the current $CD4^+$ T-lymphocyte count.[27] At $CD4^+$ T cell counts less than 200/μL, bacterial pneumonia is often accompanied by bacteremia, and *M. tuberculosis* disease is often extrapulmonary or disseminated. Moreover, below this $CD4^+$ lymphocyte count, *Pneumocystis* and *Cryptococcus* pneumonia become important considerations, whereas neither typically presents in a patient with a count significantly higher than 200 cells/μL. At $CD4^+$ T cell counts less than 50 to 100 cells/μL, endemic fungi, certain viruses (*cytomegalovirus* [CMV]), protozoa (*Toxoplasma gondii*), *nontuberculous mycobacteria* (NTM; *Mycobacterium avium* complex [MAC]), and pulmonary involvement from *Kaposi sarcoma* (KS) become important considerations. Many of these diseases present with extrapulmonary or disseminated manifestations that may dominate the clinical presentation.

FIBEROPTIC BRONCHOSCOPY

Bronchoscopy should be considered for any HIV-infected patient with pulmonary disease whose severity warrants a prompt and accurate diagnosis, for patients with suspected pulmonary KS, for patients with suspected NHL (if other diagnostic procedures are more hazardous or less likely to provide the diagnosis), for patients whose diagnosis remains unknown despite less invasive diagnostic studies (e.g., induced sputum), and for patients whose empirical therapy is failing.

The decision to perform BAL with or without *transbronchial biopsy* (TBB) depends on the suspected diagnosis and on the sensitivities of these procedures for that diagnosis. At the beginning of the AIDS epidemic, both BAL and TBB were usually performed during the initial bronchoscopy. Currently, BAL alone is generally performed when *Pneumocystis* pneumonia (PCP) is suspected.[28] The sensitivity of BAL fluid examination for *Pneumocystis* is 97% or higher; therefore, a negative BAL fluid examination for *Pneumocystis* rules out the diagnosis of PCP in all but the rarest cases.[28]

In contrast, TBB improves the sensitivity of bronchoscopy for diagnosing other pathogens, including TB and endemic fungal pneumonias. Furthermore, tissue confirmation from TBB or another biopsy specimen is required for a definitive diagnosis of invasive aspergillosis, CMV pneumonia, and NHL. Therefore, when the clinical and radiographic features suggest one of these diseases, both BAL and TBB are warranted during the initial bronchoscopy.

INFECTIOUS COMPLICATIONS

In this section the major pulmonary infectious complications of HIV disease are reviewed according to category of infectious microorganism (see Table 123.1).

BACTERIA

Recurrent bacterial pneumonia, defined as two or more episodes within 12 months, is an AIDS-defining illness.[29,30] During the ART era (1996 to the present), the incidence of community-acquired bacterial pneumonia among HIV-infected persons has declined.[31–35] The shift to earlier initiation of ART over time has further contributed to a decrease in bacterial pneumonia. For example, initiation of ART early in individuals with $CD4^+$ cell counts greater than 500 cells/μL resulted in a lower incidence of bacterial infection, including pneumonia, compared to individuals who

had ART initiated when the CD4+ cell count fell below 350 cells/μL or when AIDS complications developed.[36]

However, despite a decrease in incidence since the introduction of ART, bacterial pneumonia remains more common in PLWH compared to uninfected persons, and is a leading cause of morbidity even for persons on ART and with CD4+ cell counts in the normal range.[37–39] In the United States and Western Europe, bacterial pneumonia is now the most common HIV-associated pneumonia in populations on ART.[40] Several factors may account for the persistence of bacterial pneumonia despite effective ART. For one, cigarette smoking is prevalent in HIV-infected populations, and is associated with increased rates of pneumonia in HIV-infected patients at all CD4+ lymphocyte cell counts,[30,38,41,43] whereas smoking cessation decreases the risk for pneumonia.[44] Injection drug use also remains a risk factor for bacterial pneumonia in the ART era. As patients are aging, conditions such as COPD, heart disease, and cancer also contribute increased risk for bacterial pneumonia.[45]

Several bacterial species cause pneumonia in HIV-infected patients. Similar to community-acquired bacterial pneumonia in non–HIV-infected populations, *Streptococcus pneumoniae* and *Haemophilus* species are the most frequently identified pathogens in people with HIV infection and account for approximately 50–60% of cases combined,[30,46] and they remain the most commonly isolated bacteria in the ART era.[47,48] *Staphylococcus aureus* can be isolated as a cause of community-acquired pneumonia in patients both with and without a history of injection drug use,[47,49,50] and *Pseudomonas aeruginosa* is a cause of community-acquired bacterial pneumonia in HIV-infected persons with advanced AIDS (eFig. 123.1). Other bacteria that are occasional causes of community-acquired bacterial pneumonia in HIV-infected persons include *Legionella* species, *Rhodococcus equi,* and *Nocardia* species; these are discussed in detail later.

Of hospital-acquired pneumonias, the two most common bacterial causes in HIV-infected persons are *S. aureus* and *P. aeruginosa.* Both of these organisms are more likely to be isolated in patients with lower CD4+ lymphocyte counts.[46,51] Staphylococcal pneumonia is frequently complicated by bacteremia, methicillin resistance, and high mortality.[51] *S. pneumoniae* and *Klebsiella pneumoniae* are also relatively frequent causes of pneumonia in HIV-infected hospitalized patients.[51]

Clinical Features. In HIV-infected persons, the clinical and radiographic features of bacterial pneumonia are similar to those in immunocompetent persons, with a few important exceptions.[52] Of note, HIV-infected individuals have a substantially increased risk for bacteremia and invasive disease due to *S. pneumoniae*. The rate of pneumococcal bacteremia in HIV-infected patients has been estimated to be up to 100 times greater than that in age-matched non–HIV-infected persons.[53] Findings that confer greater risk for bacteremic pneumococcal pneumonia include alcohol abuse, cigarette smoking, recent hospitalization, and presence of comorbid illnesses.[54] The risk of invasive pneumococcal disease is decreased in those on ART and in those who have received pneumococcal vaccine.[55] However, although the incidence of invasive pneumococcal disease has decreased in the current era, the clinical presentation can be severe and may be complicated by respiratory failure.[56] Providers should consider HIV testing for individuals with unknown serostatus presenting with invasive pneumococcal disease.[55]

CD4+ Lymphocyte Count. Bacterial pneumonia can develop throughout the course of HIV infection and at any CD4+ T cell count. As the CD4+ T cell count declines, the incidence of bacterial pneumonia and the frequency of bacteremia increase. Most cases of *P. aeruginosa* pneumonia are seen in HIV-infected patients with a CD4+ T cell count less than 100 cells/μL and usually less than 50 cells/μL.[57,58]

Imaging. As illustrated in Figure 123.1, the majority of bacterial pneumonias due to *S. pneumoniae* in HIV-infected patients present with segmental, lobar, or multilobar consolidation on chest radiograph.[59] Radiographic findings of pneumococcal pneumonia do not appear to be different among patients on ART than in those not on ART.[60] Although less common, focal or diffuse alveolar patterns and interstitial opacities in association with *S. pneumoniae* or *Haemophilus influenzae* are also seen.[61,62] Pneumonia due to *P. aeruginosa* may present with focal consolidation, similar to pneumococcal or *Haemophilus* pneumonias, although a substantial proportion of radiographs demonstrate cavitary opacities.[57,63]

Diagnosis. The diagnostic approach to bacterial pneumonia is the same for HIV-infected as for non–HIV-infected persons.[27,64] Blood cultures should be obtained, particularly in those with low CD4+ cell counts, given the increased risk for bacteremia in this group.[65] Thoracentesis should be considered for patients with pleural effusion, especially if the effusion is large or if there is concern for empyema.

Figure 123.1 Pneumococcal pneumonia. Frontal chest radiograph in a 50-year-old HIV-infected man with positive urinary pneumococcal antigen shows homogeneous opacity with air bronchograms, extending to the pleural surface, representing a lobar pneumonia pattern, typical of pneumococcal pneumonia. (Courtesy Stephen Aston, MBChB; Malawi-Liverpool–Wellcome Trust Clinical Research Programme.)

Efforts to culture the causative bacteria to enable drug susceptibility testing are especially important in communities where drug-resistant bacteria are prevalent.

Pneumococcal urinary antigen testing offers the potential for early, specific diagnosis. In a study of 70 adults with pneumococcal pneumonia, 47 of whom were HIV infected, pneumococcal urinary antigen testing had a sensitivity of 81%, specificity of 98%, positive predictive value of 98%, and negative predictive value of 82%.[66] The test performed equally well in HIV-infected and non–HIV-infected persons.

Serum procalcitonin and C-reactive protein levels may assist in the differentiation of bacterial community-acquired pneumonia and pulmonary TB in HIV-infected patients; procalcitonin and C-reactive protein levels were higher in patients with bacterial pneumonia than in patients with pulmonary TB, although overlap exists between these causes of pneumonia, particularly in regions endemic for tuberculosis.[67,68] Because procalcitonin increases in response to bacterial and not viral infections, levels are sometimes used as a biomarker of bacterial pneumonia.[69] Elevated procalcitonin levels can predict increased mortality in HIV-infected patients with lower respiratory tract infections due either to TB or to bacterial causes.[70]

Treatment. The treatment of patients with community-acquired pneumonia is similar for HIV-infected and non–HIV-infected persons (see Chapter 46).[27,64] The choice of antimicrobial agent should be based on the results of a sputum Gram stain, the presence of comorbid conditions (e.g., COPD, congestive heart failure, alcohol use), the clinical and radiographic presentation, and the severity of the pneumonia. As in non–HIV-infected persons, treatment should be initiated promptly. Initial empirical therapy should include coverage against frequently identified organisms (e.g., *S. pneumoniae* and *Haemophilus* species). Local prevailing drug resistance patterns must be considered when the antibiotic is selected. Empirical monotherapy with a macrolide is not advised in HIV-infected patients, particularly when they are already on macrolide prophylaxis for MAC because of increasing pneumococcal resistance to macrolides.[27] Patients on *trimethoprim-sulfamethoxazole* (TMP-SMX) prophylaxis may be more likely to have penicillin- and TMP-SMX–resistant *S. pneumoniae.*[71] For patients with $CD4^+$ T cell counts less than 100 cells/μL, especially if associated with recent hospitalization, neutropenia, or broad-spectrum antimicrobial use, coverage of *P. aeruginosa* should be included. Evaluation for opportunistic infections should also be considered in patients who have $CD4^+$ T cell counts less than 200/μL.

Prevention. Pneumococcal vaccine should be given to HIV-infected patients. For adult (age 19 years and older) immunocompromised patients, including those with HIV who have not been previously immunized, current recommendations from the Advisory Committee on Immunization Practices are for the 13-valent pneumococcal conjugate vaccine to be given first, followed by the 23-valent pneumococcal polysaccharide vaccine 8 weeks or more later.[72] For those who have already received the 23-valent pneumococcal polysaccharide vaccine, the 13-valent pneumococcal conjugate vaccine should be given at least 1 year later. A repeat dose of the 23-valent pneumococcal polysaccharide vaccine should be given 5 years after the first, with another dose given after age 65 years. These recommendations may be revised based on ongoing clinical trials; refer to the Advisory Committee on Immunization Practices and *Centers for Disease Control and Prevention* (CDC), *National Institutes of Health* (NIH), and the *HIV Medicine Association of the Infectious Diseases Society of America* (HIVMA/IDSA) guidelines for additional details.[27,72] Because influenza is a major risk factor for bacterial pneumonia, prevention also includes yearly administration of inactivated or recombinant influenza vaccine in all HIV-infected individuals.

OTHER BACTERIA

Legionella pneumonia is an infrequent cause of bacterial pneumonia in HIV-infected patients and can be community or hospital acquired.[73] Cases have been reported in persons with severe immunosuppression and in individuals with well-controlled HIV on ART.[74] The chest radiograph typically reveals alveolar opacities; bilateral involvement is common. Extrapulmonary manifestations can also be seen, especially of the gastrointestinal tract and central nervous system. In one series, respiratory failure developed in 12 of 15 hospitalized, HIV-infected subjects (80%) with *Legionella* pneumonia and 3 died.[74] Although *Legionella pneumophila* is the most common species identified, other *Legionella* species have been reported. Rapid diagnosis of *Legionella* pneumonia can be obtained with urinary antigen testing. However, cultures and/or serology should still be considered as part of the diagnostic evaluation because the urinary antigen primarily detects *L. pneumophila* serogroup 1 and can have a lower sensitivity in cases of mild disease.[75] Its performance has not been prospectively evaluated in HIV-infected patients.

R. equi pulmonary disease has been reported in HIV-infected persons. A review of more than 100 reported cases of *R. equi* infection found that approximately two-thirds were in HIV-infected persons, with pulmonary disease present in the majority.[76] HIV-infected persons were more likely to have *R. equi* bacteremia or extrapulmonary manifestations, or both, than persons without HIV infection. Most cases present when the $CD4^+$ T cell count is less than 200 cells/μL and usually less than 100 cells/μL.[76] In one multicenter series of 67 HIV-infected patients with *R. equi* infection, the mean $CD4^+$ T cell count was 35 cells/μL (range, 1–183 cells/μL).[77] The chest radiograph can reveal cavitary lesions that may mimic TB or nocardiosis, or focal consolidation that may mimic bacterial pneumonia.[78] Sputum, blood, bronchoscopy, and pleural fluid specimens can establish the diagnosis of *R. equi* pneumonia.[77] The optimum treatment regimen and duration are not well defined.[76] Combination antimicrobial therapy is generally recommended, and treatment for a minimum of 2 months (and frequently 6 months) is often required. Because relapses are common, chronic suppressive therapy is probably indicated.

Nocardia asteroides is the most common species identified in several reports of *Nocardia* infection in HIV-infected patients, and the lung is the most commonly affected site. Most cases present when the $CD4^+$ T cell count is less than 200 cells/μL. In one series of 30 HIV-infected patients with nocardiosis, the mean $CD4^+$ T cell count was 109 cells/μL

(median, 92 cells/μL; range, 12–266 cells/μL).[79] The presenting symptoms often mimicked TB. Imaging (eFig. 123.2) usually reveals cavitary lesions or lobar or multilobar opacities, especially in the upper lung zones, although reticulonodular opacities, solitary masses, and pleural effusions are also seen.[80] Sputum or bronchoscopy can establish the diagnosis of pulmonary nocardiosis. A modified *acid-fast bacilli* (AFB) stain may provide an early presumptive diagnosis in the proper clinical setting. Long-term TMP-SMX is the treatment of choice.

MYCOBACTERIA

Early in the AIDS epidemic, mycobacteria were recognized as major sources of HIV-associated morbidity and mortality. Initially, disseminated MAC was noted to develop in HIV-infected patients. Subsequently, the strong association between HIV and *M. tuberculosis* and NTM, such as *Mycobacterium kansasii,* became clearer. Other NTM are also occasionally identified as causes of pneumonia in HIV-infected persons.

Mycobacterium tuberculosis

TB is the most prevalent opportunistic infection complicating HIV worldwide. Unlike most HIV-associated infections, *M. tuberculosis* is transmissible from person to person, including to those without HIV infection. In fact, clusters of transmission of TB that include at least one HIV-infected person are larger, last longer, and have a shorter time period between successive cases than clusters composed of solely non-HIV persons.[81]

The AIDS epidemic contributed to marked increases of TB throughout the world, especially in low-income countries, where it is often the first manifestation of HIV and the leading cause of mortality. The *World Health Organization* (WHO) estimated that there were 862,000 cases of TB in persons with HIV in 2018, with the vast majority of these cases in sub-Saharan Africa.[82] There are also approximately 11 million HIV-infected individuals with latent TB. More than 208,000 HIV-infected persons died of TB in 2019, making it the leading cause of death in HIV-infected populations worldwide.[82]

The AIDS epidemic has also affected TB in the United States. Before 1985, the incidence of TB in the United States regularly declined by 5–6% per year. From 1985–92, the AIDS epidemic led to dramatic increases in TB cases. Since 1992, TB cases have continued to decline, and in 2019, 8920 new TB[83] cases were reported, the lowest number since TB reporting began in 1953.[84] The proportion of TB cases with known HIV infection has also decreased from 15% in 2003 to 4.9% in 2019.[83,84]

It remains unclear whether HIV-infected persons are more likely to acquire infection after exposure to *M. tuberculosis* than non–HIV-infected persons, but it is clear that HIV infection increases the risk for development of primary TB disease, as well as progressing from *latent tuberculosis infection* (LTBI) to active tuberculous disease. Instead of a 5% lifetime risk of disease, the risk for TB among HIV-infected persons with LTBI in the pre-ART era has been estimated to be as high as 10–16% per year.[27] Even with effective ART, the risk of TB disease among HIV-infected persons exceeds that of non–HIV-infected persons.

Multidrug-resistant tuberculosis (MDR-TB), defined as resistance to at least isoniazid and rifampin (also known as rifampicin in many countries), poses a particularly grim prospect for the HIV-infected person. The risk of drug-resistant TB has been reported to be greater among HIV-infected patients than among others, and drug-resistant TB appears to be associated with decreased survival, particularly in those with lower $CD4^+$ T cell counts or in individuals not receiving ART.[85–87] Factors that lead to acquired drug resistance include an inadequate initial treatment regimen, patient nonadherence with the prescribed regimen, and the addition of a single drug to a failing regimen. MDR-TB can also develop as a result of exogenous reinfection from a multidrug-resistant source.[88]

Extensively drug-resistant tuberculosis (XDR-TB), defined as resistance to at least isoniazid and rifampin, plus resistance to any fluoroquinolone and at least one second-line injectable drug, was first reported in 2006.[89] It has been documented in all regions of the world and in HIV-infected persons.[90–92]

Clinical Features. Worldwide, TB is the most common initial manifestation of HIV infection.[93] Thus any person diagnosed with TB should also undergo testing for HIV. The clinical and radiographic features of TB in both HIV-infected and non–HIV-infected persons vary and are fully discussed in Chapter 53. HIV infection is independently associated with an increased risk for extrapulmonary TB.[94] HIV infection is also associated with a lower frequency of cavitary TB, especially in patients with fewer than 200 $CD4^+$ T lymphocytes/μL at the time of TB diagnosis.[95]

$CD4^+$ Lymphocyte Count. TB may develop throughout the course of HIV infection, regardless of the $CD4^+$ lymphocyte count, but the incidence of TB increases as the count decreases. The clinical expression of TB in HIV-infected persons is determined by the degree of immunodeficiency, as indicated by the $CD4^+$ lymphocyte count (see eTable 123.1). Persons with early HIV disease without profound depletion of $CD4^+$ T cells typically present with a picture suggestive of reactivation TB, with disease usually limited to the lungs. In contrast, persons with more advanced HIV disease typically present with findings resembling primary pulmonary TB, often with disseminated or extrapulmonary TB. Any extrapulmonary site may be involved; common sites include lymph nodes (usually cervical, supraclavicular, and axillary), bone marrow, genitourinary tract, central nervous system, and liver.[96]

Imaging. The prevalence of specific chest radiograph features of TB also depends on the degree of immunodeficiency. Early in the course of HIV infection, TB mirrors that encountered in immunocompetent persons: upper lung zone opacities, often with cavitation, on chest radiograph. However, with profound depletion of $CD4^+$ T cells, TB often presents with middle and lower lung zone opacities (Fig. 123.2, eFig. 123.3); with diffuse opacities, including a miliary pattern (eFig. 123.4); or with a normal chest radiograph. As the $CD4^+$ lymphocyte count declines, cavitation becomes less common[95] and intrathoracic adenopathy (Fig. 123.3, eFig. 123.5) becomes more common. ART also affects the chest radiographic appearance in HIV-infected patients with TB;

eTable 123.1 Manifestations of HIV-Associated Tuberculosis Related to Extent of Immunodeficiency

Feature	HIV With Minimal Depletion of $CD4^+$ T Cells (≥350/μL)	HIV With Marked Depletion of $CD4^+$ T Cells (<200–350/μL)
Extrapulmonary	10–15%	>50%
Radiographic distribution	Upper zones	Lower and middle zones
Radiographic findings		
Cavitation	Common	Uncommon
Adenopathy	Uncommon	Common
Miliary	Uncommon	Common
Pleural effusion	Uncommon	Rare

Modified from Murray JF. Cursed duet: HIV infection and tuberculosis. *Respiration.* 1990;57:210–220; with data from Geng E, Kreiswirth B, Burzynski J, Schluger NW. Clinical and radiographic correlates of primary and reactivation tuberculosis: a molecular epidemiology study. *JAMA.* 2005;293(22):2740–2745.

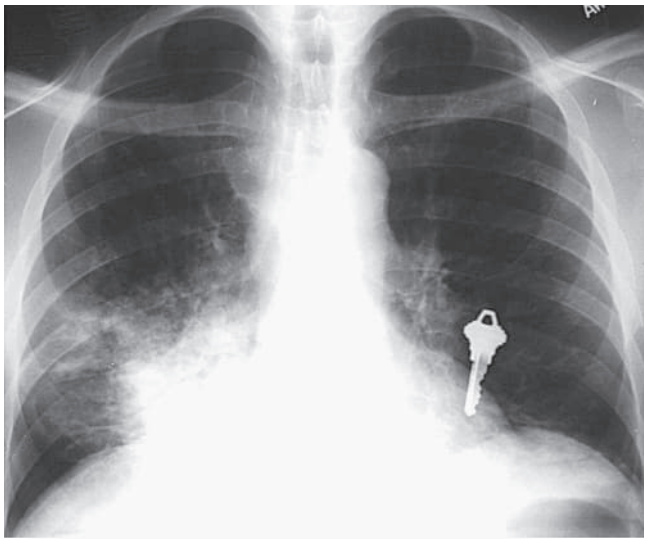

Figure 123.2 Tuberculosis in patient with HIV and a low CD4⁺ count. Frontal chest radiograph of an HIV-infected patient showing focal right lung consolidation with air bronchograms. Culture of sputum revealed *Mycobacterium tuberculosis* that was rifampin resistant. Knowledge of the patient's CD4⁺ lymphocyte count (<50 cells/μL) and understanding that tuberculosis can present with middle to lower lung zone consolidation during "late" HIV infection were instrumental in making the diagnosis of tuberculosis. The key was in the patient's pocket. (Courtesy L. Huang.)

Figure 123.3 Tuberculosis in patient with HIV and a low CD4⁺ count. Frontal chest radiograph of an HIV-infected patient showing mediastinal adenopathy. Culture of biopsy material revealed *Mycobacterium tuberculosis.* Among HIV-infected persons, the proportion of cases that present with intrathoracic adenopathy on chest radiograph increases as the CD4⁺ lymphocyte count decreases. (From Murray JF, Mills J. Pulmonary complications of HIV infection. *Am Rev Respir Dis.* 1990;141:1356–1372, 1582–1598.)

in one study of 209 patients, 82% of patients receiving ART presented with a radiographic pattern of TB resembling that in immunocompetent persons, compared with 44% of patients not receiving ART ($P < 0.001$).[97]

Diagnosis. The diagnostic approach to TB is the same for HIV-infected as for non–HIV-infected persons, especially isolation and identification of *M. tuberculosis* by culture or by nucleic acid amplification (see Chapter 53). Three sputum specimens should be examined for AFB and cultured for mycobacteria.[27] Current recommendations support the use of nucleic acid amplification testing of at least one sputum specimen because these tests can confirm the presence of TB and detect drug resistance in smear-positive patients and because nucleic acid amplification testing is more sensitive than AFB smear, allowing more rapid diagnosis of TB in smear-negative, culture-positive samples.[27,98–100] The WHO recommends the use of Xpert MTB/Rif (Cepheid) nuclear amplification test as an initial test for HIV-associated TB and in MDR-TB.[101] A new Xpert MTB/Rif test has been developed (MTB/Rif Ultra), and it improves upon the sensitivity of the prior version, especially in smear-negative cases.[27] In patients with a nonproductive cough or scant secretions, sputum induction should be performed. Virtually any specimen can be studied for mycobacteria, including sputum, pleural fluid, urine, cerebrospinal fluid, and BAL fluid; transbronchial needle aspiration, fine-needle, and bone marrow aspirates; and all biopsy and tissue specimens. Blood cultures are specific and should be obtained, especially from those persons with a CD4⁺ lymphocyte count less than 200 cells/μL.

All cultures positive for *M. tuberculosis* should be submitted for susceptibility testing because the results are essential in identifying cases of drug resistance and in tailoring definitive treatment. More rapid identification of drug-resistance may be possible with genotypic testing to identify drug-resistance mutations in places where these tests are available.[27,98,99,102]

Treatment. The treatment of patients with TB is similar for HIV-infected and non–HIV-infected persons (see Chapter 54).[27] Because TB is transmissible, persons with suspected TB should be rapidly evaluated and started on appropriate antituberculous treatment to reduce the risk of transmission. The detection of AFB on smear, a positive molecular test or culture for TB, regardless of the source, is an indication for empirical antituberculosis treatment until final identification is obtained. HIV-infected persons with suspected TB should be started on four antituberculous drugs: isoniazid, rifampin, pyrazinamide, and ethambutol along with pyridoxine.[27,103] Directly observed therapy is recommended,[27] and daily rather than intermittent TB therapy is recommended.[104] If resistance to rifampin is suspected or confirmed, moxifloxacin or levofloxacin and an aminoglycoside or capreomycin should be included in the initial regimen and a TB expert consulted.[27] When results of species identification and susceptibility testing become available, treatment can be tailored as needed. In the United States the response to TB therapy and the time to convert sputum cultures from positive to negative appear to be similar in HIV-infected and non–HIV-infected patients.[103] In sub-Saharan Africa, however, the likelihood of death, especially during the first 2 months of therapy, and the likelihood of relapse after apparently successful treatment is considerably higher in HIV-infected than in non–HIV-infected patients.[105]

HIV-infected patients with TB are more likely to experience toxicity from antituberculous drugs than are non–HIV-infected persons.[106] HIV-infected patients are frequently receiving additional medications, and it is often difficult to distinguish an adverse drug effect to antituberculous drugs from those of other medications. As a result,

the first-line antituberculous drugs (especially isoniazid and rifampin) should only be discontinued permanently if there is strong evidence that these specific medications were the cause of toxicity.[103]

Despite challenges in ART use during TB therapy, ART given concurrently with TB treatment rather than sequentially has been associated with decreased mortality, greater AIDS-free survival, and more rapid conversion of sputum smears and culture in randomized studies.[27,107–111] Thus all HIV-infected individuals with pulmonary TB should receive ART.[27] If the patient is naive to ART, it is recommended that ART be initiated within 2 weeks of TB treatment initiation in individuals with $CD4^+$ cell counts less than 50 cells/μL and within 8 weeks in all others.[27] Note: In patients with TB meningitis (with or without pulmonary TB) and low $CD4^+$ counts, early ART may pose a risk for severe adverse effects, and an HIV-TB expert should be consulted to assist in this decision.[27] Individuals receiving ART should continue its use during TB therapy, but ART may need to be modified to minimize drug-drug interactions.

Clinicians need to be aware of several challenges of ART use during TB treatment. HIV-infected patients with TB who begin therapy for both *M. tuberculosis* and HIV infection may develop *immune reconstitution inflammatory syndrome* (IRIS), a paradoxical reaction presenting as exacerbation of clinical and radiographic features, which is more common with ART started early during antituberculosis therapy and among those with disseminated TB.[108–112] Furthermore, simultaneous treatment of HIV and *M. tuberculosis* poses additional challenges in terms of drug interactions. HIV *protease inhibitors* (PIs) and certain *non-nucleoside reverse transcriptase inhibitors* (NNRTIs) have significant interactions with the rifamycins, especially rifampin, principally related to the induction or inhibition (or both) of the hepatic *cytochrome P-450* (CYP) enzyme system.[103] Decreased drug levels are associated with development of drug resistance by both HIV and *M. tuberculosis,* whereas increased drug levels are correlated with toxicity. In persons receiving PIs, rifabutin is preferred over rifampin because it is a less potent CYP 3A4 inducer. Coadministration of rifampicin with *integrase strand transfer inhibitors* (INSTIs) is associated with a reduction in their trough levels. However, doubling the dose of INSTIs such as raltegravir was associated with optimal antiviral levels (bictegravir and elvitegravir should not be used with rifamycin-based therapies). Results from clinical trials on rifampicin and dolutegravir in active TB are expected soon (ClinicalTrials.gov Identifier: NCT02178592).[113] Information on the interactions between specific antiretroviral drugs and different rifamycins is regularly updated and can be found on such websites as the CDC website http://www.cdc.gov/tb and the U.S. Department of Health and Human Services AIDSinfo website https://aidsinfo.nih.gov/. Clinicians caring for HIV-infected patients with TB should consult experts for aid in management before initiating TB or HIV therapy.

Prevention of Exposure. In health care facilities, all persons with HIV infection and signs or symptoms compatible with TB should be placed in respiratory isolation until three sputum smears or molecular tests are negative. Prevention of transmission of drug-resistant TB is particularly important.

Prevention of Disease. HIV-infected persons are at high risk for progressing from LTBI to active TB. Therefore HIV-infected persons should be tested for LTBI by either a *tuberculin skin test* (TST) or *interferon-γ* (IFN-γ) release assay when HIV infection is first identified.[27,114] HIV-infected persons who are at risk for exposure to *M. tuberculosis* (either ongoing or repeated) should be tested for LTBI annually with TST.[27] In addition, persons who initially had a negative test but subsequently experienced an increase in their $CD4^+$ lymphocyte count to greater than or equal to 200 cells/μL due to ART should be retested for LTBI.[27] Any individual with a positive test for LTBI should be screened for symptoms and chest radiographic findings suggestive of active TB, and LTBI treatment should be given only to those without evidence of active TB.[27]

Several studies document that the risk of LTBI reactivation is virtually eliminated if an HIV-infected person who has been infected with a drug-susceptible organism takes adequate LTBI treatment.[27,114–116] HIV-infected persons with a positive TST (defined as 5-mm induration or greater), a positive IFN-γ release assay, or with a history of either of these and who have not received prior treatment for either LTBI or active TB should receive LTBI treatment. HIV-infected individuals who are close contacts of anyone with active TB should also receive treatment.[27] The standard treatment is isoniazid (300 mg daily) plus pyridoxine for 9 months.[27] Alternative treatments include isoniazid (plus pyridoxine) plus rifapentine (both weight-based dosing) once weekly for 12 weeks or rifampin daily for 4 months. Expert consultation should be sought for patients receiving ART or for individuals exposed to drug-resistant TB. Routine use of preventive therapy in anergic or purified protein derivative–negative HIV-infected persons is not generally recommended.[27,114]

Mycobacterium avium Complex

As discussed in Chapter 55, MAC consists of several related *Mycobacterium* species, including *M. avium* and *M. intracellulare.* With the use of ART, however, the incidence of disseminated MAC has declined since 1996.[1,117,118] MAC is ubiquitous in the environment, with species found in water and soil. Acquisition of infection in PLWH is chiefly through the gastrointestinal tract and occasionally through the lungs.[119] Person-to-person transmission is believed to be uncommon. Although numerous subspecies can cause pulmonary disease, cases of disseminated MAC are most frequently caused by *M. avium*, which suggests that there are important differences in exposure to or virulence of these particular strains.

Clinical Features. Isolated pulmonary disease from MAC is rare in the context of AIDS.[120] The most common clinical presentation is disseminated MAC disease, characterized by a febrile wasting syndrome consisting of fever, night sweats, fatigue, anorexia, and weight loss; other manifestations include abdominal pain and chronic diarrhea, hepatosplenomegaly, lymphadenopathy, progressive anemia, and, rarely, extrabiliary obstructive jaundice.[121] Laboratory abnormalities include anemia, which is often severe, and an elevated alkaline phosphatase level.

$CD4^+$ Lymphocyte Count. More than 95% of cases of disseminated MAC are seen in HIV-infected patients whose

$CD4^+$ lymphocyte count is 50 cells/μL or less.[121] Other risk factors for disseminated MAC include a plasma HIV viral level greater than 1000 copies/mL, history of previous opportunistic infection, and previous MAC colonization of the respiratory or gastrointestinal tract.[27]

Imaging. The chest radiograph is typically normal, even when the organism is cultured from respiratory tract secretions.[119] Focal pneumonia has been reported (eFig. 123.6) but is extremely rare,[120] as is presentation with solitary or multiple pulmonary nodules (eFig. 123.7). More frequently seen, but still uncommon, are endobronchial lesions without pneumonia.[122] These endobronchial lesions appear to be submucosal "pearls" (eFig. 123.8) with many AFB on biopsy. Lymphadenopathy, with or without necrosis, is a common imaging manifestation of thoracic MAC infection in HIV-infected patients (eFig. 123.9). Many of the cases of isolated pulmonary MAC were reported in patients who received ART, thus raising the possibility that this particular manifestation is an example of immune reconstitution. Clinicians should be aware of this possibility when starting patients on ART because IRIS may be seen either in patients with diagnosed disease or in those with subclinical infection.

Diagnosis. In HIV-infected patients with MAC, the organism can be cultured from numerous sites, with blood, bone marrow, liver, or lymph nodes representing the most productive sources.[121] Cultures should be performed on both solid and liquid culture media to increase sensitivity. The sensitivity of blood cultures for disseminated MAC has ranged from 86–98% of cases in which disseminated disease was confirmed by autopsy. The diagnosis of disseminated MAC can also be established by cultures from any normally sterile body site. Often, MAC is cultured from respiratory specimens such as sputum or BAL fluid, but, depending on the clinical situation, this finding may not indicate either pulmonary or disseminated disease.[119,123] If patients have abnormal chest radiographs with positive sputum cultures, the diagnostic criteria for immunocompetent hosts recommended by the *American Thoracic Society* (ATS) and IDSA, listed in Table 55.3, should be applied.[123] Species identification can be performed with a variety of techniques, including line probe assays, 16S ribosomal RNA gene sequencing, single- and multigene sequencing, and matrix-assisted laser desorption ionization–time of flight mass spectrometry, depending on laboratory capabilities.[124] The pathologic findings of MAC infection are characteristic but not definitive; AFB are remarkably abundant and are often packed within foamy macrophages or histiocytes; granulomas are usually absent or poorly formed.

Treatment. As emphasized in Chapter 54, the key to any regimen is the use of at least two drugs, including a macrolide: clarithromycin (500 mg twice daily) is preferred, but azithromycin (500–600 mg daily) can be substituted if needed.[27] One of these should be combined with ethambutol (15 mg/kg/day). Sensitivity testing of isolates to clarithromycin or azithromycin should be performed. Use of a third or fourth agent, such as rifabutin (300 mg daily), an aminoglycoside (i.e., amikacin 10–15 mg/kg intravenously daily), or a fluoroquinolone (i.e., levofloxacin 500 mg daily or moxifloxacin 400 mg/day), can be considered in patients with advanced immunodeficiency, high mycobacterial burden, or the inability to take ART.[27] As with TB, the use of rifabutin must be carefully scrutinized with concurrent administration of an NNRTI or a PI.

Prevention of Exposure. Although MAC can be found in environmental sources such as food and water, there are no specific recommendations regarding exposure avoidance as a prevention strategy.[27] Similarly, although the presence of MAC in a stool or respiratory specimen is predictive of disseminated disease, routine screening is not recommended.

Prevention of Disease. The CDC, NIH, and HIVMA/IDSA guidelines recommend that MAC primary prophylaxis be administered to HIV-infected patients with a $CD4^+$ lymphocyte count less than 50 cells/μL, no clinical evidence of disseminated MAC, and who have no options for a fully suppressive ART regimen.[27] Primary prophylaxis is not recommended for PLWH who are immediately initiated on ART.[27] Preferred MAC prophylaxis regimens include azithromycin (1200 mg weekly or 600 mg twice weekly) or clarithromycin (500 mg twice daily). Rifabutin is an alternative regimen if patients are intolerant of azithromycin or clarithromycin.[27] If rifabutin is to be used, TB must first be excluded because its use for MAC has been associated with rifampin monoresistance in *M. tuberculosis*. Individuals with a history of disseminated MAC should receive secondary prophylaxis/chronic maintenance therapy with a MAC treatment regimen cited earlier. In the setting of ART with increases in the $CD4^+$ lymphocyte count to greater than 100 cells/μL for at least 6 months—and after a minimum of 12 months of a macrolide-based MAC treatment regimen—most patients can discontinue therapy without relapse.[27] Initiation of secondary prophylaxis should be considered for PLWH if a fully suppressive ART regimen is not possible and the patient has $CD4^+$ counts consistently less than 100 cells/μL.

Mycobacterium kansasii

As described in Chapter 55, *M. kansasii* has a geographic distribution, predominantly in the southern and central United States.[123] Clusters of disease have also been reported in Europe, Asia, and Africa. Before the AIDS epidemic, infection and disease due to *M. kansasii* were uncommon. Thereafter, a dramatic increase in the incidence associated with HIV infection was observed, even in areas where *M. kansasii* was not thought to be endemic. Although rates of opportunistic infection from MAC and *M. kansasii* have generally declined in PLWH in the combination ART era, an increasing proportion of pulmonary mycobacterial disease due to NTM, including from *M. kansasii,* has been reported around the world.[125,126] Although *M. kansasii* pulmonary disease can be clinically indistinguishable from TB,[127] person-to-person transmission has not been documented, and infection is thought to arise from environmental sources, with tap water being most commonly implicated.

$CD4^+$ Lymphocyte Count. Similar to TB in HIV-infected persons, *M. kansasii* pneumonia can develop at any $CD4^+$ lymphocyte count. Most HIV-infected patients with *M. kansasii,* however, have evidence of severe immunodeficiency

with $CD4^+$ lymphocyte counts typically less than 100 cells/μL.[127–129] In the ART era, Canueto-Quintero and colleagues[127] reported a mean $CD4^+$ lymphocyte count of 20 cells/μL among 25 HIV-infected patients with *M. kansasii.* Witzig and coworkers[129] found that 32 of 49 HIV-infected patients (65%) with *M. kansasii* had isolated pulmonary disease (mean $CD4^+$ lymphocyte count, 75 cells/μL), whereas the remainder had disseminated disease (mean $CD4^+$ lymphocyte count, 28 cells/μL).

Imaging. The chest radiographic findings of *M. kansasii* vary. The most common radiographic findings resemble TB and include alveolar opacities, diffuse opacities, and cavities (see Fig. 55.6; eFig. 123.10); masses, intrathoracic adenopathy, and pleural effusions have also been reported. In a series of 83 HIV-infected patients with *M. kansasii,* the most frequent findings were consolidation (66%) and nodules (42%); abnormalities were most often located in the midlung and lower lung zones (89%), and in 10%, radiographs were normal.[130]

Diagnosis. The diagnosis of *M. kansasii* rests on its isolation and subsequent identification by culture. Pulmonary disease can be diagnosed by all of the techniques used for the diagnosis of TB. Unlike TB, however, in which identification of *M. tuberculosis* is diagnostic of disease, the identification of *M. kansasii* can occasionally represent colonization rather than disease.[131] The ATS/IDSA guidelines have defined criteria for diagnosis of NTM pulmonary disease that includes *M. kansasii* (see Table 55.3).[123] Nucleic acid probe testing, high-pressure liquid chromatography, and biochemical tests can be used for species identification.

Treatment. Treatment options for *M. kansasii* pulmonary disease include azithromycin (250–500 mg daily) or clarithromycin (1000 mg daily), with rifampin (600 mg daily) plus ethambutol (15 mg.kg daily). An alternative regimen for treatment of *M. kansasii* pulmonary disease consists of isoniazid (300 mg daily), rifampin (600 mg daily), and ethambutol (15 mg/kg daily).[123] Isolates should be tested for sensitivity to rifampin. If rifampin resistance is present, testing for susceptibility to other potential agents should be performed. Patients should also receive pyridoxine (50 mg daily) during treatment. Treatment options require consideration of drug-drug interactions and adjustment of regimens, such as avoidance of rifampin and substitution with rifabutin in those on PI or NNRTIs. Pyrazinamide is not useful because all *M. kansasii* isolates are resistant. Patients should receive treatment for a minimum of 12 months after their cultures become negative.

Prevention. There are no recommended prevention strategies for *M. kansasii*.

Other Mycobacteria

MAC and *M. kansasii* account for the great majority of NTM infections complicating HIV. Other mycobacteria, however, have occasionally been identified.[121,132] Increased frequency of exposure or specific defects in host defenses might account for the predominance of MAC and *M. kansasii* over other NTM in AIDS patients; differences in the virulence of the various mycobacterial species are also likely to play an important role.

FUNGI

Several fungi cause pulmonary disease in HIV-infected persons.[133] *Pneumocystis jirovecii,* formerly called *Pneumocystis carinii,* remains a common cause of HIV-associated pneumonia. *Cryptococcus neoformans,* the most common cause of meningitis in HIV-infected persons, often presents with an associated pneumonia. The endemic fungi *Histoplasma capsulatum, Coccidioides immitis, Penicillium marneffei,* and, to a lesser extent, *Blastomyces dermatitidis* are among the chief causes of HIV-associated disease seen in their particular geographic regions, and all have important pulmonary presentations. Finally, invasive aspergillosis is often a devastating pulmonary disease seen in HIV-infected persons with severe immunodeficiency. Further information about fungal pulmonary diseases is provided in Chapters 56 and 57.

Pneumocystis jirovecii

PCP remains the most common AIDS-defining opportunistic infection in the United States, even though its overall incidence has declined.[1] Early in the AIDS epidemic, PCP accounted for nearly two-thirds of AIDS-defining diagnoses, and PCP developed in an additional 15–20% of patients at some time during their HIV disease. Two factors—the use of ART and *Pneumocystis* prophylaxis—dramatically reduced the number of cases. Nevertheless, PCP remains a risk, chiefly among persons who are unaware of their HIV infection, those who fail to seek medical care, and those who fail to adhere to or respond to ART or *Pneumocystis* prophylaxis.[134–136]

History and Epidemiology. *Pneumocystis* was initially recognized as a human pathogen in the 1940s and 1950s. Despite more than a century of experience, several gaps in our understanding of this omnipresent organism remain.[137–140] One major obstacle that has impeded further advances has been the inability to culture *Pneumocystis* in vitro. Although mammals are the only known hosts of *Pneumocystis* and a number of mammals are susceptible to infection, *Pneumocystis* strains are species specific.[141] Although *Pneumocystis* can be transmitted between mammals of the same species, animal studies that have attempted to transmit *Pneumocystis* from one species to another have been unsuccessful.[141] In recognition of the host-species specificity of *Pneumocystis,* the *Pneumocystis* that causes *Pneumocystis* pneumonia in humans is now referred to as *P. jirovecii,* in honor of Otto Jirovec, the parasitologist credited with first identifying *Pneumocystis* as the cause of pulmonary disease in humans.[142,143]

The ecologic niche for *P. jirovecii* and its mode of transmission is unknown.[139,144,145] The inability to maintain human *Pneumocystis* in culture suggests that *P. jirovecii* may be unable to grow outside of its human host.[146,147] Given its species specificity, it is doubtful that other mammals are the reservoir for *P. jirovecii.* This host-species specificity also implies coevolution of humans and *P. jirovecii* that, in turn, implies long-term carriage of *P. jirovecii* in its human host. Infection with *P. jirovecii* is almost ubiquitous. Up to 85–100% of the U.S. population have antibodies to *P. jirovecii* by the age of 3 years.[148,149] In the setting of severe immunodeficiency, PCP can affect significant proportions of people. These studies and others suggest that activation of latent infection is a cause of *P. jirovecii* disease among

immunocompromised hosts. Outbreaks of newly acquired infection after de novo exposure to persons with PCP have also been documented, which suggests person-to-person transmission of *P. jirovecii* and the rapid development of disease. Results of studies that have used molecular tools to detect *Pneumocystis* are consistent with transmission of *P. jirovecii* from patients with PCP to their household and hospital contacts,[150,151] probably via inhalation of a *Pneumocystis*-containing aerosol.[152,153]

Risk Factors. Risk factors for PCP among HIV-infected adults include a $CD4^+$ lymphocyte count less than 200 cells/μL, a history of PCP, and oropharyngeal candidiasis.[154,155]

$CD4^+$ Lymphocyte Count. Approximately 95% of adolescent and adult cases of PCP are seen in HIV-infected patients whose most recent $CD4^+$ lymphocyte count is less than 200 cells/μL or $CD4^+$ percentage is less than 14%.[155]

Clinical Features. HIV-infected adults, unlike other immunocompromised persons, usually have a prolonged prodromal illness associated with PCP, often several weeks in duration.[156,157] This duration of symptoms can often be used to distinguish PCP from pyogenic pneumonia, which typically presents with 3 to 5 days of symptoms. Classically, PCP presents with fever, nonproductive cough, and dyspnea on exertion. High temperature, rigors, purulent sputum, and pleuritic chest pain are uncommon and can be used to distinguish PCP from pyogenic pneumonia.

Physical examination of the chest may be normal. When abnormal, the most frequent findings on lung auscultation are inspiratory crackles, which have been reported to be associated with a greater disease severity and an increased mortality.[157] Oxygen desaturation with exertion is a sensitive but nonspecific indicator of PCP.

Numerous studies have shown that the serum *lactate dehydrogenase* (LDH) level is increased in patients with PCP; however, an elevated serum LDH level does not establish the diagnosis of PCP, nor does a normal serum LDH value rule out the diagnosis. β-D-glucan, has been reported to be a potential diagnostic tool for PCP.[158,159] Immunoassays are another new diagnostic approach that could be used as a point-of-care test, especially in resource-limited settings.[160]

Imaging. Classically, PCP presents with bilateral, symmetrical reticular opacities (eFig. 123.11) or as granular opacities (eFig. 123.12A)[161]; these opacities typically begin in the perihilar region and extend outward as the disease severity increases. The ground-glass opacity appearance is particularly associated with the chest CT manifestations of this disorder (eFig. 123.12B). On occasion, the opacities are unilateral or asymmetrical (eFig. 123.13); a lobar or focal radiographic pattern is uncommon. Thin-walled cysts, or pneumatoceles, are seen in 10–20% of cases (Fig. 123.4).[162] Pneumatoceles may be single (eFig. 123.14A) or multiple (eFig. 123.14B–D), and small or large, and predispose patients to pneumothorax (eFig. 123.15), which is another radiographic presentation of PCP. Usually pneumatoceles resolve (see eFig. 123.14B–D), but occasionally they persist despite successful therapy.

Nearly any radiographic finding, including focal, lobar, or segmental consolidation (eFigs. 123.16 to 123.18), nodules (eFig. 123.19) with or without cavitation, and a miliary pattern, can be seen occasionally.[162] Intrathoracic adenopathy and pleural effusions are rarely due to PCP. These radiographic findings should prompt a search for an alternate or at least a coexisting process, such as bacterial pneumonia, TB, fungal pneumonia, or pulmonary.

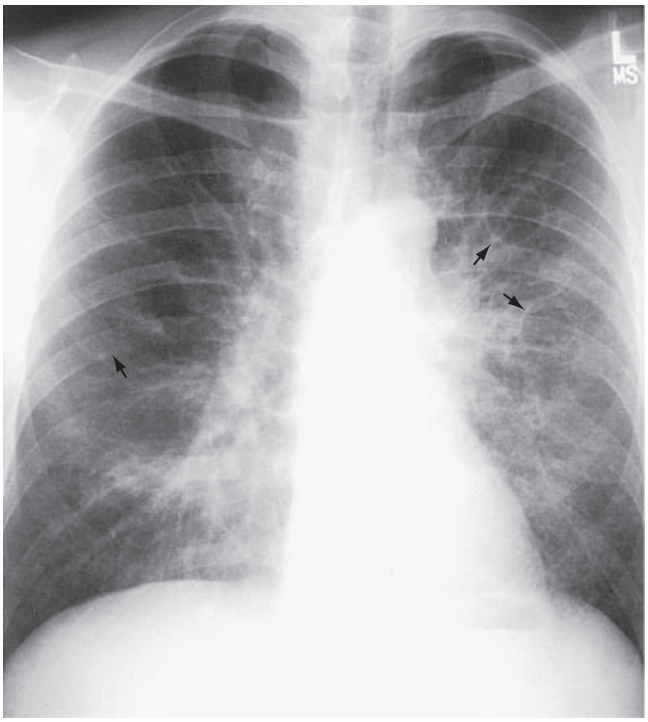

Figure 123.4 *Pneumocystis* pneumonia. Frontal chest radiograph of an HIV-infected patient with *Pneumocystis* pneumonia showing bilateral, predominantly perihilar, granular opacities, and three pneumatoceles (*arrows*). Pneumatoceles may be single or multiple in number, small or large in size, and may predispose patients to pneumothorax. (Courtesy L. Huang.)

KS PCP may also present with a normal chest radiograph. In several studies, a normal radiograph was present in 0–39% of patients with PCP.[161–165] In persons with a high clinical suspicion for PCP but a normal chest radiograph, high-resolution chest CT can be useful.[164]

Diagnosis. The diagnosis of PCP depends on microscopic visualization of *P. jirovecii* cysts or trophic forms (or both) on stained respiratory specimens. Often, the procedures to obtain these respiratory specimens (e.g., bronchoscopy) are lacking in the areas of the world with the greatest burden of HIV/AIDS.[165]

The standard methods for detection of *P. jirovecii* have been with cyst wall stains, such as methenamine silver and toluidine blue-O or with Giemsa and Diff-Quik, which stain both the cystic and trophic forms; monoclonal antibodies to *P. jirovecii* are also used.[166] *Polymerase chain reaction* (PCR)-based techniques have also been used and have been reported to be more sensitive but also less specific than these other methods.[166,167]

Sputum induction is an appropriate initial diagnostic procedure for PCP, but the sensitivity of induced sputum testing is less than 100%, and thus a negative result should be followed by bronchoscopy with BAL performed in the most

affected lobe visualized on chest radiograph.[28] For patients with diffuse radiographic disease, BAL in the right middle lobe is usually performed. For patients with an upper lung zone predominance on radiograph, lavage in both an upper lobe and the right middle lobe should be considered.

Treatment. The treatment of choice for patients with mild, moderate, and severe PCP remains TMP-SMX administered for 21 days.[27] The usual dose of TMP is 15 mg/kg/day (range, 15–20 mg/kg/day), and that of SMX is 75 mg/kg/day (range, 75–100 mg/kg/day), divided into three or four daily doses (eTable 123.2). Dosing may be intravenous (recommended for patients with moderate or severe PCP) or oral, and patients started on intravenous TMP-SMX can switch to oral formulations after clinical improvement. Adverse effects from TMP-SMX are frequent in HIV-infected patients and include rash, fever, gastrointestinal complaints (i.e., nausea, vomiting), elevated aminotransferases, hyperkalemia, and bone marrow suppression, especially anemia and neutropenia; these often develop during the second week of therapy. In a proportion of HIV-infected patients, the side effects of TMP-SMX are treatment limiting. Rare adverse reactions include Stevens-Johnson syndrome, toxic epidermal necrolysis, and a clinical syndrome resembling septic shock. Studies are conflicting regarding the presence of potential TMP-SMX drug resistance in *Pneumocystis,*[168,169] but patients who develop PCP despite receiving TMP-SMX prophylaxis can usually be treated with TMP-SMX.

For patients with allergy to or intolerance of TMP-SMX, alternative treatment regimens (see eTable 123.2) include intravenous pentamidine, clindamycin plus primaquine, TMP plus dapsone, and atovaquone.[27] Several reports demonstrate efficacy of echinocandans for PCP.[170,171] As in TB, HIV-infected patients with PCP who begin therapy for *Pneumocystis* and initiate ART may develop paradoxical reactions, usually a temporary exacerbation of clinical and radiographic features but occasionally respiratory failure due to immune reconstitution.[172,173] The diagnosis of IRIS is one of exclusion. Patients with paradoxical reactions only rarely require discontinuation of antiretroviral therapies, and symptomatic therapy is recommended.

Corticosteroid Therapy. Corticosteroids should be given to adults or adolescents with documented or suspected PCP if they have an arterial Po_2 level less than 70 mm Hg or an alveolar-arterial Po_2 difference greater than 35 mm Hg. Corticosteroids, either oral prednisone or intravenous methylprednisolone, should be started at the same time that anti-*Pneumocystis* treatment is begun, regardless of whether the diagnosis has been confirmed.

Early in the AIDS epidemic, acute respiratory failure secondary to PCP, if severe enough to warrant mechanical ventilation, had a mortality rate of 86% or greater.[175] Although the mortality associated with acute respiratory failure secondary to PCP remains significant (≈30–50%),[176,177] HIV-infected patients with PCP and respiratory failure requiring mechanical ventilation should be managed with lung-protective strategies as for patients with acute respiratory distress syndrome.[178] At least one retrospective study[176] suggests that ART may be beneficial in these cases, although prospective randomized clinical trials in the intensive care unit involving mechanically ventilated patients are lacking.[179,180]

Prevention of Exposure. The natural reservoir for human *Pneumocystis* remains unknown.[181] Environmental and human reservoirs have been suggested.[144,182] Whether PCP results from reactivation of latent infection or also from a recent infection is debated; reports of clusters of PCP among different immunocompromised populations support the theory that PCP can result from a recent exposure and person-to-person transmission. In accordance, some authorities have argued that HIV-infected and other immunocompromised persons at risk for PCP should avoid close contact with any individuals who have PCP. However, the current CDC, NIH, and HIVMA/IDSA guidelines state "there are insufficient data to support isolation as standard practice to prevent PCP."[27]

Prevention of Disease. HIV-infected adults or adolescents (including those on ART) who have a $CD4^+$ lymphocyte count less than 200 cells/μL or a $CD4^+$ percentage less than 14% should receive primary *Pneumocystis* prophylaxis, and persons with prior PCP should receive secondary prophylaxis (eTable 123.3).[27] Once started, HIV-infected adults and adolescents should remain on PCP prophylaxis, unless their $CD4^+$ lymphocyte counts increase from less than 200 cells/μL to greater than 200 cells/μL for at least 3 months as a result of ART.[27] Discontinuation of PCP prophylaxis can be considered in those with a $CD4^+$ lymphocyte count between 100 and 200 cells/μL if the HIV RNA level remains below the limits of detection for at least 3 to 6 months as a result of ART.[27]

TMP-SMX, dapsone, atovaquone suspension, and aerosolized pentamidine are the standard options for PCP prophylaxis.[27] TMP-SMX is the first-line choice for primary and secondary prophylaxis against *Pneumocystis.* For those patients intolerant of TMP-SMX, dapsone and atovaquone are both oral drugs that can be used. Many authorities would add pyrimethamine (plus leucovorin) to these drugs for patients with a history of PCP, a $CD4^+$ lymphocyte count less than 100 cells/μL, or both. For patients who are *T. gondii* immunoglobulin G antibody positive, pyrimethamine should be added. Monthly aerosolized pentamidine remains an effective and well-tolerated prophylaxis option; however, caution must be exercised when using this drug for secondary prophylaxis or in patients with a $CD4^+$ lymphocyte count less than 100 cells/μL because prophylaxis breakthrough may be more frequent in this population.

Cryptococcus Species

Cryptococcosis is caused by *C. neoformans or Cryptococcus gattii,* encapsulated fungi that can infect either healthy or immunocompromised people; these fungi are characterized by a polysaccharide capsule that can be detected using India ink or mucicarmine staining.[183] *Cryptococcus* is transmitted by aerosol. *C. neoformans* is global in distribution and is most commonly isolated from bird excrement, decaying fruit, and soil. Most cryptococcal disease in HIV-infected persons is due to *C. neoformans*. *C. gattii* has been isolated from Australia, South America, the Pacific Northwest of the United States, and southwestern Canada, where outbreaks of disease have been reported; sporadic cases have

eTable 123.2 Treatment Regimens for *Pneumocystis* Pneumonia*

Treatment Regimen	Dose(s), Frequency	Toxicities
MILD PCP† (Pao_2 > 70 mm Hg *AND* ALVEOLAR-ARTERIAL Po_2 DIFFERENCE < 35 mm Hg)		
TMP-SMX	15–20 mg/kg (TMP component) daily (q6–8 hr)	Fever, dermatologic, gastrointestinal, hematologic
TMP *plus* dapsone	15–20 mg/kg daily (q6–8 hr) 100 mg once daily	Dermatologic, gastrointestinal, hematologic
Clindamycin *plus* primaquine	1800 mg daily (q6–8 hr) 30 mg (base) once daily	Dermatologic, gastrointestinal, hematologic
Atovaquone	750 mg three times daily	Dermatologic, gastrointestinal
MODERATE-SEVERE PCP‡ (Pao_2 ≤ 70 mm Hg *OR* ALVEOLAR-ARTERIAL Po_2 DIFFERENCE ≥ 35 mm Hg)		
TMP-SMX	15–20 mg/kg (TMP component) daily (q6–8 hr)	Fever, dermatologic, gastrointestinal, hematologic
Pentamidine	3–4 mg/kg IV once daily	Renal, pancreatic
Clindamycin *plus* primaquine	1800–2400 mg (q6–8 hr) 30 mg (base) once daily	Dermatologic, gastrointestinal, hematologic

*Recommended duration of therapy = 21 days.
†Oral route is preferred for patients with mild PCP who are treated as outpatients.
‡IV route is preferred, at least until clinical improvement, for patients with moderate to severe PCP. Adjunctive corticosteroids (prednisone 40 mg PO twice daily for 5 days, then 40 mg PO once daily for 5 days, then 20 mg PO once daily for 11 days or potency-equivalent Solu-Medrol IV) should also be administered.
IV, intravenous; Pao_2, arterial partial pressure of oxygen; PCP, *Pneumocystis* pneumonia; PO, orally; TMP-SMX, trimethoprim-sulfamethoxazole.

eTable 123.3 Prevention of *Pneumocystis* Pneumonia

Prevention Regimens	Alternative Dosing	Comments
Trimethoprim-sulfamethoxazole 1 double-strength tablet daily	One single-strength tablet daily or 1 double-strength tablet 3 times weekly	Also effective prophylaxis against *Toxoplasma gondii* and many bacterial pathogens
Dapsone 100 mg daily		Combine with pyrimethamine and leucovorin in persons who are *T. gondii* immunoglobulin G antibody positive Consider combining with pyrimethamine and leucovorin when used for secondary prophylaxis
Atovaquone suspension 1500 mg daily or 750 mg twice daily		Improved bioavailability compared to tablets
Aerosolized pentamidine 300 mg monthly via RespirGard II nebulizer		May be associated with increased risk of extrapulmonary disease

been reported in the southeastern United States. *C. gattii* is more likely to infect immunocompetent hosts, although it also causes disease in HIV-infected individuals.

Clinical Features. Although the portal of entry is the lung, cryptococcal pulmonary infection is often asymptomatic or minimally symptomatic, and the most commonly encountered manifestation of cryptococcal disease is meningitis.[184–186] Less than 5% of patients with cryptococcal disease present with isolated pneumonia.[185,187] However, autopsy studies suggest that pulmonary disease is underdiagnosed, particularly in settings where diagnostic facilities are limited.[188] When present, the most frequent respiratory complaints are cough and dyspnea.[185,186] Pleuritic chest pain and productive cough have also been reported,[190] perhaps distinguishing pulmonary cryptococcosis from PCP. Although rarer, cases of acute respiratory failure have been reported.[188]

CD4⁺ Lymphocyte Count. In most cases, cryptococcosis infects patients with a $CD4^+$ lymphocyte count less than 200 and typically less than 100 cells/μL. A study of 1644 patients reported a median $CD4^+$ count of 24 cells/μL with a range of 0 to 480 cells/μL.[184] A study from Uganda from the ART era reported a median $CD4^+$ count of 23 cells/μL.[191]

Imaging. Cryptococcal pneumonia most commonly presents with diffuse bilateral interstitial opacities.[190,192] In one study,[193] interstitial opacities were most frequently reported in 60 of 92 radiographs (65%) (eFig. 123.20), followed by hilar adenopathy (27%) (eFig. 123.21), pleural effusion (14%), focal consolidation (13%) (eFig. 123.22), nodular opacities (11%) (eFig. 123.23), and cavitation (11%) (Fig. 123.5). Rarely, radiographic findings include a miliary pattern (eFig. 123.24),[194] solitary pulmonary nodules,[195] pulmonary masses,[196] isolated pleural effusion,[197] and pneumothorax.[198] Cryptococcal pneumonia may also present with a normal chest radiograph.[193]

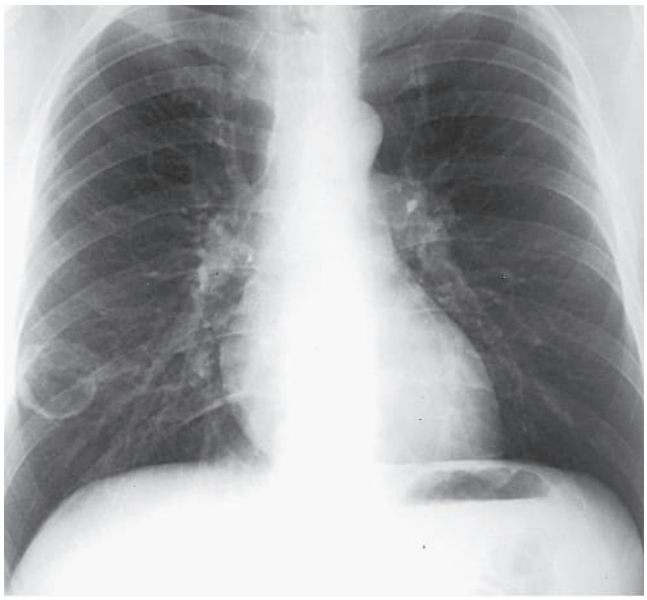

Figure 123.5 Cryptococcal infection. Frontal chest radiograph of an HIV-infected patient showing a solitary cavitary lesion in the right lower lung field. Culture of bronchoalveolar lavage fluid revealed *Cryptococcus neoformans*. In HIV-infected patients, cryptococcal disease can present with a wide range of chest radiographic findings, including a normal chest radiograph. (From Stansell JD: Fungal disease in HIV-infected persons: cryptococcosis, histoplasmosis, and coccidioidomycosis. *J Thorac Imaging.* 1991;6:28–35.)

Diagnosis. The diagnosis of cryptococcal infection begins with the *cryptococcal antigen* (CRAG) test, which can be performed on serum, cerebrospinal fluid, urine, BAL fluid,[199] or pleural fluid. The serum CRAG test is sensitive and specific for cryptococcemia. A negative serum CRAG virtually rules out a diagnosis of cryptococcal meningitis but can be seen rarely in some cases of isolated pulmonary cryptococcosis. A positive serum CRAG test should prompt an evaluation for disseminated disease, especially meningitis, but false-positive results can be seen in the presence of rheumatoid factor or infection with the fungus *Trichosporon asahii* (formerly *T. beigelii*), or with bacteria from the *Stomatococcus* or *Capnocytophaga* genera. However, a positive CRAG can sometimes be found in individuals without clinical evidence of disease and can portend a worse outcome; screening of individuals with low $CD4^+$ cell counts and preemptive treatment are advocated.[27,200–202] Blood fungal cultures are specific and should be obtained as part of the diagnostic evaluation. New cutaneous lesions may be signs of dissemination and should prompt consideration for biopsy.

Pulmonary cryptococcosis is usually diagnosed by culture of sputum or BAL fluid and occasionally of pleural fluid. Specimens from TBB and pleural biopsy can also be diagnostic. Batungwanayo and coworkers[190] found that BAL diagnosed 27 of 33 cases (sensitivity, 82%) of cryptococcal pneumonia compared with TBB, which diagnosed 10 of 21 cases (sensitivity, 48%). In some cases, cultures are negative, but a BAL or pleural fluid CRAG test can establish the diagnosis.[193] Because the treatment is identical, the diagnosis of pneumonia may be inferred in the presence of disseminated cryptococcal disease (e.g., meningitis) and a compatible radiographic presentation. However, other opportunistic infections such as PCP may be present concurrently and can demonstrate identical radiographic findings.

Treatment. There are no randomized controlled trials for HIV-infected patients presenting with isolated cryptococcal pneumonia or with concurrent cryptococcal pneumonia and meningitis.[203] Some experts would treat isolated mild cryptococcal pneumonia with fluconazole alone (400 mg daily for 12 months) in combination with effective ART; however, patients with clinically significant cryptococcal pneumonia should be considered at high risk for early deterioration and treated similarly to those with disseminated disease during the induction phase of therapy using the lipid formulation of amphotericin B (3–4 mg/kg/day) in combination with flucytosine for at least 2 weeks.[27,204] Treatment should be continued until the patient is clinically improved, at which point the patient can be switched to fluconazole (400 mg daily) to complete at least an 8-week course of consolidation therapy. The patient should then be maintained on fluconazole (200 mg daily) to complete at least 12 months of maintenance azole therapy. IRIS may develop in patients with cryptococcosis who begin dual therapy for *C. neoformans* and HIV infection and has been associated with increased mortality. Therefore, a delay in

initiation of ART for at least the initial 2 weeks of induction therapy and potentially through the entire consolidation therapy phase is recommended.[27,205] Patients who had cryptococcal meningitis may present with aseptic meningitis and have elevated intracranial pressure. In addition, patients with cryptococcal pneumonia and nodules on chest radiograph may develop cavitation of their nodules or new intrathoracic adenopathy.[205]

Prevention. There are no specific recommendations regarding exposure avoidance, but screening for *C. neoformans* with serum CRAG testing among HIV-infected individuals with $CD4^+$ lymphocyte counts less than 100 cells/μL in high-burden countries and preemptive treatment with fluconazole significantly reduces mortality due to cryptococcal meningitis.[200,204,206] Some experts advocate screening of asymptomatic HIV-infected individuals in the United States with $CD4^+$ cell counts less than 100 cells/μL.[27] Primary prophylaxis is not recommended in the United States.[27]

Histoplasma capsulatum

Histoplasmosis is caused by the dimorphic, soil-dwelling fungus *H. capsulatum.* The fungus is found on all continents except Antarctica, but it is most common in North America and the Caribbean basin.[207] The heaviest concentration is found in the Mississippi, Ohio, and St. Lawrence River valleys. In these areas the fungus exists in environments related to the enrichment of the soil with bird or bat excrement, which helps promote sporulation. In the soil the fungus exists in a mycelial form producing asexual spores, the characteristic tuberculate macroconidia, and microconidia. Microconidia are easily aerosolized when disturbed and inhalation leads to primary pulmonary infection that is usually clinically silent.

Once deposited in the alveoli, *H. capsulatum* transforms into its yeast (or parasitic) form, and an area of pneumonitis develops. During this period before cell-mediated immunity develops, the organism spreads to regional lymph nodes and to reticuloendothelial organs. Two to 3 weeks after exposure, a flulike syndrome with fever, chills, myalgias, a nonproductive cough, and chest pain develops in about 40% of immunocompetent individuals. As covered in Chapter 56, 99% of these cases spontaneously resolve with the development of specific cell-mediated immunity. In contrast, progressive disseminated histoplasmosis develops in HIV-infected and other persons deficient in cell-mediated immunity. Although most cases of HIV-associated histoplasmosis appear to result from de novo exposure, the disease can reactivate. These cases account for the histoplasmosis seen in nonendemic areas, such as San Francisco or New York.[208]

Clinical Features. Although the portal of entry is the lung, in HIV-infected persons, histoplasmosis most often presents as a febrile wasting illness with disseminated infection. In a large series of 72 HIV-infected patients with disseminated histoplasmosis, 69 patients (96%) presented with fever and weight loss; in approximately 10% of cases, the presentation was dramatic with a sepsis-like syndrome associated with hypotension, respiratory failure, liver and renal failure, and coagulopathy.[209] Prognosis in these patients is poor. Respiratory complaints at presentation, chiefly cough and dyspnea, are found in patients who are likely to have abnormal chest radiographs.[209,210]

$CD4^+$ Lymphocyte Count. Most cases of disseminated histoplasmosis are seen in patients with $CD4^+$ lymphocyte counts less than 100 cells/μL and often less than 50 cells/μL. Isolated respiratory disease is more likely in patients with $CD4^+$ cell counts greater than 300 cells/μL.[27] Frequent laboratory findings include anemia, leukopenia, thrombocytopenia, and liver function test elevations. Serum LDH and serum ferritin elevations, often pronounced, have also been reported.[27,207]

Imaging. Disseminated histoplasmosis presents with a normal chest radiograph in 35–55% of cases.[192,209,211] The most frequent abnormalities are diffuse, coarse reticular or reticulonodular opacities as shown in Fig. 123.6. On occasion, alveolar opacities are present[192]; focal opacities are less common and seen in 7–11% of cases.[210] Hilar and mediastinal adenopathy and calcified granulomata are each found in less than 5% of patients.[209]

Diagnosis. The workup of histoplasmosis begins with the *Histoplasma* antigen test, which is a sensitive method for rapid diagnosis of disease.[27] The antigen test can be performed on urine, serum, cerebrospinal fluid, or BAL fluid. In AIDS patients with disseminated histoplasmosis, the antigen was detected in the urine of 100% and in the serum of 92% of patients.[212] In isolated, chronic pulmonary disease,

Figure 123.6 Disseminated fungal infection. Frontal chest radiographic close-up of the left midlung of an HIV-infected patient showing a medium to coarse reticulonodular pattern characteristic of disseminated fungal disease. (From Stansell JD: Fungal disease in HIV-infected persons: cryptococcosis, histoplasmosis, and coccidioidomycosis. *J Thorac Imaging.* 1991;6:28–35.)

serum or urine antigen testing is less sensitive.[27] In patients with pulmonary involvement, antigen testing of BAL fluid combined with cytopathology evaluation can complement serum or urine testing and increase the sensitivity for diagnosis of disease.[27,213] With successful therapy, antigen values fall and, during relapses, antigen values rise; thus changes in antigen values can be useful for assessing response to therapy and for evaluating possible relapse.[214] A persistently positive *Histoplasma* antigen test indicates continued disease and warrants continued therapy. False-positive *Histoplasma* antigen test results have been seen in patients with other disseminated fungal diseases (blastomycosis, coccidioidomycosis, paracoccidioidomycosis, and penicilliosis, and rarely with aspergillosis); such results have not been described in patients with cryptococcosis or candidiasis. *Histoplasma* can also be cultured from involved sites, although growth may require several weeks. Blood fungal cultures are specific and should be obtained as part of the diagnostic evaluation. Wheat and colleagues[209] reported that fungal blood cultures were positive in 65 of their 72 cases (90%). On occasion, the peripheral blood smear reveals intracellular yeast. Other potential diagnostic sources include bone marrow, lymph node, and skin. Serologic tests are generally less helpful in those with disseminated disease but may be useful in patients who are less severely immunocompromised with isolated pulmonary disease.[27]

Treatment. A lipid formulation of amphotericin B (3 mg/kg daily) is the treatment of choice for HIV-infected patients with moderate to severe disseminated histoplasmosis, whereas itraconazole is an alternative for patients with mild disease.[27] In those who cannot tolerate itraconazole, oral posaconazole or voriconazole may be effective; fluconazole is less effective than itraconazole, and echinocandins do not have activity against *Histoplasma*.[27] Treatment with amphotericin B should be continued for at least 2 weeks or until the patient is clinically improved, at which point the patient can be switched to itraconazole to complete at least a 12-month course. Patients with isolated pulmonary disease and $CD4^+$ cell counts greater than 300 cells/μL should be treated similarly as for non–HIV-infected patients (see Chapter 56).

Coccidioides immitis

Coccidioidomycosis is caused by the dimorphic, soil-dwelling fungi *C. immitis* and *C. posadasii.* As described in Chapter 56, the chief manifestation of coccidioidomycosis is as a mild flulike, often undiagnosed illness, from which most previously healthy people spontaneously recover. Chronic pulmonary disease manifests in roughly 5% of infected persons and disseminated disease in even fewer. Manifestations of coccidioidomycosis in HIV-infected persons include focal or diffuse pneumonia, cutaneous disease, meningitis, liver or lymph node involvement, or disseminated disease that can be fatal.

The fungus is endemic to the semiarid regions of North America, notably the southwestern United States (central California, southern Arizona, southern New Mexico, and western Texas) and also northern Mexico.[215] California's southern San Joaquin Valley and southern Arizona are hyperendemic areas.[215] *Coccidioides* is also found in South America, especially central Argentina. In soil the fungus exists in a mycelial form with characteristic arthrospores. When the soil is disrupted, arthrospores, whose size is optimal for deposition in the distal airways and alveoli after inhalation, become airborne. After deposition in the lungs, the arthrospores transform into spherules that may develop several hundred endospores. Rupture of the spherules allows widespread dissemination of the endospores, which then form additional spherules, replicating the cycle. Although most cases of HIV-associated coccidioidomycosis appear to result from de novo inhalation, disease may also reactivate.

Clinical Features. The clinical presentation is often nonspecific; fever and chills (68%), night sweats (36%), and weight loss (50%) are all common.[216] Although the portal of entry is the lung, coccidioidomycosis can present with disseminated disease and meningitis. Other frequently involved sites include the skin, lymph nodes, liver, and skeletal system. In one study, 42% of HIV-infected patients with coccidioidomycosis presented with disseminated disease; overall, 25% of the patients in this series died.[217] Focal pneumonia can present similarly to bacterial pneumonia, and diffuse pulmonary involvement can be difficult to distinguish from PCP.

$CD4^+$ Lymphocyte Count. The risk of symptomatic disease is highest if $CD4^+$ counts are less than 250 cells/μL.[27] Most cases of disseminated coccidioidomycosis are seen in patients with a $CD4^+$ lymphocyte count less than 100 cells/μL and often less than 50 cells/μL.[216,217] Focal pneumonia is more common when the $CD4^+$ cell count is greater than 250 cells/μL.[27] Cerebrospinal fluid examination is warranted in all patients with suspected disseminated coccidioidomycosis.

Imaging. In a series of 91 HIV-infected patients with coccidioidomycosis, diffuse reticulonodular opacities (see Fig. 56.5) were seen in 65%; focal opacities were less common in 14% of cases and consisted of focal opacities, single or multiple nodules, and cavities.[216] A miliary pattern may be seen (eFig. 123.25). Pleural effusion and hilar adenopathy as well as normal chest radiographs have all been reported.

Diagnosis. Serologic tests are useful in the evaluation of suspected coccidioidomycosis. Several studies have found an 80–90% sensitivity of complement fixation and tube precipitin tests.[218] Sensitivity of enzyme-linked immunoassays may be higher but may be less specific. False-negative titers usually arise in the most severely immunodeficient patients with diffuse pulmonary disease; in those with positive tests, the titer appeared to reflect the disease activity and proved useful for monitoring response to therapy.[219] A urinary and serum antigen test specific to *Coccidioides* has been developed and is useful for diagnosis of severe cases of coccidioidomycosis; however, other endemic fungi, including *Histoplasma* or *Blastomyces*, can cross-react.[220,221]

A definitive diagnosis can be established by isolation and identification of the fungus by culture or identification of pathognomonic giant spherules in cytologic or histologic preparations. In cases of suspected coccidioidomycosis, it is critical to alert the microbiology laboratory so that proper

precautions can be implemented to prevent laboratory transmission. Direct examination and culture of sputum, BAL fluid, or TBB can establish the diagnosis of pulmonary coccidioidomycosis in HIV-infected patients. Singh and associates[216] found that sputum culture in 13 of 19 cases (68%) and cytology in 8 of 11 cases (73%) had a high yield. BAL fluid culture diagnosed 29 of 42 cases (69%), and BAL fluid cytology diagnosed 32 of 48 cases (67%); in addition, TBB culture diagnosed 8 of 10 cases (80%), and biopsy histology diagnosed all 14 cases (100%).

Treatment. Either amphotericin B or a lipid formulation of amphotericin B is the treatment of choice for HIV-infected patients with severe (i.e., diffuse) pulmonary or disseminated coccidioidomycosis.[27] Treatment with amphotericin B should be continued until the patient is clinically improved, at which point the patient can be switched to fluconazole or itraconazole. Monitoring complement-fixing antibody titers every 12 weeks can be useful to assess response to therapy.[27] In patients with clinically mild infection, such as focal pneumonia, fluconazole or itraconazole may be used throughout.[27] Although clinical experience is limited, voriconazole or posaconazole may be considered in refractory coccidioidomycosis.[222] In patients with severe, diffuse disease, lifelong suppressive therapy with fluconazole or itraconazole should be continued after initial treatment is complete, particularly in those with meningeal involvement because the risk of relapse is high.[27] In patients who have had focal coccidioidal pneumonia and who have had a sustained response to ART with $CD4^+$ lymphocyte counts greater than 250 cells/μL, therapy may be discontinued after 12 months, but periodic surveillance with chest radiograph and *Coccidioides* serology is recommended.[27]

Aspergillus Species

Aspergillus species are found worldwide, and exposure is universal. Nevertheless, disease is infrequent unless phagocyte number or function is reduced.[223] *A. fumigatus* is the most common disease-causing species and accounts for approximately 90% of cases of invasive aspergillosis. Although invasive aspergillosis is a well-documented complication of various immunodeficiency disorders, particularly in patients with hematologic malignancy or organ transplantation, it is an uncommon problem in patients with HIV disease. Risk factors for the development of aspergillosis other than HIV-induced immunodeficiency included use of corticosteroids, neutropenia, marijuana use, and broad-spectrum antimicrobial drugs.[224] In the ART era and also with the introduction of voriconazole, the incidence of invasive aspergillosis has further declined.[225] Holding and coworkers[226] reported an aspergillosis incidence of 3.5 cases per 1000 person-years among HIV-infected individuals enrolled in the CDC-led Adult and Adolescent Spectrum of HIV Disease Study.

Clinical Features. The entire spectrum of *Aspergillus*-related lung disease (see Chapter 57) has been observed in HIV-infected persons, from colonization of the respiratory tract or a preexisting cavity, to tracheobronchitis or obstructing bronchial aspergillosis, to invasive aspergillosis, by far the most severe manifestation.[224,227–229] Most patients with invasive aspergillosis have a $CD4^+$ lymphocyte count less than 100 cells/μL. Risk factors for the disease are decreased phagocyte number and function, as determined by neutropenia and/or monocytopenia and use of corticosteroids or broad-spectrum antibiotics. However, in a study from France, fewer than half of the cases of invasive aspergillosis in HIV-infected patients met criteria for risk factors established for the European Organisation for Research and Treatment of Cancer/National Institute of Allergy and Infectious Diseases Mycoses Study Group.[225] Patients with aspergillosis typically present with fever, cough, dyspnea, and occasionally with pleuritic chest pain. Hemoptysis is another presenting feature. The imaging findings are variable and include unilateral or bilateral opacities, cavitary lesions (eFigs. 123.26 and 123.27), nodular (eFig. 123.27) and pleural-based opacities, and pleural effusions.[230]

Diagnosis. The definitive diagnosis of aspergillosis requires demonstration of tissue invasion and isolation of the organism by culture. Neither sputum nor BAL is sufficient. Microscopy alone cannot distinguish *Aspergillus* species from *Fusarium* or *Pseudallescheria* species. The results of TBB are usually negative, but specimens from sputum, BAL fluid, or percutaneous aspirates are often positive on culture. The absence of histologic proof of tissue invasion is always somewhat disquieting, especially in attempting to distinguish invasive disease from possible colonization of damaged airways. Repeated isolation of the fungus in large numbers with a compatible clinical setting makes the diagnosis more tenable.

Galactomannan antigen testing on serum or BAL specimens is useful in the diagnosis of invasive pulmonary aspergillosis in other immunocompromised patients (see also Chapters 19 and 57),[231] although its performance has not been prospectively evaluated in HIV-infected patients with suspected aspergillosis. Several other fungi, including *Histoplasma* and *Blastomyces,* can cross-react.[232]

Treatment. Compared with the fungi previously discussed, there is less experience treating aspergillosis in HIV-infected patients.[223] Voriconazole is the first-line recommended therapy.[27] Alternative agents include amphotericin, caspofungin, and posaconazole. Interactions with ART drugs must be considered because the antifungal azoles inhibit specific cytochrome P-450 enzymes. Even with the prompt institution of therapy, the prognosis is poor, largely because aspergillosis is nearly always a late complication of advanced HIV disease. However, survival has improved to 70% in the ART era with use of voriconazole therapy.

Blastomyces dermatitidis

Blastomycosis is caused by the endemic, dimorphic fungus *Blastomyces dermatitidis.* Blastomycosis is coendemic with histoplasmosis throughout much of the central United States (see Chapter 56), but it is less common than histoplasmosis, and reports of HIV-associated blastomycosis are infrequent.[233,234]

Clinical Features. The largest case series reported 15 cases of HIV-associated blastomycosis; all but one patient had a $CD4^+$ lymphocyte count less than 200 cells/μL.[233] That series noted two distinct patterns of disease: One group of patients had disease clinically limited to the respiratory

system, whereas the other group had disseminated blastomycosis involving multiple organ systems, including the lungs. Eleven of 15 patients (73%) had abnormal chest radiographs, with diffuse interstitial or miliary disease (55%) as the most common radiographic finding. Definitive diagnosis requires the growth of *B. dermatitidis,* although visualization of the characteristic budding yeast form is strongly suggestive and therefore warrants antifungal therapy while awaiting the results of culture.

Treatment. Intravenous amphotericin B is the treatment of choice for HIV-infected patients with severe disease.[233,234] Treatment with amphotericin B should be continued until there is clinical improvement; patients can then be switched to oral itraconazole maintenance therapy for at least 12 months, with itraconazole continued indefinitely for AIDS patients without immune reconstitution.[235] With prompt institution of therapy, most patients with disease limited to the lungs respond well; in contrast, patients with disseminated disease do poorly (40% mortality in 30 days).[233]

Talaromyces marneffei

Talaromycosis is a disease caused by *T. marneffei,* a dimorphic, soil-dwelling fungus formerly known as *Penicillium marneffei.* It is endemic in southeastern Asian countries, and in northern Thailand, it is the third most common opportunistic infection (after TB and cryptococcosis) in HIV-infected patients with AIDS, accounting for 15–20% of all AIDS-related illnesses.[236,237] Infection can also be encountered in other regions of the world in travelers or immigrants from endemic regions. Disease is related to soil exposure, especially during the rainy season (May–October), and infection is likely acquired via inhalation. Although less frequent, reactivation of latent infection has been observed.

Clinical Features. Most cases of talaromycosis are seen in patients with a $CD4^+$ lymphocyte count less than 100 cells/μL. The clinical presentation is similar to that of TB, cryptococcosis, or histoplasmosis. The most common symptoms include fever, weight loss, cough, and generalized papular skin lesions, usually with central umbilication.[238] Symptoms are often present for weeks. In addition to the cutaneous findings, physical examination often reveals peripheral lymphadenopathy and hepatomegaly. Respiratory symptoms include cough and shortness of breath. Skin lesions of papules with central necrosis can involve the face, trunk, and extremities and are a late manifestation of infection. Anemia is a prominent laboratory finding.

Diagnosis. *T. marneffei* is most commonly a disseminated disease in HIV-infected patients, and the diagnosis is usually made by isolation of the organism from blood or bone marrow aspirate cultures. Other involved sites include the skin, lymph nodes, and lungs. Microscopy of tissue samples can detect yeast-laden macrophages. Of note, galactomannan assays typically used for *Aspergillus* can cross-react and yield a positive result with *Talaromycosis.*

Treatment. Amphotericin B, followed by itraconazole, is the standard treatment for *P. marneffei.*[27] Mild forms of disease can be treated initially with itraconazole. The duration of amphotericin B treatment is 2 weeks, followed by an additional 10 weeks of itraconazole. Voriconazole and posaconazole are alternative treatments.[27]

VIRUSES

Many viruses are known to cause pulmonary disease in immunocompromised persons. Of viral infections, CMV is regarded as a potentially important agent of pulmonary disease in HIV-infected persons.

Cytomegalovirus

CMV, a double-stranded DNA virus in the Herpesviridae family, is described in Chapter 46. The risk of exposure to CMV increases with age, and evidence of CMV infection is extremely common in healthy persons. In HIV-infected patients, CMV disease is believed to result chiefly from reactivation of latent infection; however, disease has been documented from de novo infection in recipients of solid organs, bone marrow, and blood, which raises the possibility that new infection or superinfection from exogenous sources may also arise in HIV-infected persons. Although clearly the source of significant pathologic conditions in the retina, gastrointestinal tract, and nervous system, the role of CMV in producing pulmonary disease in HIV-infected persons is debated. Many consider this ubiquitous virus a "passenger" rather than a pathogen in most instances. However, there are also clear instances in which documented pulmonary disease results from CMV.

Clinical Features. Retinitis and gastrointestinal disease are the two most common forms of HIV-associated CMV disease. CMV is a frequent isolate from the BAL fluid of patients with advanced immunosuppression who undergo evaluation for opportunistic infections, notably *Pneumocystis.* Because CMV is shed in respiratory secretions, its mere presence in BAL fluid cannot be construed as diagnostic of CMV pulmonary disease. When dual pulmonary infection is discovered, treatment directed against the coexisting disease and not against CMV usually results in clinical resolution[239]; however, sometimes CMV causes pulmonary disease, and the challenge for clinicians is to recognize these instances.[240,241]

The most common symptoms of CMV pneumonia are cough, dyspnea, and fever. In a case series,[241] these symptoms were seen in 94%, 94%, and 89%, respectively, of the 18 patients reported. Respiratory symptoms were present for up to 2 weeks in 50% and between 2 and 4 weeks in an additional 44%. Most cases of CMV disease are seen in patients with a $CD4^+$ lymphocyte count less than 50 cells/μL.[241]

Imaging. The imaging findings of CMV pneumonia vary and include reticular or ground-glass, alveolar, and nodular opacities (eFig. 123.28).[241] Pleural effusions may be seen as well.

Diagnosis. When CMV pulmonary disease is suspected in conjunction with other end-organ disease (e.g., retinitis), CMV therapy must be initiated immediately. CMV is usually a disseminated disease and commonly involves multiple organ systems. Treatment of CMV disease in one end-organ treats all affected organs, although the length of therapy

can differ by organ system. The therapeutic dilemma is much greater when only the lungs appear to be afflicted. The only precise criterion for diagnosis of CMV pulmonary disease is the demonstration of widespread specific cytopathic changes in the lungs on biopsy. Culture of BAL fluid[242] or PCR detection of CMV are not sufficient by themselves to make the diagnosis of CMV pneumonitis. Patients suspected of having CMV pneumonitis should undergo retinal examination by an ophthalmologist, even if there are no ocular complaints.

Treatment. Data for treatment of CMV pneumonia in HIV-infected patients are limited. Intravenous ganciclovir or foscarnet is recommended for severe pneumonitis.[27] Although oral valganciclovir has been suggested for less severe pneumonitis, there are no data regarding its use in this setting.[27] With these drugs, an initial course of induction therapy should be continued until there is clinical improvement; the length of induction therapy for CMV pneumonia, however, is undetermined. A 21-day course for isolated CMV pneumonitis has been recommended. After resolution of acute disease and initiation of effective ART, chronic maintenance is not regularly recommended.

Other Herpesviruses

Symptomatic pulmonary viral infection from herpesviruses other than CMV is uncommon in HIV-infected persons. Herpes simplex virus, although frequently cultured from BAL fluid, is usually a contaminant from upper airway carriage. Lower respiratory tract involvement is rare in HIV-infected persons (0.2–4% of autopsy cases) compared to other immunosuppressed hosts. Herpes simplex virus pulmonary disease causes a focal pneumonia or a diffuse interstitial pneumonitis.[243] The focal pneumonias appear to result from contiguous spread of herpes simplex virus to the lung parenchyma and are often associated with necrotizing tracheobronchitis, whereas the diffuse interstitial pneumonias appear to be a manifestation of hematogenous herpes simplex virus dissemination. Varicella-zoster virus is a rare cause of pneumonia in HIV-infected adult patients.[244] Epstein-Barr virus DNA has been identified in lung biopsy specimens of infants and children with lymphocytic interstitial pneumonitis, but the precise role of the virus in this disease is uncertain.[245]

Influenza

Influenza-related mortality has been reported to be increased in adults with AIDS compared to the general population in studies using data from the United States and from sub-Saharan Africa.[246,247] Influenza generally presents similarly and has a comparable clinical course in HIV-infected as in non–HIV-infected adults. Prompt initiation of antiviral therapy directed against influenza in HIV-infected patients with suspected or confirmed disease is recommended. All HIV-infected persons should receive the inactivated or recombinant influenza vaccine annually.[27]

Coronavirus Disease 2019

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is the etiologic agent that causes *coronavirus disease 2019* (COVID-19). Emerging from Wuhan, China, in late 2019, COVID-19 has become a global pandemic. HIV-infected persons are at risk of infection similar to HIV-uninfected persons. Emerging data thus far do not show a differential risk of infection with SARS-CoV-2 or severity of disease among PLWH.[248] Because HIV antiviral therapies are being investigated as possible treatments for COVID-19, further studies on the impact of HIV treatment regimens and possible benefits of modifying ART in PLWH to mitigate risk of infection are warranted. Exposure to different classes of ART regimens may be associated with differential risk and severity of COVID-19.[249]

PARASITES

Of the classic unicellular and multicellular parasites that afflict otherwise healthy humans (see Chapter 58), several also cause pulmonary disease in HIV-infected hosts. Of these, *T. gondii* is the most frequent.

Toxoplasma gondii

Toxoplasmosis is a zoonosis caused by the intracellular protozoan *T. gondii,* with domestic cats as its definitive host, but with an infectious reservoir that encompasses all animals. Infection is transmitted to humans when raw or undercooked meat containing *T. gondii* is eaten. Domestic cat feces in litter boxes are an additional source of potential *T. gondii* infection. Infection can be transmitted vertically from mother to fetus. In HIV-infected patients, the majority of cases of toxoplasmosis result from reactivation of chronic, latent infection. Thus, the keys to preventing toxoplasmosis are prevention of exposure for those not yet infected and prophylaxis for those already seropositive. The seroprevalence of *Toxoplasma* varies. In the United States the seroprevalence is 10–50%, whereas in Western Europe the seroprevalence may be as high as 90%.

Clinical Features. Central nervous system complications of *T. gondii* are well recognized in HIV disease and include encephalitis and focal brain abscess. Pulmonary involvement is uncommon but is seen in patients with central nervous system or disseminated disease, can present as isolated pneumonia, and can rarely be associated with acute respiratory distress syndrome.[250–252] Toxoplasmosis presents at the lower range of $CD4^+$ lymphocyte counts, typically less than 50 cells/μL.[251]

Imaging. The chest radiograph usually reveals bilateral opacities, either in a fine reticulonodular pattern indistinguishable from PCP or in a coarse nodular pattern similar to that seen with TB or fungal pneumonias.[253] Pleural effusions can be seen, and a variety of other radiographic findings have also been described.[254]

Diagnosis. The diagnosis of pulmonary toxoplasmosis is usually established by bronchoscopy and study of BAL fluid.[254] *T. gondii* can be detected via Giemsa staining, PCR amplification, and culture.

Treatment. The treatment for pulmonary toxoplasmosis is identical to that for central nervous system toxoplasmosis. First-line treatment is sulfadiazine plus pyrimethamine with leucovorin to lessen the likelihood of hematologic toxicities associated with pyrimethamine.[27] The preferred

alternative regimen is clindamycin plus pyrimethamine with leucovorin.[27]

Other Parasites

In general, pulmonary helminth infections are uncommon in HIV-infected persons.[255,256] Both pulmonary cryptosporidiosis and pulmonary microsporidiosis in HIV-infected patients with concurrent intestinal disease have been reported and may result from aspiration or hematogenous spread.[257] The most common respiratory symptoms are cough, dyspnea, and pleuritic chest pain.[257] The diagnosis of *Strongyloides stercoralis* pulmonary disease (eFig. 123.29) can be made by either sputum study or bronchoscopy.[258,259] *Strongyloides* hyperinfection syndrome has also been reported in HIV-infected patients[260] but is uncommon, even in countries where the parasite is endemic.[261]

NONINFECTIOUS DISORDERS

As more people with HIV/AIDS are living longer on effective ART, noninfectious complications and comorbid illnesses have increased in frequency.[262] HIV-infected patients appear to have an increased risk for a number of noninfectious pulmonary diseases, including COPD, lung cancer, and PAH.[263] Increasing age and a high prevalence of cigarette smoking combined with an independent risk from HIV infection itself may all contribute, particularly to the increases in COPD and lung cancer.[264,265]

MALIGNANCIES

HIV-associated malignancies, particularly KS and NHL, may involve the thorax, including the lung parenchyma, airways, pleura, or hilar or mediastinal lymph nodes. Intrathoracic disease from either neoplasm is usually a manifestation of disease already recognized elsewhere, but occasionally both KS and NHL may present with isolated pulmonary disease.[266]

Kaposi Sarcoma

The most common AIDS-defining, HIV-associated malignancy is KS, although its incidence has decreased dramatically with ART.[267–269] KS is an angioproliferative tumor associated with *human herpesvirus 8* (HHV8; also termed the KS-associated herpesvirus).[270–272] KS most commonly presents with mucocutaneous involvement. The lymph nodes, gastrointestinal tract, and lungs can also be involved. Approximately 90–95% of cases of KS in HIV-infected individuals in the United States are seen in MSM.[273]

Clinical Features. Pulmonary KS is detected clinically in approximately one-third of patients with known KS, with the proportion detected at autopsy approaching 50–75%. Most but not all patients with pulmonary KS have concomitant mucocutaneous disease. Huang and coworkers[274] found that 85% of 168 consecutive patients diagnosed with pulmonary KS by bronchoscopy had evidence of mucocutaneous involvement at the time of bronchoscopy. The 15% without mucocutaneous involvement had pulmonary disease that ranged from isolated tracheal lesions to diffuse endobronchial involvement. A significant proportion (about one-third) of patients with pulmonary KS also have a concurrent opportunistic infection.[274] These observations underscore the need to evaluate each patient with KS who presents with respiratory symptoms, not only for pulmonary KS but also for opportunistic infection. Patients with pulmonary KS who develop opportunistic infection may also experience a rapid progression of their KS that mimics an infectious process.

Pulmonary KS presents at the lower range of $CD4^+$ lymphocyte counts, typically less than 100 cells/μL.[274] Additional immunologic risk factors for KS in the ART era include CD4/CD8 ratio of 0.5 or less or a $CD8^+$ T cell count greater than 1000/μL, regardless of the $CD4^+$ T cell count.[275]

Imaging. Pulmonary KS characteristically presents with bilateral opacities in a central or perihilar distribution, as shown in Figure 123.7 and eFigure 123.30A. Typical chest radiograph findings include peribronchial cuffing and "tram track" opacities (in about 90%); linear opacities, nodules or nodular opacities of varying size (80%); and pleural effusions (50%).[276] Chest CT findings in patients with pulmonary KS (see eFig. 123.30B–D) include flame-shaped areas of peribronchovascular ground-glass opacity and nodularity, often with interlobular septal thickening and pleural effusion, and less commonly, lymphadenopathy. Atypical imaging manifestations of KS are occasionally encountered (eFig. 123.31). Although radiographic findings strongly suggest the diagnosis of pulmonary KS in HIV-infected MSM, no findings are diagnostic for KS. Therefore, patients with suspected pulmonary KS should have their diagnosis confirmed.

Diagnosis. The diagnosis of pulmonary KS is usually established by bronchoscopy. The observation of characteristic endobronchial, red or violaceous, flat or slightly raised lesions is sufficient to diagnose pulmonary involvement

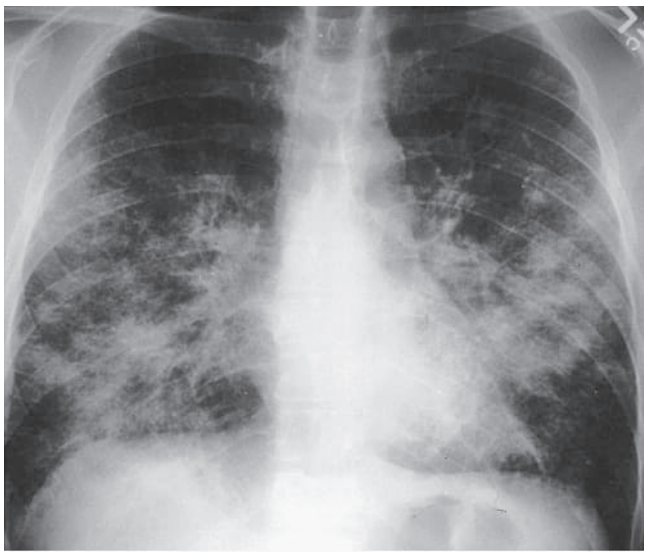

Figure 123.7 Kaposi sarcoma. Frontal chest radiograph of an HIV-infected patient with pulmonary Kaposi sarcoma diagnosed by bronchoscopy showing the characteristic bilateral, perihilar distribution of abnormalities consisting of nodules and nodular opacities. (Courtesy L. Huang.)

(Fig. 123.8). The presence of these mucosal lesions does not preclude a concurrent infection, nor does their absence in the observable airway preclude more distal disease or parenchymal, pleural, or nodal involvement. TBB is typically not required, although it can establish a diagnosis in patients in whom there is a strong clinical and radiographic suspicion for pulmonary KS but who have no visible endobronchial lesions. HHV8 may be detected in BAL. Pleural effusions, if present, are exudative. Cytologic evaluation of pleural fluid and thoracoscopic biopsy of the pleura in patients with KS are not typically useful for diagnosis.[277]

KS is negative on gallium scans. In contrast, opportunistic infections and NHL are gallium avid. Among HIV-associated pulmonary diseases, this unique feature of KS has created a clinical niche for the use of gallium scans. Patients with cutaneous KS who develop new respiratory complaints should undergo a thorough evaluation to rule out a concomitant opportunistic infection or other process.

Treatment. Tumors can regress in size and number in response to ART, and therefore combination ART is recommended for all patients with KS.[278] Treatment of more advanced disease also includes intralesional or systemic chemotherapy. Mortality in patients with KS may be related to an increased rate of other malignancies, particularly lymphomas.[279] Of malignancies, KS is the most likely to be associated with IRIS in patients who initiate ART.

Non-Hodgkin Lymphoma

Almost all HIV-associated NHLs are of B cell origin. Most are classified as small, noncleaved Burkitt, diffuse large cell with centroblastic features, or diffuse large cell with immunoblastic features.[280] The majority are associated with Epstein-Barr virus infection. Many HIV-infected patients have an advanced stage of disease at the time of presentation. As with KS, the incidence of NHL has declined dramatically in the era of ART and is projected to continue to decrease through 2030.[269,281]

Clinical Features. Most HIV-infected patients with NHL present with disseminated disease and extranodal involvement.[282] Frequent extranodal sites include the liver, spleen, bone marrow, meninges, gastrointestinal tract, and pericardium. Intrathoracic involvement is seen in a smaller proportion. The reported incidence of intrathoracic disease ranges up to 31% of patients at the time of clinical diagnosis and is usually higher at the time of autopsy. On occasion, the lung is the only site involved.

NHL can present at a wide range of $CD4^+$ lymphocyte counts, although typically patients are more severely immunocompromised. Prolonged HIV viremia and recent immunosuppression are risk factors for NHL, with risk increasing as the $CD4^+$ count declines to less than 500 cells/μL and particularly when less than 50 to 100 cells/μL.[283]

Imaging. The most common chest radiograph findings include single (Fig. 123.9; eFig. 123.32) or multiple parenchymal nodules (eFig. 123.33), nodular opacities or masses (eFig. 123.34), lobar opacities, and diffuse interstitial opacities (eFig. 123.35).[284] More rarely, cases of endobronchial lesions have been reported.[285] Pleural effusions are the most common radiographic abnormality, seen in 40–70% of cases, and are often bilateral.[284] Bilateral hilar and mediastinal adenopathy can be found in up to 60% of patients. Isolated intrathoracic adenopathy without identifiable extrathoracic nodal involvement is a rare presentation for HIV-associated NHL.

Diagnosis. The diagnosis of NHL requires demonstration of malignant lymphocytes on cytology or biopsy specimens.

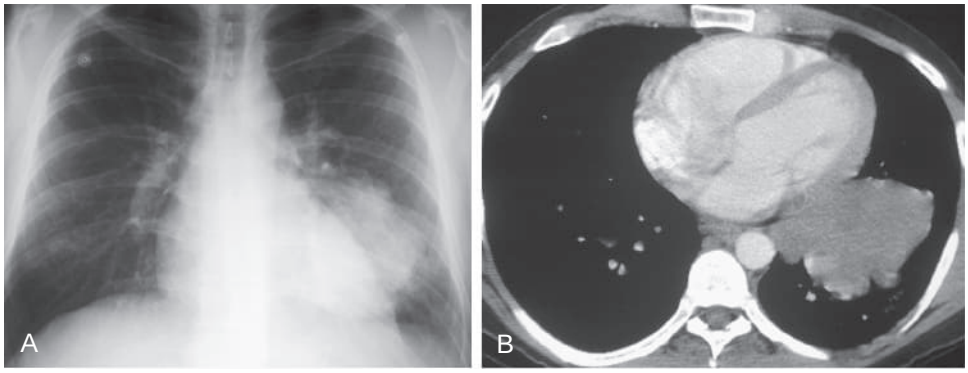

Figure 123.9 Non-Hodgkin lymphoma. (A) Frontal chest radiograph from a patient with AIDS with non-Hodgkin lymphoma showing a large left lower lobe mass. (B) Axial computed tomography shows a mass in the left lower lobe without an air bronchogram, suggestive of a neoplasm. (Courtesy Michael B. Gotway, MD.)

Most often the diagnosis is made by needle aspiration or biopsy of an extrathoracic site. Persons who present with isolated intrathoracic involvement should undergo bronchoscopy with biopsies (e.g., transbronchial and/or endobronchial ultrasound guided), if abnormal lesions and nodes are within reach through the bronchoscope,[284] whereas fluoroscopic or CT-guided fine-needle aspiration should be considered for more distal lesions. Other options include mediastinoscopy and open-lung biopsy. For patients with pleural effusions, pleural fluid cytology, biopsy, or both are often diagnostic.[284] Pleural fluid is exudative, lymphocytic predominant, and often has very high levels of LDH.[284] The yield of pleural cytology is significantly higher in HIV-associated pulmonary lymphoma than in non–HIV-infected cases.[286]

Treatment. Pulmonary involvement in NHL is treated as part of systemic disease. Median survival from AIDS-related NHL has greatly improved as a result of combining ART with chemotherapy.[287] Chemotherapy is frequently complicated by the development of opportunistic infections, particularly PCP, and by the presence of decreased bone marrow reserve. Therefore, *Pneumocystis* prophylaxis should be considered in all cases, particularly in patients treated with steroids, who are lymphopenic, and/or in whom the $CD4^+$ lymphocyte count remains less than 200 cells/μL.

Primary Effusion Lymphoma

Classic primary effusion lymphoma is a distinct subtype of NHL that presents with isolated effusions in body cavities, including the pleura (eFig. 123.36), pericardium, and peritoneum in the absence of a discrete nodal or extranodal mass.[288] A rare disease, these tumors are found nearly exclusively in HIV-infected MSM. HIV infection is usually advanced, with $CD4^+$ lymphocyte counts less than 200 cells/μL.[288] HIV-infected patients with primary pleural effusion lymphoma typically present with symptoms related to the space-occupying nature of the effusion (i.e., dyspnea). Diagnosis is established by pleural fluid histology and identification of HHV8, which can be found in all cases.[289] Primary effusion lymphomas usually lack classic B cell and T cell markers.[278] Treatment options include ART and systemic chemotherapy. Antiviral therapy, immunomodulatory agents, or proteasome inhibitors have also been tried. Prognosis is poor, with median survival of approximately 6 months.

Multicentric Castleman Disease

Multicentric Castleman disease (MCD) is a rare lymphoproliferative disorder of the plasma cell type.[290] It is characterized histologically as angiofollicular lymph node hyperplasia.[277] MCD may be associated with KS in HIV-infected and in non–HIV-infected patients. Most HIV-infected patients with MCD are also infected with HHV8. MCD can be seen in patients with controlled or uncontrolled HIV. Common presenting symptoms and signs of systemic MCD can mimic lymphoma and include fever, weakness, generalized lymphadenopathy (eFig. 123.37), anemia, hypergammaglobulinemia, and hemophagocytic syndrome in life-threatening forms of MCD.[277] Presenting symptoms and signs include cough, dyspnea, and crackles on lung examination. Chest radiographic findings include reticular and/or nodular interstitial patterns, with mediastinal lymphadenopathy and, less commonly, bilateral pleural effusions.[277,291] Bronchovascular nodularity, consolidation, and mediastinal lymphadenopathy have been described on chest CT.[292]

The diagnosis of MCD is typically based on pathologic evaluation of an involved lymph node or extranodal mass that confirms MCD and excludes other diseases such as TB or lymphoma. Involved cells are B cells with plasma-cell differentiation. HHV8-infected cells can be detected by immunohistochemistry, and HHV8 may be detected by PCR in BAL fluid. Prognosis is generally poor, and disease can recur. Treatment options are based on expert opinion and include initiation of ART, if the patient is not already on it, rituximab, and potentially systemic chemotherapy depending on the extent of involvement. Antiviral therapy may be considered, although efficacy data are limited. Cases of IRIS, some of them fatal, have been reported in patients with MCD initiated on ART.

Non–Small Cell Lung Cancer

The incidence of non–small cell lung cancer, but not small cell lung cancer, is greater among HIV-infected persons than among non–HIV-infected persons.[266] Whether this increased incidence is due to HIV infection or to other potential confounders, such as increased smoking among HIV-infected populations, has been controversial. However, several cohort studies have demonstrated an increased risk associated with HIV that remains significant even after adjusting for smoking.[293–295] Whereas AIDS-defining cancers such as KS and NHL have decreased, non–AIDS-defining cancers in HIV-infected patients have increased, primarily among HIV-infected persons age 50 years and older and are projected to remain elevated.[269,281,296] In HIV-infected persons, lung cancer is now the most common infection-unrelated, non–AIDS-defining cancer and is a leading cause of mortality.[269,296–301]

Clinical Features. HIV-infected patients develop lung cancer at slightly younger ages than do non–HIV-infected patients, after controlling for demographic differences (50 vs. 54 years in one study).[302] Most HIV-infected patients in whom lung cancer develops are cigarette smokers. The characteristic presentation and radiographic finding of bronchogenic carcinoma are similar in HIV-infected and non–HIV-infected patients (eFig. 123.38). Although all pathologic types are seen, adenocarcinoma has been the most frequent pathologic type reported, similar to that seen in non–HIV-infected patients; squamous cell carcinoma is the second most frequently observed pathologic type.[294,295] Stage of lung cancer at presentation is similar by HIV status, with nearly 70% of all patients diagnosed at stage III/IV in the absence of screening.[295,303]

Although lung cancer can develop at any $CD4^+$ lymphocyte count, immunodeficiency is postulated as a mechanism for the enhanced risk for lung cancer associated with HIV.[298,304,305] A low $CD4^+$ cell count is associated with a greater risk for lung cancer in some studies but is not a consistent marker of risk in all studies. Immune dysregulation, reflected by a lower CD4/CD8 ratio over time preceding cancer diagnosis, has also been associated with an increased risk for lung cancer.[306] There is no clear relationship between HIV viral load and use of ART with lung cancer risk.[293]

Prior lung disease and pulmonary infections, particularly bacterial pneumonia and TB, increase the risk for

subsequent lung cancer.[307] In some studies, previous pneumonia explains the excess risk of lung cancer observed in those with HIV, particularly in those with well-controlled HIV disease.[308] Whether pneumonia reflects immune deficiency in the lung that also predisposes to lung cancer, or whether pneumonia triggers mechanisms that spur carcinogenesis or decrease immune surveillance is unclear.

Diagnosis and Treatment. Diagnosis and treatment of lung cancer in an HIV-infected patient is similar to that in a non–HIV-infected individual. Ongoing areas of controversy include the role of newer immune therapies and checkpoint inhibitors in HIV-infected patients, although initial data suggest potential benefits and acceptable side-effect profiles.[309] Median survival in HIV-infected patients with lung cancer is similar to age-matched non–HIV-infected lung cancer patients.[303]

Lung cancer screening with annual low-dose CT appears to have a similar beneficial effect on mortality in HIV-infected smokers who have well-controlled HIV as in older, non–HIV-infected heavy smokers in the National Lung Cancer Screening Trial.[310–312] Adapting the Cancer Intervention and Surveillance Modeling Network lung cancer policy screening model to HIV-infected persons demonstrated similar benefits and harms when screening individuals meeting the same criteria as people without HIV, namely, current or formers smokers age 55 to 74 years with 30 pack-years of smoking and who quit within the past 15 years, if they are adherent to ART and have well-controlled HIV disease. Smoking cessation should also be prioritized to decrease the risk of lung cancer in people living with HIV.

PULMONARY ARTERIAL HYPERTENSION

Studies have reported an increased frequency of PAH in the HIV-infected population, with a prevalence of approximately 0.5%,[313] and HIV-associated PAH is classified in the WHO Group 1 PAH category, rather than pulmonary hypertension due to cardiopulmonary conditions such as left heart disease (Group 2) or chronic lung disease (Group 3) (see Chapter 84). A systematic review and meta-analysis reported a prevalence in HIV-infected adults of 0.5% based on right heart catheterization and a higher prevalence of 8.5% based on cardiac echocardiography. The pathology of HIV-associated PAH is indistinguishable from that of idiopathic PAH, and therefore similar pathogenetic mechanisms may be involved. In addition, HIV viral proteins,[315] chronic inflammation due to underlying HIV, and use of illicit drugs (e.g., cocaine, methamphetamine)[316] in HIV-infected persons likely contribute. Animal studies indicate that HIV-associated PAH is associated with skewing of monocytes and alveolar macrophages toward a proinflammatory, profibrotic phenotype and a diminished capacity to down-regulate chronic inflammation.[317] In these same animal models, the use of statins has reduced inflammation and prevented the development of PAH.[318]

HIV-infected persons may also have pulmonary hypertension due to other causes (e.g., underlying cardiac or pulmonary disease) that are also increased in prevalence in HIV populations, and thus this diagnosis must be considered when evaluating persons with HIV and cardiopulmonary complaints.[319]

Clinical Features. In a review of 131 cases of PAH in HIV-infected patients,[320] the presenting symptoms and radiographic, pulmonary function, electrocardiographic, echocardiographic, and pathologic findings were similar to those in non–HIV-related idiopathic PAH (see Chapter 84).

Diagnosis. As with idiopathic PAH, the diagnosis of HIV-associated PAH requires confirmation of elevated pulmonary arterial pressures and the exclusion of secondary causes. Higher levels of endothelin-1 are associated with HIV-associated PAH assessed by both cardiac echocardiogram and right heart catheterization.[321]

Treatment. The optimal treatment of HIV-associated PAH is unclear.[322] In general, patients should receive antiretroviral therapy because this will reduce HIV RNA levels and HIV-related immune activation and inflammation. Cessation of illicit drug use is also paramount. Similar to patients with idiopathic PAH, patients with HIV-associated PAH and WHO functional class II, III, or IV should be referred to a specialist for PAH-specific therapy. In general, the choice of therapy is similar to that in persons without HIV.[323] In persons with HIV who are on an ART regimen that contains a pharmacologic boosting agent (i.e., ritonavir or cobicistat), certain endothelin receptor antagonists and phosphodiesterase inhibitors may require dose adjustments.

OBSTRUCTIVE LUNG DISEASE

A variety of PFT abnormalities are seen in people living with HIV infection. Spirometry is frequently abnormal, and *diffusing capacity for carbon monoxide* (D_{LCO}) is reduced.[324–329] Although pulmonary function abnormalities are more common in smokers, impairment in D_{LCO} has been reported in HIV-infected individuals without a history of smoking,[330] and HIV has been found to be an independent risk factor for decreased D_{LCO}.[331,332] Spirometry results are variable, with some studies reporting similar findings in populations with and without HIV infection,[331] an increased risk of airflow obstruction in those with HIV,[334] or a concurrently decreased *forced expiratory volume in 1 second* (FEV_1) and *forced vital capacity* (FVC) in those with HIV.[335,336] Nonetheless, the prevalence of abnormal spirometry is high in persons with HIV infection, with 37% of patients in the national Lung HIV Study having abnormal spirometry (27% obstructed and 10% restricted pattern).[337]

Risk factors for decline in lung function over time include uncontrolled HIV disease, pulmonary infections, and current smoking.[324,340] Although earlier data were conflicting based on observational studies suggesting increased airway obstruction in HIV-infected individuals receiving ART,[330,342] a randomized controlled trial of timing of ART initiation found no association between ART and lung function decline.[341] Impairment in FEV_1 and D_{LCO} in HIV-infected individuals is associated with decreased health status, an increased burden of respiratory symptoms, and higher mortality.[343,344]

COPD

COPD is common in HIV-infected populations, diagnosed in approximately 15–20%. HIV appears to increase risk for

COPD, independent of smoking and pulmonary infections related to HIV.[334,345–348] Although not all studies have found a significant difference in the prevalence of COPD among those with and without HIV,[335,336] a systematic review and meta-analysis of 30 studies found that the prevalence of COPD was significantly higher in PLWH than in non-HIV control subjects, even after adjusting for cigarette smoking.[349]

Emphysema is a common subphenotype of COPD in PLWH.[346,350,351] HIV is also associated with a greater risk of chronic respiratory symptoms consistent with chronic bronchitis, another major subphenotype of COPD.[352] Emphysema in HIV-infected patients has been found to be more severe and diffuse when compared to uninfected patients in some studies,[350] although HIV was not associated with an increased risk of radiographic emphysema in other studies.[353] As in investigations comparing PFTs, differences in HIV-infected and control populations, nadir $CD4^+$ and timing of ART initiation, and varying prevalence of exposure to risk factors, including cigarette smoking, may account for the varying results in these studies.

Inflammation and immune dysfunction related to HIV are associated with greater risk of COPD, suggesting a role for HIV in disease pathogenesis. The prevalence of COPD is higher in individuals with HIV who have lower $CD4^+$ cell counts and higher HIV viral load.[324,333,335,338] Severity of immunocompromise before start of ART, reflected by a nadir $CD4^+$ cell count less than 200 cells/μL, and ongoing immune dysfunction, reflected by a low CD4/CD8 ratio (<0.4), are also associated with radiographic emphysema in those with HIV.[350,355] Chronic inflammation and immune activation, which can persist despite ART in individuals with well-controlled HIV, have also been associated with COPD in HIV. Levels of inflammatory markers, such as C-reactive protein and interleukin-6, are higher in HIV-infected individuals with airflow obstruction and low D_{LCO}.[356,357] In addition, markers of immune activation, such as soluble CD14, the lipopolysaccharide coreceptor, are higher in HIV-infected individuals with emphysema,[350] and soluble CD163 is increased in HIV-infected persons with a low FEV_1/FVC ratio and low D_{LCO}.[358]

Data are limited on the impact of HIV on the clinical course of COPD. Rates of COPD exacerbation may be higher in those with HIV.[359,360] COPD is a significant risk factor for increased frailty, decreased physical function, and increased mortality in HIV-infected persons.[361,362]

Asthma

HIV-infected individuals may have asthma that precedes their HIV infection or that develops after the onset of HIV. HIV-infected patients are more likely than non–HIV-infected patients to have bronchial hyperresponsiveness to methacholine.[328] In one clinic-based study, a history of asthma was reported in 21% and current asthma in 17% of 136 patients attending a primary care clinic for HIV infection.[363] Another study found that physician-diagnosed asthma was present in 21% of participants, and bronchodilator responsiveness was present in 9%.[364] The prevalence of asthma may be increasing in adolescents with HIV, as one study of 1201 HIV-positive youth found that asthma incidence increased significantly from 2008–14 compared to the period 2004–07.[365] $CD4^+$ lymphocyte counts greater than 200 cells/μL are associated with current asthma in those with HIV infection,[363] and one report has linked use of asthma medication to ART use in HIV-infected children, suggesting that immune responses are important, but this association has not been replicated in all cohorts.[364,366] Other factors such as female sex and obesity have also been found to be associated with asthma in HIV-infected individuals.[364]

Treatment of COPD and Asthma

In general, treatment of asthma and COPD should be similar to that for the non–HIV-infected population (see Chapters 62 and 64) because data are limited on whether and how to tailor therapy for obstructive lung disease for people living with HIV. Attention to drug-drug interactions between antiretrovirals and respiratory medications is required. PIs, particularly ritonavir, can increase systemic levels of inhaled or intranasal fluticasone and other inhaled corticosteroids leading to Cushing syndrome or adrenal suppression.[367] Beclomethasone has the least interaction and is the preferred inhaled corticosteroid when used in combination with strong CYP3A4 inducers, including boosted regimens (cobicistat, ritonavir) and most PIs. Use of inhaled corticosteroids for COPD in individuals with HIV also requires careful monitoring for oral candidiasis and bacterial pneumonia.[368] In terms of long-acting β-agonists, no clinically significant interactions have been reported between olodaterol and formoterol with antiretroviral medications. However, salmeterol can interact with different antiretrovirals to cause QTc prolongation. Long- or short-acting muscarinic antagonists (ipratropium or tiotropium) do not have known clinically significant drug-drug interactions with antiretrovirals and represent first-line bronchodilator therapy for COPD.

INTERSTITIAL PNEUMONITIDES

Although opportunistic infection and neoplasia dominate the clinical spectrum of HIV-associated pulmonary diseases, a small number of patients present with signs and symptoms attributable to one of the interstitial pneumonitides, *lymphocytic interstitial pneumonitis* (LIP) or *nonspecific interstitial pneumonitis* (NSIP).[369]

Lymphocytic Interstitial Pneumonitis

Clinical Features. The most striking feature of HIV-associated LIP is the effect of age on its incidence. Early in the AIDS epidemic, one-third to one-half of AIDS-defining diagnoses in HIV-infected children in high-income, industrialized countries were due to LIP. In contrast, LIP is rare in adults[370] and adolescents[371] but has now been described in all settings, including low- and middle-income settings.[372]

The chest radiograph presentation of LIP is nonspecific (Fig. 123.10) and is characterized by bilateral reticulonodular interstitial opacities with a middle to lower lung zone predominance.[373] Hilar or mediastinal adenopathy is occasionally seen. Chest CT scans may reveal small (2- to 4-mm) nodules, often in a peribronchovascular distribution (eFig. 123.39), or diffuse areas of ground-glass opacity.[374]

Diagnosis and Treatment. The definitive diagnosis of LIP requires histologic confirmation by biopsy. There are so

Figure 123.10 Lymphocytic interstitial pneumonitis. Frontal chest radiograph of an HIV-infected patient showing diffuse reticulonodular infiltration. Biopsy specimen revealed lymphocytic interstitial pneumonitis.

few studies of LIP among HIV-infected adults that neither definitive therapy nor benefit of therapy has been determined. Cases of LIP that responded to ART alone have been reported.[370,375]

Nonspecific Interstitial Pneumonitis

NSIP is a pulmonary disorder characterized histologically by infiltration of mononuclear cells, predominantly lymphocytes and plasma cells, into the peribronchiolar and perivascular interstitium (see Chapter 90). NSIP has been reported with various frequencies in HIV-infected patients. Because it is a histologic diagnosis, its incidence depends on the frequency with which biopsy is performed during the diagnostic evaluation.

Clinical Features. The clinical features of NSIP are indistinguishable from those of PCP; however, NSIP may present at $CD4^+$ lymphocyte counts greater than 200 cells/μL, whereas PCP rarely (≤5%) does. For example, in a series of 67 HIV-infected patients with NSIP, the mean $CD4^+$ lymphocyte count in the patients with NSIP was 492 cells/μL compared with 57 cells/μL for the matched control subjects with PCP.[376] The chest radiographic presentation of NSIP is usually a nonspecific diffuse interstitial pattern, which is also indistinguishable from that of PCP; however, one study reported that 16 of 36 (44%) patients with HIV-related NSIP had normal radiographs.[377]

Diagnosis and Treatment. The diagnosis of NSIP requires both histologic confirmation and the exclusion of other etiologies. The natural history of HIV-associated NSIP is poorly understood, but it usually resolves or stabilizes without therapy.[376] Observation is all that is required, but if the patient becomes severely ill, repeat bronchoscopy and biopsy are indicated to look for a different, usually infectious, disorder.

SARCOIDOSIS

Although sarcoidosis would seem an unlikely disorder among patients with HIV, a number of cases of sarcoidosis or sarcoid-like disease have been reported in this population. Many of these case reports have correlated the use of ART with the development of sarcoidosis.[378,379] Whether sarcoidosis in HIV represents a manifestation of IRIS is debated. Approximately 75% of HIV-infected patients with sarcoidosis have $CD4^+$ lymphocyte counts greater than 200 cells/μL.[378]

Both the clinical and imaging findings (eFig. 123.40) of sarcoidosis in HIV-infected patients mirror findings of sarcoidosis in non–HIV-infected patients.[378,379] As described in Chapter 93, granulomatous inflammation of the lungs and other involved organs is characteristic. Stains and cultures of tissue should be obtained and, to diagnose sarcoid, must be negative for microorganisms (e.g., mycobacteria, fungi). Lymphocytic alveolitis with a high percentage of $CD4^+$ lymphocytes may be encountered.[380] Management should follow guidelines as outlined for non–HIV-infected persons with sarcoidosis.

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

IRIS describes a paradoxical worsening of clinical status related to recovery of the immune system after a period of immunosuppression. The syndrome typically develops after the initiation of ART in HIV-infected patients. IRIS manifests as an exuberant host inflammatory response to previously recognized (paradoxical IRIS) or subclinical infections (unmasking IRIS). IRIS may also result from an inflammatory or immune response to cancer or self-antigens, as cases of IRIS have been reported to present with worsening tumor or autoimmune disease.[381]

Clinical Features. Numerous disease processes have been associated with IRIS. These include many infections, sarcoidosis, autoimmune conditions, and tumors.[382,383] Among infectious triggers, mycobacterial infections, particularly *M. tuberculosis* (eFig. 123.41) and MAC, are most frequently encountered. Fungal infections, including PCP and *Cryptococcus,* and viral infections, such as CMV, can also be exacerbated by IRIS. The majority of cases of IRIS are seen within the first 1 to 3 months after the initiation of ART, although cases may present several months after the initiation of ART.[383]

Diagnosis and Treatment. The diagnosis of IRIS requires compatible clinical features and exclusion of alternative causes for worsening clinical status. IRIS is frequently associated with starting ART in close proximity to treatment for an acute opportunistic infection.[384,385] IRIS is more likely when ART is initiated in individuals with a very low $CD4^+$ cell count, generally less than 100 cells/μL, although IRIS can develop in response to TB at higher $CD4^+$ cell counts. IRIS is also more likely when there is a rapid virologic and immunologic response to ART.

Despite the risk of IRIS, studies support starting ART concurrently or very soon after starting treatment of opportunistic infection because this strategy results in improved survival.[109–111,386] Recommendations regarding the exact timing of ART initiation depend on the patient's $CD4^+$ cell

count, type of infection or complication, and organ system involved.

In resource-limited countries, TB is among the most common opportunistic infections in HIV-infected patients. Prednisone decreased risk of TB-associated IRIS in high-risk individuals in the PredART Clinical Trial. HIV-infected patients with $CD4^+$ cell counts less than 100 cells/μL who are within 30 days of initiation of TB treatment had a significantly decreased risk of TB-associated IRIS when given prophylactic prednisone for 4 weeks (40 mg daily for 14 days, followed by 20 mg daily for 14 days) without evidence of increased risk for other severe infections or cancers.[387] Sequelae of TB-associated IRIS may include worsening of lung function,[388] although declines in FEV_1 and FVC after ART initiation were less apparent in individuals in the PredART study.[389] These findings raise the possibility that TB-associated IRIS may contribute to the overall high prevalence of abnormal spirometry in HIV-infected patients after TB.

In patients who develop IRIS, ART should generally be continued, although careful review on a case-by-case basis is required and expert consultation is recommended.[27] Nonsteroidal anti-inflammatory agents can be used to decrease inflammation. Steroids may be indicated if the excessive inflammatory response can be particularly harmful, for example, in TB meningitis or with other life-threatening lesions, such as those involving the central nervous system or those causing airway compromise. Optimal steroid dosing is uncertain. However, in one trial of patients with moderately severe paradoxical TB-IRIS, outcomes were improved in patients treated with prednisone at 1.5 mg/kg per day for 2 weeks, followed by 0.75 mg/kg per day for the next 2 weeks.[390]

Key Points

- Without effective combination *antiretroviral therapy* (ART), *human immunodeficiency virus* (HIV) infection results in immune dysregulation, dysfunction, and deficiency, with a progressive decline in $CD4^+$ T lymphocytes. HIV infection also causes alteration in several lines of host defense in the lungs and respiratory tract. As a result, HIV-infected persons are at increased risk for a wide spectrum of opportunistic infections.
- The peripheral $CD4^+$ lymphocyte count influences the risk for pulmonary complications in HIV-infected persons; as the $CD4^+$ count decreases, the risk of opportunistic infections and HIV-associated malignancies increases.
- Worldwide, tuberculosis is the most common infectious lung complication and a major cause of HIV-associated morbidity and mortality.
- Bacterial pneumonia and *Pneumocystis* pneumonia are also common infectious lung complications associated with HIV.
- Noninfectious conditions encountered with increased frequency in patients with HIV include chronic obstructive pulmonary diseases, lung cancer, and pulmonary arterial hypertension.
- *Immune reconstitution inflammatory syndrome* (IRIS) can develop after the initiation of ART in HIV-infected patients. IRIS results from the reconstitution of the immune system leading to exuberant host inflammatory responses to previously recognized (paradoxical IRIS) or subclinical infections (unmasking IRIS).
- The differential diagnosis for pulmonary diseases in HIV-infected patients is broad, and the clinical features and radiographic findings of many diseases may overlap significantly. Definitive diagnosis is highly recommended in patients with HIV. When feasible, early bronchoscopy with bronchoalveolar lavage for opportunistic pathogens should be performed in patients with pneumonia who do not have an established microbiologic diagnosis.
- Treatment of noninfectious lung diseases in HIV-infected patients generally follow guidelines for uninfected persons. When initiating therapy for lung diseases, careful attention to drug-drug interactions with antiretrovirals is indicated.

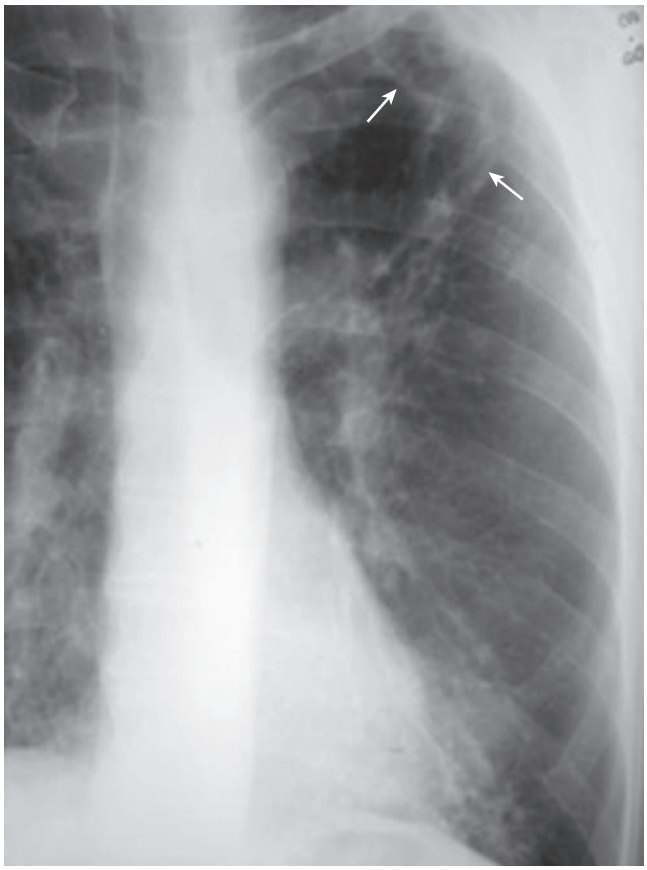
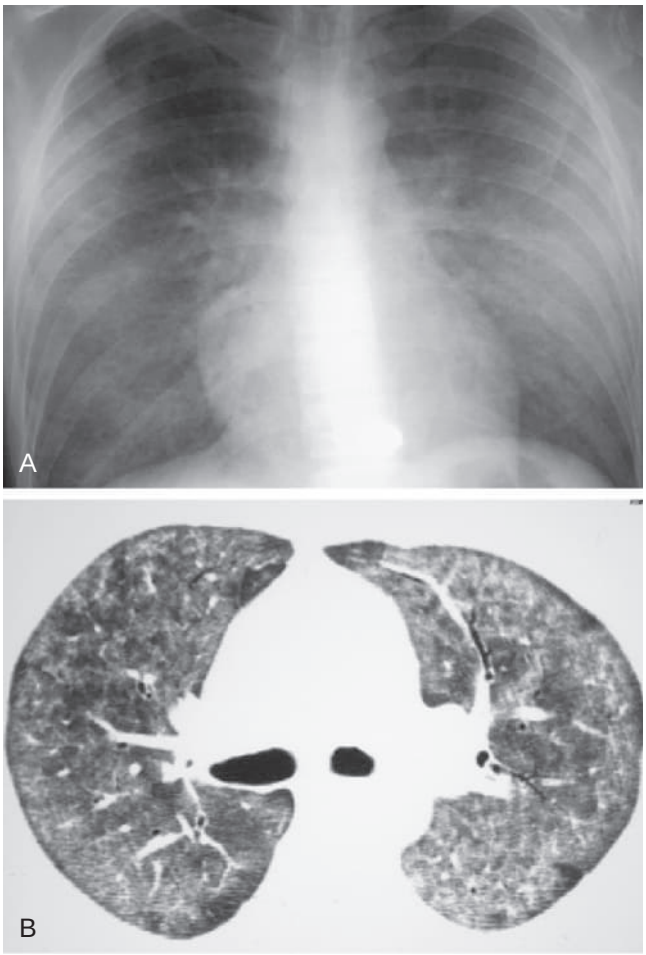
(B) Axial enhanced chest computed tomography confirms presence of enlarged aortopulmonary lymph nodes (*arrowhead*) as well as left tracheobronchial lymphadenopathy. Note the presence of low attenuation areas, consistent with necrosis. (Courtesy Michael B. Gotway, MD.)

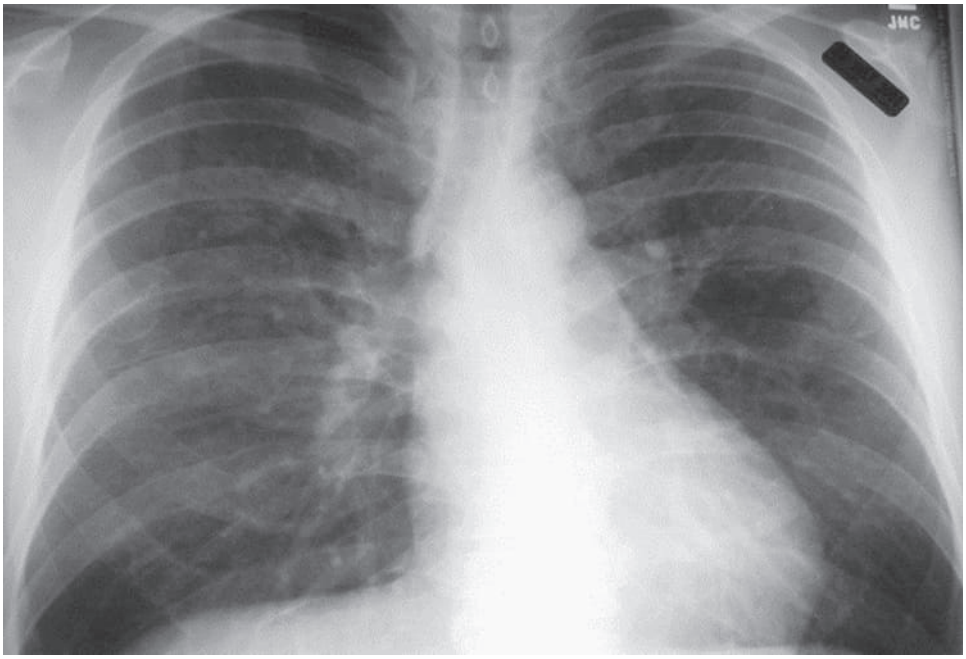


eFigure 123.10 *Mycobacterium kansasii* pulmonary infection. Frontal chest radiograph performed in an HIV-infected patient with a $CD4^+$ count less than 50 cells/μL shows linear bronchovascular thickening in the left upper lobe associated with left apical thin-walled cavities (*arrows*). (Courtesy Michael B. Gotway, MD.)

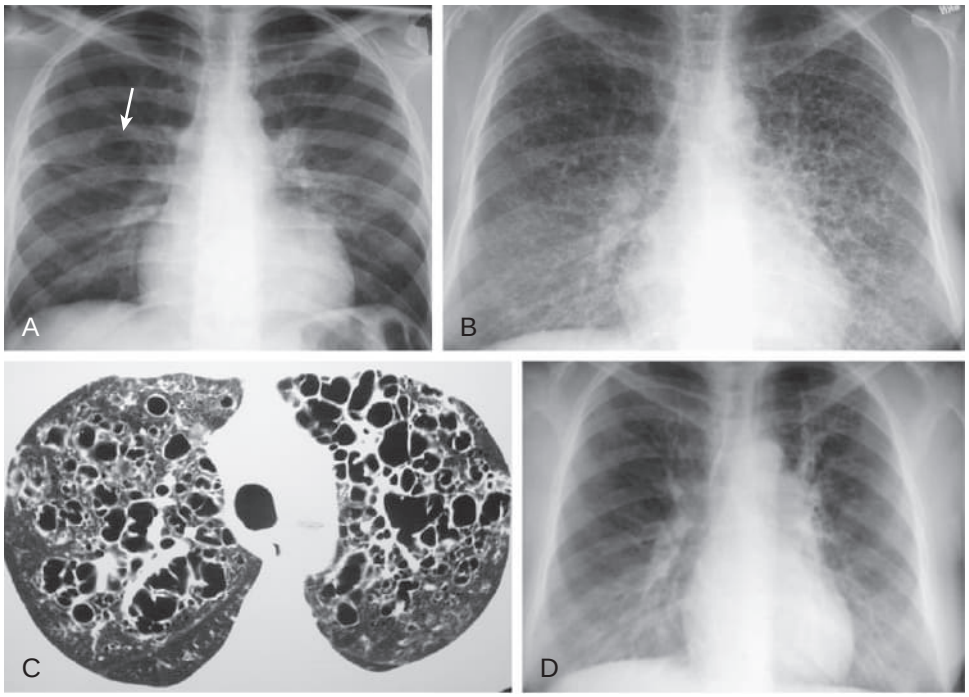
eFigure 123.11 Typical imaging appearance of *Pneumocystis jirovecii* pneumonia. Frontal chest radiograph in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL shows bilateral, symmetric perihilar indistinctness. Sputum induction recovered *P. jirovecii.* (Courtesy Michael B. Gotway, MD.)



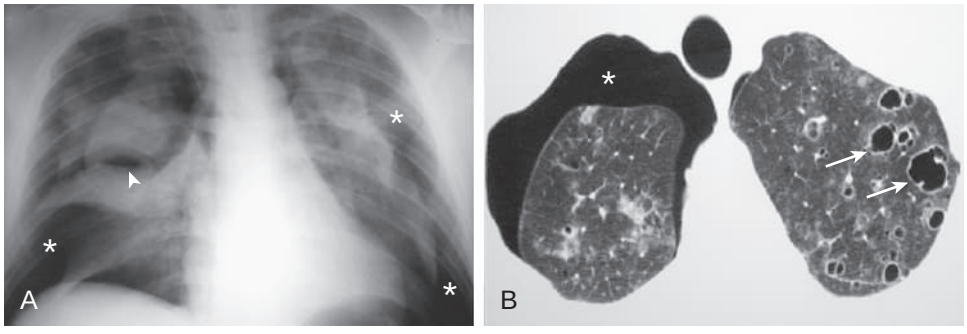
eFigure 123.12 Typical imaging appearance of *Pneumocystis jirovecii* pneumonia. (A) Frontal chest radiograph in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL shows bilateral, interstitial thickening with increased attenuation consistent with a granular or ground-glass appearance (increased pulmonary attenuation without obscuration of the underlying vascular and bronchial margins). Sputum induction recovered *P. jirovecii.* (B) Axial chest computed tomography displayed in lung windows shows the typical appearance of multifocal, bilateral ground-glass opacity in HIV-infected patients with *P. jirovecii* pneumonia. (Courtesy Michael B. Gotway, MD.)



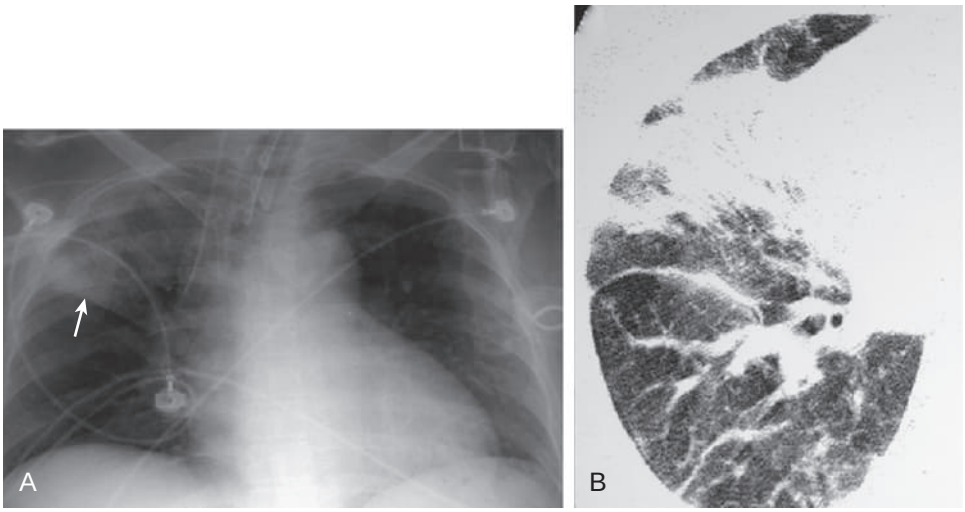
eFigure 123.13 Atypical imaging appearance of *Pneumocystis jirovecii* pneumonia. Frontal chest radiograph in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL shows faint predominantly right perihilar bronchovascular indistinctness; minimal left perihilar indistinctness is present. Asymmetry or frankly unilateral pulmonary findings are an atypical imaging manifestation of *P. jirovecii* pneumonia. Nevertheless, in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL such an imaging appearance is suspicious for *P. jirovecii* pneumonia. (Courtesy Michael B. Gotway, MD.)



eFigure 123.14 Imaging appearance of *Pneumocystis jirovecii* pneumonia: pneumatocele formation. (A) Frontal chest radiograph in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL shows bilateral mild bronchovascular thickening and indistinctness, consistent with *P. jirovecii* pneumonia. A thin-walled right perihilar cyst (*arrow*) is present, consistent with a pneumatocele. (B) Frontal chest radiograph in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL shows innumerable bilateral linear, reticular, and cystic foci. (C) Axial chest computed tomography displayed in lung windows shows numerous, bilateral thin-walled cysts with a few areas of ground-glass opacity also visible. The appearance is somewhat reminiscent of Langerhans cell histiocytosis. (D) Follow-up chest radiograph obtained several months after part A shows resolution of the cysts. (Courtesy Michael B. Gotway, MD.)

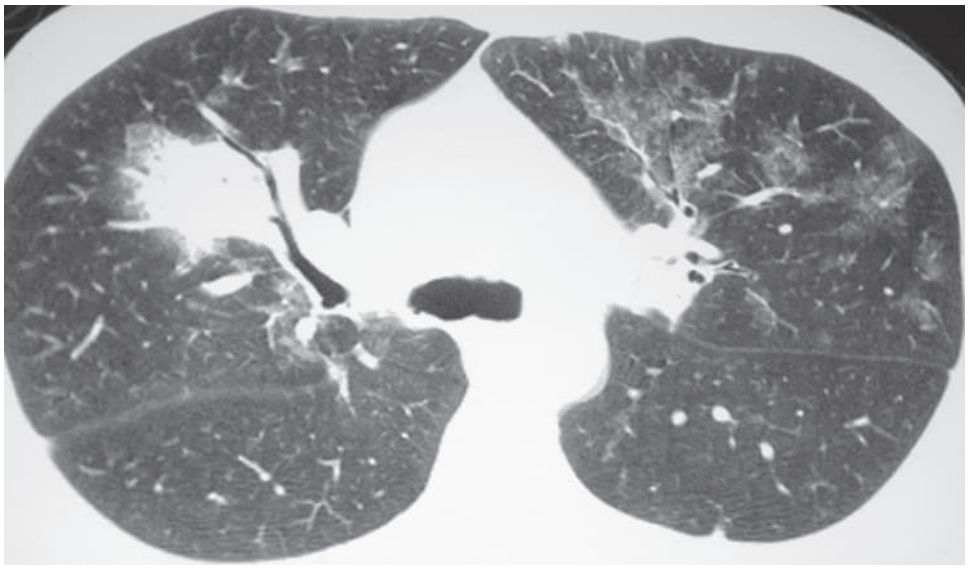


eFigure 123.15 Imaging appearance of *Pneumocystis jirovecii* pneumonia: pneumothorax due to pneumatocele formation. (A) Frontal chest radiograph in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL shows bilateral pneumothoraces (*asterisk*) on the right side tracking into the fissural surfaces (*arrowhead*). (B) Axial chest computed tomography displayed in lung windows in a different patient shows patchy bilateral ground-glass opacity, consistent with *P. jirovecii* pneumonia, complicated by thin-walled cysts (*arrows*), representing pneumatoceles. A right-sided pneumothorax (*asterisk*) is present. (Courtesy Michael B. Gotway, MD.)

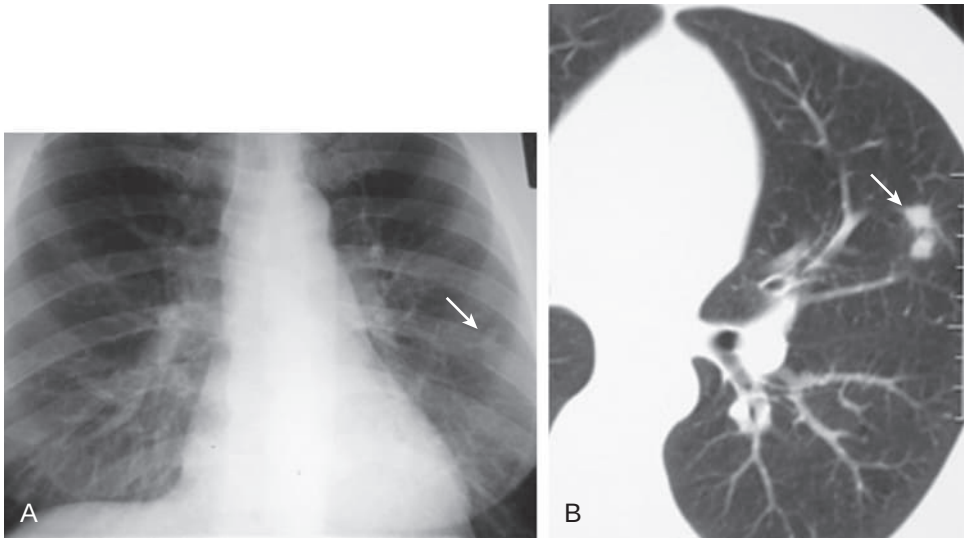


eFigure 123.16 Atypical imaging appearance of *Pneumocystis jirovecii* pneumonia: focal consolidation. (A) Frontal chest radiograph in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL shows focal right upper lobe opacity (*arrow*), demarcated by the right horizontal fissure. (B) Focused axial chest computed tomography displayed in lung windows in a separate patient shows air space consolidation in the right middle lobe. Sputum induction recovered *P. jirovecii* in both patients. (Courtesy Michael B. Gotway, MD.)

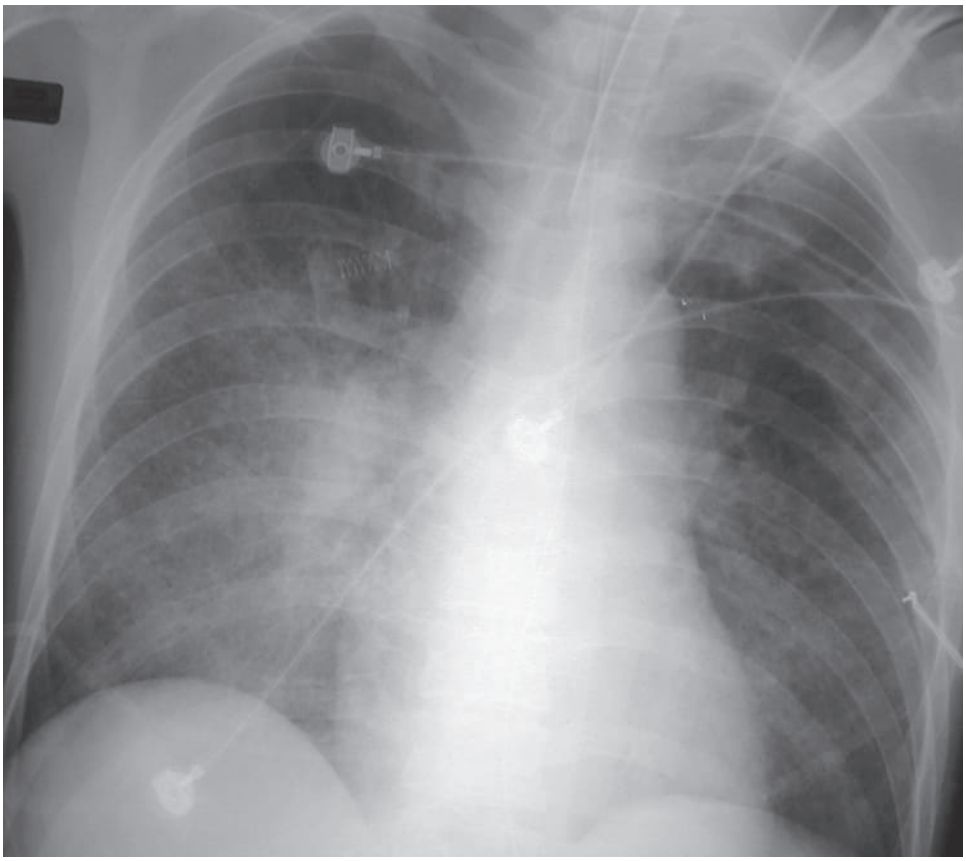
eFigure 123.17 Frontal chest radiograph in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL shows patchy bilateral opacities consistent with *Pneumocystis jirovecii* pneumonia. The more focal left midlung opacity (*arrow*) raises the possibility of a second, superimposed process, but no other organisms could be recovered and the pulmonary abnormalities resolved with treatment of *P. jirovecii.* (Courtesy Michael B. Gotway, MD.)



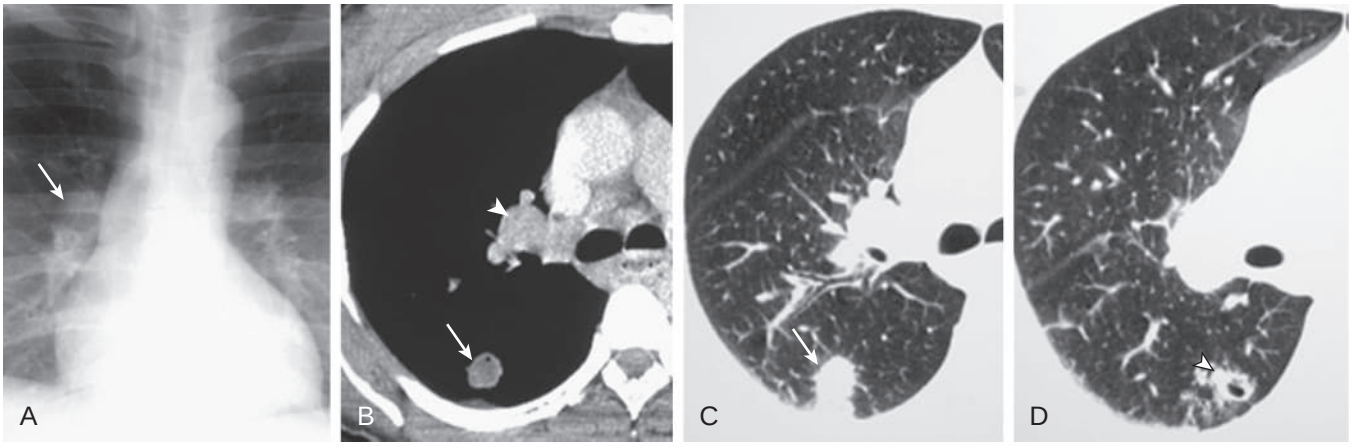
eFigure 123.18 Atypical imaging appearance of *Pneumocystis jirovecii* pneumonia: focal lung opacity. Axial chest computed tomography displayed in lung windows performed in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL shows air-space consolidation in the right upper lobe. Patchy left upper lobe ground-glass opacity is also present, consistent with *P. jirovecii* pneumonia. The patient underwent transthoracic percutaneous lung biopsy of the focal opacity to exclude the possibility of a second process superimposed on *P. jirovecii* pneumonia; this biopsy showed only *P. jirovecii* organisms. (Courtesy Michael B. Gotway, MD.)



eFigure 123.19 Atypical imaging appearance of *Pneumocystis jirovecii* pneumonia: focal nodules. (A) Frontal chest radiograph in an HIV-infected patient with a $CD4^+$ count less than 200 cells/μL shows faint left midlung nodular opacity (*arrow*). (B) Axial chest computed tomography displayed in lung windows shows two focal lingular nodules (*arrow*). Transthoracic percutaneous lung biopsy showed only *P. jirovecii* organisms. (Courtesy Michael B. Gotway, MD.)

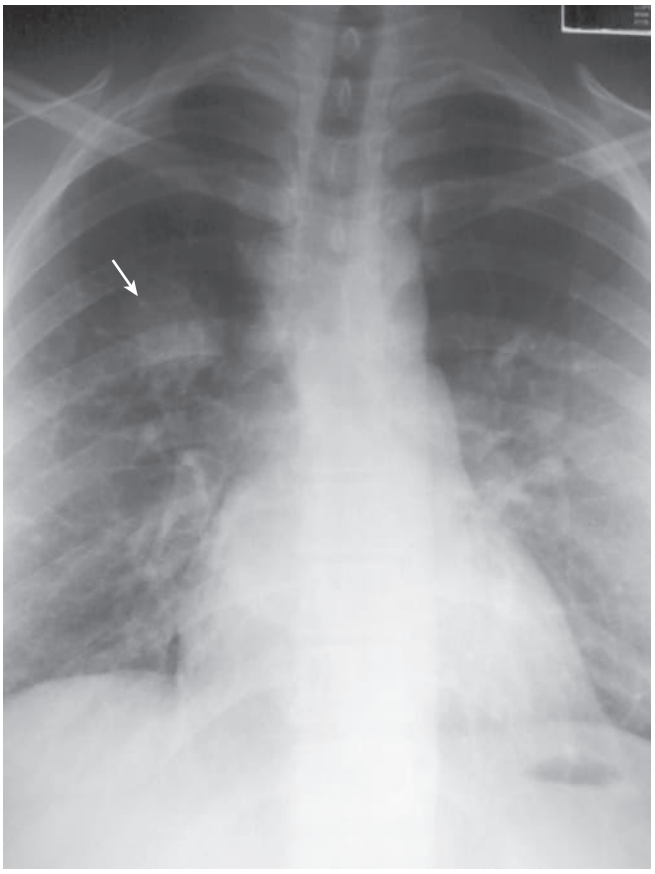


eFigure 123.20 Cryptococcal pulmonary infection: interstitial appearance. Frontal chest radiograph in an HIV-infected patient with a low $CD4^+$ count shows bilateral, right-greater-than-left, perihilar ground-glass attenuation and linear, interstitial thickening, suspicious for *Pneumocystis jirovecii* pneumonia; however, the opacities were proven to be the result of cryptococcal pulmonary infection. (Courtesy Michael B. Gotway, MD.)

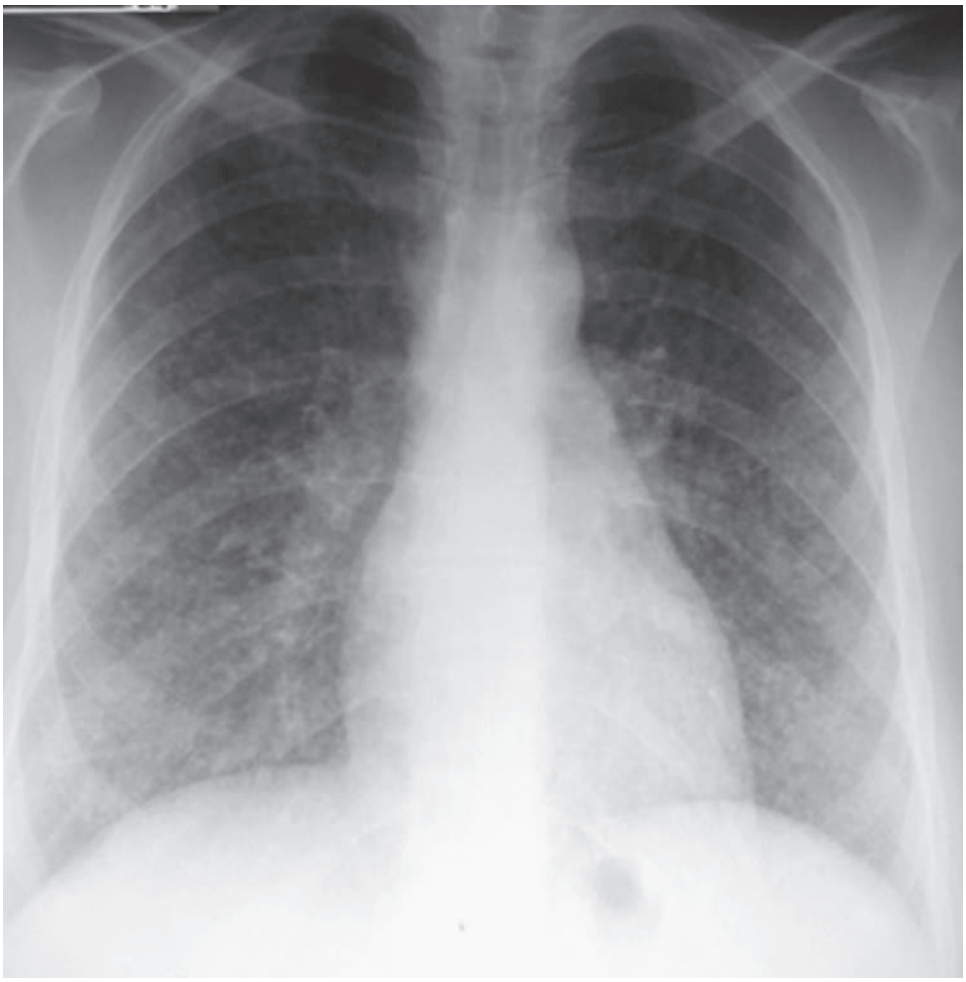


eFigure 123.21 Cryptococcal pulmonary infection: thoracic lymphadenopathy and nodules. (A) Frontal chest radiograph in an HIV-infected patient with a low $CD4^+$ count shows right hilar lymph node enlargement (*arrow*). (B–D) Axial chest computed tomography displaced in soft tissue (B) and lung windows (C–D) confirms right peribronchial lymph node enlargement (*arrowhead*, B) and shows a nodule in the right lower lobe (*arrows,* B–C); note the tiny focus of cavitation evident within the nodular anteriorly in part B). A separate cavitary nodule (*arrowhead*, D), with surrounding satellite opacities, is seen slightly more inferiorly in the superior segment of the right lower lobe. (Courtesy Michael B. Gotway, MD.)

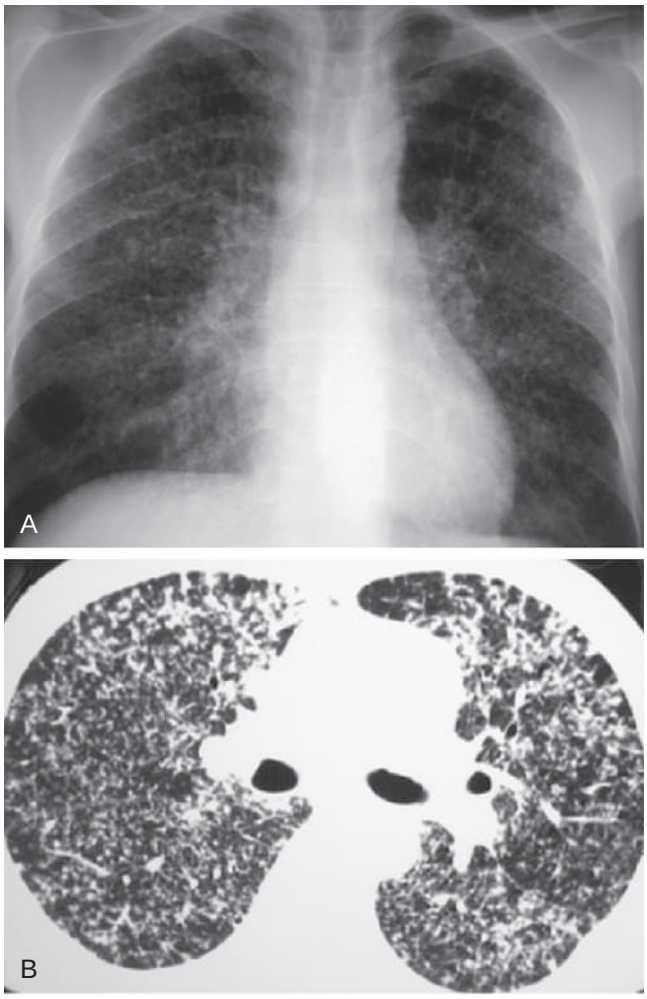
eFigure 123.22 Cryptococcal pulmonary infection: focal pulmonary opacity. Frontal chest radiograph in an HIV-infected patient with a low $CD4^+$ count shows focal right lower lobe consolidation superimposed on more diffuse interstitial thickening throughout the right lung. (Courtesy Michael B. Gotway, MD.)



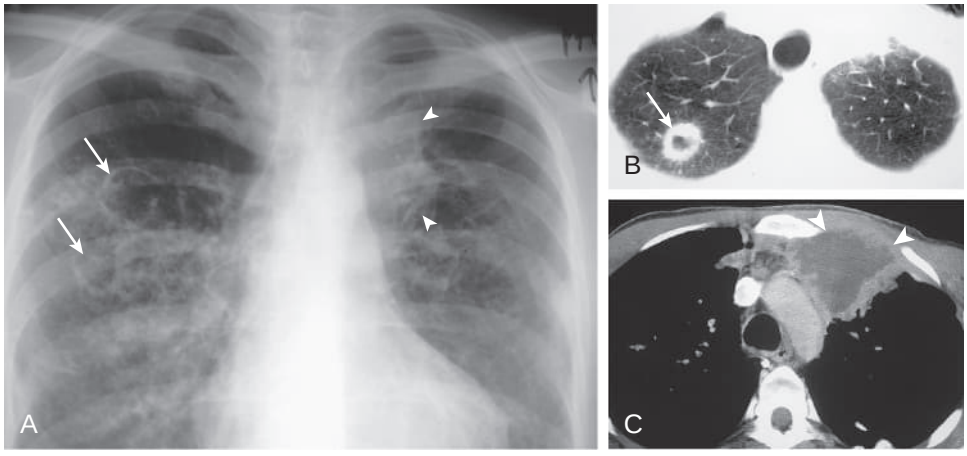
eFigure 123.23 Cryptococcal pulmonary infection: pulmonary nodule. Frontal chest radiograph in an HIV-infected patient with a low $CD4^+$ count shows a right suprahilar pulmonary nodule (*arrow*). Transthoracic percutaneous lung biopsy demonstrated cryptococcal infection. (Courtesy Michael B. Gotway, MD.)



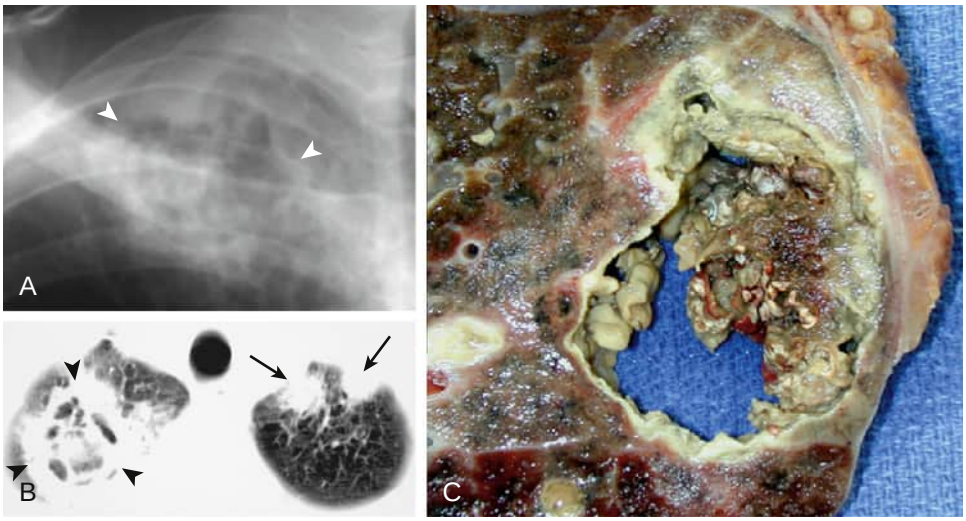
eFigure 123.24 Cryptococcal pulmonary infection: miliary infection. Frontal chest radiograph performed in an HIV-infected patient with a low $CD4^+$ count shows numerous symmetrical bilateral small pulmonary nodules. (Courtesy Michael B. Gotway, MD.)



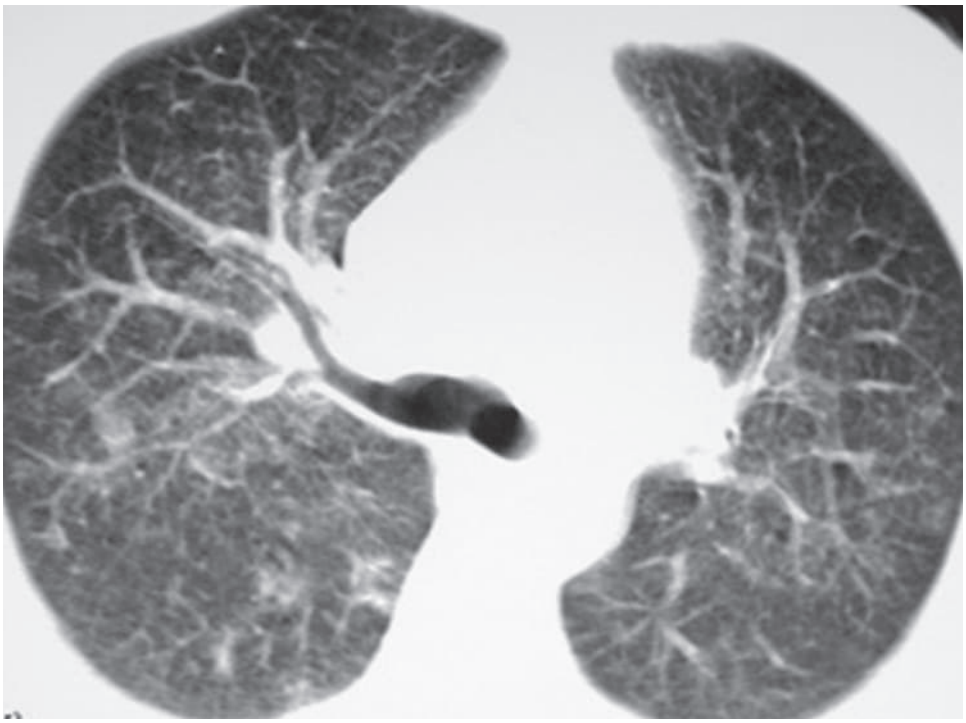
eFigure 123.25 *Coccidioides immitis* pulmonary infection: miliary infection. (A) Frontal chest radiograph in an HIV-infected patient with a low $CD4^+$ count shows numerous symmetrical bilateral small pulmonary nodules. (B) Axial chest computed tomography shows numerous bilateral pulmonary nodules, consistent with a random small nodular, or miliary, pattern. Bronchoscopy with transbronchial biopsy proved *C. immitis* infection. (Courtesy Michael B. Gotway, MD.)



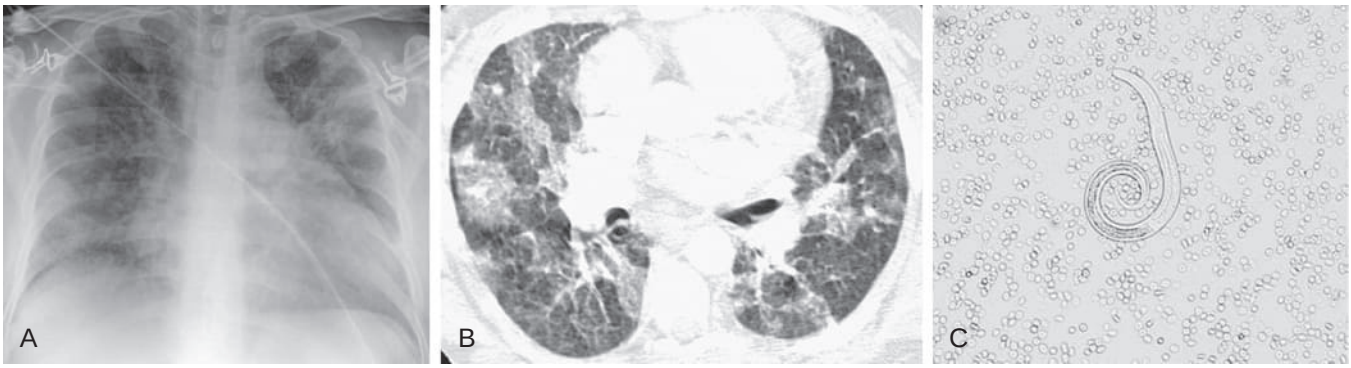
eFigure 123.26 *Aspergillus* pulmonary infection. (A) Frontal chest radiograph in an HIV-infected patient with a low $CD4^+$ count shows right upper lobe cystic lesions (*arrows*) with surrounding small nodules and left superior mediastinal soft tissue (*arrowheads*). Axial chest computed tomography displayed in lung windows (B) and soft tissue windows (C) shows a right apical cavity (*arrow*, B) and a necrotic mass in the left superior mediastinum (*arrowheads*, C) invading the chest wall anteriorly. Transthoracic percutaneous lung biopsy of the left-sided mass recovered *Aspergillus fumigatus*. (Courtesy Michael B. Gotway, MD.)



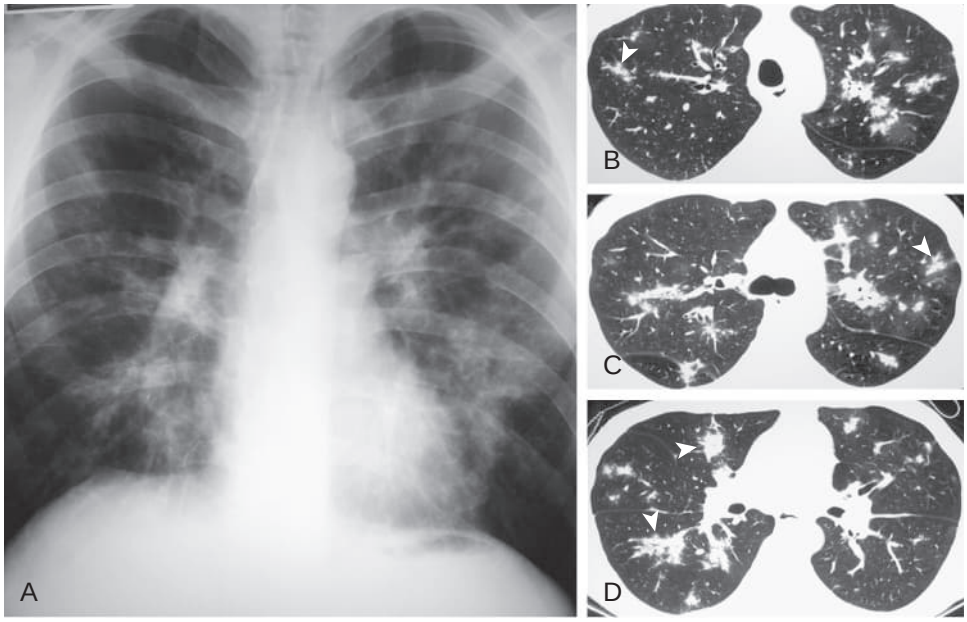
eFigure 123.27 *Aspergillus* pulmonary infection. (A) Focused frontal chest radiograph in an HIV-infected patient with a low CD4+ count shows an irregular cavity (*arrowheads*) in the right apex. (B) Axial chest computed tomography displayed in lung windows shows a complex cavity with internal opacity (*arrowheads*) and right apical lung nodules (*arrows*). (C) Postmortem right lung specimen shows a necrotic right apical cavity with complex internal material, correlating with the computed tomography findings. Numerous areas of arterial and venous invasion with thrombosis and infarction were identified, and *Aspergillus fumigatus* was recovered from the material within the cavity. (Modified from Gotway MB, Dawn SK, Caoili EM, et al. The radiologic spectrum of pulmonary *Aspergillus* infections. *J Comput Assist Tomogr.* 2002;26:159–173.)



eFigure 123.28 Cytomegalovirus infection. Axial chest computed tomography in an HIV-infected patient with a low CD4+ count shows patchy, variably sized pulmonary nodular opacities. The imaging features are very nonspecific. (Courtesy Michael B. Gotway, MD.)

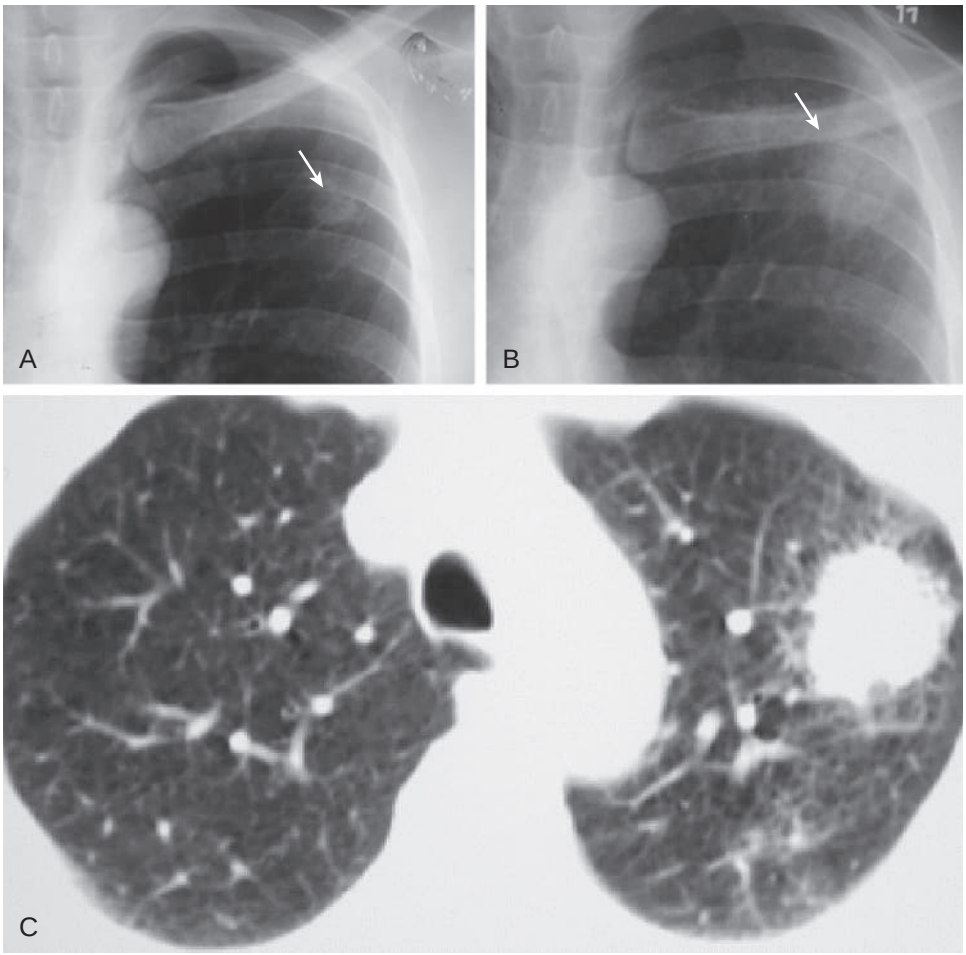


eFigure 123.29 *Strongyloides stercoralis* pulmonary infection. (A) Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows nonspecific bilateral areas of linear opacity and interstitial thickening, predominating in the perihilar regions. (B) Axial chest computed tomography displayed in lung windows shows patchy, multifocal, bilateral areas of ground-glass opacity associated with mild linear and reticular opacities. (C) Surgical lung biopsy recovered *S. stercoralis* organisms. (A–B, Courtesy Michael B. Gotway, MD.)

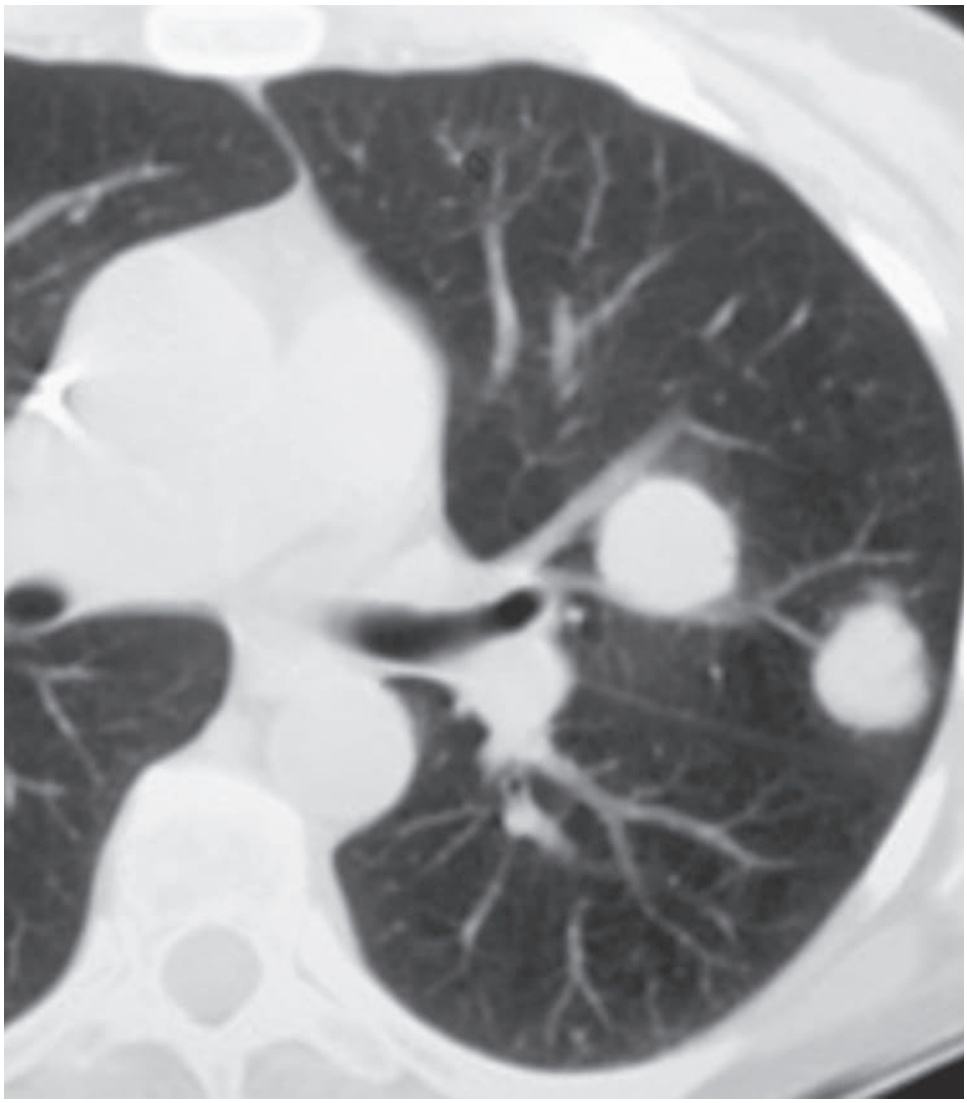


eFigure 123.30 Pulmonary Kaposi sarcoma: typical imaging appearance. (A) Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows multifocal, bilateral, perihilar bronchovascular thickening and nodularity. (B–D) Axial chest computed tomography displayed in lung windows shows patchy multifocal peribronchovascular nodular thickening (*arrowheads*). Note the presence of some patchy peribronchovascular ground-glass opacity (left upper lobe in B–C). (Courtesy Michael B. Gotway, MD.)

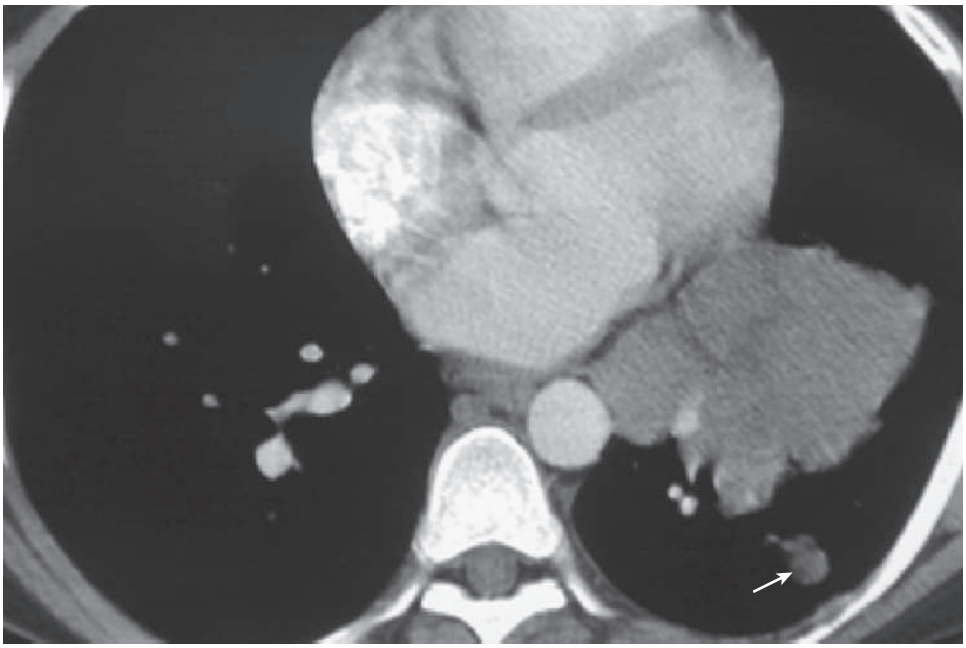
eFigure 123.31 Pulmonary Kaposi sarcoma: atypical imaging appearance. (A) Frontal chest radiograph in an HIV-infected woman with cardiomyopathy and a low CD4⁺ count shows cardiomegaly and a faint peripheral left lung nodular opacity (*arrow*). (B) Frontal chest radiograph 8 months after part A shows growth in the peripheral left lung opacity (*arrow*). (C) Axial chest computed tomography displayed in lung windows performed at the time of part B shows a subpleural, superior segment left lower lobe nonspecific nodule (*arrowhead*); this nodule was not calcified. Percutaneous transthoracic fine-needle aspiration and core lung biopsy was performed but was nondiagnostic. Surgical lung biopsy subsequently proved to be Kaposi sarcoma. (Courtesy Michael B. Gotway, MD.)



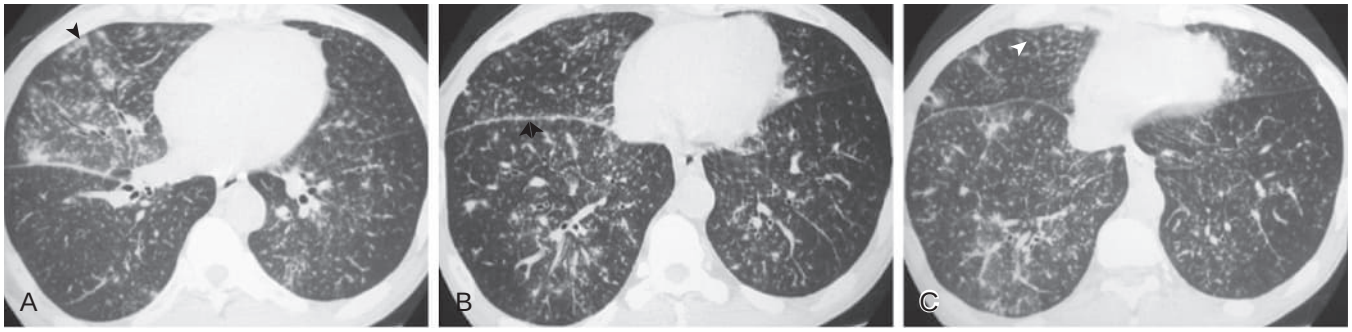
eFigure 123.32 Non-Hodgkin lymphoma in HIV infection: solitary nodule/mass. (A) Frontal chest radiograph in an HIV-infected patient with a low $CD4^+$ count shows an ill-defined left upper lobe nodule (*arrow*). (B) Frontal chest radiograph obtained 3 months after part A and after presumptive antimicrobial therapy shows that the left upper lobe lesion (*arrow*) has grown into a mass. (C) Axial chest computed tomography displayed in lung windows shows a poorly defined peripheral left upper lobe mass. Percutaneous transthoracic fine-needle aspiration and core lung biopsy showed non-Hodgkin lymphoma. (Courtesy Michael B. Gotway, MD.)



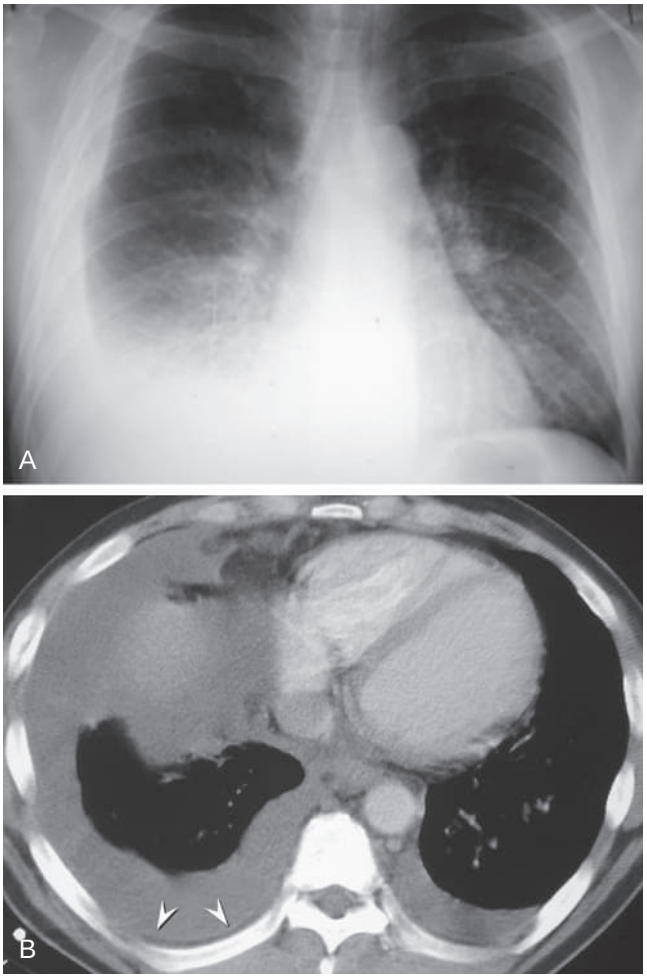
eFigure 123.33 Non-Hodgkin lymphoma in HIV infection: multiple nodules. Axial chest computed tomography performed in an HIV-infected patient with a low $CD4^+$ count displayed in lung windows shows two circumscribed, minimally lobulated left upper lobe nodules proven by percutaneous transthoracic fine-needle aspiration and core lung biopsy to be due to non-Hodgkin lymphoma. (Courtesy Michael B. Gotway, MD.)



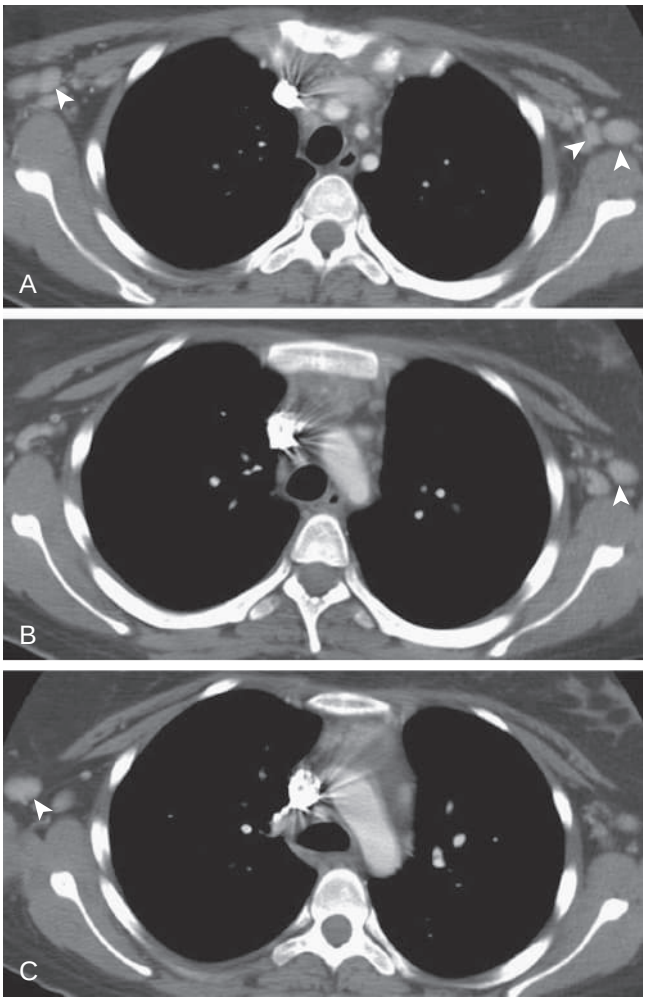
eFigure 123.34 Non-Hodgkin lymphoma in HIV infection: pulmonary mass. Axial chest computed tomography performed in an HIV-infected patient with a low $CD4^+$ count displayed in soft tissue windows shows a left lower lobe soft tissue mass proven by percutaneous transthoracic fine-needle aspiration and core lung biopsy to be due to non-Hodgkin lymphoma. An additional tumor nodule (*arrow*) is also present. (Courtesy Michael B. Gotway, MD.)



eFigure 123.35 Non-Hodgkin lymphoma in HIV infection: small nodules in a perilymphatic distribution. (A–C) Axial chest computed tomography performed in an HIV-infected patient with a low $CD4^+$ count displayed in lung windows shows innumerable small, well-defined nodules distributed along the fissures (*double arrowheads,* B), in the centrilobular region (*arrowhead,* A), and along mildly thickened interlobular septae (*arrowhead,* C). These nodules are located in the regions of pulmonary lymphatics; this small nodular pattern is referred to as a perilymphatic nodule distribution at high-resolution computed tomography. Bronchoscopy with transbronchial biopsy showed that these nodules were due to non-Hodgkin lymphoma. (Courtesy Michael B. Gotway, MD.)



eFigure 123.36 Primary effusion lymphoma in HIV infection. (A) Frontal chest radiograph in an HIV-infected patient with a low $CD4^+$ count shows a right pleural effusion and moderate, right-greater-than-left linear interstitial thickening. (B) Axial enhanced chest computed tomography displayed in soft tissue windows shows bilateral pleural effusions; trace pleural thickening (*arrowheads*) may be present on the right. Thoracentesis showed the presence of lymphoma. (Courtesy Michael B. Gotway, MD.)



eFigure 123.37 Multicentric Castleman disease in HIV infection. (A–C) Axial enhanced chest computed tomography displayed in soft tissue windows performed in an HIV-infected patient with a low $CD4^+$ count shows bilateral, mildly enhancing axillary lymphadenopathy (*arrowheads*), proven to reflect Castleman disease on excision. (Courtesy Michael B. Gotway, MD.)

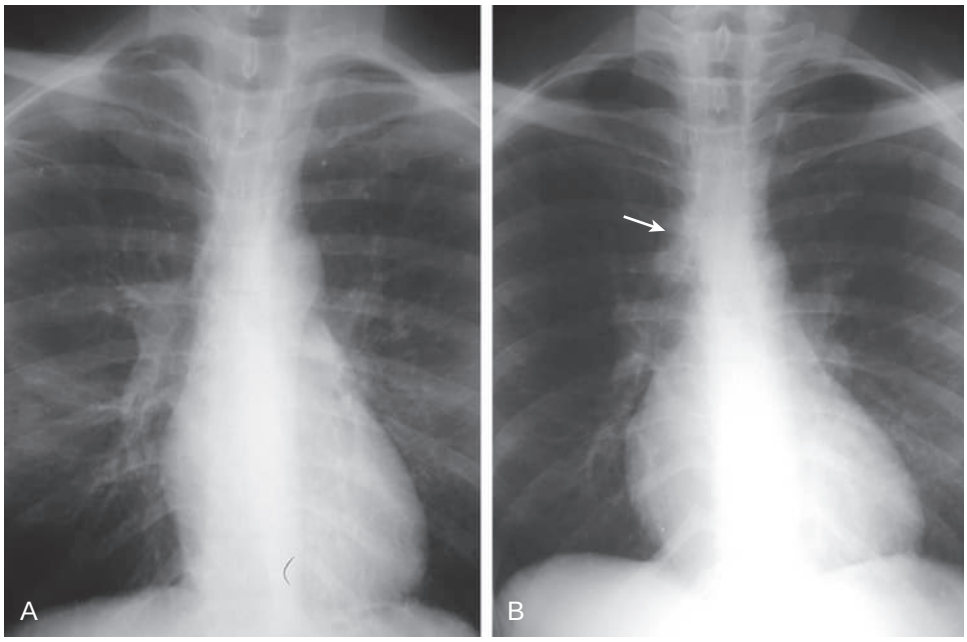
(B) Axial enhanced chest computed tomography displayed in soft tissue windows shows bilateral lymph node enlargement (*arrows*). (C–D) Chest computed tomography displayed in lung windows shows the upper lobe predominant perilymphatic nodules (*arrowheads*) typical of sarcoidosis. (Courtesy Michael B. Gotway, MD.)



eFigure 123.41 Immune reconstitution inflammatory syndrome. (A) Frontal chest radiograph appears normal in an HIV-infected patient with a low $CD4^+$ count, in whom *Mycobacterium tuberculosis* was recently diagnosed. (B) Frontal chest radiograph performed 2 months after institution of combination antiretroviral therapy shows development of right paratracheal lymphadenopathy (*arrow*). (Courtesy Michael B. Gotway, MD.)

KEY POINTS

INTRODUCTION

Primary immune deficiency disorders (PIDDs) are genetic defects of the immune system that predispose individuals to infection, malignancy, and autoimmunity.[1,2] Most PIDDs are inherited but, in some disorders, such as *common variable immunodeficiency* (CVID), a family history may be absent. Furthermore, in some diseases, somatic mutations, not germline mutations, are the cause.[3]

The frequency of clinically important PIDDs is approximately 30 to 50 per 100,000 individuals.[4] Although PIDDs may manifest and be diagnosed in children, some PIDDs, such as CVID, commonly manifest in young adulthood, and approximately 20% of patients with CVID are diagnosed at 50 years of age or older. Therefore, older age should not be used to exclude the diagnosis of a PIDD, and most persons affected with PIDD are adults, not children.[5] Of the patients in the United States who are receiving *intravenous immune globulin* (IVIG), 23% are 30 to 44 years old, and 34% are 45 to 65 years old.[5] The increasing age of patients with PIDD is the result, in part, of improvements in recognition, diagnosis and treatment, and longer survival.[4]

A diagnostic evaluation for PIDD is often overlooked in the evaluation of patients with pulmonary infections. Early diagnosis and treatment of PIDD can reduce the morbidity and mortality associated with recurrent infections. For example, early *hematopoietic stem cell transplantation* (HSCT) (<3.5 months of age) results in dramatically improved outcomes in infants with *severe combined immunodeficiency* (SCID).[6,7] Treatment with high-dose IVIG or *subcutaneous immunoglobulin* (SCIG) can prevent many of the infectious sequelae in patients with primary antibody deficiency states.[8] Many routine childhood vaccines use attenuated, live organisms, and the use of such vaccines may lead to disseminated infections in patients with antibody or cellular immunodeficiencies and is therefore contraindicated.[9] Although early detection can improve outcomes, long delays in the diagnosis of PIDD are common.[10]

Respiratory tract infections are common in all types of PIDDs, and guidelines are available to aid in the evaluation of PIDDs in patients with pulmonary infections (Table 124.1, Fig. 124.1). Evaluation of the immune system is warranted in patients with two or more radiographically documented cases of pneumonia, a single infection of the lung with an opportunistic or unusual pathogen, or complicated pneumonia. A patient with a first pneumonia, but with a history of intractable sinus disease or recurrent gastrointestinal infection or with other disorders with increased frequency in patients with primary PIDD (e.g., autoimmunity, intractable eczema, unusual facies), should also be evaluated for a PIDD. Poor response to antibiotic therapy may also suggest an underlying PIDD.

The history and clinical presentation of patients with primary immunodeficiencies suggest the type of immunologic defect present (Table 124.2). Patients with antibody deficiencies, such as *X-linked agammaglobulinemia* (XLA), usually present after 6 months of age when maternal antibodies are no longer present. Recurrent and severe upper and lower

respiratory tract infections are the usual mode of presentation. In contrast, diseases associated with cellular immunodeficiencies usually begin in infancy or early childhood. Infections include disseminated and severe viral infections, as well as those caused by opportunistic or unusual pathogens such as nontuberculous mycobacteria, *Pneumocystis*, *Candida*, or other fungi. Diarrhea and malabsorption are common, and growth is delayed. Complement deficiencies may manifest in a manner similar to antibody deficiencies or with recurrent *Neisseria* sp infections. In contrast to patients with cellular immunodeficiencies, growth is usually not delayed in patients with complement or antibody deficiencies. Phagocyte defects such as chronic granulomatous disease (from *nicotinamide adenine dinucleotide phosphate* [NADPH] oxidase deficiency) may manifest with severe infection with catalase-positive organisms (*Staphylococcus, Pseudomonas, Klebsiella,* or *Serratia*).

A common misconception is that opportunistic pathogens cause most infections in patients with primary immunodeficiencies; actually, many infections in immunodeficient patients are with pathogens common in the community. In patients with PIDD, however, these infections may be of unusual severity and respond poorly to therapy. For example, recurrent infections with *Streptococcus pneumoniae* are frequent in patients with antibody deficiencies, complement deficiencies, *toll-like receptor* (TLR) signaling deficiencies (e.g., MyD88, *IL-1 receptor–associated kinase* [IRAK]-4), and mutations in *nuclear factor-κB essential modulator* (NEMO).[11] Although this chapter deals exclusively with PIDDs, it is essential to evaluate

Table 124.1 General Criteria That Warrant an Immunologic Evaluation

Chronic infections
Recurrent infections
Opportunistic or unusual pathogens
Unusual sites of infections
Incomplete clearing of infection
Poor response to antimicrobial therapy
Associated conditions (unusual facies, tetany, failure to thrive, intractable sinus infections, intractable diarrhea, thrush, intractable eczema, autoimmunity)

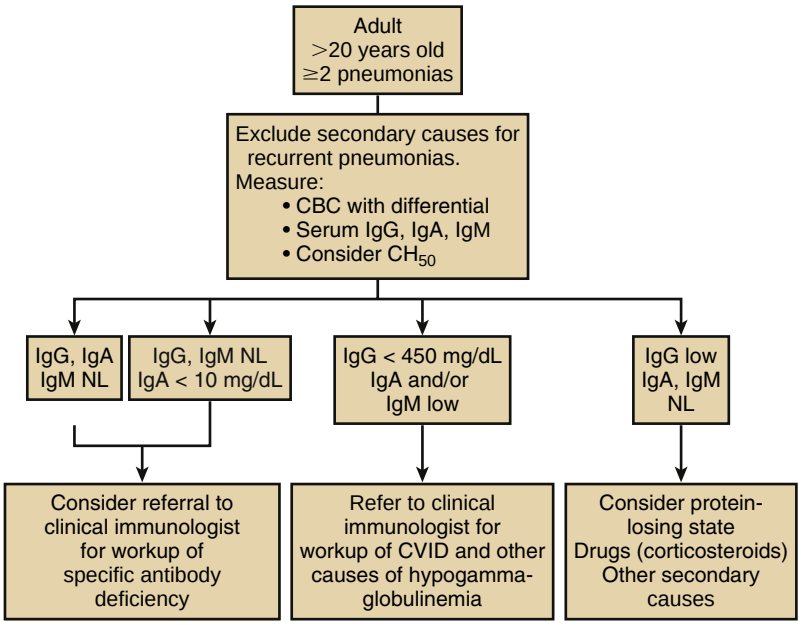

Fig. 124.1 Algorithm to screen adult patients with recurrent pneumonias for primary immunodeficiency. In an adult, with *common variable immunodeficiency* (CVID) as the most common diagnosis, a screening approach is shown. It would be unusual for an adult to present with a phagocytic defect or combined immunodeficiency; thus, antibody levels, *complete blood count* (CBC), and complement are appropriate for initial screening. An absent CH_{50} is consistent with complement deficiency and should result in referral to the clinical immunologist, whereas a low CH_{50} is consistent with complement consumption. Ig, immunoglobulin; NL, normal.

Table 124.2 Examples of Infections in Specific Primary Immunodeficiencies

Type Of Immunodeficiency	Example	Mode of Presentation
Antibody (humoral)	XLA, CVID	Upper and lower respiratory tract infections (encapsulated and atypical bacteria), giardiasis
Cellular (for clearance of intracellular organisms)	IFN-γ/IL-12/IL-23 axis	Atypical mycobacterial, *Salmonella,* and *Pseudomonas* infections, opportunistic infections
Combined (B cell and T cell)	SCID (multiple causes)	Opportunistic infections, upper and lower respiratory tract infections, thrush, intractable diarrhea, failure to thrive
Phagocyte	CGD	Recurrent abscesses (*Staphylococcus aureus, Burkholderia cepacia),* fungal infections (*Aspergillus* sp)
Complement	C5-C9	Recurrent *Neisseria meningitidis* infections

CGD, chronic granulomatous disease; CVID, common variable immunodeficiency; IFN, interferon; IL, interleukin; SCID, severe combined immunodeficiency; XLA, X-linked agammaglobulinemia.

Table 124.3 Screening Tests for Immune Function

Immune Function	Quantitative Assays	Functional Assays
Antibody immunity	Flow cytometry: $CD19^+$ or $CD20^+$ B cells	IgG, IgA, IgM, IgE levels* Specific antibody response to immunization*
Cellular immunity	CBC with differential* Flow cytometry for: $CD3^+CD4^+$ T cells $CD3^+CD8^+$ T cells $CD16^+CD56^+$ NK cells FISH for 22q11 and 10p11 deletion	Cutaneous delayed hypersensitivity T cell mitogen responses
Phagocyte	CBC with differential* Flow cytometry for: LFA-1 (CD18/CD11a) CD15	Oxidase function (DHR,* NBT) Enzyme assays (MPO, G6PD) Chemotaxis assays
Complement	C3, C4 Specific complement components Complement split products (C3a, C4a)	CH_{50} (classical pathway)* AH_{50} (alternative pathway)*

*Preferred initial screening tests.
CBC, complete blood count; DHR, dihydrorhodamine; FISH, fluorescence in situ hybridization; G6PD, glucose-6-phosphate dehydrogenase; Ig, immunoglobulin; LFA-1, lymphocyte function antigen 1; MPO, myeloperoxidase; NBT, nitroblue tetrazolium; NK, natural killer.

patients with recurrent or severe pulmonary infections for secondary immunodeficiencies or other medical conditions that compromise immunity (e.g., human immunodeficiency virus infection, lymphoproliferative disorders and malignancy, malnutrition, immunosuppressive drugs, protein-losing states, kidney failure, liver failure, heart failure, sickle cell disease, chronic liver disease, diabetes mellitus).

DIAGNOSTIC WORKUP

Readily available and inexpensive screening tests should be used in the initial evaluation of a patient with possible immunodeficiency (Table 124.3).[12,13] Abnormalities found in these screening tests indicate the need for additional studies in collaboration with a clinical immunologist. Genetic testing using either gene panels or whole-exome sequencing is increasingly used to make a definitive diagnosis; as the cost of DNA sequencing decreases, genetic testing may become the preferred strategy to diagnose PIDDs. The goal in the evaluation of immunodeficient patients is to define the causal genetic abnormality so that optimal treatment and prophylaxis can be provided.

ANTIBODY DEFICIENCIES

The quantitative measurement of immunoglobulin G (IgG), IgA, and IgM is the single best test to screen for primary antibody deficiencies, whereas low IgE levels are useful in evaluating patients with possible CVID.[14] Serum IgE levels are undetectable in more than 80% and are lower than the normal range in 90% of patients with CVID. In contrast, elevated IgE can raise the suspicion of an undiagnosed or undertreated atopic disease. Undiagnosed or inadequately treated asthma is a frequent cause for referral to clinical immunologists for recurrent respiratory tract infection.

The pattern of the levels of IgG, IgA, and IgM may provide insight into the etiology of antibody deficiency. For example, in steroid-induced hypogammaglobulinemia, IgG levels are usually moderately depressed (usually >400 mg/dL), and the magnitude of reduction reflects the dosage and duration of corticosteroid treatment,[15] whereas IgA and IgM levels tend to be preserved. In CVID, IgG levels are usually more profoundly depressed (<400 mg/dL); IgA levels are reduced (<10 mg/dL) in 90% of patients, and IgM levels are reduced (<25 mg/dL) in approximately 80% of patients.[14,16,17] Patients with CVID have a profound defect in their ability to make antigen-specific antibodies following immunization.[18]

The enumeration of B cells by flow cytometry using monoclonal antibodies directed against the CD19 or CD20 surface antigens may also provide clues to the type of B cell immunodeficiency. In X-linked and *autosomal recessive* (AR) agammaglobulinemia, B cells are usually severely reduced in number, whereas B cells are severely reduced or absent in only 10–15% of patients with CVID. It is important to obtain a careful medication history because agents such as rituximab, a chimeric monoclonal antibody directed against CD20, can lead to profound decreases in B cell numbers for months after treatment.

In assessing response to immunization, it is important to immunize with both a protein and polysaccharide antigen and to assess the response 4 to 6 weeks after immunization. The immunologic requirements to make antibodies (e.g., T cell help, cytokine requirements) in response to immunization with a protein or polysaccharide antigen differ. Some patients with normal quantitative immunoglobulins or selective IgA deficiency exhibit a selective inability to make antibody to polysaccharides, but not to protein antigens.[19] This immunologic defect (specific antibody deficiency) results in recurrent sinopulmonary infections and, in selected instances, may require replacement immunoglobulin therapy.

Protein antigens commonly used to assess specific antibody responses include tetanus and diphtheria toxoids. The *Haemophilus influenzae* type B (Hib) vaccine and the conjugated pneumococcal vaccines (Prevnar) use conjugates of the capsular polysaccharide (polyribose phosphate) to a protein carrier. Quantitation of antibodies to these vaccines measures competence of the immune system to make specific antibodies to a protein, not purely to polysaccharide antigens. Many adults have not been immunized to Hib, thus making the Hib vaccine particularly useful in the evaluation of this group of patients.

Polysaccharide antigens used to test antibody responses are available in two unconjugated vaccines: the pneumococcal polysaccharide (Pneumovax) and *Salmonella typhi* Vi polysaccharide vaccines. When using the pneumococcal vaccine, the measurement of antibody responses to several (12 or more) capsular antigens is indicated. There is considerable controversy about what constitutes a normal response to the pneumococcal vaccine, and a clinical immunologist should make the interpretation of specific

antibody responses.[20,21] Furthermore, there is substantial variability in the measurement of antibody responses to specific pneumococcal antigens among commercial laboratories. Therefore, prepneumococcal and postpneumococcal polysaccharide antibody titers should be obtained from the same laboratory.[22] When using the *S. typhi* vaccine, the interpretation of antibody response is a bit more clear. This is because, in contrast to the pneumococcal vaccine, most persons in the United States and other industrialized countries have not been immunized with the *S. typhi* Vi vaccine. Therefore, the specific antibody response is to a neoantigen, which makes interpretation of the results more straightforward. Furthermore, antibodies directed against the Vi polysaccharide are not present in commercially available immunoglobulin preparations in the United States, thereby allowing for the assessment of antibody response even during treatment with IVIG or SCIG.[23] Importantly, children younger than 2 years frequently do not make antibody responses to polysaccharide antigens. Thus, the use of polysaccharide vaccines to diagnose antibody-deficient states in this age group is not indicated.

CELLULAR IMMUNODEFICIENCY

Many patients with impaired cellular immunity have either reduced T cell numbers or abnormal T cell function, or both (see Table 124.3). T cell numbers are easily determined by flow cytometry. The CD3 antigen measures the total number of T cells, whereas CD4 and CD8 antigens are present on the T helper and T cytotoxic subsets, respectively. The pattern of abnormalities in the number of cells in specific lymphocyte subpopulations (T cells, *natural killer* [NK] cells, B cells) is helpful in guiding identification of the molecular abnormality in SCID (Table 124.4). In all forms of SCID and many other combined immunodeficiencies, the numbers of naive T cells are low. Therefore, the measurement of the numbers of naive ($CD3^+CD45RA^+$) and memory ($CD3^+CD45RO^+$) T cells is also essential in the global assessment of patients with possible PIDDs. T cell function can be assessed by testing cutaneous *delayed-type hypersensitivity* (DTH). In the DTH test, a small amount of an antigen is injected into the dermis, and a positive reaction is indicated by induration (>2 mm) 48 to 72 hours later at the site of the injection. Antigens such as tetanus toxoid, *Candida,* and *Trichophyton* may be used because most individuals will have had a prior immune response to these antigens. However, DTH responses are frequently absent in normal infants, so in vitro assays of T cell function are indicated in this group of patients instead. In many cases, T cell proliferation studies in response to mitogens such as phytohemagglutinin have replaced DTH responses because they are not substantially affected by age, are highly reproducible, and are easily obtained.

Table 124.4 Common Etiologies of Severe Combined Immunodeficiencies

Form of SCID	Prevalence	Absent Cell Type	Inheritance
Common γ chain IL-2 receptor deficiency	19%	T/NK	X-linked
IL-7R	12%	T	AR
ADA deficiency	10%	T/B/NK	AR
RAG1/RAG2	17%*	T/B	AR
JAK3	6%	T/NK	AR

*Total prevalence of patients with mutations in either the *RAG1* or *RAG2* gene.
ADA, adenosine deaminase; AR, autosomal recessive; IL, interleukin; JAK, Janus activating kinase; NK, natural killer; SCID, severe combined immunodeficiency.

PHAGOCYTE DEFICIENCIES

The initial screening test for phagocytic defects includes a complete blood count, with quantitation of leukocyte number and morphology (see Table 124.3). Functional studies of phagocytes include the *dihydrorhodamine* (DHR) or nitroblue tetrazolium tests, which measure the generation of superoxide free radicals; defects in these tests are seen in *chronic granulomatous disease* (CGD).[24]Advantages of the DHR test include its ease, rapidity, and reproducibility, along with the capacity to detect CGD carrier states; it is the preferred test and has largely replaced the nitroblue tetrazolium test. In the DHR test, phagocytes are loaded with the fluorescent dye DHR and are activated with phorbol myristate acetate. Activated phagocytes then produce superoxide free radicals that reduce DHR, thus leading to a change in fluorescence quantitated by flow cytometry. Other functional assays for phagocytes include enzyme assays for myeloperoxidase and glucose-6-phosphate dehydrogenase, chemotaxis assays, phagocytic tests, and bactericidal assays. Abnormalities in the adhesion molecules CD18 and CD15 that result in leukocyte adhesion deficiency 1 and leukocyte adhesion deficiency 2, respectively, can be detected by flow cytometry.

COMPLEMENT DEFICIENCIES

The screening tests for complement deficiency states associated with increased infections are the CH_{50} and AH_{50}, which measure the integrity of the classical and alternative pathways of complement activation, respectively (see Table 124.3).[25] The CH_{50} measures the volume (or dilution) of serum required to lyse 50% of the antibody-coated erythrocytes; AH_{50} is a similar measure testing the alternative pathway but without antibody opsonization. Abnormalities in CH_{50} or AH_{50} could result from inappropriate activation and consumption of complement or from deficiencies in individual components of complement. Often these possibilities can be distinguished by the measurement of two or more individual components (e.g., C3 and C4) of the classical or alternative complement pathway and the measurement of complement split products. Complement *consumption* is indicated by low levels of more than one component of complement, which may vary over time, and by the elevation of complement split products (C3a and/or C4a). The CH_{50} level in this instance is typically low, but not absent. In contrast, in complement *deficiency* states the CH_{50} level is zero with fixed, depressed levels of an individual member of the complement pathway without elevated levels of complement split products.

ANATOMIC DEFECTS

Other structural defects should be considered in a patient with recurrent sinopulmonary infections, particularly in a patient with a relatively normal immune workup. In patients with certain syndromes, such as DiGeorge syndrome or CHARGE syndrome (coloboma, heart defects, atresia choanae, growth retardation, genital abnormalities, and ear abnormalities), or in patients with neurologic impairment, recurrent aspiration pneumonias can mimic a primary immunodeficiency. In these cases, the pneumonias are typically dependent and basilar. Investigation of these patients may include a swallow study and pH probe analysis to detect gastroesophageal reflux. In addition, primary ciliary dyskinesia can be mistaken for a primary immune defect and should be considered in any patients with recalcitrant sinusitis, bronchiectasis, and recurrent pneumonias.[26] Ciliary biopsy with electron microscopy, genetic studies, and nasal and exhaled nitric oxide may suggest a ciliary defect, and treatment is similar to that in patients with cystic fibrosis.[26] Finally, any disease that affects the normal barrier function of the skin (e.g., eczema) or mucosal surfaces can lead to recurrent infections.

GENETIC TESTING

Over the past 10 years, advances in genetic sequencing technologies have allowed the description of a large number of PIDDs. There are currently more than 350 genetic defects that may affect the immune system and, with increased use of next-generation sequencing, unusual and surprising presentations of known PIDDs are being detected.[27] It is now easier, less expensive, and faster to screen for several hundred PIDDs with a single sequencing panel than to try to predict which PIDD is present in a patient with recurrent infections.[28] These panels, however, should be interpreted by an immunologist familiar with these diseases and with interpretation of genetic data. Benign variants of these genes are common, and their detection may lead to misdiagnosis and unnecessary laboratory evaluation and unnecessary intervention.

ANTIBODY DEFICIENCIES

One of the hallmarks of antibody, or humoral, immune deficiencies is recurrent respiratory tract infections, including sinusitis, bronchitis, bronchiectasis, and pneumonias.[29] Infections with encapsulated bacteria, such as *S. pneumoniae* and *H. influenzae,* are most common; infections with viruses, especially enteroviruses, also contribute. Chronic gastrointestinal infections, such as giardiasis, also accompany antibody deficiencies. Noninfectious pulmonary complications, such as granulomatous and interstitial lung disease or autoimmune cytopenias, may also be clues to an immunodeficiency.

X-LINKED AGAMMAGLOBULINEMIA

XLA (Bruton's agammaglobulinemia) is a primary antibody deficiency with an estimated frequency of 1 in 190,000 male births.[30,31] Mutations in the gene for Bruton's tyrosine kinase (*BTK*) are responsible for this immunodeficiency.[32] BTK is required for B cell receptor signaling through phosphorylation of phospholipase Cγ2 and other targets, and BTK is essential for the survival and differentiation of immature B cells. Nearly all patients with XLA have a marked deficiency in B cells (<2% of lymphocytes) and profound hypogammaglobulinemia. BTK is also expressed on myeloid cells and platelets but not on NK cells or T cells, and as many as 25% of patients with undiagnosed XLA and infection have concomitant neutropenia, which may contribute to the severity of infection.[33] T cell function is normal in XLA. XLA accounts for approximately 85% of inherited forms of agammaglobulinemia, with AR forms of agammaglobulinemia caused by mutations in *IGHM, IGLL1, CD79, BLNK, PIK3R1,* or *TCF3* accounting for the remainder.[32]

Small or absent tonsils and lymph nodes are the only characteristic physical findings in XLA. Most patients with XLA have recurrent upper (otitis media, sinusitis) and lower respiratory tract infections, with more than 50% of patients having recurrent infections by 1 year of age and nearly all patients symptomatic by the age of 5 years. The most common pathogens causing pneumonia are encapsulated bacteria (*S. pneumoniae* and *H. influenzae*).[30] Respiratory tract infections with atypical bacteria such as *Mycoplasma pneumoniae* or *Ureaplasma urealyticum* are also frequent. Gastrointestinal tract infections develop in nearly one-fourth of patients and are most commonly caused by *Giardia lamblia,* although bacteria (*Salmonella* sp, *Shigella* sp, *Campylobacter fetus, Helicobacter pylori*) and viruses (*Rotavirus,* enteroviruses) are other common causes. Disseminated infections that include encephalitis resulting from infection with enteroviruses, in particular echovirus, were formerly major causes of mortality in patients with XLA, although these infections are less frequent with use of high-dose immunoglobulin replacement therapy.[30]

The pulmonary complications of XLA or AR agammaglobulinemia, including bronchiectasis and right heart failure, are major causes of morbidity and mortality.[30] Complete pulmonary function tests and a *high-resolution computed tomography* (HRCT) scan of the chest are indicated in the initial evaluation of these patients. High-dose IVIG decreases pulmonary infections, but it may not prevent progression of bronchiectasis. Bronchiectasis, if detected, should be treated with daily pulmonary hygiene (e.g., inhaled β-agonists, hypertonic saline, chest physiotherapy) and aggressive antimicrobial therapy for intercurrent pulmonary infections. The efficacy of rotating antibiotics or long-term antimicrobial therapy in patients with bronchiectasis and immunodeficiency is unknown (see also Chapter 69).

IVIG and SCIG are the most commonly used forms of antibody replacement for treatment of XLA and CVID. Compared with IVIG, SCIG has fewer infusion-related and late-onset adverse reactions.[34] High doses of immunoglobulin (400 to 600 mg/kg per month) are superior in preventing infections compared with "conventional" doses of IVIG (100 to 150 mg/kg), and the optimal dose should be based on prevention of infection rather than level of IgG.[35,36] Intercurrent sinopulmonary infections should be aggressively treated with appropriate antimicrobial therapy to include coverage of common encapsulated bacteria and atypical bacterial pathogens (*Mycoplasma* sp, *Ureaplasma*).[37]

A pitfall in managing patients with antibody deficiencies (e.g., XLA, CVID) is that serologic assays in the diagnosis of infections can yield false-positive or false-negative results. With the exception of IgA and IgG subclass deficiency, patients with antibody deficiency typically do not make specific antibodies in response to exogenous antigens. Therefore, antibody studies to detect specific pathogens are unreliable. Diagnostic studies that detect microbial antigens or nucleic acids (polymerase chain reaction assays) and/or microbiologic cultures must be used in place of serologic assays.

COMMON VARIABLE IMMUNODEFICIENCY

CVID, also known as acquired hypogammaglobulinemia, is a primary immunodeficiency affecting approximately 1 in 20,000 to 50,000 live births.[38] CVID is a clinical syndrome representing a group of disorders that exhibit the common phenotype of abnormal antibody production and defective vaccine responses. Although variable, the mean onset of symptoms in patients with CVID is in the third decade of life. The diagnosis can be delayed up to 10 years after the onset of symptoms.[16,17,39,40] Unlike in XLA, T cell abnormalities are common in patients with CVID and contribute to the more protean clinical manifestations of this disease.[16,17] The diagnosis of CVID should be considered in any person older than 2 years with recurrent respiratory tract infections (e.g., two or more confirmed pneumonia cases).

The etiology of CVID is largely unknown, but multiple genetic mechanisms have been implicated. Heterozygous variants in *TACI* are found in approximately 5–10% of patients, and these variants increase the risk of developing CVID, whereas biallelic mutations always lead to CVID.[41–46] Other monogenic disorders that lead to CVID include mutations in *ICOS,* TNFRSF13C *(BAFF-R), CTLA4, LRBA, XIAP, SH2D1A,* and many others.[47] The presentation of these disorders can vary greatly, but they usually exhibit defective immunoglobulin levels and responses to vaccines. For example, genetic variants *CTLA4* and *LRBA* manifest with immune dysregulation and autoimmunity, whereas variants in *XIAP* and *SH2D1A* manifest with Epstein-Barr virus–driven lymphoproliferation, but all can have laboratory findings consistent with CVID.[48–50] Broad genetic screening (whole-exome sequencing or extensive genetic panels) should be considered in patients with CVID with an early onset and/or severe phenotype because monogenic defects will be found in more than 25% of such patients.

The definitive diagnosis of CVID requires demonstration of a low serum level of IgG (usually <450 mg/dL), low serum IgA and/or IgM, impaired capacity to make specific antibodies in response to immunization or infection, and the exclusion of other primary or secondary antibody deficiencies.[51] B cell subset analysis by flow cytometry is valuable in predicting risk to develop certain complications of CVID. Low numbers of switched memory B cells ($CD27^+$, IgM^-, IgD^-) in the peripheral blood are frequently found in patients with lymphoproliferation, splenomegaly, and systemic granulomatous disease involving the lungs and other organs.[17,52–54] T cell abnormalities are found in approximately 40% of patients and include anergy, T cell lymphopenia, and poor in vitro proliferative responses to mitogens and antigens.

Nearly all patients present with recurrent respiratory tract infections, including bronchitis, sinusitis, otitis media, and pneumonia. Common pathogens include encapsulated (*H. influenzae, S. pneumoniae*) or atypical (*Mycoplasma* sp) bacteria.[16,37,55] Pulmonary infections can also be caused by gram-negative rods, especially in patients with long-standing CVID or impaired cellular immunity. Opportunistic organisms cause fewer than 10% of infections in patients with CVID.[56] Apart from respiratory tract infections, bone and joint infections caused by these organisms have also been reported. Gastrointestinal tract infections with pathogens similar to those found in XLA (*Campylobacter jejuni, Salmonella* sp, *G. lamblia*) are also common.[16,57] More recently, norovirus has been implicated in the enteropathy associated with CVID.[58] The prevalence of hepatitis is increased in CVID and hepatitis is found in approximately 12% of patients. The prognosis of hepatitis C is poor, and the disease may be rapidly progressive in patients with CVID.

The mortality of CVID related to common infectious pathogens has declined with the increased use of high-dose immunoglobulin replacement.[8] Noninfectious complications of CVID, including chronic lung disease, malignancy, liver disease, and gastrointestinal tract disease, have now become risk factors for early mortality.[17] Although patients with CVID are unable to make antibodies to foreign antigens, they exhibit an increased propensity to make autoantibodies. Consequently, the prevalence of autoimmune disorders, in particular idiopathic thrombocytopenic purpura and autoimmune hemolytic anemia, is increased.[16,17]

Patients with CVID are at high risk for developing malignancy. In particular, the prevalence of non-Hodgkin lymphomas and gastric carcinoma is increased in CVID, and these cancers are major causes of morbidity and mortality.[59–61]

The pulmonary disorders associated with CVID are also major causes of mortality.[29,52,54,62–64] It is essential to screen patients with CVID with HRCT of the chest to define pulmonary disease because chest radiographs and pulmonary function tests are not sensitive to diagnose *interstitial lung disease* (ILD) or airways disease in patients with CVID. For example, HRCT of the chest detected ILD in 31% and bronchiectasis in 64% of patients with CVID, whereas pulmonary function tests and routine chest radiographs detected ILD or bronchiectasis in only 6% of patients.[65] Bronchiectasis is the most common pulmonary disorder in CVID, and it develops in more than 30% of patients. It is not clear whether early diagnosis along with globulin replacement therapy can prevent the development of bronchiectasis in patients with CVID.[40] Bronchiectasis in patients with CVID is managed with standard approaches including mobilization of pulmonary secretions through the use of medications such as hypertonic saline or β_2-agonists combined with chest physiotherapy and the long-term administration of macrolides.[66–68] Cryptogenic organizing pneumonia has also been described and appears to respond to corticosteroid therapy.[69,70]

Diffuse ILD, including granulomatous lung disease, lymphocytic interstitial pneumonia, follicular bronchiolitis, and bronchiolitis obliterans with organizing pneumonia (cryptogenic organizing pneumonia), develops in approximately 10–25% of patients with CVID; these disorders are refractory to IVIG therapy.[52,54,62–64,71]

The term *granulomatous-lymphocytic interstitial lung disease* (GLILD) is used to characterize the pulmonary disorder specific to CVID and monogenic CVID-like disorders. In comparison with sarcoidosis, GLILD exhibits a lack of spontaneous remission; a poor response to corticosteroid therapy; panhypogammaglobulinemia with low numbers of switched memory B cells; a high prevalence of autoimmune disease, in particular immune thrombocytopenia; a history of recurrent infections; and large areas of organizing pneumonia on biopsy.[72,73] Patients with GLILD and CVID frequently have hepatosplenomegaly with diffuse adenopathy, and they are at increased risk for developing non-Hodgkin lymphoma.[52,54,72] GLILD represents a multisystemic lymphoproliferative and granulomatous disease because granulomas are not limited to the lung but may be found in virtually any organ, including bone marrow, liver, spleen, and lymph nodes. In GLILD, HRCT demonstrates multiple abnormalities, including mediastinal adenopathy, ground-glass abnormalities, areas of consolidation, and small and large nodules. The parenchymal abnormalities in GLILD are typically in the lower lung zones (Fig. 124.2), a finding that contrasts with sarcoidosis, which is predominantly a micronodular, upper lung zone disease.[72,74]

The etiology of GLILD is unknown. However, increasing numbers of monogenic defects have been found in patients with CVID and GLILD, including mutations in *TACI*, *LRBA*, *CTLA4*, and *XIAP* and hypomorphic variants in *RAG1*.[29] Untreated GLILD can cause progressive pulmonary fibrosis (Fig. 124.3).[74]

In the diagnostic evaluation of patients with suspected GLILD or other forms of ILD, it is essential to obtain sufficient tissue to exclude the diagnosis of lymphoma and other parenchymal diseases. Video-assisted thoracoscopic surgery is currently the most definitive method to obtain the diagnosis. Cryobiopsy performed by bronchoscopy is a promising diagnostic modality, although definitive studies comparing the diagnostic sensitivity and specificity between thoracoscopic surgery and bronchoscopic cryobiopsy in the evaluation of ILD are lacking.

Corticosteroids are the most commonly used immunosuppressive agents in patients with GLILD.[75] However, disease relapse on discontinuation or weaning of corticosteroids is common, and it is unclear whether corticosteroids alter disease progression. A retrospective study of 39 patients with CVID and GLILD over 12 years showed that rituximab and antimetabolite therapy (azathioprine or mycophenolate mofetil) substantially improved the HRCT scores of the chest in over 90% of patients.[75a] Several measures of lung function also improved. Relapse-free survival was 57% at 5.4 years or longer. Damaging mutations in genes that predispose to the development of CVID (*TNFRSF13B*) or cause a CVID-like PID (*CTLA4, KMT2D, BIRC4*) were present in 21% of patients. The efficacy of rituximab and antimetabolite therapy was similar in patients with or without damaging mutations. Immunosuppression was tolerated well, and infections were uncommon (Fig. 124.4).[76] This approach has also been used successfully for pediatric patients.[77] Other treatments have included monotherapy with rituximab,[78] low-dose cyclosporine, tacrolimus,[79] and infliximab.[80]

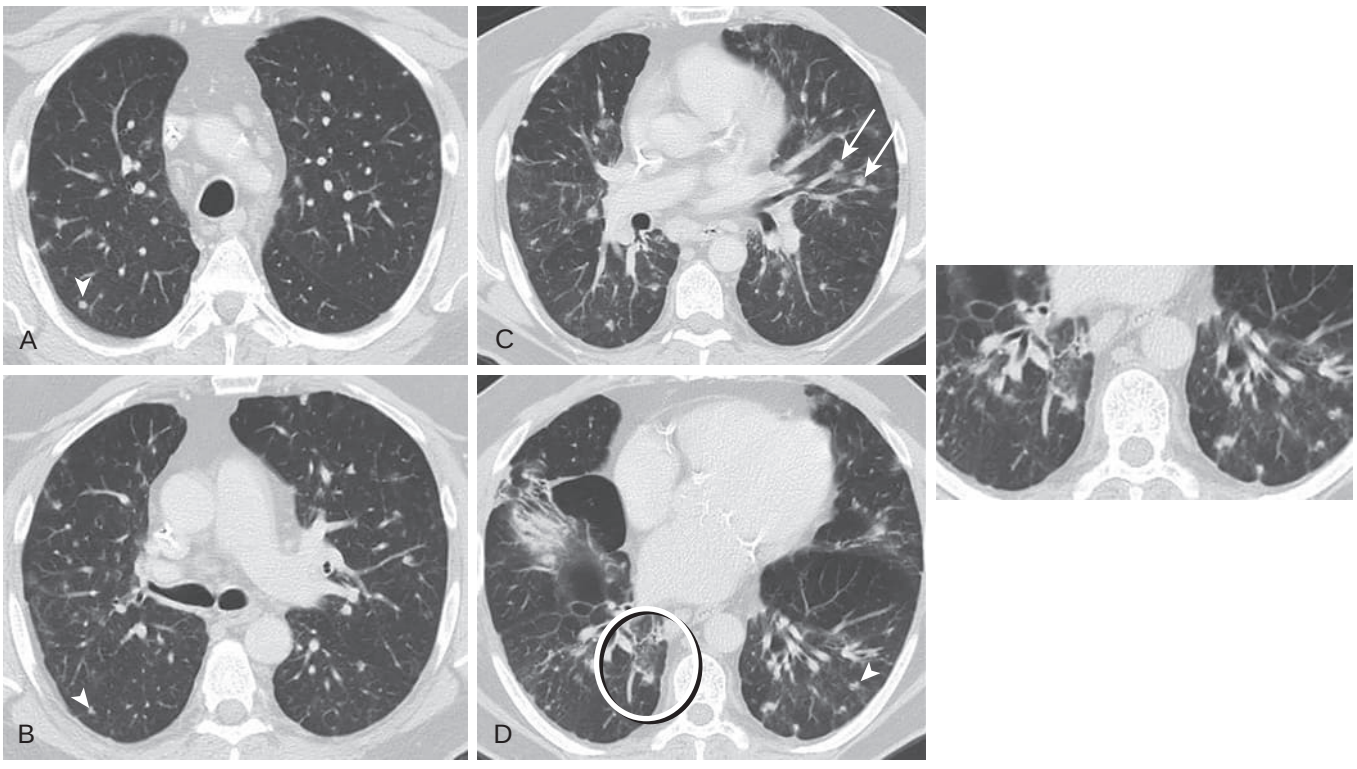

Fig. 124.2 Axial chest computed tomography showing typical features of granulomatous-lymphocytic interstitial lung disease. (A–D) Granulomatous-lymphocytic interstitial lung disease is characterized by the presence of larger nodules (*arrows*) and smaller nodules (*arrowheads*) and areas of ground-glass opacity (*circle*), with a somewhat lower lobe predominance. Nonspecific mediastinal lymph node enlargement is visible (in A and B). (Courtesy Michael B. Gotway, MD.)

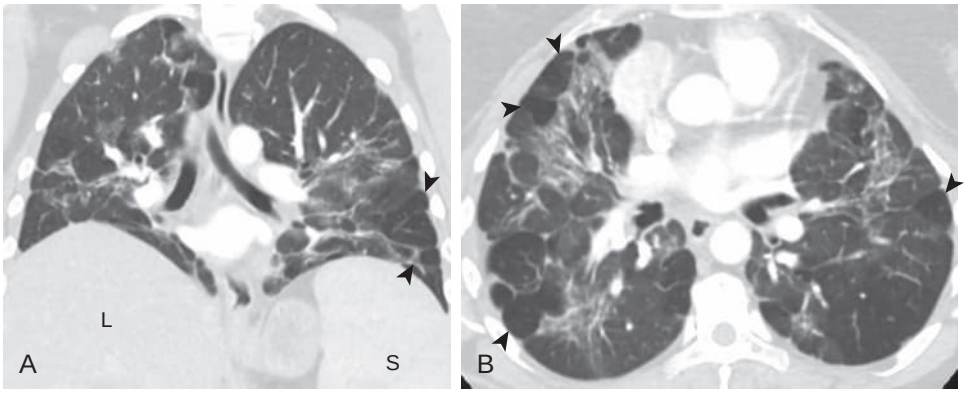

Fig. 124.3 Computed tomography in granulomatous-lymphocytic interstitial lung disease. (A) Coronal and (B) axial chest computed tomography in a patient with long-standing untreated granulomatous-lymphocytic interstitial lung disease. Imaging shows severe pulmonary fibrosis, manifesting as band-like linear opacities associated with architectural distortion and lobular low-attenuation areas of irregular air space enlargement (*arrowheads*). Hepatosplenomegaly is evident. L, liver; S, spleen. (Courtesy Michael B. Gotway, MD.)

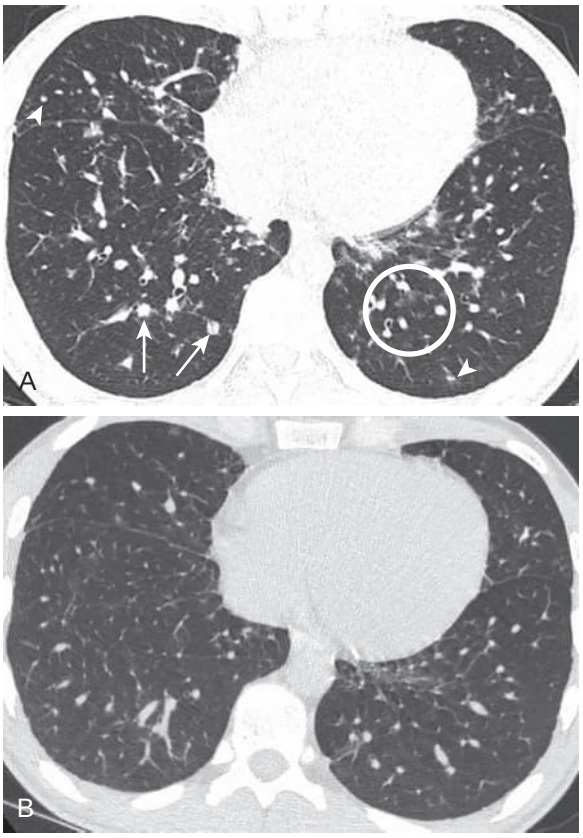

Fig. 124.4 Axial high-resolution of the chest of a patient with granulomatous-lymphocytic interstitial lung disease before and after treatment. (A) Computed tomography shows small nodules (*arrowheads*) and relatively larger nodules (*arrows*) and foci of ground-glass opacity (*circle*). (B) Following treatment with rituximab and azathioprine, there is marked improvement of the lung parenchymal findings. (Courtesy Michael B. Gotway, MD.)

The combination of hypogammaglobulinemia and thymoma is distinct from CVID and is known as Good syndrome.[81–83] Various immune abnormalities have been described in Good syndrome; the most common are hypogammaglobulinemia, absent or low numbers of B cells, and low numbers of $CD4^+$ T cells. Apart from thymoma and pulmonary infections, diffuse panbronchiolitis has also been described.[84] Importantly, thymoma is often not apparent on routine chest radiograph, a finding that reinforces the need to perform an HRCT scan of the chest on all patients with CVID or CVID-like disorders. Resection of the thymoma is recommended, although this does not resolve the immunodeficiency or autoimmunity.[81]

IMMUNOGLOBULIN A DEFICIENCY

The frequency of IgA deficiency varies among different ethnic groups, but the overall incidence may be as high as 1 in 400 live births.[85,86] The etiology of IgA deficiency remains obscure. Rarely, IgA deficiency may evolve into CVID, and familial cases of both IgA deficiency and CVID arise, suggesting a common genetic basis.[87] Medications, such as anticonvulsant agents, can cause IgA deficiency or hypogammaglobulinemia, and immunoglobulins may normalize with discontinuation of the drug.

There is considerable controversy about whether IgA deficiency alone predisposes to infection.[86,88] Most patients with IgA deficiency do not have increased frequency of infections, and the disorder is often discovered during an evaluation for problems unrelated to infection. However, some patients with IgA deficiency have recurrent infections, predominantly respiratory tract infections.[88] Certain of these patients may have a concomitant IgG subclass deficiency and/or deficiencies in mannose-binding lectin, and these abnormalities may contribute to their susceptibility to infection.[89] Unlike patients with more severe forms of antibody deficiency, such as CVID or XLA, antibody replacement is not warranted with isolated IgA deficiency. Indeed, patients with very low IgA levels are predisposed to adverse reactions to administration of IVIG because of the presence of anti-IgA antibodies in their circulation.[90] In patients with IgA deficiency and concomitant IgG subclass deficiency who have recurrent and persistent respiratory tract infections, determination of the antibody response following vaccination should be used to ascertain whether antibody replacement is warranted.[91]

Infectious complications associated with IgA deficiency include recurrent upper (otitis media, sinusitis) and lower respiratory tract infections, as well as gastrointestinal infections such as giardiasis.[88] The prevalence of atopic diseases (asthma, allergic rhinitis, eczema) and autoimmune diseases (systemic lupus erythematosus, celiac disease, rheumatoid arthritis) is increased in patients with IgA deficiency.[90]

SPECIFIC ANTIBODY DEFICIENCY

Specific antibody deficiency is a primary antibody deficiency disorder characterized by normal levels of IgG, IgA, and IgM but an inability to make specific antibodies, most commonly in response to purified polysaccharide antigens such as in Pneumovax.[19,92,93] Patients with specific antibody deficiency present with recurrent sinopulmonary infections, similar to other forms of hypogammaglobulinemia.

The diagnosis is made by demonstrating abnormal specific antibody responses following immunization with polysaccharide vaccines, most commonly the unconjugated pneumococcal vaccine. Cellular immunity is normal in this disorder. The initial treatment of specific antibody deficiency is similar to that of IgA deficiency; however, antibody replacement may be indicated in patients who have recalcitrant sinopulmonary infections and in whom more conservative treatment fails.

IMMUNOGLOBULIN G SUBCLASS DEFICIENCY

IgG subclass deficiency is defined by normal total serum IgG levels with a low level of one or more IgG subclasses. There are four isotypes of IgG in humans: IgG1, IgG2, IgG3, and IgG4. The predominant subclass is IgG1, accounting for more than 60% of the total IgG. In some patients evaluated for recurrent sinopulmonary infections, low levels of one of the IgG subclasses are found. However, the significance of IgG subclass abnormality is unclear[94,95] because IgG subclass deficiencies, including genetic deletions of IgG subclass loci, have been found in healthy individuals.[96] Because the clinical significance of isolated IgG subclass deficiencies is unclear, the measurement of IgG subclasses is not warranted in the initial evaluation of patients with recurrent sinopulmonary infections. In patients whose isolated IgG subclass deficiency is associated with recurrent infections, antibody replacement should be considered if the antibody response to vaccination is defective.

HYPER–IMMUNOGLOBULIN M SYNDROME (B CELL INTRINSIC)

Hyper-IgM syndrome (HIGM) is a descriptive term that reflects abnormalities in serum quantitative immunoglobulin levels (high serum IgM level with low serum IgA and IgG levels), which is found in several otherwise dissimilar types of immunodeficiencies (Table 124.5).[97] Despite the name, high levels of IgM are an inconsistent feature of HIGM.[30,98] Grouping these distinct immunodeficiencies together, some of which are intrinsic B cell abnormalities and others of which are complex combined cellular and humoral immunodeficiencies, can lead to diagnostic confusion. Nevertheless, the classification remains widely used. Although we group HIGM under "predominantly antibody deficiencies," only mutations in *activation-induced cytidine deaminase (AICD)* or *uracil nucleotide glycosylase (UNG)*, which are selectively expressed in B cells, result in a pure antibody deficiency. The other forms of HIGM, which are more severe, are complex cellular and humoral immunodeficiencies (CD40 deficiency, CD40-L deficiency, NEMO), and are discussed in the combined immunodeficiency section of this chapter.

Mutations in *AICD* or *UNG*

Mutations in *AICD*[99] or *UNG*[100] are causes of AR forms of HIGM. AICD and UNG are essential for class switch recombination,[101] hence, mutations result in high serum levels of IgM, with low serum levels of IgG and IgA. Patients with mutations in either *AICD* or *UNG* have a similar clinical phenotype with impaired humoral immunity and intact cellular immunity,[102] resulting in recurrent upper and lower respiratory tract infections and gastrointestinal tract infections. Lymphadenopathy is frequent, and autoimmunity (autoimmune hemolytic anemia and idiopathic thrombocytopenic purpura) develops in approximately 20% of patients.

Table 124.5 Etiologies of Hyper-IgM Syndrome

Mutation	Inheritance	Clinical Phenotype
CD40L	X-linked	Abnormal cellular immunity, neutropenia in 50%, early onset, recurrent sinopulmonary infections, *Pneumocystis jirovecii* pneumonia, chronic diarrhea from *Cryptosporidium* infection, diarrhea, inflammatory bowel disease, autoimmunity
CD40	Autosomal recessive	Similar to CD40-L mutation
NEMO (IKK-γ) or *IKBA (IκBα)*	X-linked (NEMO) Autosomal dominant (IKBA)	Impaired cellular immunity, variable serum levels of IgM or IgA, ectodermal dysplasia (most), recurrent pyogenic infections, viral infections, mycobacterial infections
AICD or *UNG*	Autosomal recessive	Impaired humoral immunity, normal cellular immunity, later age of onset than other types of hyper-IgM syndrome, increased autoimmunity and lymphadenopathy
Unknown	Variable	Similar to *AICD/UNG* mutations

AICD, activation-induced cytidine deaminase; Ig, immunoglobulin; IKBA, IκBα; IKK, IκB kinase; NEMO, nuclear factor-κB essential modulator; UNG, uracyl nucleotide glycosylase.

DEFICIENCY IN BOTH CELLULAR IMMUNITY AND ANTIBODY PRODUCTION (COMBINED IMMUNODEFICIENCIES)

Combined immunodeficiencies are so named because they have features of antibody deficiencies and defects in cell-mediated immunity. These patients present with respiratory and gastrointestinal tract infections similar to patients with antibody deficiencies, but they also present with opportunistic infections (e.g., viruses, *Pneumocystis*, mycobacterial disease). These patients tend to be chronically ill, may have growth problems, and can have manifestations of autoimmunity.

HYPER–IMMUNOGLOBULIN M SYNDROME (COMBINED)

X-Linked Hyper-IgM Syndrome

The *X-linked form of hyper-IgM syndrome* (XHIGM), which accounts for approximately two-thirds of cases of all forms of HIGM, results from a mutation in the CD40 ligand (CD40-L) gene.[102,103] Mutations within the CD40 gene are a rare cause of AR HIGM, which has a clinical phenotype similar to that of XHIGM.[104] CD40-L is expressed on activation of CD4 T cells and interacts with CD40, which is expressed on the surface of B cells. The interaction of CD40 on B cells with CD40-L on activated T cells in conjunction with specific cytokines (e.g., *interleukin*

[IL]-4, IL-21) is required for immunoglobulin class switching. Consequently, mutations in CD40-L (or CD40) result in a failure to class switch, thereby leading to defective production of IgG, IgA, and IgE and to increased levels of IgM. CD40 is also expressed on monocytes and dendritic cells, and the lack of CD40-L T cell interaction with CD40 on monocytes and dendritic cells leads to decreased production of IL-12 with a decreased generation of *type 1 T helper* (Th1) cells and impaired cellular immunity.[105,106] In patients with XHIGM, serum levels of IgG are consistently low, and serum levels of IgA are reduced in the majority of patients. Serum levels of IgM are high in approximately 50% of patients.[103] Antibody responses to immunization show a weak IgM response, without development of IgG- or IgA-specific responses and the absence of immunologic memory. The numbers of switched memory B cells ($CD27^+$, IgD^-, IgM^-) are extremely low.[107] Neutropenia is found in approximately 50% of patients and may require treatment with *granulocyte colony-stimulating factor* (G-CSF). Intrinsic neutrophil defects, including impairment of the respiratory burst and decreased microbicidal activity, are also common in XHIGM.[107]

Patients with XHIGM have recurrent infections beginning early in life. More than one-half of patients with XHIGM are diagnosed by the age of 1 year and nearly all by 4 years of age. Pneumonia, frequently caused by infection with *Pneumocystis jirovecii,* is common, seen in as many as 80% of patients. Sinusitis, otitis media, and other respiratory tract infections are also common. Intractable diarrhea, sometimes caused by infection with *Cryptosporidium*, develops in nearly one-third of patients. Infection of the central nervous system (encephalitis, meningitis), frequently from infection with echovirus, is a major cause of morbidity and mortality. Pulmonary alveolar proteinosis has been described in XHIGM,[108] likely the result of abnormalities in alveolar macrophage function. Treatment of XHIGM includes antibody replacement, prophylaxis against *P jirovecii*, and treatment with G-CSF for neutropenia. HSCT is increasingly the treatment of choice for XHIGM, although it remains unclear whether transplantation improves mortality.[109]

Mutations of NF-κB Essential Modifier

Hypomorphic mutations within the *NF-κB essential modulator* (*NEMO*) gene, an X-linked gene, cause an immunodeficiency characterized by recurrent pyogenic infections, increased susceptibility to mycobacterial infections, and variable B cell and T cell abnormalities.[110,111] NEMO, also known as IKK-γ, is part of the *IκB kinase* (IKK) complex. IKK is responsible for phosphorylating the inhibitor of NF-κB (IκBα), thereby releasing NF-κB and allowing for its nuclear translocation. The protean immunologic and clinical manifestations of mutations in *NEMO* reflect the importance of NF-κB in multiple biologic processes. Approximately 80% of patients with mutations in *NEMO* have ectodermal dysplasia (abnormal teeth, decreased numbers of sweat glands, fine hair, frontal bossing). The ectodermal dysplasia in these patients is caused by the inability of the ectodysplasin A receptor to induce activation of NF-κB. The susceptibility to mycobacterial infection is likely the result of an inability of CD40 ligation to activate the NF-κB pathway, thus leading to deficient IL-12 production by monocytes and dendritic cells and deficient interferon (IFN)-γ production by T cells and NK cells.[112]

Results of common immunologic screening tests of immune function may be normal in up to 40% of patients with NEMO deficiency. Hypogammaglobulinemia or decreased specific responses to vaccination are found in approximately 60% of patients, and a high serum level of IgM is found in only 15% of patients. NK cell function has been reported to be abnormal in all patients with mutations in *NEMO,* and NK cell function determination may be a helpful adjunctive screening test for this disorder.[111,113]

Patients with *NEMO* mutations have severe infections usually beginning early in life. Common sites of infection include the lung, sinuses, middle ear, skin, and deep tissues (abscesses), bloodstream, gastrointestinal tract, and central nervous system. Pyogenic infections are frequently caused by *Staphylococcus aureus, S. pneumoniae,* and *H. influenzae,* and they are observed in nearly 90% of patients. Mycobacterial infections (pneumonia, cellulitis, lymphadenitis, osteomyelitis) are seen in more than 40% of patients and are usually caused by *Mycobacterium avium-intracellulare.* Severe viral infections (encephalitis, gastroenteritis, viremia) develop in approximately 20% of patients. Herpesviruses (herpes simplex virus, cytomegalovirus) and adenoviruses are the most frequent viral pathogens. Opportunistic infections with *P. jirovecii* or fungi develop in 10% of patients. Autoimmune disease—in particular inflammatory colitis—manifests in approximately 20% of patients and can lead to intractable diarrhea. Treatment of patients with *NEMO* mutations includes immunoglobulin replacement and antimicrobial prophylaxis (*Pneumocystis,* mycobacteria). HSCT is increasingly performed in these patients but may not improve the inflammatory bowel disease.[114]

Combined Hyper-IgM Syndrome Caused by Other Mutations

Mutations in genes whose products act in the CD40-L to CD40 and related pathways also cause HIGM with combined cellular and antibody deficiencies. These include mutations in CD40, *phosphatidylinositol 3-kinase catalytic delta* (PIK3CD), *phosphatidylinositol 3-kinase regulatory subunit 1 alpha* (PIK3R1), *inducible T cell co-stimulator* (ICOS), and certain DNA repair proteins.[115] These forms of HIGM are rare and have clinical manifestations comparable in severity to those of XHIGM.

SEVERE COMBINED IMMUNODEFICIENCY

SCID is a syndrome that encompasses a variety of molecular defects that result in absent or severely impaired T cell and B cell number and function.[116,117] One commonly used method to classify SCID is based on whether the molecular defects decrease the numbers of T, B, and/or NK cells (see Table 124.4). The molecular defects that lead to SCID include mutations that cause abnormalities in cytokine signaling (e.g., the common γ chain of the IL-2 receptor; Janus activating kinase 3 [JAK3], or IL-7 receptor) and T cell receptor signaling (e.g., CD45, ZAP-70, CD3ζ, CD3ε, CD3δ), defective T cell and B cell receptor gene recombination (e.g., *RAG1, RAG2*), defective nucleotide salvage pathway (*adenosine deaminase* [ADA] deficiency), and defects in the expression of major histocompatibility complex class I or class II molecules. X-linked SCID, caused by the mutation in the *common γ chain of the IL-2 receptor* ($IL2R\gamma_c$), is the most common form of SCID. $IL2R\gamma_c$ is used by the receptors for IL-2, IL-4,

IL-7, IL-9, IL-15, and IL-21. Consequently, the immunodeficiency resulting from mutation of the IL2Rγ_c is caused by the combined effects of loss of function of these cytokine receptors. Atypical forms of SCID may also result from mutations of genes associated with classical SCID that are *hypomorphic*, meaning that the mutation leads to a protein with reduced function. One such example is Omenn syndrome, which has clinical manifestations including severe skin disease (erythroderma, granuloma, desquamation), hepatosplenomegaly, lymphadenopathy, and high IgE levels.[118]

The clinical presentation of SCID is characterized by severe infections, most commonly of the respiratory and gastrointestinal tract, in early infancy. Infections are caused by common and opportunistic pathogens, and disseminated infections are frequent. Pneumonitis caused by cytomegalovirus, adenovirus, respiratory syncytial virus, or *Pneumocystis* can be the presenting sign and should be investigated in infants, particularly if they have other manifestations of the syndrome, including oral thrush, persistent diarrhea, and impaired growth. Engraftment of maternal T cells in an infant with SCID can lead to graft-versus-host disease. The prompt treatment of infection, administration of IVIG, and prophylaxis against *P. jirovecii* are indicated until HSCT can be performed. In the event blood transfusions are needed, only irradiated, cytomegalovirus-negative blood should be used. Live, attenuated vaccines should not be given to infants with known or suspected SCID.

Early diagnosis and treatment by HSCT (<3.5 months of age) of SCID lead to a markedly improved prognosis.[6] Population-based screening of newborns for SCID was implemented in Wisconsin in 2008, and now all states screen newborns for SCID because it is included in the Uniform Panel of newborn screening tests recommended by the U.S. government.[119,120]

In the absence of newborn screening, such as with immigrants or other populations that may be resistant to newborn screening, the lack of a thymic shadow on chest radiograph and severe lymphopenia (<2500/μm) in an infant with recurrent infections should prompt further studies to evaluate the diagnosis of SCID. The diagnosis of SCID is confirmed by enumerating lymphocytes and subsets of naive T cells, B cells, and NK cells by flow cytometry and abnormal proliferation of T cells to mitogens.

HSCT is the preferred treatment for SCID, except for SCID caused by ADA deficiency, where ADA enzyme replacement is also efficacious. Gene therapy for X-linked SCID and SCID caused by ADA deficiency has resulted in immune reconstitution, and gene therapy for ADA-induced SCID is now approved by the European Medicines Agency.[107,121–123] The retroviral vectors used in earlier studies of gene therapy resulted in insertional mutagenesis with activation of the proto-oncogene *LMO-2* leading to γδ T cell leukemia in some patients. Current trials of gene therapy for SCID use self-inactivating lentiviral vectors, which appear safer in trials to date.[124]

COMBINED IMMUNODEFICIENCIES OR SYNDROMIC IMMUNODEFICIENCIES

Certain immunodeficiencies involve genes whose products have functions beyond the immune system, including in development. Many of these immunodeficiencies are associated with characteristic anatomic anomalies and dysfunction in other organ systems.

DIGEORGE SYNDROME

DiGeorge syndrome (DGS), also known as 22q11.2 deletion syndrome or velocardiofacial syndrome, is one of the most common primary immunodeficiencies, found in approximately 1 in 3000 live births. Most patients with DGS have hemizygous deletion of varying degrees in chromosome 22q11.2, with rare cases caused by deletion of 10p13. The molecular basis for many of the clinical manifestations of DGS appears to be deletions or mutations in *TBX1*, a T-box transcription factor important in embryonic development.[125] Other genes are thought to contribute to the phenotype in DGS because patients with identical deletions of 22q11.2 may have markedly different clinical phenotypes. Patients with DGS exhibit characteristic facies, including hypertelorism (wide spacing of the eyes), saddle nose, shortened philtrum, and low-set ears.[126] Other common features of DGS include hypoplasia of the thymus and parathyroid glands, cardiac abnormalities, velopharyngeal insufficiency, speech delay, developmental delay, and behavioral and psychiatric problems. The velopharyngeal insufficiency may contribute to the risk of aspiration pneumonia. Nearly 90% of infants diagnosed with DGS have cardiac abnormalities, and screening for DGS should be considered in an infant with any form of congenital heart disease, especially for those forms associated with DGS, such as interrupted aortic arch, truncus arteriosus, tetralogy of Fallot, and anomalous aortic arch, with or without a ventral septal defect.[126]

The immunodeficiency associated with DGS is highly variable and correlates with the degree of thymic hypoplasia.[126] Patients with *complete* DGS, comprising less than 0.5% of DGS patients, have a profound deficiency of T cells, similar to patients with SCID, and require thymic transplantation.[127] In contrast, most patients with DGS are referred to as having *partial* DGS. Patients with partial DGS may have moderately diminished numbers of T cells, and T cell defects in these patients are usually mild, with relatively normal in vitro and in vivo assessment of T cell function. Intact thymic function is essential for deletion of autoreactive T cells and the production of T regulatory cells. Consequently, patients with DGS have an increased prevalence of autoimmune disorders, including juvenile arthritis, autoimmune hemolytic anemia, and immune thrombocytopenia.[128] Studies of humoral function have yielded conflicting results, and abnormalities in humoral immunity requiring immunoglobulin replacement therapy are infrequent in DGS.[129]

Most patients with DGS tolerate live virus vaccines without complications, but an assessment of humoral and cellular immune function should be performed before administration of these vaccines. Infectious complications of partial DGS usually include recurrent sinopulmonary infections and otitis media. Structural and functional abnormalities of the palate may contribute to recurrent sinus disease and aspiration pneumonia in these patients. Opportunistic infections other than oral and esophageal thrush are infrequent in partial DGS. Patients with complete DGS are highly susceptible to infection with opportunistic pathogens, thus reflecting the much more severe

cellular immunodeficiency. In these patients, attenuated, live virus vaccines should be avoided, and irradiated blood products should be used to avoid graft-versus-host disease until thymic transplantation can be accomplished.

WISKOTT-ALDRICH SYNDROME

Wiskott-Aldrich syndrome (WAS) is an X-linked disorder characterized by recurrent infections, eczematous skin disease, and thrombocytopenia caused by a mutation in the *WAS protein (WASp)* gene.[130,131] The function of WASp is complex, but through its interaction with a variety of adaptor molecules and kinases, WASp is involved in the integration of cytoplasmic signaling with the reorganization of the actin cytoskeleton. WASp is critical in the formation of immunologic synapses (i.e., the molecular interface between lymphocytes and target cells or antigen-presenting cells), cellular motility, cellular trafficking, and protection against autoimmunity.[130,131] Mutations in the WASp gene cause four distinct diseases: (1) classic WAS, (2) X-linked thrombocytopenia, (3) intermittent thrombocytopenia, and (4) congenital X-linked neutropenia without other features of WAS.

The laboratory evaluation of patients with WAS usually demonstrates increased levels of serum IgE and IgA with a low level of IgM and a normal level of IgG. Despite normal serum IgG levels, antibody responses following immunization to polysaccharide antigens are consistently impaired.[131] T cell and NK cell function is frequently abnormal, resulting in a partial combined immunodeficiency.[132] Decreased platelet counts, platelet function, and platelet size are hallmarks of the disorder and lead to the marked bleeding diathesis.

The clinical expression of WAS includes prolonged bleeding episodes beginning in infancy, recurrent pyogenic infections, autoimmunity, eczematous dermatitis, and an increased prevalence of Epstein-Barr virus–related lymphomas. Upper and lower respiratory infections caused by encapsulated organisms (*S. pneumoniae* and *H. influenzae*) are common and reflect the inability of patients with WAS to make specific antibodies to polysaccharide antigens. Pulmonary infections with opportunistic pathogens (*P jirovecii,* herpesviruses) are also common. Infection and hemorrhage are frequent causes of death. The treatment of WAS includes aggressive treatment of intercurrent infections and immunoglobulin replacement.[130,131] Thrombocytopenia usually responds to splenectomy. HSCT is the treatment of choice for WAS, with long-term survival rates higher than 70%.[130,131] Gene therapy using a lentiviral vector to introduce a normal WAS gene into hematopoietic stem cells has been used in patients lacking a suitable stem cell donor, with satisfactory short term outcomes.[133,134] Interim analysis of an ongoing study examining this approach has revealed that it is safe and corrects the hematologic and immunologic abnormalities.[135]

ATAXIA-TELANGIECTASIA

Ataxia-telangiectasia (AT) is an AR disorder caused by a mutation in the *AT* gene, which is involved in the repair of DNA breaks.[136,137] The clinical manifestations of AT include neurologic dysfunction (cerebellar ataxia, oculomotor apraxia, delayed motor development), telangiectasias, and immunodeficiency. Elevated levels of carcinoembryonic antigen and alpha-fetoprotein are present in nearly all patients with AT. The mutation in the AT gene leads to an increased radiosensitivity and the increased incidence of malignancies such as lymphomas and epithelial tumors. Serum immunoglobulins are usually normal in AT, but selective IgA deficiency and impaired responses to polysaccharide antigens are common. Patients with AT develop recurrent sinopulmonary infections either because of the immunodeficiency or as a result of a swallowing dysfunction, usually in infancy or early childhood. Lung involvement can reflect recurrent infections and bronchiectasis, recurrent aspiration related to worsening neurologic status, or ILD, which develops in approximately 20% of patients with AT.[136–138] The optimal treatment of the ILD in AT is not known, although corticosteroids have been used with some success.[138] Even though there is no definitive treatment of AT, antibody replacement has been used in patients to prevent the infectious complications.

HYPER–IMMUNOGLOBULIN E SYNDROME

Hyper-IgE syndrome (HIES), also known as Job's syndrome, is a syndrome characterized by recurrent skin and lung infections, severe eczema, and elevated levels of serum IgE. There are two forms of HIES. The more common *autosomal dominant* (AD) form of HIES is caused by mutations in the transcription factor *signal transducer and activator of transcription-3* (STAT-3) and has extraimmunologic features (connective tissue disorders, skeletal abnormalities) not present in the AR forms that result from variants in *PGM3* or *DOCK8*.[139–142] Biallelic mutations in the transcription factor *ZN341*, which regulates STAT-3 transcription, also results in a phenotype similar to the AD form of HIES.[143]

The most common AR form of HIES is caused by mutations or large deletions in the gene coding for the *dedicator of cytokinesis 8* (DOCK8), a protein involved in intracellular signaling.[144,145] DOCK8 deficiency is characterized by cutaneous viral infections (human papillomavirus, molluscum contagiosum), and neurologic complications, but it lacks the characteristic facies present in the AD form of HIES.[145,146] Biallelic mutations in *PGM3*, which is involved in glycosylation of proteins, causes an immune deficiency with severe atopy and neurologic abnormalities.

The clinical features of HIES appear in early infancy and include moderate to severe eczema, eosinophilic pustular folliculitis, skin abscesses, mucocutaneous candidiasis, and recurrent cases of pneumonia with pneumatoceles.[140,147] Pneumatoceles are thought to be a consequence of disordered healing following primary infection of the lung. Common primary pathogens in HIES syndrome include *S. aureus, S. pneumoniae, H. influenzae,* and *Candida albicans*. Secondary infection of the pneumatoceles with *Aspergillus* sp or *Pseudomonas aeruginosa* may lead to invasion of the pulmonary vasculature leading to pulmonary hemorrhage or central nervous system infection, which are major causes of death.[147,148] The signs and symptoms of serious infection are frequently absent in patients with HIES. Abscesses may develop without signs of external inflammation (cold abscess), or pneumonia may be present with limited clinical symptoms. Bronchopulmonary fistula leading to empyema

may form following pulmonary surgery performed to manage the complications of HIES.[149]

Patients with AD HIES have a characteristic facies (coarse facial features with a protuberant mandible and forehead, hypertelorism, and a broad, fleshy nasal tip), retained primary teeth, severe osteopenia with fractures following minimal trauma, scoliosis, and hyperextensible joints.[150] In addition, patients with HIES have a proclivity to develop aneurysms, particularly of the coronary arteries.[151]

The diagnosis of HIES cannot be made by routine assays of immunologic function. Typical abnormalities in the laboratory evaluation of patients with HIES include an elevated IgE (>2000 IU/mL) and eosinophilia. These laboratory abnormalities are not pathognomic of HIES and may be present in patients with severe atopic dermatitis. Elevated levels of serum IgE may wane with age, and a normal IgE level does not exclude the diagnosis of HIES.

An understanding of the molecular pathogenesis of HIES was significantly advanced with the discovery that mutations in the *STAT3* gene are the cause of this disorder. [139] The *STAT3* gene codes for a transcription factor essential for the biologic activities of numerous cytokines, including IL-6 and IL-10.[152] The absence of the anti-inflammatory effects of IL-10 likely contributes to the dysregulated inflammatory response seen in HIES patients.[153] IL-6 is required for the genesis of $CD4^+$ Th17 cells in humans, and Th17 cells are therefore deficient in HIES.[154] Th17 cells are important in the defense against extracellular bacteria and fungi.[155]

The treatment of HIES focuses on the prevention and prompt treatment of infection. Antimicrobial prophylaxis is often given to prevent infection with *S aureus*. The role of antifungal prophylaxis is unknown. Optimal skin care, including the use of bleach baths, topical corticosteroids, and hydrating measures for eczema, is essential. Antibody replacement, antimicrobial prophylaxis, and IFN-γ may benefit some patients.[156,157] HSCT of the STAT-3 form of HIES improves the immunodeficiency but does not necessarily improve the extraimmunologic features, including preexisting pneumatoceles.[158] HSCT for the AR-HIES caused by DOCK8 deficiency results in a marked improvement of the immunodeficiency and is now considered the treatment of choice.[146,159]

PHAGOCYTE DISORDERS

There are several clinical indications for evaluation for phagocyte abnormalities, including neutropenia or the lack of neutrophilia with significant infection, infections with unusual or opportunistic pathogens (e.g., fungi such as *Aspergillus;* bacteria such as *Serratia marcescens, Burkholderia cepacia,* or *Nocardia*), unusual sites of infection (e.g., recurrent osteomyelitis, abscesses in the brain, lung, or liver), systemic bacterial infections, recurrent skin infections, upper or lower respiratory tract infections, and cold abscesses.[160] Apart from infection, patients with phagocyte defects may have ongoing chronic inflammatory responses in the skin (e.g., eczematoid dermatitis) or mucous membranes (e.g., periodontitis, aphthous stomatitis) and disordered inflammatory responses leading to delayed or abnormal wound healing.

DEVELOPMENTAL DEFECTS IN NEUTROPHILS

Cyclic neutropenia is an AD disorder caused by mutations in the gene for *neutrophil elastase-2 (ELA2)*. It is thought that mutations of *ELA2* induce premature apoptosis of neutrophil precursors by induction of the unfolded protein response.[161,162] In cyclic neutropenia, there is a regular, 21-day fluctuation of neutrophils and other blood components (platelets, monocytes, reticulocytes). During periods of neutropenia, patients are predisposed to bacterial infection with pyogenic bacteria and opportunistic pathogens. The diagnosis of cyclic neutropenia should be suspected when neutropenia coincides with recurrent infections.

Congenital agranulocytosis (Kostmann syndrome) typically appears in early infancy with life-threatening infections such as cellulitis, meningitis, perirectal abscesses, pneumonia, or sepsis. Patients with congenital agranulocytosis have severe neutropenia with an absolute neutrophil count of less than 200 cells/mm^3. The clinical manifestations of congenital agranulocytosis are more severe than those of cyclic neutropenia. Most cases of congenital agranulocytosis are AR, resulting from mutations in the gene for *HAX1*, a mitochondrial protein thought to protect myeloid cells against apoptosis.[163] Other causes of congenital neutropenia include mutations in *WASp, GFI*, and *G6PC3*.[27,163] Administration of G-CSF is indicated in cyclic neutropenia and congenital agranulocytosis because it is effective in increasing neutrophil counts and reducing infection in the majority of patients with these disorders. In patients with severe neutropenia unresponsive to G-CSF, HSCT should be performed.[164]

LEUKOCYTE ADHESION DEFICIENCY

The influx of leukocytes, including neutrophils, to sites of infection involves production and release of neutrophils from the bone marrow, activation of neutrophils by chemotactic factors with subsequent adhesion of neutrophils to the endothelium, and transmigration of neutrophils through the endothelium of postcapillary venules. The first step in the egress of neutrophils from the circulation to sites of infection is mediated by the rolling (loose) adhesion of neutrophils to endothelium, mediated predominantly by CD15s (sialyl $Lewis_x$) on the neutrophil and its counter-ligands (E-selectin, P-selectin) on the endothelium. The following step in adhesion, which is of higher affinity, is mediated predominantly by the interaction of the integrin *leukocyte function–associated antigen* (LFA-1; CD11a/CD18) on the leukocyte with its counter-ligand intracellular adhesion molecule-1 on the endothelium. Integrins are composed of two subunits (α, β) which are non-covalently associated. The common β chain (CD18) associates with CD11a (LFA-1), CD11b (Mac-1 or CR3), CD11c (gp150/95), and CD11d, which are expressed on a variety of leukocytes. Therefore, mutations in CD18 reduce the cell surface expression of CD11a/CD18, CD11b/CD18, and CD11c/CD18, resulting in defects in the endothelial adhesion of all leukocytes. Defects in CD18 and CD15s lead *to leukocyte adhesion deficiency type I* (LAD-I) and *LAD*

type II (LAD-II), respectively.[165,166] LAD type III, a rare AR disorder, is caused by a mutation in the gene encoding kindlin-3, a member of a protein family that may regulate integrin function.[167,168]

LAD-I is divided into two broad categories based on whether the deficiency of LFA-1 is severe (<0.5% of normal levels) or moderate (5–10% of normal levels).[169] Patients with a complete deficiency in LFA-1 expression present in the neonatal period with delayed separation of the umbilical cord, infection of the umbilical cord (omphalitis), and severe infections of the skin, gingiva, gastrointestinal, and upper and lower respiratory tracts. Moderate deficiencies of LFA-1 result in a milder phenotype, with delayed diagnosis. Patients with LAD-I exhibit neutrophilia, even in the absence of systemic infection, because of the inability of leukocytes to adhere to the endothelium. The definitive diagnosis of LAD-I deficiency is made by the demonstration of low levels of LFA-1 on neutrophils by flow cytometry. The treatment of LAD-I includes the aggressive use of antimicrobials in the treatment of infection. HSCT is the only definitive treatment for patients with severe deficiencies of LFA-1.[170]

LAD-II is an extremely rare disorder characterized by developmental delay, mental retardation, and recurrent infection similar to LAD-I. A mutation in the guanosine diphosphate–fucosyl transporter leads to the absence of CD15s on leukocytes and expression of the Bombay blood phenotype.[171]Oral fucose administration can induce the expression of CD15s, leading to improvement of the central nervous system abnormalities and decreased infection,[172] although this has not been successful in all patients with LAD II. LAD III is characterized by a profound bleeding tendency, recurrent bacterial and fungal infections, and failure to form pus despite marked leukocytosis.[166–168]

CHRONIC GRANULOMATOUS DISEASE

CGD is a rare (1 in 200,000) immunodeficiency caused by mutation in one of the four subunits of the *phagocyte NADPH oxidase* (PHOX; NOX2) system.[173] The function of NADPH oxidase is to transfer an electron to molecular oxygen (O_2), leading to the formation of superoxide.[174,175] Approximately two-thirds of cases of CGD are X-linked as a result of mutations in the g91phox subunit of NADPH oxidase.[176,177] Mutations of the other subunits of NADPH oxidase (p22, p47, p67) are AR and account for the remainder of cases.[173]

The clinical manifestations of CGD usually begin early in life (mean age of onset, 4.4 years) but they may not manifest until adulthood.[173,176] CGD is characterized by recurrent infections with catalase-positive organisms (*Aspergillus* sp, *S. aureus, B. cepacia,* and others). Tuberculosis is common in CGD patients where tuberculosis is endemic, and vaccination with live, attenuated bacille Calmette-Guérin can cause local and disseminated infection.[178] Residual NADPH oxidase function, which is more common in AR forms of CGD, leads to a milder phenotype, delayed onset of disease, and longer survival.[179,180] Pneumonia and skin infections are the most common infections, but osteomyelitis, liver abscesses, lymphadenitis, and anorectal infections are also frequent.[173] Aerosolized exposure to organic dust can lead to fulminant fungal pneumonia termed "mulch pneumonitis" and may be the presenting manifestation of CGD, especially the AR forms.[181,182] Prolonged antimicrobial or antifungal therapy, often in conjunction with systemic corticosteroids, is necessary to treat many of the infectious complications of CGD.[176,183,184] The most common chest computed tomography abnormalities include areas of consolidation and nodular opacities, both associated with either infection or granulomatous inflammation.[173,185,186] Invasive aspergillosis is the most common primary cause of death. Autoimmune diseases appear to be increased in CGD, and most patients develop inflammatory colitis. Carriers of X-linked CGD are at increased risk for discoid lupus, photosensitivity, and inflammatory bowel disease.[187] Carriers with skewed X-inactivation that results in less than 10% of neutrophils with a normal respiratory burst may have a clinical phenotype similar to X-linked CGD.[188] The diagnosis of CGD is readily made by the DHR test for phagocyte NADPH oxidase function.

Apart from infectious complications, disordered inflammation and wound healing are hallmark manifestations of the disease.[183,189] Inflammatory granuloma formation may lead to urinary or gastrointestinal tract obstruction, which is treated by systemic corticosteroids. Noninfectious, granulomatous ILD also can be seen.[190] Exuberant granulation tissue leads to disordered wound healing, including wound dehiscence following surgical procedures. The molecular basis for the disordered inflammatory response characteristic of CGD is complex. Comparison of global gene expression of normal and X-linked CGD neutrophils indicate that CGD neutrophils constitutively overproduce proinflammatory mediators and exhibit defective apoptosis resulting from the overproduction of the antiapoptotic protein Bcl-xl.[191] Additionally, on apoptosis, CGD neutrophils do not properly externalize phosphatidylserine, the ligand that enables macrophages to recognize and clear apoptotic cells.[192] Consequently, there is a delay in the removal of apoptotic CGD neutrophils by macrophages.[193] The deficiency in uptake of apoptotic cells may also lead to decreased production of anti-inflammatory mediators such as transforming growth factor-β, thereby contributing to the overproduction of inflammatory cytokines.[183] Thus, the increased production of proinflammatory mediators, reduced apoptosis, and delayed clearance of apoptotic neutrophils all likely lead to the disordered inflammatory response in CGD.

Therapy of CGD includes aggressive treatment of infection, including early surgical incision and drainage.[194] Prophylactic administration of trimethoprim-sulfamethoxazole markedly reduces infection, especially infections caused by *S. aureus.*[195] Prophylactic itraconazole reduces serious fungal infections.[196] Interferon-γ reduces infections and decreases mortality in both X-linked and AR CGD, although the utility of IFN therapy has been questioned.[197,198] HSCT is the preferred treatment for CGD when an appropriate donor is available.[199] Gene therapy using γ-retroviruses in patients with X-CGD resulted in only a short-lived improvement in immunity, likely because of a lack of a

selective advantage of stem cells harboring the transduced gene, and it was complicated by retroviral insertional mutagenesis leading to myelodysplasia. Further refinements in gene therapy for CGD are needed to make this a viable therapeutic option.[200]

GATA-2 DEFICIENCY

An AD inherited deficiency in GATA-2 underlies a unique combined immunodeficiency.[201–207] This rare disorder is also known as "dendritic cell, monocyte, B and NK cell deficiency," familial myelodysplasia/leukemia with lymphedema, or MonoMac (monocytopenia with *Mycobacterium avium* complex).

As the many names illustrate, the clinical manifestations, which usually appear in adolescence or adulthood, are diverse. The immunologic features include a loss of dendritic cells, monocytes, NK cells, and B cells. Patients may develop pulmonary alveolar proteinosis not associated with anti–granulocyte-macrophage-CSF antibodies (see Chapter 98). Opportunistic infections with nontuberculous mycobacteria, usually *M. avium* complex, are common. Infection with human papillomaviruses leads to warts, increased carcinomas in situ, and cervical carcinoma. The bone marrow typically shows cytogenic abnormalities, fibrosis, megakaryocyte dysplasia, and cytopenias, and leukemia may develop. The monocytopenia may precede the clinical manifestations by years. HSCT is the only known cure for the disorder.[208]

MENDELIAN SUSCEPTIBILITY TO MYCOBACTERIAL DISEASE

Th1 cells are defined by their capacity to produce high levels of cytokines (IL-2, IFN-γ, tumor necrosis factor-α) essential in the generation of a robust cellular immune response. Interferon-γ, which is also produced by NK cells, interacts with a heterodimeric receptor, *IFN-γ receptor 1* (IFN-γR1), the ligand-binding subunit, and *IFN-γ receptor 2* (IFN-γR2), which is required for downstream signaling. On ligand binding by IFN-γR1/R2, the *Janus kinases 1 and 2* (JAK1 and JAK2) are activated, which phosphorylate the STAT-1 protein in the cytoplasm, thus leading to homodimerization of STAT-1, translocation to the nucleus, and transcriptional activation of STAT-1–dependent genes. One important biologic function of IFN-γ is to induce the production of IL-12 p70 by dendritic cells and macrophages, a positive feedback loop to induce more production of IFN-γ by NK cells and T cells. IL-12 p70 is composed of two disulfide-linked subunits, p35 and p40, the latter of which also associates with the p19 subunit to form IL-23. The *IL-12 receptor* (IL-12R) is composed of two subunits, IL-12Rβ1 and IL-12Rβ2. IL-12Rβ1 also serves as part of the heterodimeric IL-23 receptor (IL-12Rβ1 and IL-23R). Thus, the IFN-γ/IL-12/IL-23 axis is intrinsically linked by the biologic functions of IFN-γ and IL-12, the shared cytokine subunit of IL-12 and IL-23 (p40), and the common cytokine receptor subunit of IL-12R and IL-23R (IL-12Rβ1).

Table 124.6 Etiologies of Mendelian Susceptibility to Mycobacterial Disease*

Gene	Inheritance	Defect	Patients With MSMD	Treatment
IFNγR1	AR/AD	C/P	39%	AR-C: HSCT AD-P: IFN-γ
IFNγR2	AR	C/P	4%	AR-C: HSCT AR-P: IFN-γ
STAT1	AD	P	5%	Varies depending on location of mutation
IL12B	AR	C	9%	IFN-γ
IL12Rβ1	AR	C	40%	IFN-γ
NEMO (IKK-γ)	X-linked	P	3%	HSCT

*Rare cases of MSMD caused by mutations in *ISG15* (AR) or *IRF8* (AD/AR) have been found.

AD, autosomal dominant; AR, autosomal recessive; C, complete deficiency; HSCT, hematopoietic stem cell transplantation; IFN, interferon; MSMD, mendelian susceptibility to mycobacterial disease; P, partial deficiency.

Mutations of the genes including *IFN-γR1* or *IFN-γR2*, *STAT-1*, *IL-12B*, *IL-12Rβ1*, and *NEMO* (see earlier discussion) define a group of primary immunodeficiencies known as *mendelian susceptibility to mycobacterial disease* (MSMD) (Table 124.6).[27,209] Given the marked heterogeneity in inheritance, the functional consequences of mutations in these 6 genes (complete or partial) leads to 13 distinct genetic disorders associated with MSMD. Patients with mutations in one of these six genes are susceptible to infection with *Mycobacteria* and/or *Salmonella*, but they are usually resistant to infections with most other pathogens.[210,211] This narrow susceptibility to infection in humans is somewhat surprising given the importance of Th1 responses in combating infection with a wide variety of pathogens in studies using mice.

AR complete IFN-γR1 deficiency is characterized by infection with environmental mycobacteria, including rapid growers such as *Mycobacterium fortuitum*, and *Salmonella*, at an early age (<3 years). Without treatment with HSCT, the disorder is fatal. AD partial IFN-γR1 deficiency has a much less severe phenotype, with a mean age of onset at 13 years of age. These patients are susceptible to infection with environmental mycobacteria and may develop disseminated disease following vaccination with bacille Calmette-Guérin. Additionally, patients with partial IFN-γR1 deficiency are predisposed to mycobacterial osteomyelitis, a complication that should trigger an evaluation for this disorder. AR complete IFN-γR2 deficiency and AR partial IFN-γR2 deficiency are rare, and the described phenotype to date is similar to AR complete IFN-γR1 deficiency and AD partial IFN-γR1 deficiency, respectively. The phenotype of patients with a STAT-1 mutation varies depending on the site of the mutation in the gene.

AR complete mutations of IL-12B result in a markedly increased susceptibility to infection with *Salmonella* in addition to mycobacterial disease. Similarly, AR complete IL-12Rβ1 deficiency, which is the most common

cause of MSMD, also results in an increased susceptibility to infection with mycobacteria and *Salmonella.* Patients with deficiency in IL-12B and IL-12Rβ1 are also susceptible to mucocutaneous candidiasis.[212,213] The clinical phenotype of AR complete IL-12Rβ1 deficiency is milder than complete defects in IFN-γR1 or IFN-γR2 and only a few patients succumb to disease. Interferon-γ is useful in the treatment of patients with either IL-12B or IL-12Rβ1 deficiency.

DISORDERS IN INNATE IMMUNITY

As described in depth in Chapter 15, innate immunity provides early responses to infectious challenges, before the generation of antibody or T cell responses. Although polymorphisms in innate immune receptors have been associated with increased susceptibility to certain common infections, defects in genes encoding adaptor molecules that coordinate signaling from multiple innate receptors are associated with more severe immunodeficiencies. Similarly, defects in humoral mediators of innate immunity, such as complement proteins, can be associated with recurrent and severe infections.

MYD88 AND IRAK-4 DEFICIENCIES

Toll-like receptors (TLRs) are a family of pattern recognition receptors activated following microbial infection, resulting in activation of innate immune responses. TLRs recognize conserved motifs derived from a variety of pathogenic microorganisms, including bacteria, fungi, and viruses. Upon ligand binding, all members of the TLR family, with the exception of TLR3, use MyD88 as a key adaptor molecule to recruit IRAKs leading to signaling resulting in the activation of the transcription factors NF-κB and activator protein-1. Mutations in either MyD88 or IRAK-4 result in phenotypically similar primary immunodeficiencies characterized by noninvasive and invasive infections (meningitis, septicemia, liver abscess) predominantly with *S. pneumoniae* (40% of patients) or *S. aureus* (26% of patients) and *P. aeruginosa* (18%).[214–217] No severe infections with viruses, fungi, or parasites have been observed, a surprising finding based on the broad immunodeficiency found in mice with targeted deletion of MyD88. The onset of invasive infections is early in life, with most before the age of 2 years but, for unknown reasons, the condition improves with age. Nearly all deaths in patients with IRAK-4 deficiency take place by 8 years of age. Patients with MyD88 or IRAK-4 deficiency are frequently unable to generate a normal inflammatory response (e.g., fever, increased C-reactive protein and white blood cells), and this contributes to the severity of the infections. Results of standard screening tests of immune function are often normal. Peripheral blood mononuclear cells exhibit decreased inflammatory cytokine production in response to IL-1 and to all TLR agonists except agonists of TLR3. The proper management of patients with MyD88 or IRAK-4 mutations remains to be determined, but prophylactic antibiotics and antibody replacement are considered essential.

COMPLEMENT DEFICIENCIES

Complement has many important functions that include the modulation of inflammatory responses (e.g., vasodilation, leukocytosis, and chemotaxis), clearance of immune complexes, modulation of the immune response (e.g., enhanced production of antibodies), and microbial elimination (e.g., opsonization, neutralization, and microbicidal activity). Complement may also be important in the efficient removal of apoptotic cells, thereby resulting in the presentation of self-antigens and the induction of autoimmunity. Deficiencies in components of the complement system are usually manifest by an increased propensity to infection or autoimmunity. There are several indications for the evaluation of the complement system, such as a strong family history of autoimmune diseases, recurrent infections caused by encapsulated bacteria, a family history of meningococcal disease, infection caused by unusual types of meningococcus (Y, W-135), age older than 9 years at the time of meningococcal disease, and recurrent angioedema.

Defects in the early components of complement (C1q, C1s, C2, C4) typically lead to autoimmune disease, primarily systemic lupus erythematosus.[218] Redundancies in the complement pathway, including the alternative and mannose-binding lectin pathways, may explain why only a minority of patients with early complement deficiencies will develop serious bacterial infections. Encapsulated bacteria (*S. pneumoniae, H. influenzae*) are the most common pathogens in persons with recurrent infection resulting from deficiency in early complement components.[25] C2 deficiency is the most common early component deficiency, seen in 1 in 10,000 to 1 in 28,000 live births.

The classical, alternative, and mannose-binding lectin pathways all converge at C3. For this reason, deficiencies in C3 result in more severe infections than deficiencies in other components of complement. Patients with C3 deficiency have an increased prevalence of autoimmune disease and present in a manner similar to patients with antibody deficiency.

Deficiencies in the late components of the complement pathway (C5 to C9) are predisposed to infection with *Neisseria meningitidis and Neisseria gonorrhoeae.* For unclear reasons, meningococcus serogroups W-135 and Y account for the majority of meningococcal infections in these patients. The prevalence of autoimmune disease is also increased, but to a much lesser extent than with deficiencies in the early components of the complement cascade. Patients with late-component deficiencies usually have the onset of infection at an older age, and many are asymptomatic well into adolescence.[25] Deficiencies in components of the alternative pathway (factor D, properdin) are extremely rare and present with recurrent bacterial infections, including infections with *Neisseria* sp. Properdin deficiency is an X-linked disorder, in contrast to the other complement deficiencies.

Therapy for complement deficiencies is primarily supportive. Individuals should be vaccinated against common bacterial pathogens associated with complement deficiency (e.g., *S. pneumoniae, H. influenzae, N. meningitidis*). Prophylactic antibiotics may be used in selected situations.

Key Points

- Patients with recurrent upper airway infections, intractable sinusitis, or more than one radiographically documented case of pneumonia should be evaluated for primary immune deficiency disorders. Abnormal screening tests for primary immune deficiency disorders should lead to referral to a clinical immunologist for a specific diagnosis.
- Although infection with opportunistic pathogens should always lead to a search for primary or secondary immunodeficiencies, infections in patients with primary immune deficiency disorders are often caused by common pathogens.
- Primary immune deficiency disorders frequently are not diagnosed in a timely manner, thus leading to increased morbidity and mortality. Treatment can include replacement antibody for humoral immunodeficiencies or, in those with a severe phenotype, hematopoietic stem cell transplantation.
- Primary immune deficiency disorders can be caused by deficiencies in antibody production, cellular immunity, complement, or phagocyte function. In an adult, common variable immunodeficiency is the most common diagnosis, and phagocytic defects and combined immunodeficiencies are rare.
- Although immunodeficiency in adults is more commonly secondary than primary, primary immune deficiency disorders are seen in adults. In fact, there are more adults with primary immune deficiencies than children.
- Diffuse interstitial lung disease develops in 10–25% of patients with common variable immunodeficiency and has been termed granulomatous-lymphocytic interstitial lung disease.
- In patients with profound antibody deficiencies, diagnosis of microbial infection cannot rely on serologic (antibody) responses but must instead use culture or detection of microbial antigens or nucleic acids.

MALIGNANCY AFTER TRANSPLANTATION
KEY POINTS

INTRODUCTION

Over the past 50 years, hematologic cell and solid organ transplantation have transformed the outlook for millions of individuals who experience life-threatening hematologic disorders and end-stage organ failure. Long-term outcomes for transplant recipients have improved with advances in the transplantation procedures as well as in supportive care.[1-4] However, transplant recipients are vulnerable to a variety of pulmonary complications that are diagnostically and therapeutically challenging for the chest physician. In addition to acute lung injury and infections complicating the early posttransplant period, providers must also contend with previously unanticipated chronic lung problems that arise in long-term transplant survivors. This chapter reviews infectious and noninfectious complications common to both *hematopoietic cell transplantation* (HCT) (also known as stem cell transplantation) and *solid organ transplantation* (SOT), followed by noninfectious complications specific to HCT and SOT. After HCT, the majority of the noninfectious complications happen in allogeneic transplants; concerns in autologous HCT are discussed where relevant. Given the emergence of lung transplantation as a distinct field within pulmonary medicine, the discussion regarding noninfectious complications in SOT focuses primarily on heart, kidney, and liver transplantation. The unique noninfectious complications of lung transplantation are covered in greater detail in Chapter 140.

HCT is a curative form of cellular therapy for a number of malignant and nonmalignant hematologic or immune disorders that replaces diseased or nonfunctioning bone marrow with healthy stem cells. To allow cellular engraftment into the patient's bone marrow, patients must undergo a conditioning regimen of cytotoxic chemotherapy with or without total body irradiation. *Myeloablative* conditioning regimens eliminate the recipient immune system in order to reduce the risk of malignancy relapse but carry increased risk of subsequent organ toxicity. *Nonmyeloablative* or reduced-intensity conditioning regimens are increasingly used to reduce organ toxicities for older recipients. The patient's marrow is then rescued by an infusion of healthy stem cells. *Allogeneic* HCT utilizes cells harvested from bone marrow or peripheral blood from related or unrelated individuals; umbilical cord blood is an alternative donor source that may be used if an appropriate matched donor is not found. *Autologous* HCT uses stem cells harvested from the patient's own blood. The use of allogeneic versus autologous cells depends on the disease indication; acute leukemias are generally treated with allogeneic HCT, while some lymphomas and multiple myeloma are preferentially treated with autologous HCT. Autoimmune diseases, such as systemic sclerosis[5] and multiple sclerosis,[6] are primarily treated with autologous transplants. Engraftment following stem cell infusion generally takes 2 to 3 weeks. In allogeneic HCT, donor T cells may attack recipient tissues, a condition called *graft-versus-host disease* (GVHD), requiring intensified immunosuppression; GVHD does not happen in autologous HCT. GVHD is a life-threatening disease that can involve nearly every organ system but preferentially affects the skin, lungs, mucous membranes, gastrointestinal tract (including the liver), and eyes. If an allogeneic HCT recipient has successfully engrafted without evidence of GVHD, long-term immunosuppression may not be required. This contrasts with SOT recipients, who have

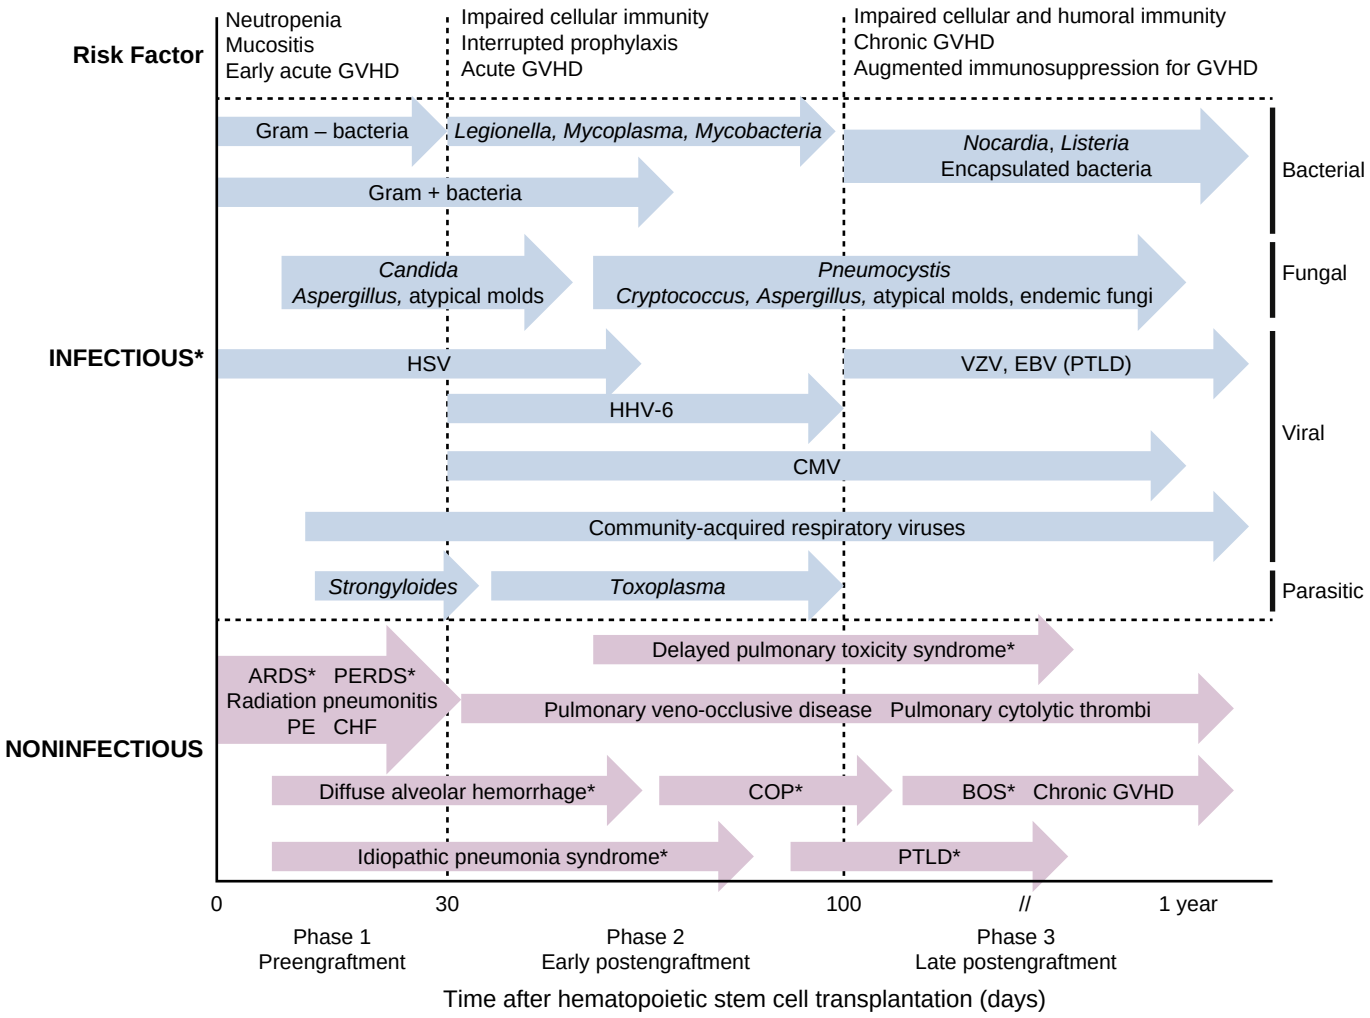

Figure 125.1 Hematopoetic cell transplantation: timeline of infectious and noninfectious pulmonary complications. Complications develop in a temporal relationship to the transplant conditioning regimen and immune status of the transplant recipient. In the immediate preengraftment phase (<1 month) prior to engraftment, patients experience profound neutropenia as well as immediate effects of the procedure. The early postengraftment phase (1–3 months) is a period of impaired cellular immunity as well as extrinsic immunosuppression for treatment of acute *graft-versus-host disease* (GVHD); this remains a vulnerable period for lung infections and acute lung injury. During the late postengraftment phase (>3 months), community-acquired infections and opportunistic infections in the setting of chronic GVHD treatment as well as chronic forms of noninfectious lung disease emerge. *Consider diagnostic bronchoscopy to (1) establish or exclude an infectious etiology and/or (2) diagnose a noninfectious process. ARDS, acute respiratory distress syndrome; BOS, bronchiolitis obliterans syndrome; CHF, congestive heart failure; CMV, cytomegalovirus; COP, bronchiolitis obliterans organizing pneumonia/cryptogenic organizing pneumonia; EBV, Epstein-Barr virus; HHV-6, human herpes virus-6; PE, pulmonary embolism; HSV, herpes simplex virus; PERDS, peri-engraftment respiratory distress syndrome; PTLD, posttransplant lymphoproliferative disorder; VZV, varicella-zoster virus. (Modified from Soubani AO. Respiratory infections following hematopoietic stem cell transplantation. In: Agusti C, Torres A, eds. *Pulmonary Infection in the Immunocompromised Patient: Strategies for Management.* West Sussex, UK: Wiley-Blackwell; 2009:213-256, and Afessa B, Peters SG. Chronic non-infectious pulmonary complications in hematopoietic stem cell transplantation. Diagnostic bronchoscopy in solid-organ and hematopoietic stem cell transplantation. *Ann Am Thorac Soc.* 2013;10[1]:3949.)

functioning immune systems but require intense immunosuppression early after transplant and ongoing degrees of immunosuppression lifelong to prevent graft rejection. The level of immunosuppression in SOT varies; small intestine, lung, heart, and multiorgan transplant recipients, who are at higher risk for organ rejection, often receive a higher intensity of immunosuppressive therapy.

Transplant recipients are subject to specific infectious and noninfectious complications in relation to the stage of immunocompromise and graft biology. The risk of these complications can be conceptualized as immediate (<1 month), early (1 to 3 months), and late (>3 months) periods roughly corresponding to the degree of intrinsic immunocompromise and augmented immunosuppression (Figs. 125.1 and 125.2). Infections are common in the immediate and early periods and continue to contribute to morbidity and mortality in the late period. Noninfectious complications arise immediately posttransplant as a consequence of the grafting procedure as well as of the allograft itself; these complications can lead to lifelong immunologic consequences for the recipient. For example, recipients of HCT are often pancytopenic from their underlying hematologic malignancy or disease, cytotoxic chemotherapy or immune modulation, and radiation or ablative chemotherapy required prior to graft infusion. After engraftment, cellular and humoral immune reconstitution may not be

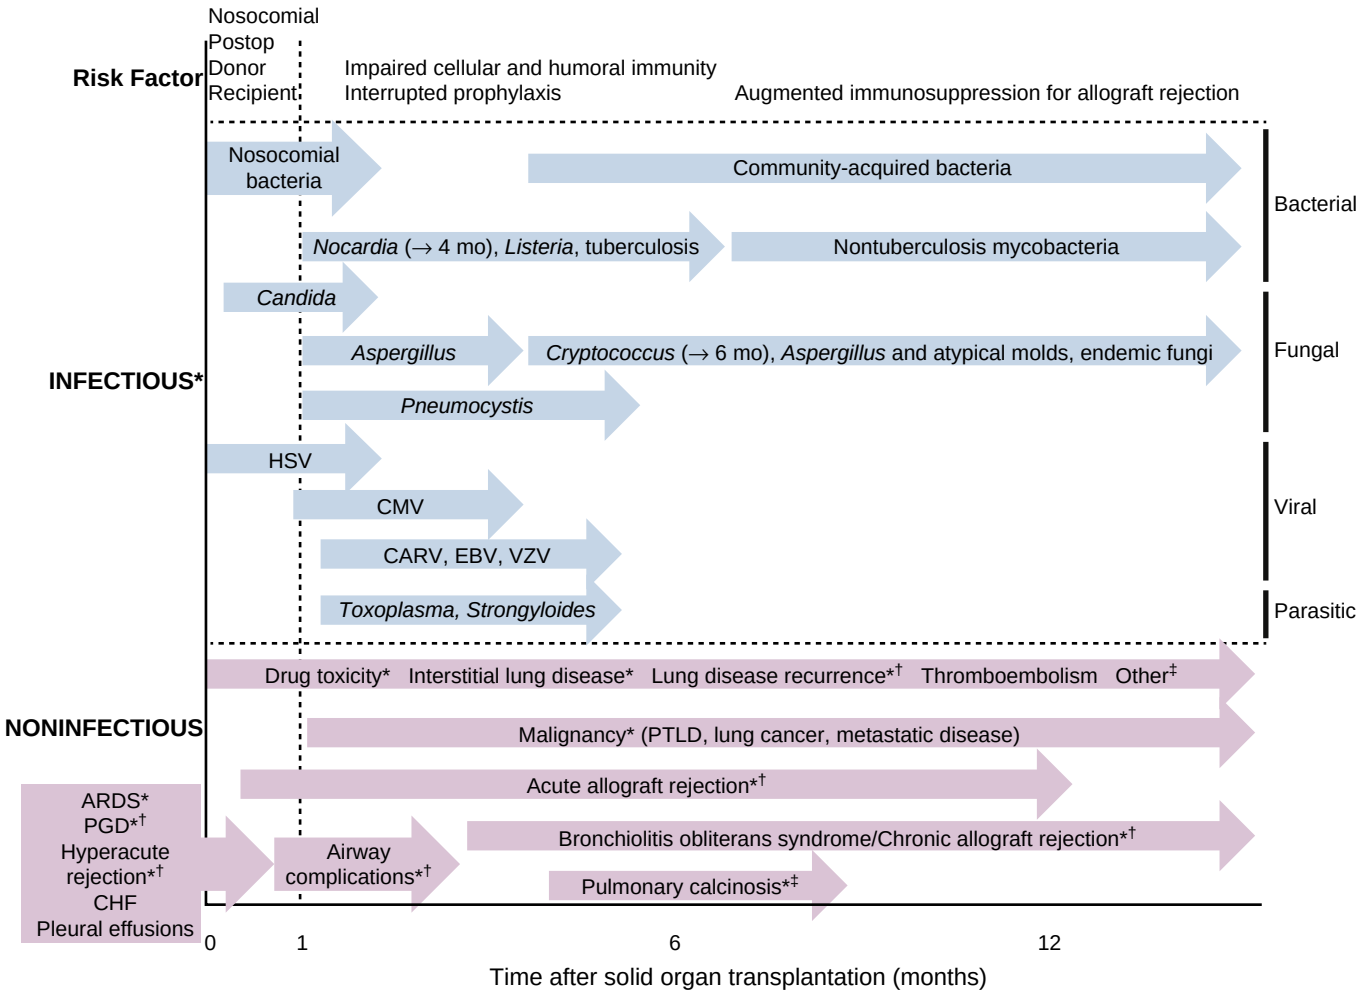

Figure 125.2 Solid organ transplantation: timeline of infectious and noninfectious pulmonary complications. The immediate postoperative period for a solid organ transplant recipient is complicated by nosocomial infections as well as surgical complications leading to acute respiratory failure. In the months after transplant, pharmacologic immunosuppression to prevent graft rejection leads to opportunistic infections. Later posttransplant, community-acquired infections predominate and noninfectious complications include malignancy, drug toxicity, and thromboembolism. Of note, bronchiolitis obliterans syndrome is a common late complication of lung transplantation (see Chapter 140). *Consider diagnostic bronchoscopy to (1) establish or rule out an infectious etiology; (2) diagnose a noninfectious etiology, such as acute allograft rejection, malignancy, or interstitial lung disease; or (3) inspect bronchial anastomoses and other airway abnormalities. †Lung transplant recipients only. ‡Diagnostic bronchoscopy is warranted for pulmonary metastatic calcinosis for atypical presentations on imaging in renal transplant recipients. ARDS, acute respiratory distress syndrome; CARV, community-acquired respiratory viruses; CHF, congestive heart failure; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HSV, herpes simplex virus; PGD, primary graft dysfunction; PTLD, post-transplant lymphoproliferative disorder; VZV, varicella-zoster virus. (Modified from Harris B, Lowy FD, Stover DE, Arcasoy SM. Diagnostic bronchoscopy in solid-organ and hematopoietic stem cell transplantation. *Ann Am Thorac Soc*. 2013;10(1):39-49 and based on data from Fishman JA: Infection in solid-organ transplant recipients. *N Engl J Med*. 2007;357:2601-2614.)

complete for months to years. Prevention and treatment of GVHD during the early (acute GVHD) and late (chronic GVHD) periods require prolonged immunosuppression for some individuals.[7] In the immediate posttransplant period, SOT recipients undergo intense immunosuppression with glucocorticoids and agents directed towards T lymphocytes to prevent immediate graft rejection as well as postoperative stresses that can lead to acute respiratory failure. After this period, lifelong immunosuppression is required for solid organ graft survival. Organ dysfunction, antibiotic effects on the microbiome, drug-related adverse effects, alterations in nutritional intake, and posttransplant depression are just some of the factors that may contribute to prolonged immunosuppression in transplant recipients.

INFECTIOUS COMPLICATIONS

The lung is a leading site of infection for transplant recipients. With newer and more efficacious anti-infective agents and improved prophylactic strategies, the impact of pulmonary infections has shifted from early in the course of transplant to later during posttransplant survival. Successful strategies for preventing and treating opportunistic fungal and viral infections have also led to the emergence of resistant pathogens.[8-10] Radiographic and clinical presentations of various infectious pneumonias are often indistinguishable from one another (Fig. 125.3) and from noninfectious lung disease.[7] Coinfection with more than one pathogen is also common. Because of these concerns as well as the

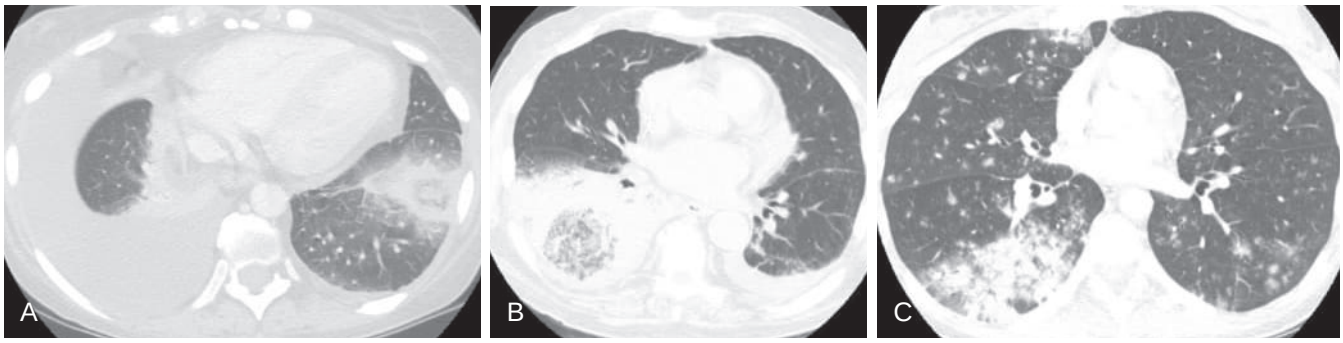

Figure 125.3 Pulmonary infections in allogeneic hematopoietic cell transplant recipients. Infectious pneumonia is caused by a broad spectrum of pathogens that can present similarly on chest imaging. Thus, bronchoscopy is important for determining the underlying pathogen. These examples represent chest computed tomography images from hematopoietic cell transplant recipients who underwent bronchoscopy to diagnose the lung opacities. The pathogens identified were methicillin-sensitive *Staphylococcus aureus* (A), *Rhizomucor oryzae* (B), and human metapneumovirus (C). Note the reverse halo, or "bird's nest" sign in B, which is suggestive of mucormycosis.

potential adverse effects of empiric therapy, a specific diagnosis should be pursued whenever possible. Bronchoscopy with analysis of the *bronchoalveolar lavage* (BAL) fluid remains the diagnostic procedure of choice for the evaluation of enigmatic pulmonary consolidations or opacities in both HCT and SOT.[11] Diagnostic yield is highest when bronchoscopy is performed prior to empiric antimicrobials and within 24 hours of presentation.[12,13] Because many of these infections are rare, a comprehensive review is beyond the scope of this chapter, which focuses on the most clinically relevant entities.

BACTERIAL PNEUMONIA

After HCT, the precise incidence of bacterial pneumonia is difficult to ascertain due to the frequent use of empiric broad-spectrum antibiotics in the early posttransplant period. Nevertheless, bacterial pneumonia has been reported in 7–11% of allogeneic and 5–15% of autologous HCT recipients.[14-16] The most common bacterial pathogens include *Escherichia coli, Pseudomonas aeruginosa, Klebsiella pneumoniae, Staphylococcus aureus,* and *Streptococcus pneumoniae*.[16,17] In addition to early neutropenia, important risk factors for early pneumonia after HCT include mucositis from total body irradiation, alterations in the gut microbiome, acid suppression, and prolonged immunosuppression.[18,19] Iron affects innate and cellular immunity by several mechanisms, including inhibition of macrophage and lymphocyte function.[20,21] Iron overload, which is common in HCT recipients who receive frequent blood transfusions pre- and posttransplant, has been associated with increased risk of infectious pneumonia (primarily bacterial and fungal) in these patients.[22,23]

In SOT, bacterial pneumonia is an important source of early posttransplant morbidity and mortality and is often the source of sepsis. In liver transplant patients, the incidence of bacterial pneumonia is 8–23%, mostly presenting in the early postoperative period as ventilator-associated or health care–associated pneumonia[24-27]; risk factors for early-onset pneumonia (<1 month) include increased severity of end-stage liver disease (quantitated as the model for end-stage liver disease score) pretransplant, prolonged intubation, and restrictive pattern on preoperative pulmonary function testing.[24-26] In heart transplant patients, the incidence of early postoperative pneumonia is as high as 34%; risk factors include preoperative intubation and perioperative blood transfusion and the use of extracorporeal membrane oxygenation.[28] In renal transplant patients, bacterial pneumonia is second only to urinary tract infections as an infectious cause of morbidity and mortality, with pneumonia requiring hospitalization in 12% of patients in a cohort of 1467 patients; risk factors for mortality include elevated C-reactive protein, nosocomial multidrug-resistant organisms, and the need for renal replacement therapy.[29]

Most early posttransplant bacterial pneumonias in SOT are health care facility–acquired species and are therefore more likely to be multidrug-resistant pathogens. The most frequently documented bacterial pathogens are gram-negative bacteria, including *P. aeruginosa* (eFig. 125.1), *K. pneumonia, E. coli, Acinetobacter* sp., and *Stenotrophomonas maltophilia* as well as gram-positive bacterial, including methicillin-resistant *S. aureus.*[25,27,30] Beyond the early transplant period, as immunosuppression is modified, SOT recipients experience pneumonia with community-acquired organisms such as *S. pneumoniae, Haemophilus influenzae,* and *Moraxella catarhallis*.[31] A causative agent is often never identified and patients are treated empirically.[32]

Transplant patients are also at increased risk for infections from less commonly encountered nosocomial and opportunistic bacteria. Intrinsically antibiotic-resistant pathogens such as *Burkholderia* sp. and *S. maltophilia* are more common in transplant recipients due in part to selection pressure from antibiotic therapy.[33-35] In addition, *Nocardia* sp. are often seen in transplant patients, particularly those treated with high-dose glucocorticoids, often presenting as nodules that mimic fungal pneumonia.[35,36] *Legionella* sp. pneumonias can be devastating infections in transplant patients, with reports of nearly 30% mortality.[36] *Legionella* infections, including those with non-pneumophila species and non-serotype 1 *Legionella pneumophila*, should be considered, particularly in patients with community-acquired pneumonia or among clusters of inpatient pneumonias.[37]

MYCOBACTERIAL INFECTIONS

In HCT, active *tuberculosis* (TB) is rare, in part due to a low rate of *latent tuberculosis infection* (LTBI) in this population, the use of fluoroquinolone prophylaxis, and possibly the up-regulation of T helper type 1 immune activation during transplant conditioning, which may protect against active TB infection.[38,39] In a study from the University of Minnesota, estimates of the prevalence of active TB following HCT ranged from 0.23–0.79%[40] but can be expected to vary substantially between countries. In a contemporary series of 2531 autologous and allogeneic HCT recipients in a low endemicity region, there were no cases of active TB after a minimum of 3 years of follow-up, which included 63 patients identified with LTBI, of which 46% never received treatment for LTBI.[39] Rates of TB in HCT have been reported to be higher in regions where the prevalence of TB in the population is higher.[41] Experts disagree on the value of routine versus targeted LTBI testing among HCT recipients, but treatment is recommended to patients who have documented LTBI (see also Chapter 42).

In SOT, the incidence of active TB ranges from 1.2–12%, depending on the prevalence of TB in the corresponding population.[42] The highest incidence is in kidney transplant recipients, but lung transplant recipients are also at high risk.[43] Donor-derived mycobacterial infections have been reported.[44] All potential SOT recipients should be tested for LTBI with a tuberculin skin test and/or an interferon-gamma release assay.[45] Neither the tuberculin skin test nor interferon-gamma release assay can distinguish between latent and active disease and may yield false-negative results in immunocompromised patients, although interferon-gamma release assay may be better than tuberculin skin test, particularly in patients with liver or kidney disease.[43] Additional screening with chest radiography should be considered in patients with negative or indeterminate tuberculin skin test/interferon-gamma release assay in high-risk epidemiologic areas. Therapy for LTBI is recommended prior to transplant.[43]

LTBI can be treated with rifampin-based regimens[46] or with isoniazid-based regimens (see Table 42.4).[47] Therapy for active TB should follow standard guidelines and include isoniazid, rifampin, pyrazinamide, and ethambutol.[42,48] The use of rifampin can be a problem due to the increased risk of hepatotoxicity and the induction of cytochrome P450 isoenzymes, which can reduce serum concentrations of several immunosuppressants and azole antifungals, potentially leading to allograft rejection and infection. During rifampin treatment, doses of the immunosuppressants cyclosporine, tacrolimus, and sirolimus must be increased and signs of rejection closely monitored.[43] Rifampin is used most frequently due to its potent antituberculous activity, but rifabutin may be preferable because it is a less potent inducer of cytochrome P450.

In HCT, *nontuberculous mycobacterial* (NTM) pulmonary infections are uncommon, particularly in the early posttransplant period,[49,50] but NTMs are increasingly recognized as a late infectious problem. This likely reflects advances in diagnostic testing, increased long-term survival, and the changing epidemiology of NTM at large.[51] In a cohort of 1047 allogeneic HCT recipients, NTMs were identified in 2.7%, a markedly higher rate than in the general population. The vast majority of cases (93%) presented with lung disease at a median time after HCT of 343 days. NTM was associated with severe chronic GVHD and *cytomegalovirus* (CMV) viremia.[51] NTMs can also be seen in the early posttransplant period as central catheter-associated and skin infections.[49] In SOT, pulmonary NTM is primarily a concern for thoracic SOT, although disseminated NTM in renal transplant patients can contribute to allograft loss and mortality.[52] Lung transplant recipients in particular are at risk for infections at the anastomotic site with *Mycobacterium abscessus*, an organism notoriously difficult to treat.[53] NTM infections contribute to increased mortality in SOT[54] (see also Chapter 55).

FUNGAL INFECTIONS (See Chapter 57)

Aspergillus sp., primarily *A. fumigatus*, are responsible for the vast majority of fungal pneumonias, or *invasive aspergillosis* (IA). Other major *invasive fungal infections* (IFIs) that involve the sinopulmonary tract include *Mucorales* sp. (most frequently *Rhizopus, Mucor,* and *Rhizomucor* sp.), dimorphic molds, and rare infections due to *Fusarium* sp., *Lomentospora prolificans*, *Scedosporium apiospermum,* dematiaceous molds, and multiple other species.[55] In most transplant populations, patients present with primary pulmonary disease, but sinus involvement is common.[56] For lung transplant recipients, tracheobronchitis due to IA may lead to dehiscence of the bronchial anastomoses.[57,58] In addition to respiratory tract disease, IFIs can present with other manifestations, including skin nodules or gastrointestinal tract and/or central nervous system disease. It is important to note that most epidemiologic studies follow the current consensus definitions of IFI from the European Organization for Research and Treatment of Cancer and the Mycoses Study Group Education and Research Consortium and include only probable or proven IA, and thus may underrepresent the true incidence due to the difficulties of establishing the diagnosis before empiric therapy is initiated.[59]

Epidemiology and Clinical Characteristics

In the past 2 decades, improved diagnostic testing, changes in transplant practice, and novel antifungal agents have significantly reduced the burden of IFIs in the immunocompromised population.[60] Risk for fungal infections is dependent on the underlying disease, donor source, conditioning regimen, and use of glucocorticoids. The incidence of IFI ranges from 4–23% after allogeneic HCT and from 1–4% after autologous HCT.[55,61-64] Novel therapies used in conjunction with glucocorticoids for treatment of GVHD, such as ibrutinib, may further increase risk.[65,66] Additionally, risk of developing some IFIs may also be dependent on environmental variables such as temperature and rainfall. Due to improvements in antifungal therapy, mortality due to IA has improved, but IFI from non-*Aspergillus* mold species such as those caused by *Mucorales* and *Fusarium* remain highly lethal in these populations.[67-69]

In SOT, IFIs are most commonly seen in lung transplantation, followed by liver, heart, and kidney transplantation.[70–72] The 1-year cumulative incidence of IA in a multicenter surveillance cohort for lung, heart, liver, and kidney transplants was 2.4%, 0.8%, 0.3%, and 0.1%, respectively. While IA was relatively uncommon, the

mortality rate was high, ranging from 20% for lung transplants to 67% for heart and kidney transplants.[70,73] A recent study showed that the cumulative incidence of IFI in SOT is rising, particularly in lung transplantation, as the burden of disease is shifting to long-term survivors.[73] Other fungal infections, such as cryptococcosis, and endemic molds (e.g., coccidioidomycosis, histoplasmosis), which are more common in SOT recipients, are described in more detail in Chapter 56).

In HCT, the main risk factors for IFI, including IA, are prolonged neutropenia, allogeneic grafts, myeloablative conditioning, and acute GVHD.[55] Prior use of voriconazole, iron overload,[23,74] and high environmental temperatures (particularly summer season), are additional risk factors associated with mucormycosis.[69,75,76] Lung transplant recipients are often colonized with *Aspergillus* pretransplant and thus are at particular risk for lower respiratory tract disease.[58] In SOT, risk factors for IA include environmental exposures (e.g., gardening, construction), state of immunosuppression, and the need for retransplantation.[57] There is increasing evidence that CMV infection is a significant risk factor for IFI, including aspergillosis and *Pneumocystis jirovecii* pneumonia, which has been hypothesized to be due to ganciclovir-induced neutropenia as well as to virally induced cellular immune alterations.[77] More recent publications have also linked the development of IA to influenza, but data in transplant populations remain mixed.[78-82]

Symptoms of IA vary widely but often include high fever, dry cough, chest pain, dyspnea, and hemoptysis. Fever may be absent in SOT, and HCT recipients can present with only fever or be found to have asymptomatic pulmonary nodules. Tracheobronchitis may present early with wheezing and/or stridor or late with frank hemoptysis.

Diagnostic Testing

The radiographic presentation of pulmonary IA differs between HCT and SOT owing to the type of immune risk.[57] In HCT, solitary or multiple nodules and large dense consolidations are typically seen, whereas, in SOT, peribronchial consolidation, ground-glass opacities, and tree-in-bud nodules are more common[83] (eFig. 125.2). In HCT recipients early posttransplant who have yet to engraft, the "halo sign" is a classic finding of a nodule with surrounding ground-glass changes (eFig. 125.3). Fungal nodules may increase both in size and number despite appropriate therapy during neutrophil recovery posttransplant, as immune cells home to sites of infection and cause an apparent increase in inflammation.[84] Cavitation may also present during treatment (eFigs. 125.4 and 125.5). A reverse halo sign, or "bird's nest" consolidation, is suggestive of mucormycosis (see Fig. 125.3).[85]

Because clinical and radiographic presentations may be similar for bacterial infections and noninfectious etiologies (see Fig. 125.3), a microbiologic diagnosis by bronchoscopy in conjunction with serologic testing should be attempted whenever possible.[7,86] The serum galactomannan assay is useful for the diagnosis of IA in HCT but is less sensitive for SOT recipients.[87] Serum galactomannan level is also predictive of outcomes in HCT.[88] Galactomannan detected in BAL fluid is a more sensitive assay for IA; proven disease requires histologic evidence of invasion and culture evidence of mold from a sterile sample.[59] Serum β-D-glucan has been used as an alternative serum marker for IFI; however, it is not sensitive for some dimorphic molds and for mucormycosis.[89] Emerging molecular diagnostics, such as *polymerase chain reaction* (PCR) for molds from blood or BAL fluid, are used increasingly for diagnosis and are included in recently updated guidelines for management of IFI.[59,90,91]

Treatment

The availability of third-generation mold-active and orally available triazoles—voriconazole, posaconazole, and isavuconazole—has greatly improved the treatment and prevention of IA.[7,60] Infectious Disease Society of America Guidelines recommend voriconazole or isavuconazole as first-line therapy for IA; posaconazole is likely an option for IA but has only been assessed in salvage trials and prevention trials.[86] Patients who either cannot tolerate azole therapy, develop breakthrough infection on triazole prophylaxis, or who have clinical and radiologic findings suspicious for mucormycosis should be treated with liposomal or lipid-complex amphotericin B. Compared to earlier treatment, delaying treatment for mucormycosis with amphotericin B for 6 or more days after diagnosis is associated with a twofold increase in mortality.[92] Isavuconazole has also been approved for mucormycosis therapy.[93] Regardless of antifungal therapy, surgical intervention is crucial for all patients diagnosed with pulmonary mucormycosis, and all should be evaluated by cardiothoracic surgery for possible surgical resection. Following surgical intervention and prolonged amphotericin B therapy, most patients can be considered for step-down therapy with either posaconazole or isavuconazole. Treatment teams should be aware of increasing reports of azole-resistant *Aspergillus* sp. and emergence of non-*Aspergillus* pathogens.[94-96]

Prophylaxis against molds is recommended in high-risk groups, including allogeneic HCT recipients with high-grade GVHD. In low-risk patients, fluconazole can be used as primary prophylaxis but, for high-risk patients, the preferred agent is posaconazole; voriconazole is used at some centers.[97] The use of triazole prophylactic agents including fluconazole may be a reason for the rarity of early posttransplant endemic fungal infections (e.g., histoplasmosis, cryptococcosis). In lung transplant recipients, universal or preemptive prophylaxis is given with inhaled liposomal amphotericin during the early posttransplant period.[57,98] In spite of prophylactic strategies, IFIs remain a significant problem.

Pneumocystis jirovecii Pneumonia

In the setting of appropriate prophylaxis (with trimethoprim-sulfamethoxazole or dapsone, atovaquone, and pentamidine for those with sulfa allergies), *Pneumocystis jirovecii pneumonia* (PJP) is rare in HCT recipients, seen in only 0.63% and 0.28% of allogeneic and autologous HCT recipients, respectively, as demonstrated by a large registry study.[99] However, the mortality of PJP in HCT remains high, with a hazard of mortality nearly seven times higher than matched controls. In HCT, risk factors for PJP include lymphopenia, mismatched grafts, and GVHD (which is usually treated with systemic glucocorticoids).[99] In SOT, in the absence of prophylaxis, PJP developed in 5–15%, with the risk of infection greatest in the first 6 months posttransplant. Prophylaxis with low-dose trimethoprim-

sulfamethoxazole is used for a year, then discontinued, except in lung transplant patients, in whom it is continued indefinitely.[100] In non-lung SOT, PJP is rare when prophylaxis is given in the 6- to 12-month period after transplantation but rises significantly in the first year without standard prophylaxis. Risk factors include advanced age, antecedent CMV infection, and lymphopenia.[101-103] Diagnosis of PJP includes direct immunofluorescent staining of respiratory samples; PCR of respiratory samples for PJP and serum β-D-glucan assays are increasingly being used for diagnosis.[104,105] First-line therapy for PJP is intravenous trimethoprim-sulfamethoxazole, but other options, such as clindamycin/primaquine, are available for those who cannot tolerate sulfa drugs. The use of adjunctive steroids in transplant recipients may be considered, particularly in severe cases.[106]

VIRAL INFECTIONS

Herpesviruses

In HCT, preemptive treatment with ganciclovir and foscarnet has dramatically reduced the incidence of CMV disease, particularly of CMV pneumonia, which historically affected patients within the early posttransplant period.[107,108] However, the incidence of CMV pneumonia in the modern era is very low, seen in less than 1% of patients.[109-111] Late CMV reactivation has emerged as a consequence of preemptive and prophylactic strategies. HCT recipients who are CMV seropositive are at highest risk for CMV pneumonia, particularly patients who receive transplants from CMV seronegative donors or cord blood transplants.[112] This is similar for SOT, and risk is highest among lung transplant recipients.[113,114] Prophylaxis with ganciclovir and valganciclovir has significantly reduced risk in SOT recipients.[115] The application of letermovir, a novel agent targeting the DNA terminase complex, for prophylaxis has been shown to decrease the risk of CMV viral reactivation in high-risk patients.[109]

Clinically, patients with CMV pneumonia most often present with shortness of breath, hypoxemia, cough, and fever.[116] Radiographically, CMV pneumonia may present similarly to noninfectious complications, with diffuse ground-glass changes, a nonspecific lung injury pattern, or with diffuse or focal nodules and/or consolidations (eFigs. 125.6 to 125.9). Diagnosis of CMV pneumonia requires detection of CMV by viral culture, shell vial or PCR from the lower respiratory tract, or less frequently through biopsy samples demonstrating CMV-specific staining[117]; specific viral load cutoffs for CMV pneumonia among HCT recipients have been developed.[118] Treatment with CMV-active agents has significantly decreased mortality among these high-risk patients, although CMV pneumonia remains a life-threatening complication in transplant patients.[119] Drug resistance, while uncommon, can complicate therapy among transplant recipients with CMV pneumonitis.[9,120]

Herpes simplex virus and varicella zoster virus are rare causes of viral pneumonitis,[121-123] especially with acyclovir or valacyclovir prophylaxis.[124] Emerging literature suggests that *human herpesvirus-6* (HHV-6), when detected in the lower respiratory tract, is associated with increased mortality[125] and possibly acute noninfectious lung injury (see below).[126]

Community-Acquired Respiratory Viruses

Community-acquired respiratory viruses (CARVs), such as influenza A/B, respiratory syncytial virus, parainfluenza viruses, adenoviruses, metapneumovirus, rhinoviruses, and human coronaviruses are increasingly recognized as important sources of morbidity and mortality in immunocompromised transplant populations, particularly when upper respiratory tract disease progresses to lower respiratory tract disease and acute respiratory failure. Novel CARVs such as enterovirus-D68[127] and severe acute respiratory virus coronavirus 2 (SARS-CoV-2, agent of coronavirus disease 19 [COVID-19])[128] are unexpected pathogens that have also emerged over the past few years. CARVs are also associated with the development of late-onset noninfectious lung complications (see below). Adenovirus is unique because most adenovirus pneumonias in transplant recipients are not related to recent acquisition, but reactivation from latent disease.[129,130] Transplant patients with CARVs usually present with upper respiratory infection symptoms of rhinorrhea, sore throat, cough and fever, and less commonly with hypoxemia and acute respiratory failure. Typical symptoms in the general population may be absent in transplant recipients.[131,132] In a multicenter study of transplant recipients with influenza, only two-thirds presented with fever, one-third with a sore throat, and fewer than one-half with myalgias.[132] As a result, clinicians must have a low index of suspicion for testing patients. This may be most important pre-HCT because patients with symptomatic respiratory viruses should have their transplant delayed if at all possible due to associated increased risk of posttransplant mortality.[133]

On chest imaging, viral pneumonia due to CARVs presents with diffuse or patchy bilateral ground-glass opacities, tree-in-bud opacities or consolidations (eFig. 125.10). Diagnosis has increasingly shifted to multiplex PCR panels, which allow for early and rapid identification[134]; these assays can also be used on BAL samples to identify lower respiratory tract infection. A bronchoscopic diagnosis for viral etiologies remains important, even when noninvasive evaluation of CARVs has been performed, because what is detected in the upper respiratory tract (e.g., nares, pharynx) does not always reflect findings from lower respiratory tract samples.[135] In addition, transplant patients may be more likely to have multiple viruses or other co-pathogens found on assessment of the lower respiratory tract by BAL.

CARVs, such as human rhinovirus, that are not considered common causes of viral pneumonia in immunocompetent hosts, can lead to life-threatening complications in transplant patients.[136] Progression from upper respiratory infection to lower respiratory tract infection is highly dependent on timing posttransplant and the level of immunosuppression. Lung transplant and allogeneic HCT patients are at highest risk for development of lower respiratory tract infection.[137] There are few options for treatment of CARVs, although neuraminidase inhibitors (e.g., oseltamivir) are known to be effective for influenza, and ribavirin is approved for treatment of respiratory syncytial virus. Treatment of influenza should be initiated less than 48 hours after symptom onset because this has been associated with improved outcomes in transplant patients.[138] Resistance is a concern in transplant patients who are at high risk for development of oseltamivir-resistant influenza strains during the course of therapy.[139] Patients with increasing viral loads, or those who progress despite antiviral therapy, should be evaluated for drug resistance.[140] Use of ribavirin

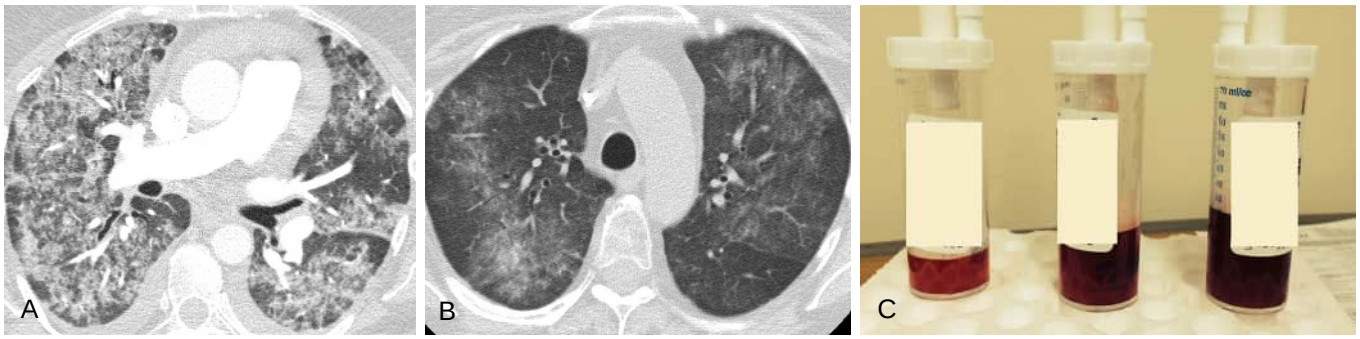

Figure 125.4 Diffuse alveolar hemorrhage after allogeneic hematopoietic cell transplantation. A 61-year-old woman with acute myelogenous leukemia received an allogeneic transplant with nonmyeloablative conditioning and total body irradiation. At day +21 after hematopoietic cell transplantation, she experienced acute shortness of breath and hemoptysis requiring mechanical ventilation; chest computed tomography showed severe diffuse pulmonary opacities (A), which were diagnosed as diffuse alveolar hemorrhage. She was treated with corticosteroids and aminocaproic acid (an antifibrinolytic) and recovered. (B) At day +120, follow-up chest computed tomography showed diffuse hazy ground-glass opacities greatest in the upper lobes. (C) Bronchoscopy revealed increasing blood return in the lavage consistent with recurrence of diffuse alveolar hemorrhage.

remains a point of debate in the transplant community due to the costs of inhaled ribavirin[141] and to the limited data supporting oral ribavirin use in these patients,[142] however, some centers use these treatments in patients with respiratory syncytial virus[143]; data supporting their use against other respiratory viruses is limited.[144]

Notably, early reports regarding the novel coronavirus SARS-CoV-2 describe a variety of presentations and clinical courses for COVID-19 in SOT recipients, including respiratory failure and critical illness.[145-148] Larger cohorts and case control studies from the early period of the global pandemic suggest that the short-term mortality rates for hospitalized patients and risk factors for death are similar to that of the general population.[148a–c] In the largest U.S. cohort to date, the level of immunosuppression was not associated with mortality.[148a] Patients with active hematologic malignancies, poor functional status, and neutropenia appear to be at higher risk for severe disease and death.[149] Among HCT recipients, data from a large transplant center in New York demonstrated that over 20% developed severe disease (defined as requiring ICU level care or goals of care changed to comfort care rather than escalation to ICU), and 70% of those with severe disease died. Optimal treatment options are under investigation. In randomized clinical trials, the novel antiviral agent remdesivir has been shown to decrease length of stay in hospitalized individuals,[150,151] and dexamethasone was shown to decrease mortality when given to critically ill patients.[151a–c] Patients with hematologic malignancies, including those undergoing transplantation, may have prolonged shedding for weeks to months following primary infection either as noted on repeat PCR testing or in some cases by culturable SARS-CoV-2.

NONINFECTOUS COMPLICATIONS OF HEMATOPOIETIC CELL TRANSPLANTATION

EARLY-ONSET COMPLICATIONS

Idiopathic Pneumonia Syndrome

Idiopathic pneumonia syndrome (IPS) is broadly defined as widespread acute alveolar injury in HCT recipients in the absence of lower respiratory tract infection, cardiac or renal dysfunction, or iatrogenic volume overload. IPS encompasses a spectrum of acute lung injuries, including *diffuse alveolar hemorrhage* (DAH), peri-engraftment syndrome, and acute fibrinous and organizing pneumonia. The classification of these entities is based on the presumed site of primary tissue injury (i.e., pulmonary parenchymal, vascular endothelial, or airway epithelial).[152] There is no pathognomic pathology because the pathology depends upon the site of injury. Diffuse alveolar injury is a common feature for the earlier, more acute forms, whereas fibrosis and alveolar granulation characterize the latter presentations (i.e., organizing pneumonia).

The clinical presentation of IPS is characterized by acute to subacute dyspnea and progressive hypoxemia associated with bilateral pulmonary opacities or ground-glass opacities on chest imaging (Fig. 125.4A–B and eFig. 125.11). This may be indistinguishable from an infectious pneumonia; hence, bronchoscopy is often necessary to exclude infectious etiologies. Indeed, anti-infective prophylaxis early posttransplant has led to reduced incidence of bacterial and CMV pneumonia.[1,60] Of the IPS subtypes, DAH is perhaps the most dramatic in presentation and associated with the highest mortality. The diagnosis is based on progressively bloodier return of BAL fluid (see Fig. 125.4C; see also Chapter 94).

The advent of less-toxic conditioning regimens prior to allografting has reduced the clinical burden of IPS.[153] A contemporary single-center analysis suggested that the incidence of IPS is approximately 3%, and risk factors include the use of total body irradiation, African ancestry, and severe pulmonary impairment prior to transplant. Mortality is high, particularly for DAH, ranging from 60–80%, and nearly 100% for those that are mechanically ventilated with concurrent renal and liver dysfunction.[153,154] Improved supportive care in the intensive care unit may be reducing early mortality, but the 1-year mortality remains high at 70%, in contrast to 30% for HCT recipients without IPS.[155]

The pathogenesis of IPS likely involves a toxic insult from the HCT conditioning regimen or an occult pulmonary infection that triggers subsequent aberrant graft-mediated immune cell injury.[156] Preclinical murine models replicating the conditions of human transplantation have

demonstrated that a cascade of donor-derived cytokines and chemokines drive the noninfectious inflammatory lung injury, which involves a cellular alveolar infiltrate and alveolar epithelial and endothelial cell injury.[157] Experimentally, it has been shown that donor-derived, not host-derived, tumor necrosis factor-α mediates the lung injury through increased major histocompatibility complex expression, neutrophil infiltration, and cell-mediated cytotoxicity.[158,159] While there is a role for alloreactive donor T cells in mediating the lung attack, direct evidence of IPS as a manifestation of acute GVHD has not been definitely established.

Although considered noninfectious, IPS may be triggered by occult infections. In light of advances in diagnostic methods such as multiplex PCR, it has been recently recognized that many cases classified as IPS had occult infections at the time of presentation. In a retrospective series of 69 patients with IPS, approximately half had pathogens detected in the BAL fluid when these newer diagnostic methods were used. The most frequent pathogens were HHV-6, human rhinovirus, CMV, and *Aspergillus* sp.[160] HHV-6, like CMV, is a human beta-herpesvirus that latently infects 95% of healthy adults and frequently reactivates during critical illness.[161] Detection of reactivated HHVs, including HHV-6, in the early posttransplant period has been associated with the subsequent development of IPS, an observation that has been experimentally replicated in murine models.[126] Moreover, the presence of HHV-6 in the BAL of patients with acute respiratory failure after HCT is associated with increased mortality.[125]

The management of IPS and DAH relies primarily on systemic corticosteroids with the addition of tumor necrosis factor-α blockade.[162,163] However, the mainstay of care for those with respiratory failure remains supportive care with lung protective mechanical ventilation.

Delayed pulmonary toxicity syndrome, characterized by acute lung injury and subsequent fibrosis after engraftment, develops in the context of autologous transplant recipients who have received bischloroethylnitrosourea (carmustine) as part of their conditioning regimen (eFig. 125.12). This was initially described in the early 1990s, and contemporary incidence is quite low. Delayed pulmonary toxicity syndrome is generally responsive to treatment with corticosteroids.[164]

Engraftment syndrome encompasses what is known to critical care physicians as peri-engraftment respiratory distress syndrome, characterized by systemic and inflammatory capillary leak in the setting of neutrophil recovery. Engraftment syndrome is best described in autologous HCT[165] and is also observed in allogeneic HCT, and is potentially associated with the onset of acute GVHD.[166,167] In children with autologous HCT, pulmonary opacities are seen in 25% or more of patients with engraftment syndrome; however, in adult recipients of myeloablative and nonmyeloablative conditioning for allogeneic transplants, the presence of pulmonary opacities with engraftment syndrome is nearly universal.[168,169] Peri-engraftment respiratory distress syndrome accounted for 2.5% of the pulmonary complications in a series of more than 1200 autologous HCT recipients at the Mayo Clinic.[15] Clinically, engraftment syndrome is characterized by fever, skin rash, and noncardiogenic pulmonary edema appearing early after transplant during neutrophil recovery. Acute respiratory failure can develop, and the pulmonary opacities are characterized by neutrophilic inflammation. Short-term prognosis is generally good with the administration of intravenous corticosteroids; however, recent studies suggest that engraftment syndrome is a marker for poor long-term survival in allogeneic HCT recipients.[167,168]

Pulmonary Alveolar Proteinosis

In the context of HCT and hematologic malignancies, pulmonary alveolar proteinosis is thought to be due to qualitative and quantitative macrophage dysfunction rather than the presence of autoantibodies against granulocyte macrophage–colony stimulating factor, a critical regulator of surfactant homeostasis, as in primary pulmonary alveolar proteinosis. Although rare, pulmonary alveolar proteinosis has been reported following autologous HCT, cord blood transplantation, and in association with respiratory viral infections.[170] Chest *computed tomography* (CT) shows diffuse or patchy ground-glass opacities that may be indistinguishable from viral pneumonia or IPS. Milky, opaque BAL fluid revealing foamy alveolar macrophages that stain positive with periodic acid–Schiff is diagnostic in the appropriate clinical setting. Treatment is directed at the underlying condition (i.e., treatment of the malignancy or infection) in addition to supportive care, including whole lung lavage (see also Chapter 98).

Pulmonary Vascular Disease

In addition to venous thromboembolic disease, rare thrombotic vascular complications can cause acute respiratory failure after HCT. Pulmonary veno-occlusive disease presents 3 to 4 months after transplant with insidious onset of fatigue and exertional dyspnea. The pathologic lesion is diffuse intimal proliferation and fibrosis of pulmonary venules.[171] Chest CT reveals ground-glass opacities, septal thickening, and mediastinal adenopathy.[172] The presence of pulmonary hypertension with normal pulmonary artery occlusion pressures should elevate suspicion of pulmonary veno-occlusive disease. Treatment with high-dose corticosteroids has been reported to be beneficial,[173] but the majority of patients succumb to progressive heart failure.[174] Pulmonary veno-occlusive disease is a clinically underrecognized cause of late morbidity, as suggested by the presence of pulmonary veno-occlusive disease in 34% of cases in an autopsy series of HCT recipients who had survived at least 1 year.[175] *Pulmonary cytolytic thrombus* is a complication specific to HCT presenting primarily in children with an onset 1 to 12 months posttransplant. Pulmonary cytolytic thrombus presents with fever, cough, respiratory distress, and chest CT findings of small peripheral nodules and diffuse opacities.[176,177] The diagnosis is made by lung biopsy, which shows vascular occlusion with entrapped leukocytes and endothelial disruption in distal pulmonary vessels adjacent to areas of infarct.[178] *Transplant-associated thrombotic microangiopathy* after HCT is caused by small-vessel endothelial injury with systemic and multiorgan manifestations. Whereas the kidneys are most commonly affected, pulmonary arteriolar involvement can lead to severe and acute pulmonary hypertension, right heart failure, and death.[179,180] It has been reported to complicate DAH after HCT.[181]

LATE-ONSET COMPLICATIONS

Given the increasing survival of HCT recipients, particularly those with allogeneic HCT, late pulmonary complications are of growing concern for survivors and their providers. The burden of late pulmonary complications is second only to infectious complications, reflected in the hospitalizations and causes of death in long-term survivors of allogeneic HCT for cancer compared with cancer patients not treated with HCT.[182] A prospective study of 200 consecutive allogeneic HCT recipients demonstrated an incidence of late-onset noninfectious pulmonary complications of 20%, confirming prior estimates from retrospective series.[183]

Bronchiolitis Obliterans Syndrome

Bronchiolitis obliterans syndrome (BOS) is the most common and well-described late noninfectious pulmonary complication, seen in 3–10% of all allogeneic transplant recipients, and 14% in those with chronic GVHD.[183-185] BOS is the clinical correlate of obliterative bronchiolitis, an end-stage pathologic entity characterized by fibrous obliteration of terminal bronchioles also seen in the context of lung transplantation, connective tissue disorders, and toxic environmental exposures.[186]

In allogeneic HCT recipients, BOS is considered a manifestation of chronic GVHD, a systemic condition in which alloreactive donor immune cells attack host tissues and promote tissue fibrosis. It is postulated that small airway epithelial injury induces alloreactive T cell–mediated inflammation and subsequent aberrant repair response leading to fibrosis.[187,188] In murine models of chronic GVHD, follicular helper T cells, donor B cell antibody production and germinal center B cells are required for the development of BOS lesions and physiologic airflow obstruction.[189] Clinical series of lung biopsies in patients who meet BOS spirometric criteria show a spectrum of pathologies, including a lymphocytic bronchiolitis, suggesting that some cases are potentially reversible with early intervention.[190]

Many factors, including conditioning regimen, donor source, and history of pneumonitis, have been implicated in the development of BOS, but only chronic GVHD has been consistently associated. There is mounting evidence that community-acquired respiratory viral infections play a role in the development of BOS.[191-194] Early subclinical lung dysfunction has been associated with BOS,[183,195] consistent with observations in lung transplantation,[196] and suggests that lung injury early posttransplant may predispose the airways to subsequent alloimmune attack.[195] However, identifying patients at risk remains a clinical challenge because respiratory viral infections and early spirometric changes are nonspecific events in many patients after allogeneic HCT.

BOS is characterized by new-onset irreversible airflow obstruction. Patients present with subacute exertional dyspnea or a cough unresponsive to antibiotics before airflow obstruction is identified by pulmonary function testing. An asymptomatic decline on routine *pulmonary infection tests* (PFTs) may alert the clinician to the diagnosis. High-resolution chest CT with inspiratory and expiratory images may show mosaic attenuation indicative of air trapping (eFig. 125.13). BOS has been described as early as 50 days and as late as 10 years posttransplant; most cases present within the first 2 years after HCT.[184,185,197,198] By the time symptoms develop, the *forced expiratory volume in 1 second* (FEV_1) is often less than 50% predicted, highlighting the importance of routine spirometric monitoring in this population.[199] Rapidly progressive airflow obstruction less than 1 year posttransplant carries a poor prognosis.[198] Contemporary series show a 2-year survival of 70–75%, which is an improvement compared with initial reports,[199,200] possibly due to increased recognition and better supportive care. The main causes of death are primary respiratory failure or lung infections.[185,199,201]

Due to the morbidity of lung biopsy in HCT recipients, the diagnosis of BOS relies on spirometric and clinical criteria. The National Institutes of Health Chronic GVHD Consensus Guidelines provide a uniform definition for BOS based primarily on spirometric criteria of FEV_1 decline and airflow obstruction and supporting evidence of small airways disease[202] (eTable 125.1). Whereas this definition provides consistency for the purposes of clinical trials, it does not reflect the full clinical spectrum of BOS. A phenotype of reduced FEV_1 with a preserved FEV_1/forced vital capacity ratio, which is well described in COPD, has also been described in BOS after HCT.[203] Moreover, early identification of disease remains a challenge with the Consensus Guidelines definition, which uses a cutoff of FEV_1 less than 75% predicted. A decline of more than 5% per year in percent predicted FEV_1 more accurately identified patients who experienced fixed airflow obstruction after HCT and was associated with increased mortality not attributable to hematologic relapse.[204]

The goal of therapy for BOS after HCT is to prevent further lung function decline, although if BOS is diagnosed and treated early, it may be possible to improve lung function. The use of an inhaled corticosteroid with a long-acting β-agonist (budesonide/formoterol) is associated with short-term improvement in FEV_1 in patients with newly diagnosed BOS.[205] The combination therapy of fluticasone, azithromycin, and montelukast, with or without prednisone, is well tolerated and associated with FEV_1 stability for most individuals.[197,206] However, the use of azithromycin in this context has been called into question in light of data associating azithromycin with hematologic relapse when given early after allogeneic HCT,[207] and an increased risk for secondary neoplasms.[201] The benefit of azithromycin has not been definitively demonstrated for BOS after HCT.[208] Secondary treatments for progressive BOS include extracorporeal photopheresis and other established immunosuppressive medications for steroid-refractory chronic GVHD.[209] Supportive care measures, including supplemental oxygen, pulmonary rehabilitation, airway clearance, and antimuscarinic bronchodilators, may help improve quality of life. Lung transplantation has been successfully performed in patients with end-stage BOS without evidence of malignancy or other end-organ complications from their allogeneic HCT.[210,211]

Restrictive Lung Dysfunction and Interstitial Lung Disease

Late-onset restrictive pulmonary dysfunction after allogeneic HCT may be due to *interstitial lung disease* (ILD),[212] as a manifestation of BOS,[213] or to truncal sclerosis from extrapulmonary chronic GVHD.[202] In some instances, the

eTable 125.1 Summary of 2014 National Institutes of Health Clinical Criteria for the Diagnosis and Staging of Chronic GVHD: Bronchiolitis Obliterans Syndrome

1. FEV_1/vital capacity <0.7 or the lower limit of normal.
2. FEV_1 <75% of predicted with ≥10% decline over <2 years and does not correct to >75% with bronchodilator.
3. Absence of infection in the respiratory tract, documented with investigations directed by clinical symptoms.
4. One of the two supporting features of BOS: (A) evidence of air trapping by expiratory CT or small airway thickening or bronchiectasis by high-resolution chest CT, or (B) evidence of air trapping by elevated residual volume or residual volume/total lung capacity ratio.
   - Only 1–3 need to be met if there is chronic GVHD in another organ.
   - Lung biopsy is required to establish chronic GVHD if BOS is the only manifestation of chronic GVHD for the purposes of enrollment on clinical trials.

BOS, bronchiolitis obliterans syndrome; CT, computed tomography; FEV_1, forced expiratory volume in 1 second; GVHD, graft-versus-host disease.

Modified from Jagasia MH, Greinix HT, Arora M, et al. National Institutes of Health Consensus Development Project on Criteria for Clinical Trials in Chronic Graft-versus-Host Disease: I. The 2014 Diagnosis and Staging Working Group report. *Biol Blood Marrow Transplant*. 2015;21:389-401, e381.

etiology for restriction is never determined. In a prospective longitudinal study of 198 allogeneic HCT recipients, restrictive lung disease not identified as ILD was responsible for 5% of the cases of late-onset lung disease.[183] Restriction, due to ILD or other causes, may develop concurrently with obliterative bronchiolitis.[214] Retrospective studies show that restrictive lung dysfunction in long-term survivors may develop in as many as 12% of adults[215]; restrictive lung dysfunction has been documented in 19–25% of children surviving at least 5 years.[216,217] Forms of ILD after HCT are diverse: histologic patterns include organizing pneumonia, nonspecific interstitial pneumonia, and lymphoid interstitial pneumonia.[212] The presence of GVHD is a common theme.[183,188,218,219] These diverse etiologies may in fact represent direct or indirect manifestations of GVHD in the respiratory system, similar to the concept of restrictive allograft syndrome in lung transplantation as a manifestation of chronic lung allograft dysfunction.[220] Restrictive lung disease may also result from late toxicity from prior chest irradiation or total body irradiation,[183,216] which is a known risk factor for acute lung injury syndromes.[155]

Organizing Pneumonia

Organizing pneumonia (OP) after HCT is considered a manifestation within the spectrum of acute lung injury in the IPS family. Because it tends to present later after transplant (after day +100), it is considered here as a late-onset ILD after HCT. The histology, as in cryptogenic OP in the general population, is characterized by a histology of patchy plugs of granulation tissue occupying distal terminal airways, alveolar ducts, and alveolar sacs; widened alveolar septa and mononuclear cell infiltration; as well as the accumulation of foamy macrophages within alveoli.[219] OP after HCT is associated with the presence of acute or chronic GVHD.[214,219,221,222] Other risk factors include donor HLA disparity, female donor-to-male recipient transplant, peripheral blood stem cell source from a related donor, and radiation as part of a myeloablative conditioning regimen.[222]

As in other settings, OP after HCT presents with cough, progressive dyspnea over days to weeks, sometimes fever, and associated hypoxemia. In a case series of 49 patients, the median time to diagnosis was 108 days after HCT, after a median symptom duration of 13 days.[219] OP misdiagnosed as infectious pneumonia or simply unrecognized may progress to acute respiratory failure. The radiographic hallmark of OP after HCT on chest CT is patchy ground-glass, linear or peribronchial opacities, often in an upper lobe distribution.[223] Given that surgical lung biopsy is uncommon, the diagnosis of OP is often made presumptively after exclusion of infectious etiologies with BAL. However, biopsy series suggest that radiographic abnormalities consistent with OP may represent a spectrum of interstitial pathologies.[212]

Treatment consists of corticosteroids. For moderate disease, it is reasonable to initiate 0.75 mg/kg/day of prednisone until there is symptomatic or radiographic improvement before initiating a slow taper over at least 4 to 6 months.[224] Anecdotally, chronic macrolide therapy has been given as an adjunctive anti-inflammatory treatment to those with refractory disease or an intolerance to prednisone.[225] Azathioprine or other immunosuppressive agents may be used in refractory disease. Overall, prognosis for OP after HCT is good because the majority of cases respond to corticosteroids. Relapse is common, particularly when the steroid taper is accelerated, which may often be necessary given the significant side effects of long-term corticosteroids.[221,226]

Figure 125.5 Chest computed tomography of patient with pleuropulmonary fibroelastosis. Apical fibrosis with traction bronchiectasis, pleural thickening, and reduced lung volumes is apparent. This patient subsequently received a lung transplant 29 years after his allogeneic bone marrow transplant. (From Bergeron A, Cheng GS. Bronchiolitis obliterans and other late pulmonary complications after allogeneic hematopoietic stem cell transplantation. *Clin Chest Med*. 2017;38:607-621 and courtesy Anne Bergeron, MD, PhD.)

Pleuropulmonary Fibroelastosis

Pleuropulmonary fibroelastosis (PPFE) is a rare entity characterized by pleural and subpleural parenchymal thickening due to elastotic fibrosis and the presence of intra-alveolar fibrosis with minimal cellular inflammation.[227] In the setting of HCT, BOS lesions are often seen along with subpleural pathology, suggesting alloimmune involvement.[214] CT findings are characterized by dense fibrosis in an apical distribution, traction bronchiectasis, pleural thickening, and volume loss (Fig. 125.5); these abnormalities may progress to include the lower lung zones.[228] In some retrospective series, PPFE identified by chest imaging is primarily responsible for restrictive lung impairment.[213] It is likely underrecognized as a complication of HCT because it can be seen late, after patients have returned to community care. In a series of 15 patients, the diagnosis of PPFE developed nearly 9 years after HCT.[229] PPFE may be the result of a cumulative series of lung insults, including total body irradiation, infectious pneumonias, and chronic GVHD.[229] Prognosis is poor because most cases progress to chronic respiratory failure. Pneumomediastinum and pneumothorax often complicate PPFE.[230,231] Lung transplantation is the only definitive therapy.[188]

NONINFECTIOUS COMPLICATIONS IN SOLID ORGAN TRANSPLANTATION

POSTOPERATIVE RESPIRATORY FAILURE

While infectious pneumonia predominates as an early complication in SOT, noninfectious complications related to the surgical procedure also impact early outcomes. Postoperative respiratory failure is a particular concern for liver transplant

recipients, who have a high rate of prolonged postoperative intubation and reintubation when mechanically ventilated for longer than 24 hours.[232] The poor medical condition of patients with end-stage liver disease, impaired respiratory muscle function from upper abdominal surgery, and volume overload leading to pulmonary edema contribute to the high incidence of acute respiratory failure.[233] Acute respiratory distress syndrome complicates 2–4% of liver transplants. Transfusion-related acute lung injury is a notable cause for respiratory failure in liver transplantation in light of the large amount of blood products that must be transfused in a patient with coagulopathy from end-stage liver disease. In addition, those with pretransplant hepatopulmonary syndrome may require prolonged postoperative ventilatory or oxygen support because the hepatopulmonary syndrome does not correct immediately after transplant,[234,235] and the mortality rate for those with severe hypoxemia is as high as 45%.[236] Patients with portopulmonary hypertension are also at increased risk for poor perioperative outcomes; many cases are not eligible for transplantation unless vasodilator therapy can bring mean pulmonary artery pressures to 35 mm because major perioperative changes in hemodynamics can result in acute right heart failure.[237]

PLEURAL EFFUSIONS

In liver transplantation, postoperative pleural effusions are the most common posttransplant pulmonary complication, ranging in incidence from 32–96%.[30] The majority are mild, right sided, and self-limited. Thoracentesis is reserved for persistent large pleural effusions or when there is a concern for infection.[30] Early postoperative pleural effusions after heart transplantation are also common.[238] In one series, the incidence of pleural effusion was 85% by 1 year posttransplant. The majority of effusions were bilateral, small, and self-limited.[234]

DIAPHRAGMATIC DYSFUNCTION

Diaphragmatic dysfunction may develop due to injury to the phrenic nerve resulting from hypothermic or mechanical damage during surgery. The incidence of diaphragmatic dysfunction after heart or heart-lung allograft surgery has been reported to be 12–43%.[239-241] This is also common after liver transplantation, attributed to right phrenic nerve crush injury at the time of suprahepatic vena cava clamping.[242]

METASTATIC PULMONARY CALCIFICATION

Metastatic pulmonary calcification (or pulmonary calcinosis) is a well-known complication of chronic renal failure characterized by deposition of calcium salts in the alveolar epithelial basement membrane. This has been reported as a rare complication in renal transplant recipients without apparent abnormalities of calcium or phosphate.[243] The lesions present as nodular opacities 2 to 12 mm in diameter that may be unilateral or diffuse with an upper lobe distribution (eFig. 125.14). Patients are often asymptomatic, but may develop dyspnea, and show a restrictive pattern as well as abnormal diffusing capacity on pulmonary function testing.[244] Progression to respiratory failure has been reported.[243]

DRUG-INDUCED PNEUMONITIS

Many agents used to maintain allograft function have been implicated in lung disease after transplantation, particularly immunosuppressive medications common to both HCT and SOT. The most common agent implicated in drug-induced pneumonitis for transplant recipients is sirolimus, an inhibitor of the *mammalian target of rapamycin* (mTOR) regulator of cell metabolism. Toxicity from sirolimus is most common in kidney transplant recipients, in which the incidence is 11%.[245,246] This agent is used alone or together with other agents to prevent graft rejection in renal transplant.[247] (The calcineurin inhibitor cyclosporine has also been associated with capillary leak and acute respiratory distress syndrome.[248-251]) Tacrolimus has been associated with cryptogenic OP.[252] Sirolimus-induced pneumonitis is commonly found in renal transplant patients, with the onset usually within 6 months, although it can develop as late as 1 year after initiation of the drug.[253] Patients present with cough, fatigue, fever, dyspnea and, on occasion, hemoptysis. Hypoxemia and crackles are present in half the cases, and chest CT findings usually include patchy bilateral peripheral consolidations and or reticular and ground-glass opacities.[245] BAL can exclude infection; lavage fluid reveals a lymphocytic or eosinophilic alveolitis. Histologic patterns of injury include OP with lymphocytic interstitial pneumonitis, pulmonary hemorrhage, diffuse alveolar damage and, rarely, pulmonary alveolar proteinosis.[245,246,253,254] The pulmonary toxicity from mTOR inhibitors is considered a class effect because the related drug, everolimus, has been reported to cause pneumonitis in 4.3% of cardiac transplant recipients.[247] As with any drug-induced lung injury, the mainstay of treatment is discontinuation of the drug, with or without a short course of corticosteroids at 1 mg/kg/day.[245] However, the need for continued immunosuppression to prevent graft rejection in SOT recipients requires that the offending agent be replaced with another appropriate agent.

MALIGNANCY AFTER TRANSPLANTATION

Transplant recipients are at high risk for developing malignancies, owing to prolonged immunosuppression, increasing age of the transplant population, and the longer survival after successful allografting.[182,255,256] In HCT, malignant neoplasms in long-term survivors contribute to excess mortality, particularly in individuals who underwent transplantation as children.[257-260] In SOT, lung transplant recipients have the highest cumulative incidence of malignancies, followed by heart, kidney, and liver recipients.[256] Mortality after SOT due to cancer is higher than that of the general population.[261] Posttransplant malignancies affecting the lung include lymphoma, bronchogenic carcinoma, and Kaposi sarcoma.[259,260,262]

Posttransplant lymphoproliferative disorder (PTLD) is a heterogenous group of disorders characterized by abnormal clonal proliferation of lymphoid cells developing in association with immunosuppression for maintenance of the allograft. Hodgkin lymphoma and diffuse large B cell lymphomas that develop in the posttransplant period may be classified as PTLD. Oncogenic viral activation with *Epstein-Barr virus* (EBV) is a key factor in 50–80% of cases,[263] and

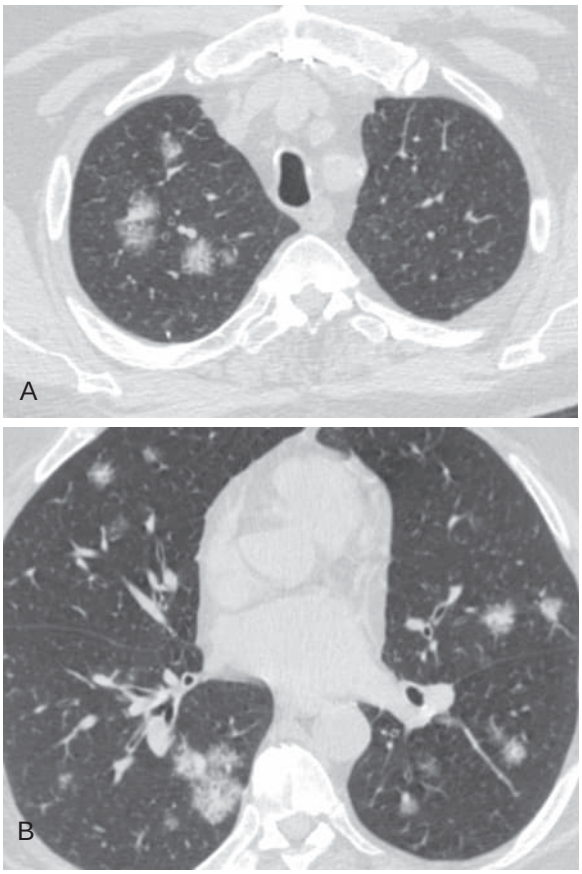

Figure 125.6 Posttransplant lymphoproliferative disorder after solid organ transplantation. A 60-year-old man presented with progressive nodular opacities 9 years after a heart transplant while on tacrolimus and mycophenylate mofetil. Numerous bilateral irregular ground-glass nodular opacities progressed in size over 2 months. (A–B) Different cuts of the same chest computed tomography scan. Infectious workup including bronchosocopy with bronchoalveolar lavage was negative. Lung biopsy revealed a diffuse large B cell lymphoma that was Epstein-Barr virus positive by in situ hybridization, consistent with posttransplant lymphoproliferative disorder. (Courtesy Cynthia Fisher, MD.)

the risk for PTLD is greatest for patients who are EBV seronegative receiving an allograft from an EBV-seropositive donor. PTLD can also arise that is negative for EBV by RNA detection on histology. For allogeneic HCT, most cases of PTLD happen within the first year while, in SOT, the cumulative incidence continues to increase.[264] The median time to presentation of EBV-negative PTLD is 109 months after renal transplantation.[265] In allogeneic HCT, the incidence of PTLD is highest in recipients of cord blood allografts (1.6%) and lowest in match-related donor grafts (0.40%).[266] The cumulative incidence of PTLD is 2.1% at 10 years in kidney transplant recipients[267] and is higher for heart, liver, and lung transplant recipients.[263,268]

PTLD arises in multiple organs, including the lymph nodes (eFig. 125.15), central nervous system, liver, gastrointestinal tract, and the lung.[263] In the lung, PTLD presents as multiple pulmonary nodules that must be distinguished from opportunistic infection or other noninfectious complications (Fig. 125.6, eFig. 125.16). Treatment strategies include reduction of immunosuppression, which carries a risk of allograft rejection. Anti–B cell therapies such as rituximab and standard chemotherapy regimens for lymphoma are used. Overall prognosis is currently poor.[264,266]

ACKNOWLEDGMENT

We acknowledge David K. Madtes, who first authored this chapter in the previous edition.

Key Points

- Pulmonary complications are common and significantly impact the clinical course for hematopoietic cell transplant and solid organ transplant recipients.
- Infectious lung complications present in relation to the immune status of the transplant recipients and prophylactic strategies.
- Infectious etiologies must be distinguished from noninfectious etiologies, often with the use of bronchoscopy, for accurate diagnosis and treatment.
- Early lung injury syndromes in hematopoietic cell recipients are rare but still have high mortality.
- Most late-onset noninfectious pulmonary complications in recipients of hematopoietic cell transplant, including bronchiolitis obliterans syndrome, are related to chronic graft-versus-host disease.
- Noninfectious pulmonary complications in solid organ transplant recipients often relate to early postoperative complications.

KEY POINTS

INTRODUCTION

This chapter is devoted to the pulmonary complications of abdominal diseases, including diseases of the retroperitoneal organs, the kidneys. The objective in each section is the same: to update the most relevant clinical, pathophysiologic, and therapeutic aspects of the principal abdominal diseases to assist the clinician in diagnosing and managing their sometimes complex and challenging pulmonary complications.

GASTROESOPHAGEAL AND GASTROINTESTINAL DISORDERS

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) is defined as "a condition which develops when the reflux of stomach contents causes troublesome symptoms and/or complications."[1] It affects up to 28% of the population in the United States.[2] In addition to the classic symptoms of heartburn and acid regurgitation, extraesophageal manifestations of GERD include chronic cough, asthma, and chronic laryngitis. Furthermore, associations between GERD and idiopathic pulmonary fibrosis, as well as post–lung transplant outcomes have been identified.

Pathophysiology

Two general mechanisms have been proposed to explain the pathophysiology of respiratory manifestations of GERD.[3] The "reflux" theory proposes that direct contact of gastric contents with the bronchial and laryngeal tissue is responsible for causing symptoms. Supporting this mechanism, Jack et al. measured tracheal and esophageal pH levels in asthmatics with GERD and found that episodes of reflux followed by a decline in intratracheal pH were associated with a marked reduction in peak expiratory flow rate.[4]

The "reflex" theory, in contrast, proposes that reflux into the distal esophagus stimulates the vagus nerve resulting in cough or bronchoconstriction. The esophagus and tracheobronchial tree are both derived from the embryologic foregut and thus share common innervation allowing for this "esophagobronchial" reflex. This reflex mechanism can be reproduced with the infusion of hydrochloric acid into the esophagus of some[5] but not all[6] patients with asthma.

The relationship between GERD and respiratory disorders is further complicated by the fact that physiologic alterations associated with asthma, cough, and their treatments may themselves promote GERD. Bronchoconstriction may result in a drop in pleural pressures and subsequent increase in the transdiaphragmatic pressure gradient, thus facilitating reflux.[7] Obstructive sleep apnea may act by the same mechanism to increase nocturnal reflux.[8] In addition, hyperinflation and air trapping may result in impaired diaphragmatic function, which is believed to impair the antireflux barrier.[9,10] Finally, bronchodilator therapies, such as theophylline and β-agonists, may further contribute by decreasing lower esophageal sphincter tone.[11,12]

Asthma

Estimates of the prevalence of GERD among asthmatics range from 30–80%, depending on the population studied and the diagnostic testing used.[13–15] In part due to the high prevalence of both diseases, establishing a causal

relationship between GERD and asthma symptoms and identifying patients likely to respond to antireflux therapy remains challenging. In a recent meta-analysis of randomized controlled trials of acid suppressive therapy in adults with asthma, *proton-pump inhibitor* (PPI) therapy was associated with a statistically significant, but unlikely to be clinically significant, improvement in morning peak flow compared to placebo (mean difference 8.7 L/min, 95% CI 2.4–15.0).[16] Subgroup analysis suggested a trend towards greater improvement in morning peak flow in studies that specifically enrolled patients with GERD (mean difference 16.9 L/min, 95% CI 0.9–33.0). PPI therapy was not associated with improvement in secondary outcomes such as *forced expiratory volume in 1 second* (FEV_1) or Asthma Quality of Life Questionnaire Score. Overall, current evidence does not support the use of empiric PPI therapy in patients with asthma without symptoms of GERD. In patients with typical esophageal symptoms such as heartburn, acid regurgitation, or nocturnal asthma symptoms, treatment for GERD with lifestyle modifications and PPI therapy is recommended and should be managed per society guidelines.[17] The role of surgery in patients with GERD-associated asthma remains uncertain. While data from observational studies suggest that surgery may improve asthma control, there is little evidence that it improves pulmonary function.[18]

Chronic Cough

In patients referred to specialty cough clinics, GERD is identified as a contributing factor in up to 41% of cases.[19,20] The relationship between GERD and chronic cough is supported by evidence that instillation of acid into the distal esophagus in patients with chronic cough increases both the frequency of cough and cough reflex sensitivity to inhaled capsaicin.[21,22] As with asthma, the benefit of antireflux therapy is unclear. Overall, evidence does not support the use of empiric acid-suppressive therapy in patients with nonspecific chronic cough without symptoms of reflux.[23] In patients with chronic cough and symptoms of reflux, patients with evidence of pathologic acid exposure (i.e., abnormal pH monitoring) may experience therapeutic benefit with acid-suppressive therapy.[19] Furthermore, combining acid-suppressive therapy with lifestyle modifications and/or weight loss may be more effective than acid-suppressive therapy alone.[24]

Other Lung Diseases

Although GERD and microaspiration have been proposed as risk factors for the development and progression of *idiopathic pulmonary fibrosis* (IPF), causal data supporting pathogenesis are lacking.[25] In a recent meta-analysis of 18 case-control studies, Bédard Méthot et al. concluded that, once smoking is accounted for, there is no association between GERD and IPF.[26] Along these lines, two meta-analyses and a pooled analysis of three large clinical trials of pirfenidone in IPF did not show a consistent improvement in IPF outcomes with antireflux therapy.[27–29] Nevertheless, consensus guidelines conditionally recommend the use of antireflux therapy in patients with IPF despite the paucity of data supporting this practice.[30]

Enthusiasm related to the use of antireflux therapies in patients with IPF and other causes of end-stage lung disease is in part derived from retrospective studies of patients referred for lung transplant.[31] In lung transplant recipients, pretransplant GERD has been associated with early allograft dysfunction and decreased early posttransplant survival.[32] Surgical treatment of GERD has also been shown to reduce the incidence of posttransplant bronchiolitis obliterans syndrome and delay its onset and progression.[33–35] Although data are limited, GERD may be particularly important in the subset of patients with scleroderma-associated interstitial lung disease given the high prevalence of concomitant gastroesophageal manifestations in this disorder.[31]

Diagnosis and Treatment

If the clinical history is typical of GERD and a trial of PPI therapy is successful, no further diagnostic workup may be required. For many patients, however, confirming a diagnosis of GERD may be necessary. Unfortunately, neither the presence of symptoms, nor the response to an empiric trial of antireflux therapy is sensitive or specific enough to diagnose GERD as a cause of respiratory symptoms.[3] The measurement of esophageal acid exposure with ambulatory pH monitoring remains the gold standard for diagnosing GERD. Traditionally, this was achieved with a catheter placed transnasally and worn for 24 hours.[36] More recently, the introduction of a catheter-free wireless pH monitoring device (pH Bravo) attached to the esophageal mucosa during upper endoscopy has gained enthusiasm because it is better tolerated and allows for longer periods of monitoring (typically 2 to 4 days).[37] Multichannel intraluminal impedance (i.e., the electrical impedance of liquid boluses between electrodes on a probe) may also be measured together with catheter-based pH assessment to allow for the detection of nonacidic reflux.[38] The utility of other imaging and endoscopic studies is limited. While upper endoscopy may reveal evidence of tissue damage such as esophagitis or Barrett's esophagus, such abnormalities are uncommon.[39] In contrast, abnormalities on fiberoptic laryngoscopy may be seen in over 80% of normal subjects, thereby limiting its utility for diagnosing GERD.[40] While lipid-laden macrophages found in bronchoalveolar lavage fluid may support the diagnosis, routine measurement is not recommended.[41]

The optimal management of patients with respiratory symptoms thought to be exacerbated by GERD remains unclear. In patients with symptomatic GERD, weight loss and elevation of the head of the bed have been shown to decrease esophageal acid exposure and improve symptoms.[42] Other lifestyle modifications, such as dietary restrictions, are not clearly effective. The majority of studies evaluating the efficacy of acid-suppressive therapy in patients with respiratory symptoms have investigated the use of twice-daily PPI.[24] This is generally the recommended practice for patients for whom the decision has been made to institute acid-suppressive therapy. The benefit of antireflux surgery in patients with respiratory disorders also remains unclear, with limited data supporting its use in patients being considered for lung transplantion.[33–35]

INFLAMMATORY BOWEL DISEASE

Extraintestinal complications of *inflammatory bowel disease* (IBD) are common and have been described in virtually all organ systems. Respiratory manifestations of IBD were first

recognized in the 1970s by Kraft et al., who described six adult patients with IBD who developed unexplained chronic bronchitis with or without bronchiectasis.[43] Although the true prevalence is unknown, respiratory system involvement is increasingly appreciated. While the pathogenesis is not completely understood, it is hypothesized that the association between IBD and pulmonary disease may be related to the shared embryonic origin of the respiratory and colonic epithelium from the primitive foregut.[44] Unlike most extraintestinal manifestations of IBD, which are more common in Crohn disease, pulmonary complications are more commonly seen in ulcerative colitis.[45] While respiratory symptoms typically develop after the diagnosis of IBD has been made, they occasionally precede the diagnosis of IBD, and their severity does not necessarily correlate with bowel disease activity.

Pulmonary Function Disturbances

A spectrum of pulmonary function test abnormalities has been reported in asymptomatic patients with IBD.[46] The most consistent finding is a mild reduction in *diffusing capacity for carbon monoxide* (DL_{CO}).[47–52] While most asymptomatic patients will have normal spirometry, some studies show a small absolute reduction in FEV_1 in IBD patients compared to controls.[52] Others have reported a small but significant increase in residual volume/total lung capacity ratio[48] and evidence of bronchial hyperresponsiveness.[53,54] These findings are concordant with evidence that many asymptomatic IBD patients will have subtle abnormalities on high-resolution *computed tomography* (CT) scans including hyperinflation, air trapping, and bronchiectasis.[48,55]

Intrinsic Pulmonary Complications

A wide array of intrinsic (noniatrogenic) respiratory manifestations of IBD have been identified, ranging from asymptomatic pulmonary function abnormalities to progressive interstitial lung disease (Table 126.1). Most symptomatic intrinsic pulmonary complications of IBD involve inflammation of the airways—anywhere from the larynx to the bronchioles—and may take the form of epiglottitis, tracheal stenosis, bronchiectasis, chronic bronchitis, or bronchiolitis. Large airway disease, particularly bronchiectasis, is the most common.[46,56,57] Patients classically present with cough and increased sputum production. Bronchoscopic examination may show mucosal inflammation and distortion of the airway lumen. Biopsy specimens may reveal mucosal ulceration, thickening of the basement membrane, and infiltration by neutrophils and plasma cells.[57,58] Bronchoalveolar lavage frequently shows a lymphocytosis.[59,60] Rarely, the inflammatory process in the trachea or subglottic space can result in significant upper airway obstruction requiring interventional bronchoscopic or surgical airway management.[46,61]

In addition to airway pathology, there is growing evidence that patients with IBD are also more likely to have other immune-mediated respiratory disorders such as asthma and allergies. A large cohort study of 8072 patients with IBD from the University of Manitoba registry demonstrated an increased likelihood of asthma in patients with IBD compared to matched controls.[62] Smaller studies have shown similar findings for allergic disease.[63] Furthermore, patients with IBD and concomitant asthma or allergies may suffer higher symptom burden and have a more severe disease course.[64,65]

Table 126.1 Noniatrogenic Respiratory Involvement in Inflammatory Bowel Disease

AIRWAY DISEASE
Epiglottic-subglottic stenosis
Tracheobronchitis
Chronic bronchitis
Chronic bronchial suppuration
Bronchiectasis
Bronchiolitis
Bronchiolitis obliterans
Diffuse panbronchiolitis
PARENCHYMAL LUNG DISEASE
Cryptogenic organizing pneumonia
Sarcoidosis
Eosinophilic pneumonia
Interstitial lung disease
Pulmonary fibrosis
Nodules
Chronic pneumonia (esophagobronchial or colobronchial fistula)
SEROSITIS
Pleural effusion
Pleuropericarditis
PULMONARY VASCULAR DISEASES
Pulmonary vasculitis
Pulmonary embolism
Chronic thromboembolic pulmonary hypertension

While less common than airway pathology, parenchymal lung disease is also associated with IBD. The majority of such cases are seen in patients with ulcerative colitis.[46] A wide spectrum of interstitial lung disease pathology has been described including cryptogenic organizing pneumonia, nonspecific interstitial pneumonia, and eosinophilic pneumonia (see Table 126.1). Of these, cryptogenic organizing pneumonia is the most common.[46] Necrobiotic pulmonary nodules may also be seen and must be differentiated from malignancy and infection.[66,67] Finally, associations between IBD and both sarcoidosis and $alpha_1$-antitrypsin deficiency have also been suggested.[46,58,68]

Lastly, growing evidence suggests that patients with IBD have an approximately threefold risk of *venous thromboembolism* (VTE) including both deep vein thrombosis and pulmonary embolism.[69,70] The risk of VTE is higher in individuals experiencing a flare of their IBD, particularly in those requiring hospitalization.[71] This risk is further increased in patients requiring systemic corticosteroids.[72] For this reason, consensus guidelines support the use of anticoagulant VTE prophylaxis in hospitalized patients with IBD who are not experiencing active bleeding.[73]

Iatrogenic Pulmonary Complications

In patients with IBD presenting with respiratory symptoms, iatrogenic complications are far more likely than

noniatrogenic causes and must be excluded. Many agents used to treat IBD are associated with direct pulmonary toxicity. The 5-aminosalicylic acid compounds mesalamine and sulfasalazine are associated with eosinophilic pneumonia, eosinophilic pleural effusions, and interstitial pneumonitis.[74] Methotrexate is well known to cause adverse effects in the lungs including potentially lethal pneumonitis. The anti–*tumor necrosis factor* (anti-TNF) biologic agents such as infliximab, adalimumab, and certolizumab have rarely been associated with acute lung injury as well as with sarcoidosis-like granulomatous disease.[75–78] If recognized early, such pulmonary toxicity often improves with removal of the offending agent and in some cases treatment with systemic corticosteroids (see Chapter 99).

In addition to drug-induced pulmonary toxicity, most agents used to treat moderate to severe IBD result in immunosuppression. Systemic corticosteroids, methotrexate, 6-mercaptopurine, azathioprine, and the anti-TNF agents are all associated with increased risk for opportunistic infections including *Pneumocystis jirovecii*, *Mycobacterium tuberculosis*, and endemic fungal infections.[74] A strong index of suspicion for opportunistic infection should be maintained for any patient with IBD on immunosuppressive agents presenting with pulmonary symptoms and abnormal chest imaging.

HEPATIC DISEASES

Pulmonary complications of advanced liver disease are common and contribute substantially to morbidity and mortality. The most concerning, hepatopulmonary syndrome and portopulmonary hypertension, affect the pulmonary vasculature. In addition, a handful of systemic diseases can affect both the lungs and the liver, and these are discussed below.

PLEURAL EFFUSION

Hepatic hydrothorax is a potentially debilitating complication of advanced liver disease that affects approximately 5–10% of patients with cirrhosis (see Chapter 108).[79,80] Such effusions develop in the absence of coexisting cardiopulmonary disease and are attributed to small diaphragmatic defects that allow ascitic fluid to pass from the abdomen into the pleural space.[81,82] Unless complicated by infection, nearly all effusions are transudative.[83] The majority (85%) are unilateral right-sided effusions, although left-sided and bilateral effusions can be seen.[80] While most patients also have ascites, hepatic hydrothorax may exist in the absence of detectable ascites, presumably because the rate of ascites production is low enough that all the ascites moves into the chest as it is produced.[84] In contrast to ascites, which may result in only mild symptoms despite large amounts of fluid accumulation, most patients with hepatic hydrothorax will be symptomatic with dyspnea and/or cough.[85]

The clinical management of hepatic hydrothorax is challenging. While some patients experience resolution of the effusion with sodium restriction and diuretic therapy, many will have refractory effusions requiring additional treatment.[80] Repeated thoracentesis often results in only transient symptom palliation with cumulative risk of complications inherent to repeated procedures.[86] Conventional thoracostomy tube drainage is not recommended given an unacceptably high risk of complications including substantial protein and electrolyte loss, infection, and renal failure.[87,88] *Transjugular intrahepatic portosystemic shunting* (TIPS) reduces portal hypertension and, in turn, reduces the volume of both ascites and pleural fluid. Initial response rates to TIPS may be as high as 70–80%, but long-term complications including shunt occlusion, worsening liver function, and hepatic encephalopathy limit its applicability.[80,89] In patients with refractory effusions who are not candidates for TIPS, video-assisted thoracoscopic surgery to repair diaphragmatic defects and/or induce pleurodesis may be considered.[90] One interesting approach is the use of indwelling pleural catheters, which at this point can best be considered as a bridge to liver transplantation or for palliation.[91,92]

PULMONARY FUNCTION DISTURBANCES

A wide variety of gas exchange abnormalities can be seen in patients with advanced liver disease. The most common finding on pulmonary function testing is a reduced D_{LCO}.[93] Obstructive physiology is relatively uncommon and, when present, is associated with a smoking history.[93–95] The coexistence of massive ascites can result in restrictive physiology as well as a reduction in D_{LCO}, which both may improve with therapeutic paracentesis or diuresis.[96] On arterial blood gas analysis, there is a tendency towards hyperventilation and hypocapnia (reduced arterial *partial pressure of carbon dioxide* [P_{CO_2}]). Several mechanisms for this respiratory alkalosis have been proposed. First, hyperammonemia and hepatic encephalopathy may induce hyperventilation.[97] Second, increased circulating levels of estradiol and progesterone may directly stimulate ventilation via activation of receptors in the central nervous system.[98] Third, ascites, hepatic hydrothorax, hepatopulmonary syndrome, and portopulmonary hypertension may all result in dyspnea with compensatory hyperventilation.[99] Although overt hypoxemia is uncommon, patients with cirrhosis will also often have lower alveolar *partial pressure of oxygen* (P_{O_2}) and a higher *alveolar-arterial* P_{O_2} *difference* [(A–a)P_{O_2}] compared to matched controls.[100]

HEPATOPULMONARY SYNDROME

Definition and Diagnosis

Hepatopulmonary syndrome (HPS) is a pulmonary vascular complication of liver disease characterized by pulmonary precapillary and capillary vasodilation and abnormal gas exchange. According to the European Respiratory Society Task Force on pulmonary-hepatic vascular disorders and the International Liver Transplantation Society, HPS is defined by the clinical triad of (1) *intrapulmonary vasodilation* (IPVD), (2) abnormal arterial oxygenation (defined as an (A–a)P_{O_2} ≥15 mm Hg or >20 mm Hg if age >64 years) in the absence of an alternative cause of hypoxemia, and (3) advanced liver disease.[101–104]

Pathologic features of HPS include pronounced dilation of precapillary and capillary peripheral branches of

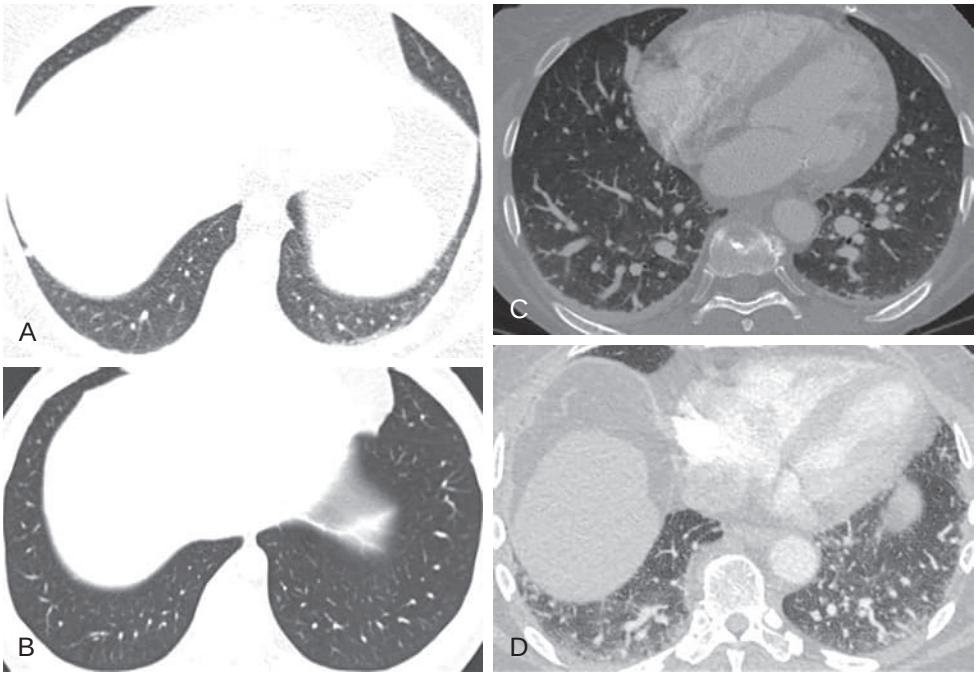

Figure 126.1 The normal appearance of peripheral pulmonary arteries in the lung bases versus the dilated peripheral pulmonary arteries in hepatopulmonary syndrome. (A–B) Unenhanced chest *computed tomography* (CT) displayed in lung windows shows the normal appearance of peripheral pulmonary arteries in the lung bases. (C–D) Enhanced CT through the lung bases in two patients with hepatopulmonary syndrome show dilated peripheral pulmonary arteries. (Courtesy Michael B. Gotway, MD.)

The demonstration of microbubbles in the left cardiac chambers is highly suggestive of the presence of intrapulmonary vascular dilations, or, alternatively, of anatomic arteriovenous malformations. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

the pulmonary vessels, a finding that can be appreciated at chest CT (Fig. 126.1), but the etiology of which remains unclear (see "Pathogenesis" section later). Pulmonary capillaries can be dilated up to 100 μm in diameter (normal capillary diameter 8–15 μm) (eFigs. 126.1 and 126.2). In clinical practice, IPVD is detected with either *contrast-enhanced transthoracic echocardiography* (CE-TTE) or technetium-labeled macroaggregated albumin lung perfusion scanning. CE-TTE is considered the gold standard and is more sensitive than lung perfusion scanning for detection of IPVD.[101] With CE-TTE, agitated saline microbubbles are injected into a peripheral vein. Normally, the microbubbles are trapped in the small capillaries of the pulmonary circulation. In the setting of IPVD, however, microbubbles pass through the enlarged pulmonary capillaries and are subsequently visualized in the left heart, typically within 3 to 6 beats after opacification of the right-sided chambers (Fig. 126.2) (Video 88.1).[103] CE-TTE can also distinguish intrapulmonary from intracardiac shunting, in which microbubbles appear in the left heart almost immediately (within 1 to 2 beats) after opacification of the right-sided heart chambers. With lung perfusion scanning, demonstration of technetium-99m-macroaggregated albumin activity over extrapulmonary organs (e.g., liver, spleen, kidneys, and brain) also indicates the presence of right-to-left shunting. Although macroaggregated albumin lung perfusion scanning cannot differentiate intracardiac from intrapulmonary shunting, it can quantify shunt severity by estimating the percentage uptake of macroaggregated albumin in the brain (normal <6%) and can be helpful to determine

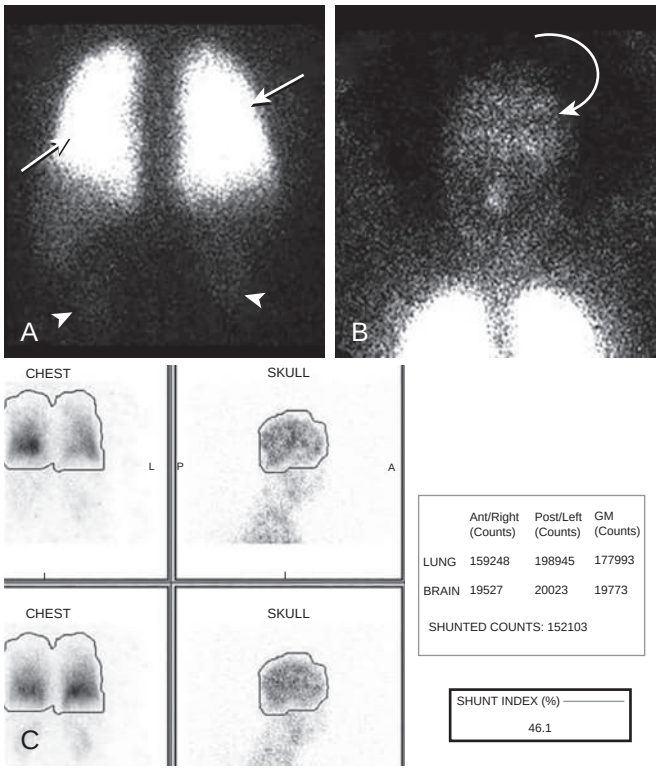

Figure 126.3 Hepatopulmonary syndrome with systemic shunt: ventilation-perfusion scintigraphy. (A) Technetium-99m–labeled albumin macro-aggregates show homogeneous tracer distribution within the lungs (*arrows*) but activity is present within the kidneys (*arrowheads*) and brain (B, *curved arrow*). The brain activity is used to calculate systemic shunting. (C) The calculated shunt index was 46.1% (*box*). (Courtesy Michael B. Gotway, MD.)

the primary cause for hypoxemia in a patient with HPS and concomitant lung disease (Fig. 126.3).[103,105]

The (A–a)Po_2, rather than the arterial Po_2, is used to define HPS because it is more sensitive for detection of abnormal arterial oxygenation. This is particularly true in patients with advanced liver disease who typically hyperventilate, resulting in a decrease in alveolar Pco_2 and an elevation in arterial Po_2 without a change in the (A–a)Po_2.[102] Pulse oximetry is insensitive for detecting HPS, so arterial blood gas testing is needed.[106] HPS severity is classified as mild, moderate, severe, or very severe, depending on the degree of hypoxemia (Table 126.2). Abnormal gas exchange in HPS can be attributed to three distinct mechanisms: *ventilation-perfusion* (V/Q) *mismatch*, *intrapulmonary shunting*, and *diffusion limitation*. *V/Q mismatch* is the predominant mechanism of hypoxemia in most patients and arises in HPS when there is increased perfusion relative to ventilation. Along these lines, most patients with HPS increase their arterial Po_2 in response to increases in inspired oxygen, as expected with V/Q mismatch. In some patients, *intrapulmonary shunting* via dilated intrapulmonary vessels and pulmonary and pleural-based arteriovenous malformations can develop, resulting in worse hypoxemia and a blunted response to supplemental oxygen.[103,107] A *diffusion limitation* has been postulated to be due to a "diffusion-perfusion defect" for oxygen in dilated pulmonary capillaries (Fig. 126.4). The hypothesis is that pulmonary vascular dilation

Table 126.2 Grading of Severity of Hepatopulmonary Syndrome*

Stage	Alveolar-Arterial Po_2 Difference	Arterial Partial Pressure of Oxygen
Mild	≥15 mm Hg or >20 mm Hg if age >64 yr	≥80 mm Hg
Moderate		<80 to ≥60 mm Hg
Severe		<60 to ≥50 mm Hg
Very severe		<50 mm Hg

*All with positive contrast-enhanced echocardiography, breathing room air at rest and at sea level.

causes inadequate diffusion of oxygen to the center of the enlarged capillary. Moreover, the coexistence of a hyperkinetic state, as is often seen in cirrhosis, results in a shorter transit time of red blood cells, which exaggerates this diffusion limitation.[108] Hypoxemia in HPS can thus be attributed to a number of factors. (See also Chapter 44.)

Epidemiology

HPS affects 5–32% of patients with advanced liver disease.[101,103] IPVD, as diagnosed by an abnormal CE-TTE, is present in 20–50% of patients with chronic liver disease,[109,110] but only half of patients with IPVD also have abnormal gas exchange and thus meet diagnostic criteria for HPS. Patients with a positive CE-TTE without coexisting gas-exchange disturbances are considered to have a *forme fruste* of HPS whose natural history is not yet known. Compared to patients with a normal CE-TTE, these patients have worse liver disease severity and an increased prevalence of autoimmune liver disease, but do not seem to have any evidence of clinical or functional impairment.[110–112] Although HPS most commonly develops in the setting of cirrhosis and portal hypertension, it can also develop in acute or chronic hepatitis and acute liver failure. There is no association between the presence or severity of HPS and age, sex, or the etiology or severity of the underlying liver disease.[109,113]

Pathogenesis

The precise mechanism underlying HPS pathogenesis remains uncertain despite numerous investigations. Whether the mechanism of IPVD and hypoxemia is related to insufficient production or metabolism of one or more circulating vasoactive substances by the injured liver or to altered clearance of putative vasodilator molecules produced by endothelial cells[114] remains unknown.

Nitric oxide (NO), a ubiquitous vasodilator considered to be a "fine-tuner" of vascular tone, is presumed to be a pivotal signaling molecule of importance in the pathobiology of HPS.[103,115] Both a constitutive isoform of *NO synthase* (NOS), expressed in endothelial cells (eNOS, or type III NOS),[116] and the *inducible NOS* (iNOS, or type II NOS), expressed in target tissues such as bronchial epithelial cells after exposure to proinflammatory cytokines,[117] have been implicated in experimental models of HPS. Increased levels of exhaled NO have also been observed in patients with HPS.[118] Interventions designed to reduce NO production, however, have not been effective in treating HPS to date.[119–121]

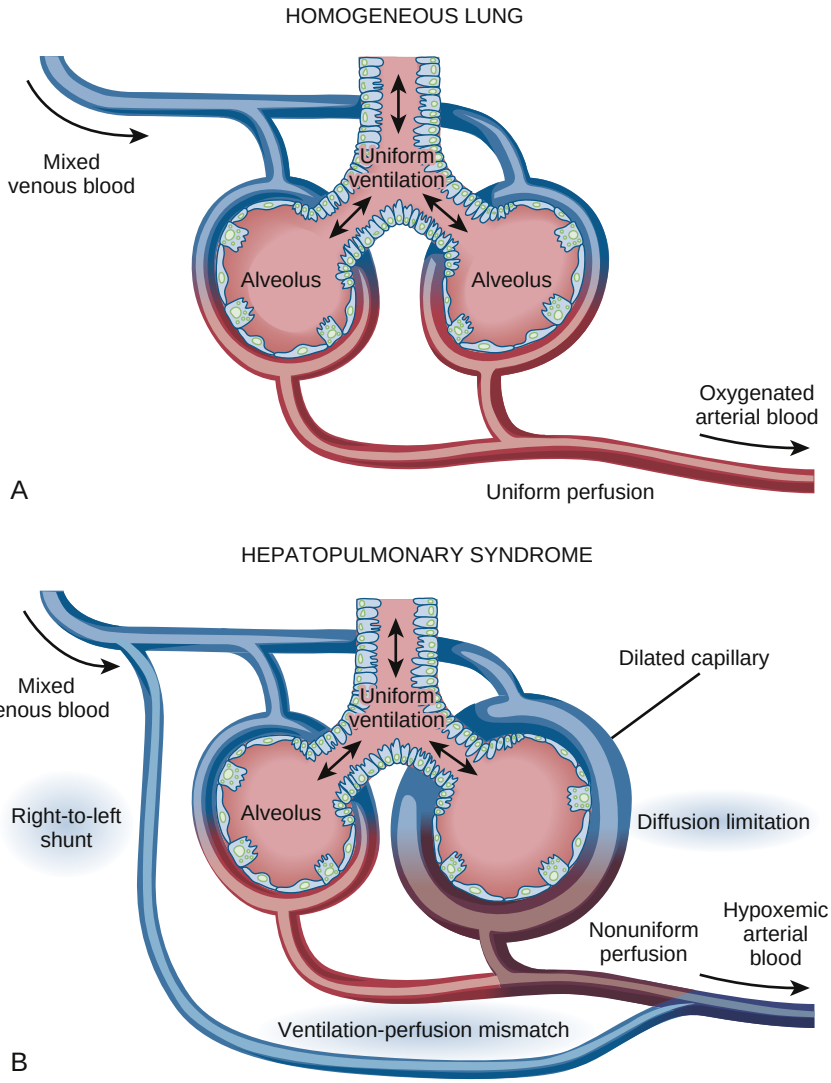

Figure 126.4 Mechanisms of arterial hypoxemia in hepatopulmonary syndrome in a two-compartment gas exchange model. (A) In the homogeneous lung of a healthy individual, with uniform alveolar ventilation and pulmonary blood flow, the capillary ranges between 8 and 15 μm in diameter and oxygen diffuses properly into the capillary while ventilation-perfusion is well balanced. (B) In hepatopulmonary syndrome, where many capillaries are dilated and blood flow is nonuniform, alveolar ventilation-to-pulmonary perfusion mismatch emerges as the predominant mechanism at any clinical stage, either with or without the presence of intrapulmonary shunt and coexistent with oxygen diffusion limitation into the center of the dilated capillaries in the most advanced stages.

Experimental studies in HPS have suggested that endothelin-1, TNF-α, monocytes, placental-derived growth factor, and increased angiogenesis play important roles in HPS disease pathogenesis.[103,122–124] Polymorphisms in genes related to the regulation of angiogenesis are associated with an increased risk of HPS, highlighting the importance of angiogenesis in disease pathogenesis.[125] Carboxyhemoglobin, a known vasodilator and breakdown product of hemoglobin, has also been found to be elevated and to correlate with abnormal blood gas parameters in HPS, suggesting a possible contributory role.[126]

Clinical Manifestations

Clinical manifestations of HPS include dyspnea, platypnea (increased dyspnea in the upright position), hypoxemia, orthodeoxia (i.e., arterial hypoxemia that worsens by at least 5% or 4 mm Hg when the patient is upright vs. recumbent), cyanosis, clubbing, and spider angiomata. Additional nonspecific features of HPS include a decreased D_{LCO} on pulmonary function testing and peripheral pulmonary vasodilation on chest CT scan.[103] Although pulmonary function tests and chest imaging are not diagnostic of HPS, they are useful tests to evaluate for concomitant lung disease, which can be present in approximately one-third of patients with HPS.[127]

Treatment

The only successful treatment for HPS is liver transplantation. Despite recent advances in knowledge regarding the pathophysiology of HPS, there are no approved medical therapies, so treatment is predominantly supportive, with the use of supplemental oxygen. Small studies have evaluated several agents that work through different mechanisms, such as methylene blue (inhibits the effect of nitric oxide on guanylate cyclase),[119,128,129] N(G)-nitro-L-arginine methyl ester (reduces nitric oxide production),[121,130] somatostatin,[131] cyclooxygenase inhibitors,[132,133] almitrine (pulmonary vasoconstrictor),[134,135] propranolol (ameliorates portal hypertension),[136,137] antibiotics (selective gut decontamination),[138,139] pentoxifylline (TNF-α inhibitor),[140] and sorafenib, a tyrosine kinase inhibitor used as a blocker of angiogenesis,[141] all with disappointing results. Garlic was associated with improved oxygenation in patients with HPS in two small studies, but these results have not been replicated in larger multicenter studies.[142,143]

Since liver transplantation remains the only known effective treatment for HPS, all patients with HPS should undergo an expedited liver transplant evaluation.[144] Patients with severe or very severe HPS (arterial P_{O_2} <60 mm Hg) are eligible to receive a *Model for End-stage Liver Disease* (MELD) exception, which awards increased waitlist priority points to expedite transplantation.[145] Youth, a good arterial P_{O_2} response to 100% oxygen, and less pretransplant hypoxemia are all factors associated with a favorable response to liver transplantation.[146] Collectively, these elements may indicate a more reactive pulmonary vasculature and less profound intrapulmonary shunting. As might be expected, the worse the hypoxemia before transplantation, the longer it takes to resolve after surgery.[147]

Prognosis

Compared to liver transplantation candidates without HPS, transplant candidates with HPS have a twofold increased pretransplant risk of death.[148] In the absence of liver transplantation, patients with HPS have a median survival of 41 months following diagnosis and an average decline in arterial P_{O_2} of approximately 5 mm Hg per year.[103] Liver transplantation is associated with improved outcomes in HPS[149] and thus should be considered in all patients with HPS.[101] Posttransplant outcomes in patients with HPS are excellent and similar to non-HPS patients, but more severe pretransplant hypoxemia (arterial P_{O_2} ≤44 mm Hg) has been associated with worse posttransplant survival.[150] Recurrence of HPS is rare and is typically related to recurrence of the underlying liver disease.[151]

PORTOPULMONARY HYPERTENSION

Definition and Diagnosis

Pulmonary arterial hypertension (PAH) associated with portal hypertension—known as *portopulmonary hypertension* (POPH)—is another mysterious pulmonary vascular disorder that develops in the setting of chronic liver disease and portal hypertension.[102,104,146] Because both the diagnosis and the outcome of POPH, particularly in relation to the effect of liver transplantation, are substantially different from those of HPS, it is important to highlight the distinctions between these two disorders (Table 126.3). According to the Sixth World Symposium on Pulmonary Hypertension, POPH belongs to Group 1 PAH and is defined by an elevated mean pulmonary arterial pressure greater than 20 mm Hg at rest, a mean pulmonary artery wedge pressure of 15 mm Hg or less, and an elevated pulmonary vascular resistance of 240 dynes•sec•cm^{-5} or greater (normal is <130 dynes•sec•cm^{-5}).[101,102,152] The presence of POPH impacts liver transplant eligibility and perioperative risk stratification, so guidelines recommend routine transthoracic echocardiography for screening in patients being considered for liver transplantation.[144] Characteristic echocardiographic findings of PAH (elevated right ventricular systolic pressure and/or right ventricular dilation or dysfunction) in the setting of portal hypertension suggest, but are not definitive for, POPH. Right heart catheterization is needed to confirm the diagnosis.

Epidemiology

POPH is found in approximately 5–6% of patients evaluated for liver transplantation.[153] Reported prevalence rates vary depending on the cohort studied and the hemodynamic definition used to define POPH. In classic retrospective postmortem studies, the prevalence of histopathologic evidence of PAH in patients with liver cirrhosis ranged from 0.25–0.73%.[154] According to these and subsequent observations, POPH has been classified as a category of PAH with hemodynamic criteria consistent with the standard classification and definition of PAH, as discussed in Chapter 84.[104,155] Independent clinical risk factors associated with an increased risk of POPH include female sex and autoimmune hepatitis, whereas hepatitis C is associated with a decreased risk. In parallel to HPS, the incidence and severity of POPH is not associated with the severity of the underlying liver disease.[153]

Pathogenesis

The pathogenesis of POPH is not known. Chemla and colleagues[156] postulated that the portosystemic shunting of vasoactive agents such as thromboxanes, serotonin,

Table 126.3 Comparison of Clinical Features of Hepatopulmonary Syndrome and Portopulmonary Hypertension

	Hepatopulmonary Syndrome	Portopulmonary Hypertension
Symptoms	Dyspnea, platypnea, fatigue	Dyspnea, fatigue, lower extremity edema, abdominal distension
Physical exam findings	Clubbing, cyanosis, spider angiomata, orthodeoxia	Jugular venous distension, prominent pulmonic component of the second heart sound, tricuspid regurgitation murmur, ascites, lower extremity edema
Prevalence	5–32%	5–6%
Gas exchange	Elevated alveolar-arterial P_{O_2} difference with mild to severe hypoxemia	Normal or mild hypoxemia
Contrast-enhanced transthoracic echocardiogram	Intrapulmonary vasodilation (late appearance of microbubbles in the left-sided chambers)	Elevated right ventricular systolic pressure and/or right ventricular dilation or dysfunction
Pathology	Precapillary and capillary vasodilation	Plexiform lesions, intimal thickening, smooth muscle proliferation and in situ thrombosis
Medical treatment	Supportive	Pulmonary arterial hypertension–targeted therapy
Effect of liver transplantation	Resolution of hypoxemia	Variable outcomes

bradykinin, and neuropeptide Y, which are normally metabolized by the healthy liver, may result in pulmonary arterial vasoconstriction. This hypothesis is supported by an increased prevalence of spontaneous portosystemic shunts in patients with POPH.[157] Recent case-control studies in patients with POPH have identified higher levels of macrophage migration inhibitory factor, a proinflammatory cytokine involved in the regulation of innate immunity, reduced levels of bone morphogenetic protein 9, an endothelial quiescence factor, and higher estradiol levels suggesting that inflammation, endothelial dysfunction, and sex hormones may play important roles in disease pathogenesis.[158–160] From a histopathologic viewpoint, the vascular lesions in POPH are indistinguishable from those identified in idiopathic PAH (see Chapter 84), namely intimal thickening, smooth muscle proliferation, plexogenic pulmonary arteriopathy, and in situ thrombosis,[161] all of which—plus vasoconstriction—contribute to the increased pulmonary vascular resistance.[162]

Clinical Manifestations

The most common symptom of POPH is shortness of breath, particularly with exertion; patients may also experience fatigue, decreased activity tolerance, chest pain, syncope, and signs and symptoms of right heart failure (lower extremity edema, abdominal distension) which can often be difficult to differentiate from decompensated cirrhosis.[163] Radiographically, both an enlarged cardiac silhouette and a pulmonary artery prominence are noted in approximately one-half to two-thirds of patients with POPH.[153,163] Generally, spirometry and lung volumes are normal or nearly normal, whereas $D_{L_{CO}}$, arterial P_{O_2}, and the $(A–a)P_{O_2}$ may be abnormal, although less so than in HPS.[153] Transthoracic echocardiography typically demonstrates an elevated right ventricular systolic pressure with or without right ventricular dilation and/or dysfunction and can be used as a screening test with reasonable sensitivity and specificity.[164] Right heart catheterization is required for diagnosis and demonstrates an elevated mean pulmonary arterial pressure and pulmonary vascular resistance. Cardiac output may be normal or elevated but can decline as right heart failure develops. Compared to patients with idiopathic and heritable PAH, patients with POPH have more favorable hemodynamics with a lower mean pulmonary arterial pressure, right atrial pressure, and pulmonary vascular resistance and a higher cardiac index at the time of diagnosis.[162]

Treatment

Treatment for POPH is similar to idiopathic PAH, although there are few prospective data to guide management, given that patients with POPH have been excluded from many clinical trials of PAH-targeted therapy. In small, uncontrolled, and predominantly single-center studies, PAH therapy in patients with POPH has been associated with improvements in exercise capacity and pulmonary hemodynamics.[165] Although there are no randomized controlled trials specific to POPH to guide therapeutic choices, currently available agents to treat PAH and POPH include epoprostenol, treprostinil, selexipag, iloprost, sildenafil, tadalafil, riociguat, bosentan, ambrisentan, and macitentan. The approach to treatment of PAH is discussed further in Chapter 84 and is typically similar for POPH, although treatment goals in POPH may be affected by liver transplant eligibility and urgency. In contrast to idiopathic PAH, calcium channel blockers should be avoided in patients with POPH because they can worsen splanchnic vasodilation.[101] Patients with POPH may also require diuretics for management of edema and right heart failure, if present. β-Blockers, which are often used for prophylaxis in patients with esophageal varices, can worsen cardiac output and exercise capacity in patients with POPH and should be avoided if feasible.[101]

Liver transplantation can be safe in selected patients with POPH with preserved right ventricular function and appropriate hemodynamic responses to PAH therapy. Similar to HPS, patients with POPH are eligible for a MELD exception to expedite liver transplantation. In contrast to HPS, however, POPH is not considered an indication for liver transplantation because posttransplant outcomes are variable; approximately half of patients with POPH remain on PAH therapy posttransplant.[166] Prospective studies are clearly needed to provide guidance regarding the role of medical therapy and liver transplantation in the management of POPH.

Prognosis

In the absence of PAH therapy or liver transplantation, survival in patients with POPH is extremely poor, with 5-year survival rates of 14%, as shown in a 2008 study.[167] Even in the modern PAH treatment era, 5-year survival in a multicenter U.S. registry was only 40%, and survival for patients with POPH was significantly worse than for those with idiopathic PAH despite better hemodynamics.[168] The presence of cirrhosis, worse liver disease severity, higher pulmonary vascular resistance, and lower cardiac index have been associated with worse survival in patients with POPH.[161,169] POPH is associated with increased perioperative risk, so screening for POPH is recommended in all candidates for liver transplantation.[144] Perioperative cardiopulmonary mortality risk can be stratified by mean pulmonary arterial pressure, and liver transplantation should be avoided in patients with a mean pulmonary arterial pressure greater than 45 to 50 mm Hg due to a high risk of death.[101,170] In selected patients with POPH who undergo liver transplantation, 1-year posttransplant survival rates are 77–85% and the risk of death is highest within the first 6 months posttransplant.[166,171]

PRIMARY BILIARY CIRRHOSIS

Primary biliary cirrhosis (PBC) is a progressive, autoimmune cholestatic liver disease characterized by diffuse inflammation and destruction of the intrahepatic bile ducts.[172] The disease primarily affects middle-aged women and serologically is characterized by the presence of antimitochondrial antibodies in up to 95% of patients. It is often associated with other autoimmune diseases including Sjogren syndrome, systemic lupus erythematosus, and scleroderma. In addition to the pulmonary manifestations common to all forms of advanced liver disease, an association between PBC and interstitial lung disease is well established. The most common pathologic finding is lymphocytic interstitial pneumonitis. Fibrosing alveolitis, interstitial fibrosis, nonnecrotizing

granulomas, and organizing pneumonia have also been described.[173] The presence of concomitant Sjogren syndrome is strongly associated with the development of interstitial lung disease.[174] As with other liver diseases, pulmonary function tests in patients with PBC frequently show a reduction in D_{LCO}, even in asymptomatic individuals.[175] Bronchoalveolar lavage may show an increased proportion of lymphocytes with $CD4^+/CD8^+$ ratios similar to those seen in sarcoidosis.[176] Other rare associations between PBC and obstructive lung disease, chest wall deformities, pulmonary hypertension, sarcoidosis, and pulmonary hemorrhage also have been described.[177]

CHRONIC HEPATITIS C

Chronic hepatitis C is characterized by chronic diffuse hepatic parenchymal inflammation and hepatic cell necrosis. Patients with untreated infection have a significant potential to progress to cirrhosis as well as to hepatocellular carcinoma.[177] Although some authors have suggested an association between chronic hepatitis C and pulmonary fibrosis, this association is controversial and remains unproven.[178,179] It has also been suggested that patients with chronic hepatitis C virus infection and coexistent COPD may experience an accelerated annual decline in FEV_1.[180]

SCLEROSING CHOLANGITIS

Sclerosing cholangitis is a chronic progressive liver disease that results in chronic inflammation of both the intrahepatic and extrahepatic bile ducts. Approximately 70% of patients with sclerosing cholangitis will have concomitant inflammatory bowel disease.[181] As with isolated inflammatory bowel disease, sclerosing cholangitis has been linked with inflammatory upper airway diseases such as bronchiectasis.[182]

ALPHA$_1$-ANTITRYPSIN DEFICIENCY

Alpha$_1$-antitrypsin deficiency is a hereditary disorder nearly always associated with the homozygous PiZZ phenotype (see Chapter 63). Infants with alpha$_1$-antitrypsin deficiency often present with hepatomegaly and evidence of cholestasis. Most children with alpha$_1$-antitrypsin–induced liver disease recover, but cirrhosis develops in about 15%, presumably from toxic effects of the mutant antitrypsin protein retained in the endoplasmic reticulum of hepatocytes.[183] Emphysema is the most common pulmonary complication and is unrelated to the presence of liver disease. This emphysema develops in adults and is characterized by panacinar emphysema, especially in the lower lung zones, and bronchial abnormalities, including bronchiectasis (Fig. 64.5 and Video 64.2).[177]

PANCREATIC DISEASES

ACUTE PANCREATITIS

Acute pancreatitis is an inflammatory disorder of the pancreas most commonly caused by gallstones or alcohol abuse. Most episodes of acute pancreatitis are mild and resolve with supportive care, but approximately 20% of cases are severe and complicated by multisystem organ dysfunction with an associated mortality of 15–25%.[184] Pulmonary complications are common and contribute substantially to morbidity and mortality. They range from mild hypoxemia to the *acute respiratory distress syndrome* (ARDS). Overall, intrathoracic complications are implicated as a contributing factor in more than 50% of deaths from acute pancreatitis.[185]

Early Respiratory Insufficiency and Imaging Abnormalities

In the early stages of acute pancreatitis, mild respiratory alkalosis and hypoxemia are common, even in patients with normal chest radiographs.[186,187] The mechanisms of hypoxemia in the setting of a normal chest radiograph remain poorly understood. Murphy et al. showed that in a small cohort of patients who developed hypoxemia, the primary cause was V/Q mismatch resulting in right-to-left intrapulmonary shunting.[188] These authors suggested that hypoxemia, even in the absence of radiologic abnormalities, may be related to changes in pulmonary vascular permeability, similar to but milder than those described in ARDS.[188] Early respiratory insufficiency is a risk factor for progressive pulmonary complications and poor outcomes independent of pancreatitis severity.[189] Therefore, asymptomatic patients with early mild respiratory insufficiency should be watched closely for signs of worsening respiratory impairment.

The majority of patients with acute pancreatitis will develop chest radiographic abnormalities during their disease course, the most common findings being pleural effusions, atelectasis, and pulmonary edema. Pleural effusions are seen in over 50% of patients.[190] The effusions typically are small, and the majority (68%) are left sided.[191] Most are exudative and, in some cases, pleural fluid amylase levels will be high.[184] The presence of pleural fluid is a marker of disease severity and is correlated with increased risk of respiratory failure and mortality.[190] Most pleural effusions associated with acute pancreatitis are self-limited and resolve without therapeutic drainage after the pancreatic inflammation subsides.

Nonspecific basilar atelectasis and consolidation are also common findings in acute pancreatitis. Pain, splinting, and increased vascular permeability are likely contributing factors. Experimental models of pancreatitis-associated lung injury also support the hypothesis that atelectasis in dependent lung regions may in part be secondary to impaired surfactant production and activation.[192] Furthermore, proinflammatory cytokines secreted in acute pancreatitis cause a decrease in diaphragmatic muscle strength and endurance, contributing to atelectasis.[193]

Acute Respiratory Distress Syndrome

The most feared pulmonary complication of acute pancreatitis is ARDS (see also Chapter 134), which develops in approximately 15–20% of patients and is responsible for up to 60% of deaths[194–196] (Fig. 126.6). It typically manifests between 2 and 7 days following the onset of pancreatitis. In patients with ARDS who survive, quality of life is frequently impaired.[197] Autopsy studies show that pathologic changes

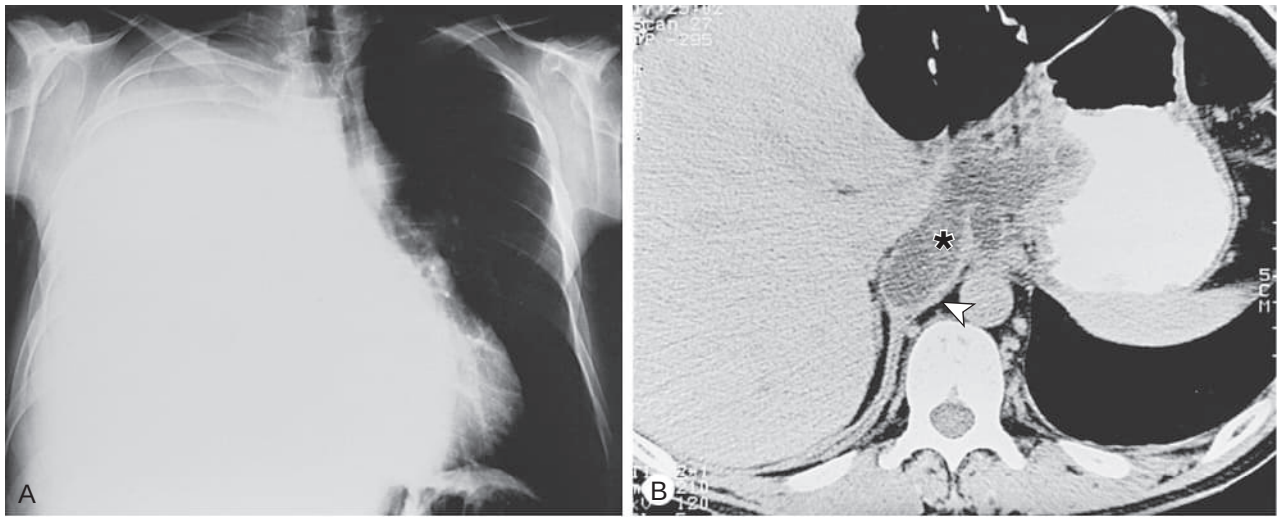

Figure 126.5 A massive pleural effusion associated with a pancreatic pseudocyst. (A) Chest radiograph demonstrates a massive pleural effusion in the right hemithorax. (B) Computed tomography scan of the upper abdomen performed after pleural drainage shows the cranial extension of the pseudocyst (*asterisk*) through the right crural insertion (*arrowhead*) and the esophageal hiatus. (Courtesy Dr. S. Navarro, Hospital Clinic, Universitat de Barcelona, Spain.)

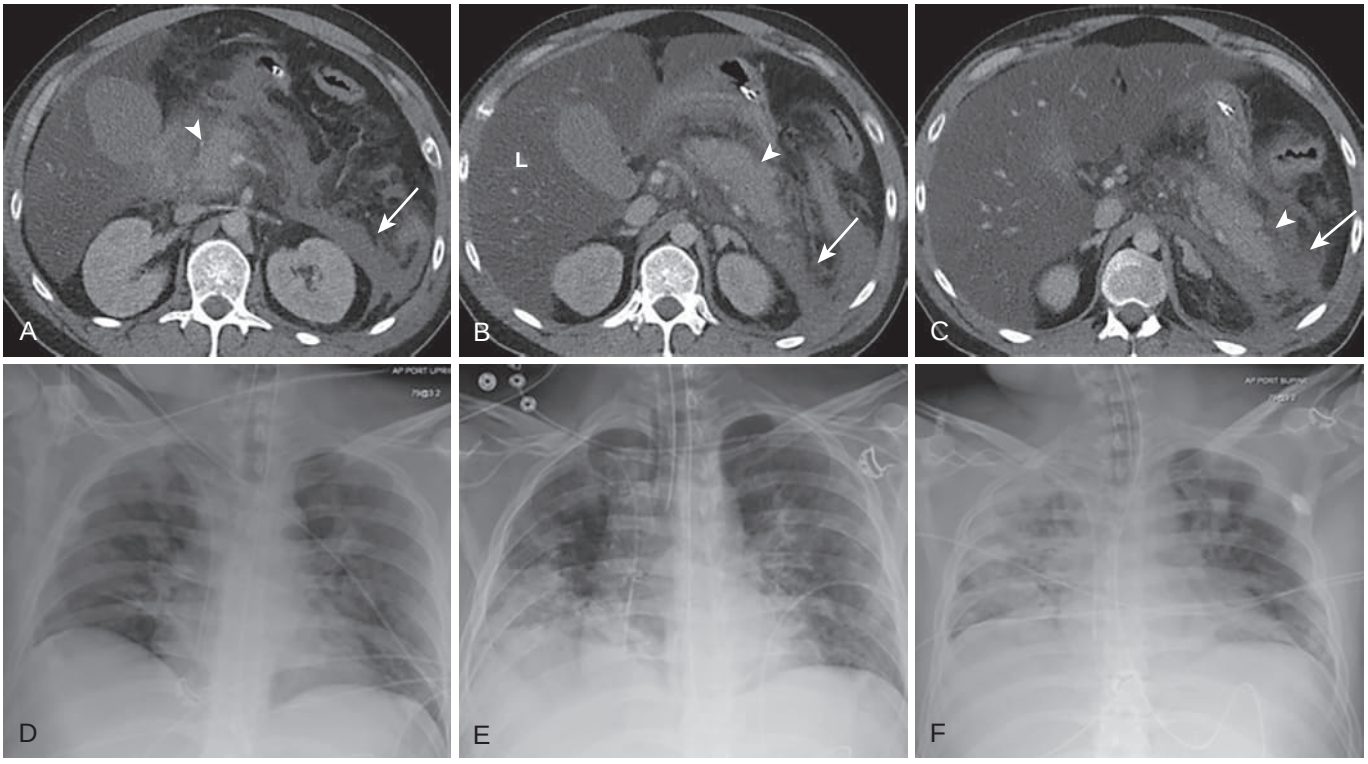

Figure 126.6 Acute respiratory distress syndrome in a patient with pancreatitis. (A–C) Axial enhanced abdominal computed tomography shows extensive inflammation surrounding the pancreas head (A, *arrowhead*), body (B, *arrowhead*), and tail (C, *arrowhead*). Fluid is present in the left anterior pararenal space (*arrows*). The liver (L) shows diffusely decreased attenuation consistent with fatty infiltration, consistent with alcohol use, the precipitating cause of the patient's pancreatitis. (D–F) Frontal chest radiographs performed at the patient's presentation, several days prior to the abdominal computed tomography (D), 6 days after presentation (E), and 14 days after presentation (F) show progressive, multilobar, right-greater-than-left opacities in a patient intubated for respiratory failure, consistent with acute respiratory distress syndrome (Courtesy Michael B. Gotway, MD.)

in the lungs are identical to those seen in ARDS caused by other conditions.[198]

Injury to the lung may result from a direct toxic effect of pancreatic enzymes, from secondary release of inflammatory mediators, or from both. Several pancreatic enzymes have the potential to induce lung injury. Animal studies suggest that elastase and lipase, which are released systemically during pancreatitis, may increase lung vascular permeability and induce lung injury.[199] Phospholipase A_2 induces the enzymatic degradation of surfactant, thereby promoting alveolar collapse and increased vascular permeability.[184,191] There is a strong correlation between serum phospholipase A_2 levels and respiratory insufficiency.[200] In addition to the direct effect of pancreatic by-products,

sequestration of activated neutrophils within the alveolar and interstitial spaces is believed to play an important role in inducing lung injury. Proinflammatory cytokines released during pancreatic injury include TNF-α and IL-8, which augment neutrophil recruitment and activation in the lungs.[191] Finally, there is evidence that reactive oxygen species, adhesion molecules, platelet-activating factor, and many other cytokines may also contribute to increased vascular permeability and induce lung injury.[191,201]

Treatment of pancreatitis-associated ARDS is supportive and does not differ from that for other forms of ARDS (see Chapter 134). Key measures include cardiovascular support and lung-protective ventilation. Although aggressive fluid resuscitation remains a pillar in the management of acute pancreatitis, overzealous resuscitation may increase the rate of both pulmonary and nonpulmonary complications.[202,203] Two small studies from the mid-1990s suggest that octreotide, a potent inhibitor of exocrine pancreatic secretion, may decrease both mortality rates and the incidence of ARDS among patients with severe acute pancreatitis.[204,205] This potential therapy warrants investigation in larger randomized controlled trials.

DELAYED COMPLICATIONS OF ACUTE PANCREATITIS

Patients who survive the initial acute inflammatory response associated with acute pancreatitis remain at risk for late pulmonary complications. Like all hospitalized patients, patients with acute pancreatitis can develop hospital-acquired infections and venous thromboembolism.[206] Most pancreatitis-associated pleural effusions will resolve within 2 weeks without intervention but, in rare cases, an effusion will persist. The presence of a persistent large pleural effusion should raise concern for development of a pancreaticopleural fistula resulting from the formation of a direct communication between the pancreas and the pleural space (see Fig. 126.5). In this setting, the pleural fluid will have very high amylase levels and may be massive in size and recur rapidly after drainage.[190] Although some patients will respond to chest tube drainage and administration of somatostatin analogues to reduce pancreatic secretions, management may require endoscopic retrograde cholangiopancreatography with stenting and, in rare cases, surgery.[207] Other rare delayed complications include mediastinal pseudocyst formation and acute mediastinitis.[206]

AUTOIMMUNE PANCREATITIS

Autoimmune pancreatitis or sclerosing pancreatitis is a rare form of chronic pancreatitis. Two forms of autoimmune pancreatitis are recognized. Type 1 autoimmune pancreatitis, also referred to as *immunoglobulin G4* (IgG4)-related pancreatitis, is characterized by a dense lymphoplasmacytic infiltrate rich in IgG4-positive plasma cells, a swirling appearance of fibroblasts called a "storiform" fibrosis and, in some cases, elevated serum IgG4 concentrations.[208] Patients with type 1 autoimmune pancreatitis frequently have disease affecting other organs including the lungs. Pulmonary involvement typically presents as interstitial pneumonia or parenchymal inflammatory pseudotumor. Lung biopsy specimens will show a similar lymphoplasmacytic infiltrate with increased IgG4-positive plasma cells.[209] Lung involvement typically improves along with administration of glucocorticoids.[210] Type 2 autoimmune pancreatitis, also referred to as idiopathic duct-centric pancreatitis, does not involve an IgG4-positive cellular infiltrate and typically only affects the pancreas.[211]

KIDNEY DISEASES

Dyspnea is commonly reported by patients with both acute and chronic kidney diseases. In patients with acute kidney injury, respiratory symptoms are often attributed to pulmonary edema or represent a manifestation of the underlying disease process, as is the case with the pulmonary renal syndromes (see Chapter 87). In patients with *chronic kidney disease* (CKD) and *end-stage renal disease* (ESRD), the pathophysiology of dyspnea is often more complex and these etiologies are discussed further in this section.

PULMONARY EDEMA

In patients with ESRD, interstitial pulmonary edema is highly prevalent, even in asymptomatic patients, and correlates strongly with measures of physical functioning.[212,213] In general, physical exam findings such as crackles on lung exam and lower extremity edema correspond poorly with the degree of interstitial edema. There is growing evidence that thoracic ultrasonography may be a more sensitive tool to identify pulmonary edema in this population.[214,215]

In patients with CKD, the etiology of the pulmonary edema is often multifactorial and may be attributed to a combination of increased pulmonary hydrostatic pressure secondary to fluid overload or congestive heart failure, reduced pulmonary capillary oncotic pressure due to hypoalbuminemia, and increased permeability of the alveolar-capillary membrane in the setting of uremia.[216] The relative importance of each of these pathophysiologic mechanisms is heavily debated.

Heart failure plays an important role in the development of pulmonary edema associated with CKD. Cardiac disorders are common in ESRD, and a variety of factors, including hypertension, diabetes mellitus, anemia, surgical arteriovenous fistulas, and ischemic heart disease, may adversely affect cardiac function.[217] In addition, patients with CKD may develop a specific "uremic cardiomyopathy," the existence of which is supported by evidence that left ventricular dysfunction may be partially reversible with dialysis or renal transplantation.[218,219]

Evidence that interstitial pulmonary edema in patients undergoing regular hemodialysis is at least partially independent of prescribed ultrafiltration rate, intradialytic weight, and pulmonary capillary wedge pressure suggests that factors in addition to heart failure and fluid overload are also likely involved.[220] Early autopsy studies showing the presence of protein-rich edema fluid, hyaline membranes, and alveolar hemorrhage in the lungs lend support to the relative importance of increased vascular permeability in the development of pulmonary edema.[221,222] The demonstration of increased protein content in edema fluid sampled directly by endotracheal aspiration reinforces this hypothesis.[223]

Regardless of the etiology, interstitial pulmonary edema remains a major source of morbidity and mortality in patients with CKD.[212,224] For many patients on dialysis, achieving the optimal balance of fluid removal with ultrafiltration while avoiding hypovolemia during dialysis can be challenging.[225] In addition, acute alveolar pulmonary edema and fluid overload are common causes of hospital and ICU admission in patients with ESRD. While many episodes will resolve with emergent dialysis, hospitalization for fluid overload is associated with high costs and poor long-term survival.[225–227]

PULMONARY HYPERTENSION

Pulmonary hypertension is highly prevalent in patients with CKD and ESRD, affecting 30–50% of patients.[228] There is significant overlap between CKD and comorbid conditions traditionally associated with pulmonary hypertension. Not surprisingly given the high incidence of comorbid cardiac disease, *World Health Organization* (WHO) group 2 pulmonary hypertension is overwhelmingly the most common form seen in this patient population. Nevertheless, other etiologies of pulmonary hypertension are also seen and, in some patients with CKD, the etiology of pulmonary hypertension may be multifactorial. Conditions such as HIV, scleroderma, and cirrhosis are associated with both WHO group 1 pulmonary hypertension and CKD. COPD and obstructive sleep apnea are highly prevalent in patients with CKD, which increases the likelihood of WHO group 3 pulmonary hypertension. Patients with CKD are also at increased risk for venous thromboembolic disease and pulmonary embolism following arteriovenous access thrombectomy, which are associated with WHO group 4 pulmonary hypertension. Finally, a significant number of patients with CKD will have "unexplained" WHO group 5 pulmonary hypertension.[228] Regardless of the etiology, there is evidence that a longer time on hemodialysis increases the risk for development of pulmonary hypertension and is predictive of increased mortality in patients on dialysis and also in those who undergo kidney transplantation.[229–231]

Echocardiography can be misleading both in diagnosing and clarifying the etiology of pulmonary hypertension in patients with CKD. In the PEPPER study of patients with stage 4 and 5 CKD with unexplained dyspnea and normal echocardiograms, 77% of patients on hemodialysis had evidence of pulmonary hypertension on right heart catheterization.[232] Of those with pulmonary hypertension, over 80% of patients had an elevated pulmonary capillary wedge pressure (postcapillary disease). This highlights the importance of right heart catheterization in the diagnosis and management of pulmonary hypertension in CKD patients.

Treatment of pulmonary hypertension in CKD is dependent on the etiology. Supplemental oxygen is recommended for all patients who are hypoxemic with a goal to maintain saturations with exercise greater than 90%. In general, targeted PAH therapies are reserved for patients with WHO group 1 pulmonary hypertension, whereas treatment for patients with disease secondary to other conditions is geared towards treatment of the underlying process. Studies of individual PAH-targeted agents are limited in patients with CKD, and more research is needed. Diuresis and/or dialysis for left-sided heart disease would be warranted; however, right heart catheterization in the euvolemic state is necessary to characterize the hemodynamic changes present.[228]

PLEURAL DISEASE

Pleural effusion is a frequent complication of CKD, particularly for patients requiring dialysis. In unselected hospitalized patients on dialysis, the prevalence is around 20%.[233,234] In symptomatic dialysis patients, the prevalence of pleural fluid on CT scan may be as high as 50%.[235] Although hypervolemia is the most common etiology, effusions secondary to uremic pleuritis, pneumonia, and atelectasis are also common.[234] Effusions are bilateral in 60% of cases and, of these, the majority of effusions are transudative. The presence of bilateral transudative effusions is strongly associated with heart failure or hypervolemia as the underlying etiology.[233–235]

In patients with unilateral effusions, non–heart failure etiologies should be strongly considered. Compared to patients with heart failure or hypervolemia, those with other etiologies are more likely to report chest pain in addition to dyspnea.[233] Unilateral effusions are frequently exudative and are most commonly parapneumonic or secondary to atelectasis.[233]

Uremic pleurisy is a fibrinous pleuritis that may result in pleural effusions, chronic pleural inflammation, and fibrosis in patients with CKD. Close to 60% of patients who die of chronic renal insufficiency will have some degree of fibrinous pleuritis identified at autopsy.[233,236] The etiology is unclear. Uremic effusions may be unilateral or bilateral and tend to be exudative, lymphocyte predominant, and frequently serosanguinous.[237] Pleuritic chest discomfort and pleural friction rub on auscultation may be present.[237,238] In rare cases the pleural fibrosis may be severe enough to cause restrictive physiology requiring surgical decortication[239] (see Chapter 112).

In addition to the pleural diseases common to all dialysis patients, patients on peritoneal dialysis can develop an acute large pleural effusion related to preexisting or acquired pleuroperitoneal communications; this complication has been estimated to present in 1–2% of patients on peritoneal dialysis.[240] The majority (90%) of these effusions are right-sided and, when sampled, are transudative and often have an overtly elevated pleural fluid glucose compared to serum.[241] There is no consensus regarding the optimal management of such patients. Options include discontinuing peritoneal dialysis and initiating hemodialysis and video-assisted thoracic surgery for pleurodesis and/or attempted repair of diaphragmatic defects.[242]

PULMONARY CALCIFICATION

Metastatic pulmonary calcification is a common consequence of CKD seen in 60–80% of dialysis patients at autopsy.[243,244] It is characterized by diffuse calcium deposits in the pulmonary parenchyma and visceral organs. In the lungs, the calcium deposition tends to be in the alveolar epithelial basement membranes.[244] The pathogenesis is complex and several factors may play a role, including (1) the effect of chronic metabolic acidosis, which results in the efflux of calcium from bones; (2) the effect of secondary hyperparathyroidism, which results in increased bone reabsorption and intestinal calcium absorption; and (3) the effect of low glomerular filtration rate, which results in hyperphosphatemia and elevation of the calcium-phosphorus product.[243,245]

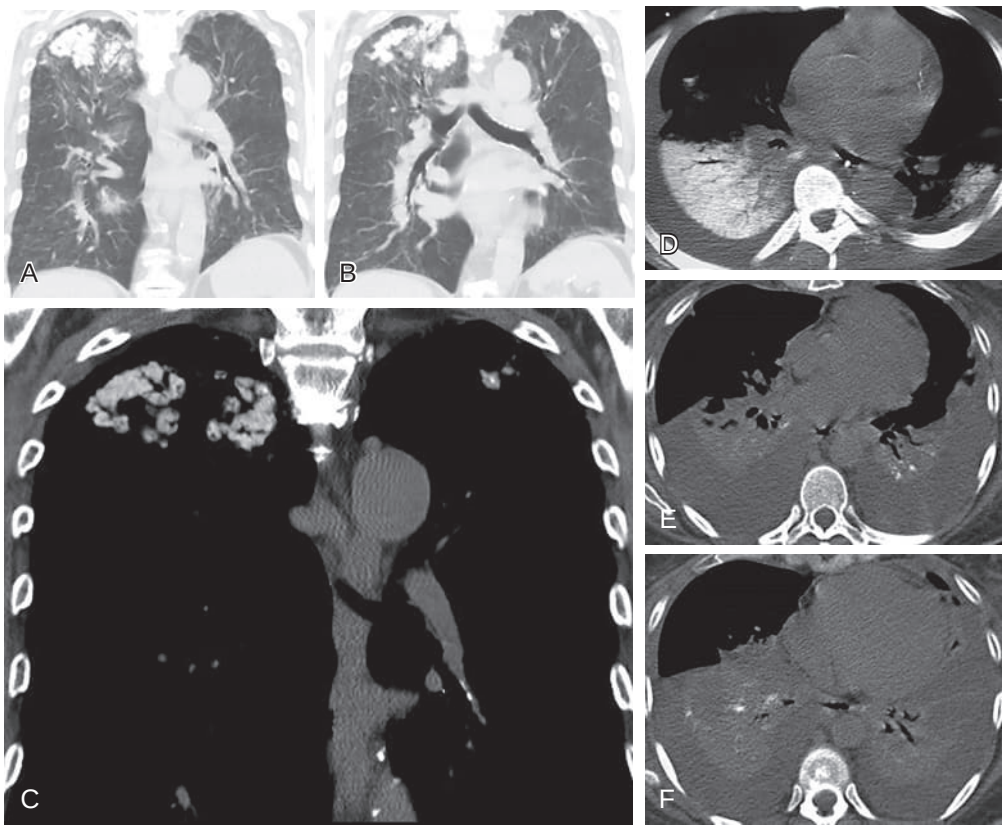

Figure 126.7 Metastatic calcinosis in patients with end-stage renal disease. (A–B) Coronal *computed tomography* (CT) scan displayed in lung windows shows confluent centrilobular hyperattenuating nodules in the apices. The calcification of these opacities is more evident with CT displayed in soft tissue windows (C). (D) In another patient, axial CT displayed in soft tissue shows more confluent lower lobe parenchymal calcification. (E–F) In a third patient, axial CT displayed in soft tissue windows shows spotty, more nodular-appearing lower lobe calcification. (Courtesy Michael B. Gotway, MD.)

While highly prevalent, metastatic pulmonary calcification is frequently undetectable by ordinary chest radiograph and most patients are asymptomatic.[243] High-resolution CT scan is more sensitive for detecting small amounts of calcification. Findings may include multiple diffuse calcified pulmonary nodules, diffuse or patchy ground-glass opacities, or high-density parenchymal consolidations (Fig. 126.7 and eFig. 126.3). Changes are often most pronounced in the upper lung zones, thought to be due to the lower carbon dioxide and higher pH in the upper zones. In contrast to infectious processes, these opacities are relatively stable over time, which may aid in the diagnosis. Pulmonary function tests are typically normal but may reveal a restrictive ventilatory defect and/or a reduction in DL_{CO}.[245] When necessary, the diagnosis can be confirmed by pulmonary uptake with technetium-99m-diphosphonate scanning.[246]

In general, treatment options are unsatisfactory. Patients with asymptomatic, nonprogressive disease do not require treatment. For symptomatic patients with progressive disease, treatment options include maintaining adequate dialysis, lowering the calcium-phosphorus product with phosphate binders, and treating hyperparathyroidism, when present.[243] Renal transplantation may either improve or worsen the condition.[243]

SLEEP DISORDERS

The high prevalence of sleep disorders in patients with CKD and, in particular ESRD, is well recognized. (Sleep disorders in the general population and their treatment are described in Chapters 119 and 122). Compared to the general population, patients with ESRD have higher rates of most common sleep disorders, including insomnia, excessive daytime sleepiness, restless leg syndrome, and sleep apnea.[247] Not only is sleep disturbance one of the most commonly reported symptoms in patients with ESRD, but it is also strongly associated with both decreased health-related quality of life and mortality.[248,249]

Insomnia is reported by up to 40–70% of patients with ESRD.[250,251] Patients may complain of difficulty initiating and maintaining sleep as well as early morning wakening. On polysomnography, patients will often exhibit poor sleep architecture including fragmented sleep, reduced total sleep time, and reduced sleep efficiency.[247] The cause of this high rate of insomnia is likely multifactorial. Patients on dialysis frequently lack the normal circadian rhythm in melatonin secretion, which may lead to disturbances in the sleep-wake cycle.[252] Coexisting medical conditions including psychiatric illnesses and chronic pain are other influences.[248] Finally, a high incidence of other sleep disorders including restless leg syndrome and sleep apnea, as well as poor sleep hygiene and the use of medications that inhibit sleep may also contribute.[247]

Sleep apnea is also significantly more common in patients with ESRD compared to the general population, reported in more than 50% of patients.[253] In the Sleep Heart Health Study, patients on hemodialysis had a fourfold increase in sleep apnea and had more episodes of severe hypoxemia compared to matched controls, even after adjusting for comorbid conditions.[254] While *obstructive sleep apnea* (OSA) is the most common form of sleep apnea seen in patients with ESRD, central sleep apnea is also described and may be underreported.

Various mechanisms have been proposed to explain the high prevalence of OSA in patients with ESRD. One possibility is that the accumulation of uremic toxins may exacerbate OSA in patients with ESRD. This theory is supported by evidence that conversion from conventional daytime hemodialysis to nocturnal hemodialysis reduces the severity of sleep apnea.[255] Another hypothesis is that fluid overload increases the susceptibility to upper airway collapse during sleep.[256] Studies in healthy subjects have shown shifting fluid to the upper body by applying high pressure to the lower body leads to both increased pharyngeal resistance and increased upper airway collapsibility.[257,258] Such data support the hypothesis that chronic fluid overload and subsequent fluid displacement during recumbency predisposes patients with ESRD to OSA.

As in the general population, continuous positive airway pressure is considered the first-line therapy for OSA in patients with ESRD.[259] Other treatments such as dental appliances and surgery have not been extensively studied in this population. There are anecdotal reports of improvement in OSA after renal transplantation, but this is not universal.[260,261]

HEMODIALYSIS-INDUCED HYPOXEMIA

Hypoxemia during hemodialysis is a well-recognized phenomenon. In general, oxygen saturation tends to drop at the start of dialysis, reaching a nadir after 30 to 60 minutes and improving to predialysis levels or higher at the end of treatment.[262] A recent large prospective cohort study of chronic hemodialysis patients identified that, even with modern dialysis techniques, the prevalence of prolonged interdialytic hypoxemia (arterial So_2 < 90% for at least one-third of the treatment time) was 10%.[263] Intradialytic hypoxemia was associated with adverse clinical outcomes, including all-cause hospitalization and mortality.

The mechanisms responsible for intradialytic hypoxemia are likely multifactorial. Initially, it was recognized that the severity of the hypoxemia varied depending on the type of dialysis membrane used as well as the dialysate composition.[264,265] For instance, intradialytic hypoxemia is more frequent with the use of acetate buffer than with bicarbonate buffer.[265] Cardiopulmonary comorbidities likely also contribute. As previously discussed, patients with ESRD have high rates of congestive heart failure, volume overload, pulmonary hypertension, pulmonary calcification, and obstructive sleep apnea, which may all contribute to hypoxemia. In addition, there is increasing evidence that COPD is a frequent and likely underdiagnosed comorbidity in patients with ESRD.[266] The importance of such cardiopulmonary comorbidities is supported by the study by Meyring-Wosten et al. in which patients with congestive heart failure or COPD were significantly more likely than other patients to experience prolonged intradialytic hypoxemia.[263]

Given the wide array of potential etiologies of intradialytic hypoxemia, the optimal management remains unknown. Not surprisingly, small studies have suggested that use of supplemental oxygen improves hypoxemia; however, whether this improves clinical outcomes remains unknown.[267]

Key Points

- Gastroesophageal reflux disease is highly prevalent. Extraesophageal manifestations include asthma and chronic cough. The benefit of acid-suppressive therapy in patients with gastroesophageal reflux–associated respiratory symptoms remains unclear.
- Inflammatory bowel diseases have been associated with a variety of chronic pulmonary diseases. These include diseases of the airways such as asthma, chronic bronchitis, and bronchiectasis and, less commonly, disorders of the lung parenchyma, such as interstitial fibrosis and cryptogenic organizing pneumonia.
- Patients with end-stage liver disease can develop characteristic pulmonary complications including hepatic hydrothorax, hepatopulmonary syndrome, and portopulmonary hypertension. Hepatopulmonary syndrome is characterized by intrapulmonary vasodilation and abnormal gas exchange and resolves following liver transplantation. Portopulmonary hypertension, in contrast, is characterized by pulmonary arterial hypertension and right heart failure, is treated with pulmonary arterial hypertension–targeted therapy, and has variable posttransplant outcomes.
- Episodes of severe acute pancreatitis are associated with a high frequency of pulmonary complications, including hypoxemia, pleural effusions, and acute respiratory distress syndrome. Pulmonary complications are a major cause of excess morbidity and mortality.
- Patients with chronic kidney disease are at risk for multiple pulmonary complications including pulmonary edema, pleural effusions, and sleep apnea. Some respiratory symptoms may be alleviated by dialysis and/or renal transplantation.

eFigure 126.3 Metastatic calcinosis in patients with end-stage renal disease. (A) Axial *computed tomography* (CT) scan displayed in lung windows shows confluent dense calcification in the apices. The calcification of these opacities is more evident with CT displayed in soft tissue windows (B). (C) Axial CT slightly caudal to (A) shows that the apical opacities have a hazy centrilobular nodular appearance, which is commonly encountered in end-stage renal disease patients with metastatic calcinosis. (Courtesy Michael B. Gotway, MD.)

KEY POINTS

INTRODUCTION

Hematologic diseases and their specific therapies can adversely affect several aspects of cardiopulmonary function by reducing the oxygen-carrying capacity of the blood, by impairing pulmonary vascular function and pulmonary immune defenses, and by damaging the pulmonary parenchyma directly. This chapter reviews the clinical manifestations, epidemiology, pathophysiology, and treatment of pulmonary complications of disorders of the hematologic system.

RED BLOOD CELL DISORDERS

ANEMIA

Anemia is defined as a reduction in the number of circulating *red blood cells* (RBCs). By decreasing the oxygen-carrying capacity of the blood, anemia can impair cardiopulmonary function. However, because multiple compensatory mechanisms exist to adjust to a reduced oxygen-carrying capacity of blood, the signs and symptoms induced by anemia depend on its degree, the rate at which it evolves, the oxygen demands of the patient, and the presence of chronic cardiopulmonary disease. For instance, in resting adults subjected to acute isovolemic anemia, oxygen delivery can be maintained at hemoglobin concentrations as low as 5 g/dL,[1] a finding also seen in individuals with chronic severe anemia.[2] As such, anemia, even when severe, rarely causes heart failure or pulmonary edema and, when it does, it is likely that heart failure from chronically high cardiac output is superimposed on some other coexisting cardiac abnormality. From the hemodynamic standpoint, as the hemoglobin level decreases (particularly with hemoglobin values < 7 g/dL), cardiac output increases, filling pressures tend to decrease, and systemic and pulmonary vascular resistances decrease. These changes are readily reversible after RBC transfusions.[2,3] Finally, when anemia is severe, in the absence of coexisting cardiopulmonary disease, gas exchange is usually well maintained.

Pulmonary hypertension (PH) is an increasingly recognized complication of chronic hereditary and acquired hemolytic anemias. Remarkably, virtually every cause of hemolytic anemia has been associated with PH (Table 127.1). The PH associated with hemolytic disorders is considered in the group 5 classification of PH, characterized by unclear/multifactorial mechanisms (see Chapter 83).[4,5] In contrast, there have been no reports of PH associated with nonhemolytic anemias, such as the anemia of chronic disease or iron deficiency anemia. This suggests that the hemolytic component of anemia is necessary for the development of PH, which is discussed in detail in the section on hemoglobinopathies.

POLYCYTHEMIA

Polycythemia is characterized by an abnormally high hematocrit (>48% and >52% in women and men, respectively), hemoglobin concentration (>16.5 or >18.5 g/dL in women and men, respectively), or RBC count. These measurements are dependent on the plasma volume and the RBC mass; thus, before classifying a patient as having true polycythemia, one must exclude a decrease in plasma volume as the etiology for these abnormalities. A state of chronically reduced plasma volume with elevated hemoglobin or hematocrit has been called Gaisböck disease,[6] spurious polycythemia, stress erythrocytosis, apparent polycythemia, and pseudopolycythemia and has been associated with use of diuretics, alcohol, obesity, hypertension, and renal disease. On the other hand, patients with true elevations in RBC mass have absolute polycythemia and are categorized as primary or secondary forms. Primary polycythemia is caused by an acquired or inherited mutation, such as in the *JAK2* gene,[7] leading to an abnormality within RBC progenitor cells; it includes polycythemia vera and rare familial variants (e.g., activating mutations of the erythropoietin receptor or Chuvash polycythemia). Secondary polycythemia is caused by a circulating factor stimulating erythropoiesis, usually related to the production of erythropoietin

Table 127.1 Hemolytic Disorders Associated With Pulmonary Hypertension

Thrombotic thrombocytopenic purpura
Hemolytic uremic syndrome
Hemolysis from mechanical heart valves
Left ventricular assist devices and cardiopulmonary bypass procedures
MALARIA

as a physiologic response to chronic hypoxia (e.g., chronic hypoxic lung disorders and disorders affecting hemoglobin oxygen affinity), but can also result from erythropoietin-secreting tumors.

Most of the symptoms of polycythemia are related to an increase in blood viscosity, which leads to impairment in systemic and pulmonary blood flow (see eFig. 85.1). Thromboembolic events have been described in approximately 30% of patients with polycythemia vera and account for 31% of their deaths.[8] Pulmonary nodular lesions secondary to thrombosis, stasis, or infarction have been described in these patients.[9] Late-stage polycythemia vera, which is characterized by myelofibrosis, may cause pulmonary and pleural masses that are related to extramedullary hematopoiesis.[10]

PH has been reported in patients with polycythemia and other myeloproliferative disorders.[9,11–14] In several case reviews, PH was common and often considered a direct cause of death.[11,13,15] The pathogenesis of PH in these disorders is not well established but can involve chronic thromboembolic disease or hypercoagulability and hyperviscosity leading to in situ thrombosis, as well as hemoglobin-dependent scavenging of endothelium-derived *nitric oxide* (NO)[16–20] and upregulation of *hypoxia inducible factor-1α* (HIF-1α)–mediated pathways, such as endothelin-1.[13]

In patients with polycythemia vera, the mainstay of therapy is phlebotomy and myelosuppression with *hydroxyurea*, to keep the hematocrit below 42% in women and 45% in men, and antithrombotic therapy with aspirin or anagrelide.[21,22] Hydroxyurea acts by inhibiting ribonucleotide reductase, the enzyme involved in transforming ribonucleosides into deoxyribonucleosides, thus inhibiting DNA synthesis and causing cell death. In case series, treatment of polycythemia vera has been shown to improve PH.[11] In patients with chronic hypoxic disorders, such as COPD and interstitial lung disease, long-term oxygen therapy should reduce the number of patients who become severely polycythemic. In patients with COPD and severe polycythemia, phlebotomy—to achieve a hematocrit of about 50%—is associated with both a decrease in *mean pulmonary artery pressure* (mPAP) and in *pulmonary vascular resistance* (PVR), as well as an improvement in exercise performance.[23] However, the use of phlebotomy should be reserved as adjunctive therapy in symptomatic patients with marked polycythemia who remain significantly polycythemic despite appropriate long-term oxygen therapy.

HEMOGLOBINOPATHIES

SICKLE CELL DISEASE

Sickle cell anemia, the most common and most severe form of *sickle cell disease* (SCD), is seen in individuals who are homozygous for a single nucleotide substitution in the β globin gene. This results in the synthesis of *hemoglobin S* (Hb S), a structural variant that, when deoxygenated, is much less soluble than normal hemoglobin (Hb A).[24,25] Deoxygenated Hb S polymerizes and aggregates inside sickled erythrocytes as they traverse the microcirculation. Rigid, dense, and sickled cells can become entrapped in the microcirculation, a process that is enhanced by their increased propensity to adhere to endothelium. Mechanistic studies in transgenic mice expressing exclusively human Hb S suggest that microvascular occlusion results in ischemia and reperfusion injury, which promotes inflammatory, thrombotic, and oxidant stress.[26–29] In patients with SCD, vaso-occlusion leads to the frequent episodes of bone pain and acute chest syndrome that complicate SCD. Furthermore, the membrane of erythrocytes containing intracellular Hb S polymer is constantly exposed to mechanical and oxidant injury as the erythrocytes traverse the microcirculation. Ultimately, cumulative membrane damage shortens red cell life span so that SCD is characterized by a chronic hemolytic anemia. Intravascular hemolysis releases cell-free hemoglobin into the plasma, which scavenges NO, a critically important gaseous signaling molecule that mediates vasodilation. Hemolysis also releases RBC arginase into the plasma, which catabolizes arginine, the substrate for NO synthesis.[17,30,31] Intravascular hemolysis thus produces a state of endothelial dysfunction, vascular proliferation, and pro-oxidant and proinflammatory stress.[32–38] After hemolysis, hemoglobin can oxidize and release heme, which has been shown to activate the *toll-like receptor 4* (TLR4) and inflammasome signaling to amplify inflammation.[39–41] In the lung microvasculature, cell-free hemoglobin and heme, and inflammatory stimuli such as lipopolysaccharide, can stimulate P-selectin–dependent platelet-neutrophil aggregates that entrap erythrocytes and further drive lung inflammation.[39]

It is estimated that about 250,000 children worldwide are born with homozygous sickle cell anemia every year.[42] Approximately 0.15% of African Americans are homozygous, and 8% have the sickle cell trait. Despite significant improvements in the life expectancy of patients with SCD, estimates of the median age at death range from 48 to 58.5 years for women and 42 to 53 years for men.[43,44]

Acute and chronic pulmonary complications of SCD are common but are often underappreciated by health care providers. Acute complications include asthma and the *acute chest syndrome* (ACS), whereas chronic complications

include pulmonary fibrosis and PH. Pulmonary complications account for a large proportion of deaths among adults with SCD.[43,45,46] According to the Cooperative Study of Sickle Cell Disease, a prospective multicenter study of 3764 patients, more than 20% of adults presumably had fatal pulmonary complications of SCD.[43] Among the 299 patients enrolled in the long-term follow-up study of patients who participated in the *Multicenter Study of Hydroxyurea in Sickle Cell Anemia* (MSH), pulmonary disease was the most common cause of mortality, accounting for 28% of all deaths.[47]

Acute Chest Syndrome

ACS represents a lung injury syndrome in patients with SCD analogous to that of the *acute respiratory distress syndrome* (ARDS). In a patient with SCD, ACS is clinically defined by the development of a new pulmonary opacity involving at least one complete lung segment, consistent with alveolar consolidation, not atelectasis, and accompanied by chest pain, fever, tachypnea, wheezing, or cough.[48]

Epidemiology. ACS is the second most common cause of hospitalization in patients with SCD and is the leading cause of both admission to an intensive care unit and premature death.[43,46] More recently, however, increased awareness, the chronic use of hydroxyurea, and the early and aggressive use of transfusion therapy appear to have decreased ACS-related morbidity and mortality, as evidenced by a lower rate of ACS in a multicenter trial of inhaled NO for vaso-occlusive crises.[49]

ACS can develop in any of the sickle hemoglobinopathies but is more common in individuals with homozygous SCD (Hb SS). In the Cooperative Study of Sickle Cell Disease, there was a 29% incidence of ACS in 3751 subjects over a 2-year period, representing an attack rate of 12.8 episodes per 100 patient-years for Hb SS disease.[43] The incidence was higher in children than in adults (24.5 events vs. 8.8 events per 100 patient-years). Up to half of ACS episodes develop in association with vaso-occlusive pain crisis, and many patients will have a painful event within 2 weeks of the diagnosis.[50,51] Because up to 20% of patients admitted with acute vaso-occlusive pain crisis will develop ACS in the first 3 days of hospitalization, physicians must be vigilant for this common and potentially lethal complication.

Steady-state laboratory parameters associated with an increased risk for the development of ACS include an elevated *white blood cell* (WBC) count, a higher hemoglobin level, and a lower fetal hemoglobin level.[50,51] In children, a number of studies now suggest that asthma is a risk factor for the development of ACS.[52–54] Other clinical events associated with increased risk for the development of ACS include major surgical procedures, acute rib infarcts, avascular necrosis of the hips, pregnancy, use of narcotics, acute anemic events, and previous pulmonary events.[50,51]

During acute hospitalization for vaso-occlusive crisis, the development of ACS is often preceded by an abrupt drop in hemoglobin levels (mean decrease of 0.8 g/dL from steady-state values) and increases in markers of hemolysis, such as *lactate dehydrogenase* (LDH). ACS may also be preceded by a drop in the platelet count (see later). Many clinicians monitor trends in hemoglobin and platelet counts and pay careful attention to patients with drops in steady-state values.

Pathophysiology. Three major mechanisms appear to be involved in the pathogenesis of ACS: infection, bone marrow fat embolization, and direct red cell intravascular sequestration causing lung injury and infarction (Fig. 127.1).

The most common etiology of ACS in both children and adults is infection by a community-acquired pathogen (eFig. 127.1), followed by an excessive inflammatory lung injury response. It is increasingly clear that patients with SCD are predisposed to develop severe lung injury triggered by relatively minor infections. Greater than 80% of adults with SCD report a history of having been admitted to the hospital for "pneumonia," which could be due to infectious pneumonia or to the infiltrates of ACS itself.[32] The National Acute Chest Syndrome Study Group analyzed 670 episodes of ACS in 538 patients with SCD to determine the cause, outcome, and response to therapy; respiratory samples obtained from sputum and bronchoalveolar lavage were analyzed for viral and bacterial infections.[48] Among the infectious agents identified most frequently were atypical bacteria, viruses, *Staphylococcus,* and *Streptococcus.* Community-acquired encapsulated bacteria were rarely isolated, despite the fact that patients with Hb SS disease usually have abnormal splenic function. Cases of severe ACS related to outbreaks of seasonal influenza have also been described.[55,56]

Fat embolization syndrome is the second most common cause of ACS and is more common in adults. It arises as a complication of vaso-occlusive pain crisis involving multiple bones, which results in bone marrow edema, infarction, and necrosis. As a result, bone marrow contents are released into the systemic circulation and trapped in the pulmonary circulation, producing acute PH, severe lung inflammation, and hypoxemia (Fig. 127.2 and eFig. 127.2).[57] Bone marrow fat released into the bloodstream is also converted by secretory phospholipase A_2 to free fatty acids, which can produce direct inflammatory lung injury.[58]

Vaso-occlusion is associated with the development of ACS in some patients, with a small percentage developing wedge-shaped pulmonary infarction (eFig. 127.3), sometimes followed by central cavitation.[59] In situ thrombosis is presumed to play a role, as suggested by a study showing segmental thromboemboli without any evidence of peripheral venous thrombosis.[60] In addition, a possible thrombotic thrombocytopenic purpura–like mechanism may exist in a subset of patients with ACS as suggested by studies demonstrating that free hemoglobin might inhibit activity of ADAMTS13, a protease whose deficiency underlies most cases of thrombotic thrombocytopenic purpura.[61–63]

Activation of Inflammatory Pathways in Patients With Sickle Cell Disease

See ExpertConsult.com for a discussion.

Clinical Features and Evaluation. The clinical features at presentation are age dependent, which likely reflects the different etiologies of ACS in different age groups, with children having a higher proportion of infectious etiologies and adults more likely to have fat embolization. Overall, 80% of patients present with fever, 62% with cough, and approximately 40% have chest pain, tachypnea, dyspnea, and abdominal, arm, leg, rib, or sternal pain.[48] Most adult patients present with severe extremity or chest pain and 24 to 72 hours later

Why do SCD patients develop severe acute lung injury, often after infection with more benign community-acquired infections, such as respiratory syncytial virus, parvovirus, rhinovirus, cytomegalovirus, Epstein-Barr virus, and herpes simplex virus? Recent data suggest that inflammatory stimuli activate innate sterile inflammatory pathways through TLR4 and the inflammasome, together with P-selectin–dependent adhesion of activated platelets and neutrophils, which form aggregates in the pulmonary microvasculature and entrap Hb S–containing erythrocytes and further stimulate release of interleukin-1β.[39,41] Of interest, in sickle cell mice, small doses of hemoglobin, heme, or lipopolysaccharide can trigger this inflammatory cascade, suggesting an overexuberant inflammatory response underlies the severe lung injury response that is so common in SCD patients. It is likely that the innate immune system is chronically activated by hemolysis and the stimulation of hemoglobin and heme in plasma, setting up the patient for a second "hit," often a community-acquired upper respiratory infection (eFig. 127.4). Clearly, a potential role for hemolysis-derived plasma-free hemoglobin and free heme as novel mechanisms in ACS is emerging. Ghosh and colleagues[64] administered lysed RBCs into the circulation of sickle cell mice, which resulted in increased pulmonary vascular permeability without affecting permeability in other organs; moreover, studies from the same group have demonstrated that *intravenous* (IV) administration of hemin to sickle cell mice induces severe and lethal acute lung injury.[65] In vitro studies also suggest that hemin induces pulmonary endothelial cell barrier dysfunction via necroptotic cell death in a TLR4-dependent manner.[66] In addition, higher plasma-free heme levels were associated with increased odds of ACS in children with SCD,[67] and genetic variants in inducible heme-oxygenase-1, the rate-limiting enzyme in heme catabolism, which causes increased hemeoxygenase-1 activity, have been associated with lower rates of ACS.[68] These data suggest that plasma-free hemoglobin and/or heme specifically may contribute directly to lung injury.

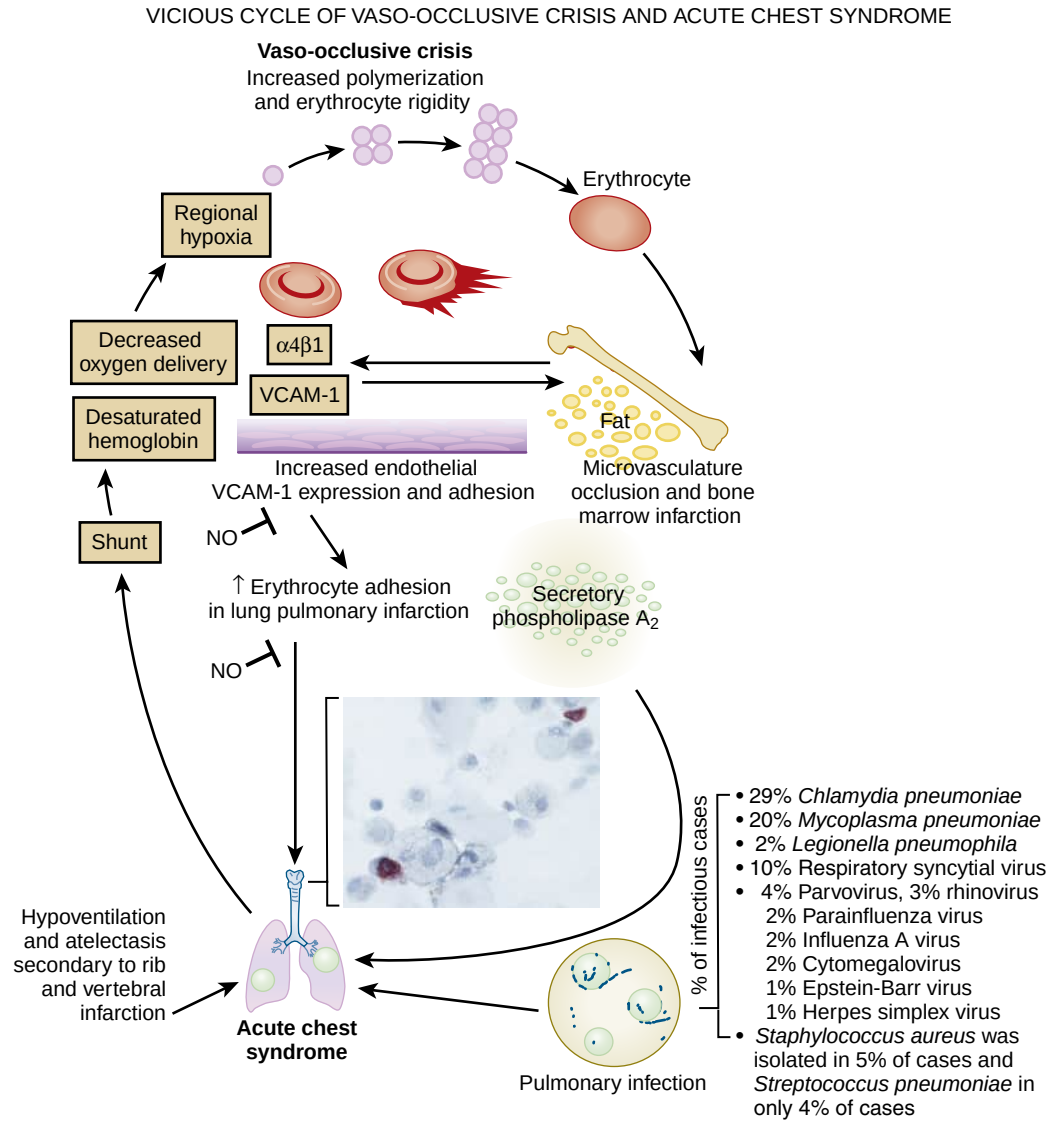

Figure 127.1 Pathogenesis of the acute chest syndrome. Three major triggers are associated with the development of acute chest syndrome: infection, bone marrow fat embolization, and direct red cell intravascular sequestration causing lung injury and infarction. Lung injury results in ventilation-perfusion mismatch/shunt and hypoxemia, which leads to increased hemoglobin S polymerization and erythrocyte vaso-occlusion. This worsens bone marrow infarction and pulmonary vaso-occlusion to promote a vicious cycle. Fat embolization can be diagnosed by oil red O staining of pulmonary alveolar macrophages, revealing the characteristic red lipid inclusions (see inset). NO can inhibit steps in the pathologic process, but NO is scavenged by free hemoglobin released by hemolysis. α4β1, an integrin dimer; NO, nitric oxide; VCAM-1, vascular cell adhesion molecule-1.

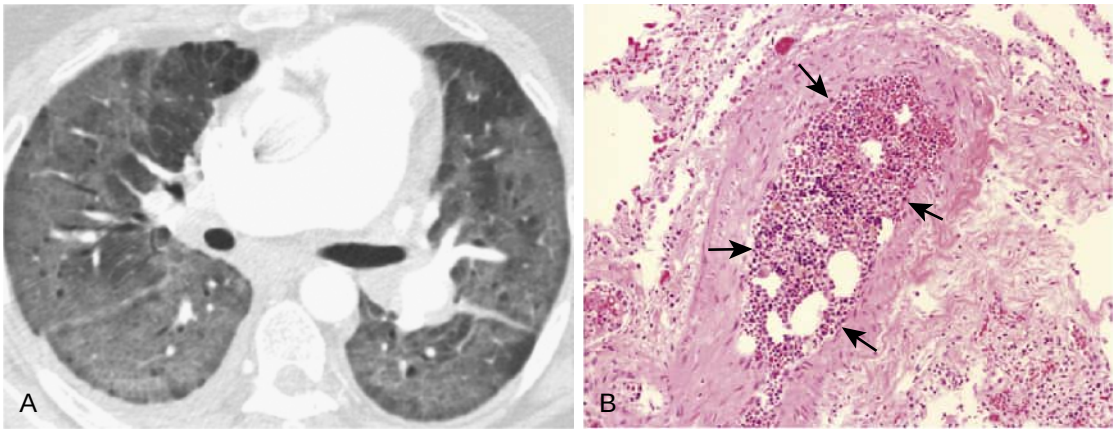

Figure 127.2 Fat embolization in acute chest syndrome. (A) Axial chest computed tomography scan of a patient with acute chest syndrome and fat embolization shows multifocal ground-glass opacity (same patient as in eFig. 127.2). (B) Postmortem examination specimen of a patient who died suddenly during an episode of vaso-occlusive crisis and acute chest syndrome demonstrating bone marrow elements *(arrows)* lodged in the small pulmonary artery. (Hematoxylin and eosin stain, magnification ×20.)

develop ACS. Reactive airway disease is observed in 13% of cases of ACS and is much more common in children. Adults are more likely to develop rapidly progressive ACS, defined as ACS progressing to respiratory failure less than 24 hours from onset of respiratory symptoms.[69]

ACS is associated with signs of systemic inflammation, with mean peak temperatures of 38.9°C and mean WBC counts of 23,000 cells/μL[40,48] Although high steady-state hemoglobin level is a risk factor for developing ACS, the acute presentation is often associated with a drop in hemoglobin and increases in hemolysis markers. A platelet count less than 200,000/μL appears to be a marker of ACS severity, associated with increased risk of neurologic complications and mechanical ventilation.[49] Secretory phospholipase A_2 levels are elevated early in the course of ACS, even before the development of radiographic changes, and have been used to predict the onset of the syndrome.[70]

Because the clinical manifestations can be indistinguishable from the other causes of ACS, the diagnosis of pulmonary fat embolization syndrome relies on the identification of oil red O–positive lipid accumulations within alveolar macrophages (see Fig. 127.1). In a 30-center clinical trial, the National Acute Chest Syndrome Study Group identified fat embolization syndrome in 16% of ACS cases in adults and children on the basis of positive lipid accumulations in alveolar macrophages.[48] Bronchoscopy has been used to help confirm the diagnosis of pulmonary fat embolization syndrome. Induced sputum may be a noninvasive alternative; in one study the yield from induced sputum sampling of alveolar macrophages was found to be similar to that from bronchoalveolar lavage.[71]

Some patients with ACS develop *systemic* fat embolization. Systemic fat embolization should be suspected in patients presenting with acute multiple organ failure, including acute hypoxic respiratory failure, right heart failure, renal and hepatic dysfunction, alterations in mental status, seizures, thrombocytopenia, and coagulopathy.[72,73] In patients with ACS, those with lipid-laden macrophages in induced sputum have significantly more extrathoracic pain, more neurologic symptoms, a lower platelet count, and higher transaminase levels than do those without lipid-laden macrophages.[71] This suggests that the fat embolization syndrome is both a major cause of ACS and has a more severe course with systemic complications.

The mean length of hospitalization for ACS is 10.5 days compared with 3 to 4 days for uncomplicated vaso-occlusive pain crisis. Thirteen percent of all patients with ACS require mechanical ventilation, and the overall mortality is 3% for all patients and 9% for adults. Risk factors for mechanical ventilation and poor outcome include a platelet count less than 200,000/μL (likely indicative of the fat embolization syndrome), a larger number of lobes involved on chest radiograph, and a self-reported or medical record history of cardiac disease. The latter complication is now thought to represent occult PH and right heart failure. In fact, in a study of 84 consecutive hospitalized patients with ACS, 13% of patients manifested right heart failure, a subgroup that had the highest risk for mechanical ventilation and death.[74] Thus, PH and right heart dysfunction likely represent a major comorbidity during ACS, and right heart failure should be considered in patients presenting with shock or severe hypoxemia.

Table 127.2 Treatment of the Acute Chest Syndrome

Oxygen therapy to maintain arterial hemoglobin oxygen saturation > 92%
Pain control and incentive spirometry to reduce chest wall splinting and pulmonary atelectasis
Close clinical observation ■ Monitor P_{O_2}/F_{IO_2} ratio ■ Particular attention to worsening respiratory function
Asthma therapy if indicated
Empirical antibiotics ■ Cover typical and atypical respiratory pathogens ■ Consider regional and seasonal risk of methicillin-resistant *Staphylococcus aureus* ■ Anticipate influenza A or B infections and treat/prevent accordingly
Transfusion therapy ■ Main indication for transfusion therapy in ACS is worsening respiratory function ■ Simple transfusion is as effective as erythrocytapheresis in the usual patient ■ Patients with high initial hemoglobin concentrations (≥9 g/dL) or patients with more severe disease should receive erythrocytapheresis ■ Transfused blood should be matched to Rh, C, E, and Kell antigens, and transfusion records documenting history of prior alloantibodies should be obtained

ACS, acute chest syndrome; F_{IO_2}, fractional concentration of oxygen in inspired gas; P_{O_2}, partial pressure of oxygen.

Treatment. In the outpatient setting, patients with a history of ACS should be treated with hydroxyurea because this therapy has been shown to reduce the risk of developing ACS by approximately 50%.[75,76] Although the precise mechanisms for this effect are largely unknown, the primary action appears to be that hydroxyurea induces the expression of fetal hemoglobin, thereby inhibiting RBC sickling. A chronic transfusion regimen is also effective in reducing the incidence of ACS.[77] Because the triggers and risk factors for ACS are well known, clinical surveillance plus aggressive and early therapy are likely to improve prognosis. This could be accomplished by close monitoring of patients during a vaso-occlusive crisis, during a febrile illness, and in the postoperative state.

If ACS develops, a range of treatment strategies is recommended, as outlined in Table 127.2. Oxygen therapy should be given routinely to maintain oxygen saturation above 92%. Aggressive pain management and incentive spirometry can minimize chest wall splinting, with consequent relief of atelectasis and hypoxemia. The use of incentive spirometry has been shown to decrease the incidence of new pulmonary opacities in patients admitted with vaso-occlusive pain affecting the chest wall.[59]

Given the high prevalence of infectious etiologies for ACS, we recommend the use of empirical antimicrobial therapy in all patients. Considering the high prevalence of atypical bacteria and encapsulated organisms, empirical coverage should include agents such as macrolides or fluoroquinolones, which are effective against these organisms. It is also important to consider alternative organisms, such as methicillin-resistant *Staphylococcus aureus* or influenza viruses, especially in patients not responding to therapy or during the annual influenza season.

Blood transfusion remains the mainstay of ACS therapy, although its value has not yet been demonstrated in randomized trials. Acute red cell transfusion increases arterial *partial pressure of oxygen* (Po_2) and hemoglobin oxygen saturation and may rapidly resolve the pulmonary event.[48,78] Because transfusion can also increase blood viscosity and the consequent risk of vaso-occlusion, it is recommended that the hemoglobin level not rise above 11 g/dL. The National Acute Chest Syndrome Study Group found no significant differences in outcomes between patients treated with simple transfusion or with *erythrocytapheresis* (i.e., RBC exchange), suggesting that simple transfusion is preferred as initial therapy.[48] For patients with high initial hemoglobin concentrations (>9 g/dL) or with more severe disease, however, erythrocytapheresis is recommended but, because most patients have a low hemoglobin at presentation, the transfusion of 2 to 4 units of packed red cells over 24 to 48 hours can usually be performed without complication. To decrease the risk of delayed hemolytic transfusion reactions related to alloimmunization against minor RBC antigens, all transfused blood should be matched to Rh, C, E, and Kell antigens.

Some initially promising treatments, including corticosteroids, inhaled NO, and *noninvasive ventilation* (NIV), have not been shown to have a role in ACS. Although treatment with corticosteroids has been shown to reduce the severity of pain and length of hospitalization, this therapy is complicated by a high rate of rebound pain and hospitalization.[79,80] One study evaluating a slow corticosteroid taper to limit rebound pain and readmission was terminated early because of slow accrual.[81] Inhaled NO does not appear to have any effect on the duration of pain crisis, narcotic use, pain scores, development of ACS, rate of ACS treatment failure, or need for transfusion.[49,82] In one small single-center randomized trial, NIV improved respiratory rate and gas exchange but did not reduce the number of patients remaining hypoxemic at day 3 and was associated with greater patient discomfort. In addition, NIV did not change transfusion rates, pain scores, narcotic dose, or hospital length of stay but instead prolonged length of stay in the step-down unit.[83] Reports of use of extracorporeal membrane oxygenation are still limited, and mortality is high.[84]

Pulmonary Hypertension

PH has emerged as a major threat to the well-being and longevity of patients with SCD. SCD could represent one of the most common causes of PH because, of the 30 million individuals worldwide with SCD,[85] approximately 10% of adults evaluated in screening studies have an mPAP greater than 25 mm Hg.

Epidemiology. Studies have shown that PH is common in patients with SCD, with prevalence as high as 30% when diagnosed by Doppler echocardiography, demonstrating a *tricuspid regurgitant jet velocity* (TRV) at least 2 standard deviations above the normal mean value (≥2.5 m/sec).[32,73,86–88] However, the prevalence seems to be much lower, at approximately 10%, when diagnosed by the gold standard diagnostic test, right heart catheterization.[89–91] Risk factors for developing PH include increased age, history of renal or cardiovascular complications, increased systemic systolic blood pressure, elevations in LDH (marker of hemolysis), elevated alkaline phosphatase, low transferrin levels, and a history of priapism in men.[30,32,92–94] Of interest, the number of vaso-occlusive episodes, markers of inflammation, fetal hemoglobin levels, or platelet counts are not risks for development of PH.[32,89,90,92,95] Although a high mPAP could result from the high cardiac output state associated with chronic anemia, this does not seem to be a major contributor to elevated mPAP because there has been no report of PH associated with nonhemolytic anemia. See Chapter 83 for details about echocardiography and diagnosis of PH.

See ExpertConsult.com for further details about the epidemiology of PH in SCD.

Mortality. An elevated mPAP increases the risk of death for patients with SCD. Several studies have demonstrated that mortality in patients with SCD significantly rises with both increasing TRV and increasing NT-proBNP level.[32,87,88,102] Similarly, multiple studies have also shown that the presence of PH documented by right heart catheterization is a major risk factor for death. Among patients with PH on right heart catheterization compared to no PH, mortality has ranged from 23% to as high as 50%, and each 10-mm Hg increase in mPAP associated with a 1.7-fold increase in the mortality.[89,91,95,103] In one study conducted by the NIH, specific hemodynamic variables were independently and significantly related to mortality, including mPAP, diastolic mPAP, systolic mPAP, *pulmonary capillary wedge pressure* (PCWP), transpulmonary gradient, and PVR.[95] These data suggest that mortality in adults with SCD and PH is proportional to the physiologic severity of pulmonary vascular disease.

Pathogenesis

See ExpertConsult.com for a detailed description of the development of PH in patient with SCD.

Clinical Features and Evaluation. The diagnostic evaluation of patients with SCD suspected of having PH should follow the same guidelines established for other causes of PH.[135,136] Given the high prevalence of PH in this population and the associated high mortality, an expert panel from the American Thoracic Society recommends that all adults with SCD undergo universal noninvasive screening with Doppler echocardiography or with assessment of steady-state plasma NT-proBNP levels.[137] In patients with SCD, as described earlier, the echocardiographic estimation of pulmonary artery systolic pressures (where pulmonary artery systolic pressure = 4 × TRV^2 + estimate of the right atrial pressure) correlates reasonably well with measured pulmonary systolic pressures by right heart catheterization.[32,138] See Chapter 83 for details about use of echocardiography and diagnosis of PH.

Although no prospective data on prevalence and risk of PH are available for children, we currently recommend that children with hypoxemia, high hemolytic rates (hemoglobin values < 7 g/dL with high LDH values), and/or recurrent ACS be screened. It is important that such screening be performed in the steady state because pulmonary pressures rise during vaso-occlusive painful crisis.[139]

A variety of studies, both retrospective and prospective, have identified a high prevalence of PH in patients with SCD. Retrospective studies have reported that 20–30% of patients with SCD have an elevated pulmonary artery systolic pressure estimated noninvasively by Doppler echocardiography by a TRV that is 2 standard deviations above the normal mean value (≥2.5 m/sec).[73,86] Autopsy studies suggest that up to 75% of sickle cell patients have histologic evidence of PH at the time of death (eFig. 127.5).[96]

These data are corroborated by three prospective studies.[32,87,88] In the *National Institutes of Health* (NIH) PH echocardiographic screening study, 23% of patients with SCD had borderline to mild elevations in pulmonary artery systolic pressures (defined by a TRV > 2.5–2.9 m/sec, which corresponds to a pulmonary artery systolic pressure of 30–39 mm Hg), and 9% had moderately to severely elevated pressures (defined by a TRV > 3.0 m/sec, which corresponds to a pulmonary artery systolic pressure of approximately 40–45 mm Hg).[32] Similar rates were found in echocardiographic screening studies performed at two other centers.[87,88]

Measurement of *N-terminal pro–brain natriuretic peptide* (NT-proBNP), a prohormone released by the right and left ventricular myocardium under pressure stress, in stored plasma samples has shown a high prevalence of abnormal values that may correlate with PH. Of those enrolled in the MSH in 1996, 30% of individuals had elevated levels, suggesting the possible presence of PH.[92] Similarly, among patients enrolled in the Cooperative Study of Sickle Cell Disease from 1978–88, 27.6% of adults had elevated levels of NT-proBNP.[97] In both studies, elevated NT-proBNP was independently associated with a higher risk of death.

PH has been shown to increase over time and with increasing age. Two centers independently reported the follow-up of adult sickle patients who on initial echocardiographic screening had normal TRVs. After 2 to 3 years of follow-up, 13–15% of these patients developed high TRVs, suggesting an increasing incidence of PH of about 4–7% per year.[93,98] Increasing age is associated with an increased risk of elevated TRV. For example, in the NIH PH echocardiographic screening study, patients with an elevated TRV were significantly older than patients without (38 ± 19 years for patients with TRV > 3.0 m/sec and 39 ± 12 years for patients with TRV 2.5–2.9 m/sec, compared with 34 ± 10 years for patients with TRV < 2.5 m/sec; $P = 0.02$).[32] An increasing number of studies suggests that PH is developing in children with SCD; however, few children have TRV values greater than 3.0 m/sec, and the implications in terms of functional capacity and associated mortality have not been determined.[94,99,100]

Epidemiologic risk factors associated with PH include a history of renal or cardiovascular complications, increased systemic systolic blood pressure, elevations in the marker of hemolysis (LDH), elevated alkaline phosphatase, and low transferrin levels.[32,92,101] In men a history of priapism was also an independent factor associated with PH.[32] These risk factors have also been observed in recently published studies using right heart catheterization to define PH.[89,90,95] Of interest, the development of PH was not associated with the number of vaso-occlusive episodes, markers of inflammation, fetal hemoglobin levels, or platelet counts.[32,89,90,92,95] Although a high mPAP could also result from the high cardiac output state associated with chronic anemia, this hyperdynamic state does not seem to be a major contributor to significant elevations in mPAP because there has been no report of PH associated with nonhemolytic anemia. In summary, PH represents a component of the systemic vasculopathy of SCD characterized by systemic hypertension, renal failure, and priapism.

Finally, three studies have provided insights into the prevalence of PH in SCD, using the gold standard diagnostic test for the disease, right heart catheterization demonstrating an mPAP of 25 mm Hg or greater. In the NIH screening study (2001–10, median follow-up of 4.4 years),[89] 86 of 533 subjects underwent right heart catheterization and, of these, 56 (10.5%) were diagnosed with PH. Similarly, in a screening study of 80 patients from Brazil, 32 (40%) had an elevated TRV and, of those who underwent right heart catheterization, eight (10% of the total population) had PH.[90] In a third large screening study of 398 patients with SCD in France using right heart catheterization,[91] 6% were shown to have PH. Of note, the French study excluded approximately 10% of patients, those with "severe" renal, liver, or lung disease, with severity defined as a creatinine clearance of less than 30 mL/min; an abnormal prothrombin time (international normalized ratio > 1.7); and chronic restrictive lung disease defined by a total lung capacity of less than 70% predicted. It is not clear why these patients would be excluded from a prevalence study of SCD-related PH, especially considering the fact that all of these complications develop as a direct consequence of SCD, and all three represent significant published risk factors for developing PH in SCD.

Epidemiologic studies suggest that the central risk factor for the development of PH in patients with SCD is the severity of hemolytic anemia (eFig. 127.6).[32,87,88,104] The association between the development of PH and the intensity of hemolytic anemia has been observed in three prospective screening studies of adult patients with SCD,[32,87,88] in an expanding number of pediatric studies,[94,99,100,105,106] and in studies using right heart catheterization to define PH.[89,90,95] This suggests that hemolysis is related mechanistically to PH. That relationship is plausible and biologically significant because free hemoglobin inactivates the intrinsic vasodilator NO.[17,31] Hemolysis also releases arginase, which depletes L-arginine, the substrate for NO synthesis.[30] These combined mechanisms result in a state of decreased NO bioavailability and "resistance" to NO-dependent vasodilation.[17]

Hemolysis and decreased NO bioavailability also induce platelet activation,[107] thrombin generation, and tissue factor activation.[108] There is also a correlation between the rate of hemolysis and the levels of procoagulant factors in blood in patients with SCD.[109–111] Hemolysis is also associated with the formation of RBC microvesicles expressing phosphatidylserine, which activates tissue factor.[111,112] These factors all contribute to an increased risk of thrombosis. In addition, sickle cell patients with functional asplenia and thalassemia patients with surgical splenectomy have increased levels of cell-free hemoglobin and red cell microvesicles, providing a potential mechanism for the hypercoagulability associated with both diseases.[111] Finally, the accumulation of redox-active heme and iron from lysed RBCs further contributes to the generation of

reactive oxygen species that can exacerbate ischemia-reperfusion injury, thrombosis, and vascular proliferative responses.[113] In fact, microthrombotic and/or thromboembolic lesions are common findings at postmortem examination in patients with SCD.[114,115] Acute or organizing thrombi in the pulmonary arteries, predominantly distal, were commonly seen in a series of 11 SCD patients with the diagnosis of PH,[116] and an association was found between the postmortem diagnoses of PH and thromboembolism in another autopsy series.[117] Functional or surgical asplenia could also contribute to the development of PH in patients with SCD. Splenectomy has been reported to be a risk factor for the development of PH (especially chronic thromboembolic PH),[118] particularly in patients with hemolytic disorders.[119–121] Loss of splenic function may trigger platelet activation, promoting pulmonary microthrombosis, and red cell adhesion to the endothelium.[122] The spleen also plays a critical function in the removal of senescent and damaged erythrocytes.[123,124] After splenectomy, moreover, the rate of intravascular hemolysis increases.[111]

Another downstream effect of hemolytic anemia includes increased endothelin-1–mediated vasoconstrictive and proliferative responses. In patients with SCD, both at steady state and during vaso-occlusive pain crises, plasma endothelin-1 levels are increased.[125] In vitro sickled erythrocytes increase endothelin-1 production by cultured human endothelial cells. All told, hemolysis acts via multiple mechanisms to block NO-induced vasodilation, activate procoagulant activity, injure endothelial cells, and exacerbate vasoconstriction and proliferation.

Chronic hypoxia and normoxic activation of HIF-related pathways are involved in the etiology of various forms of PH. SCD is also characterized by normoxic activation of hypoxic responses. In a recent study, Zhang and colleagues[126] compared clinical characteristics and *peripheral blood mononuclear cell* (PBMC) genomic profiles of subjects with SCD to those of subjects with Chuvash polycythemia, a monogenic disorder where homozygosity for von Hippel-Lindau syndrome R200W leads to posttranslational stabilization of the alpha subunits of HIF at normoxia, and increased levels of HIF-1 and HIF-2, leading to altered transcription of a number of genes and elevated systolic mPAP.[127–129] The study suggested that greater than 50% of PBMC gene expression variation in hemoglobin SS patients may be related to the hypoxic response because there was strong correlation between the gene expression profiles of the two patient populations.[126] Further, an expression quantitative trait locus in *MAPK8*, a hypoxia down-regulated gene (rs10857560) that has a prominent role in promoting apoptosis,[130] was associated with right heart catheterization–documented precapillary PH in patients with SCD. Finally, in another study, elevated levels of placental growth factor, which activates HIF-1α in normoxia and have been shown to be elevated and associated with elevated systolic mPAP in SCD. [131]

Genetic modifiers could also play a role in susceptibility to PH in SCD. Single nucleotide polymorphisms for genes in the transforming growth factor-β superfamily, including activin A receptor, type II–like 1 *(ACVRL1)*, bone morphogenetic protein receptor 2 *(BMPR2)*, and bone morphogenetic protein 6 *(BMP6)*; the β_1-adrenergic receptor *(ADRB1)*[132]; and thrombospondin-1 *(THBS1)*[133] have been associated with an elevated pulmonary artery systolic pressure in patients with SCD. Desai and colleagues[134] investigated the potential role of PBMC-derived gene signatures as biomarkers for PH in SCD.[134] The study found 631 transcripts and 12 micro-RNAs correlating with right ventricular systolic pressure (RVSP). Biologic-pathway analysis of these 631 genes revealed that pathways that have been associated with pulmonary vascular remodeling, such as Wnt signaling, calcium signaling, vascular smooth muscle contraction, and cancer pathways, were significantly overrepresented in subjects with elevated RVSP. Support vector machine analysis identified a 10-gene signature, including *GALNT13* (encoding polypeptide *N*-acetylgalactosaminyltransferase 13, a glycosyltransferase enzyme responsible for the synthesis of *O*-glycan), which distinguished patients with and without increased RVSP with 100% accuracy. This finding was then validated in a separate cohort of patients with PH documented by right heart catheterization, with an overall accuracy of 90%. A genetic association study comparing patients with an elevated RVSP and those with a normal RVSP revealed five significant single nucleotide polymorphisms within *GALNT13* associated with an elevated RVSP.

Historically, PH in patients with SCD was thought to derive from the repetitive episodes of pulmonary vaso-occlusive crisis and ACS. However, this association has not been supported by epidemiologic studies in which the number of episodes of vaso-occlusive crisis and ACS have not been shown to be associated with PH.[32,92]

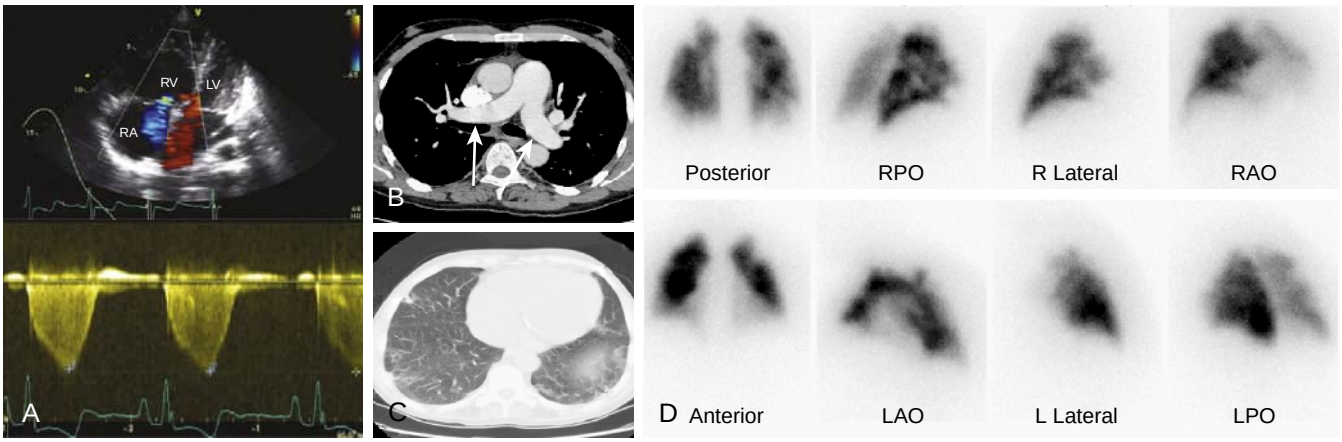

Figure 127.3 Imaging features of sickle cell disease and pulmonary hypertension. (A) *Top,* Echocardiographic apical four-chamber view of the heart, illustrating severe right ventricular (RV) and right atrial (RA) dilation and moderate tricuspid regurgitation (*blue* Doppler). *Bottom,* Doppler tracing from a patient with severe pulmonary hypertension reveals a jet velocity of greater than 4 m/sec. (B) Axial chest computed tomography scan showing enlargement of pulmonary arteries *(arrows)* in severe pulmonary hypertension. (C) Chest computed tomography showing mild pulmonary fibrosis typical of patients with sickle cell disease and pulmonary hypertension. (D) Perfusion scan demonstrating patchy areas of abnormal perfusion. Ventilation scans were normal (not shown). The diagnosis of PH in patients with SCD can be challenging (Fig. 127.3; Videos 127.1 and 127.2). Exertional dyspnea, the most typical presentation of PH, is also a cardinal symptom of chronic anemia, and therefore a high index of suspicion for PH is necessary. Other conditions that commonly present in patients with SCD, such as left ventricular dysfunction, pulmonary fibrosis, and liver cirrhosis, could also present in a similar fashion and result in PH. Patients with PH tend to be older and have higher systolic arterial blood pressure, lower hemoglobin levels, higher indices of hemolysis (such as high bilirubin or LDH values), lower hemoglobin oxygen saturation, greater degree of renal and liver dysfunction, and a higher number of lifetime RBC transfusions.[32] As such, the diagnostic evaluation of these patients should include an aggressive search for other conditions that might contribute to PH, such as iron overload, chronic liver disease, human immunodeficiency virus, nocturnal hypoxemia, and thromboembolism.

A diagnostic right heart catheterization is essential to confirm the diagnosis and exclude diastolic dysfunction (see later).[109] The 6-minute walk test is a useful surrogate for functional capacity in this patient population even considering the high prevalence of confounding factors such as the presence of avascular necrosis of the hip. Specifically, the *6-minute walk distance* (6MWD) inversely correlates with the severity of PH[113] and survival[95] and is improved by PH-specific therapy.[125]

The Doppler echocardiogram is an important tool for population screening and estimation of mPAP, but it cannot be used to diagnose or define PH in an individual patient. For a given patient, a diagnosis of PH is based on the measurement of the mPAP via a right heart catheterization. In a single individual, finding a TRV greater than or equal to 2.5 m/sec has low specificity for a diagnosis of PH,[91] with only 25% of those patients having the diagnosis of PH. Combining a TRV greater than or equal to 2.5 m/sec, a high NT-proBNP level (>164.5 pg/mL), and a low 6MWD of less than 333 m gives a positive predictive value for PH of 62%, with a false-negative rate of 7%.

Abnormal pulmonary function can be found in most patients with SCD. The pulmonary function abnormalities are characterized by mild restrictive lung disease (mean total lung capacity values of about 79% of predicted), abnormal diffusing capacity, and radiographic signs of mild pulmonary fibrosis,[46,140–144] and the severity of these defects seems to be slightly greater in those patients with PH.[145] However, in these patients, the degree of pulmonary function abnormalities is rarely severe enough to be a major contributor to the etiology of PH.

A ventilation-perfusion scan is an indispensable component of the evaluation because chronic thromboembolic PH, if amenable to pulmonary endarterectomy, is a potential curable cause of PH reported in patients with chronic hemolytic disorders. In the majority of cases, scintigraphic evidence of thromboembolic disease is uncommon, and the most common abnormality is patchy areas of abnormal perfusion, similar to findings described in other forms of PH.[145,146] Chronic thromboembolic PH is present in approximately 5% of sickle cell patients with severe PH[145] (Fig. 127.4). As such, patients should undergo imaging studies and, if suggestive of chronic thromboembolic PH, should undergo more invasive studies (i.e., angiography) to exclude this potentially surgically treatable condition.

NT-proBNP levels can be used as a PH biomarker for diagnosis and risk stratification in patients with SCD.[92] In a contemporaneous cohort, NT-proBNP levels were higher in patients with SCD-associated PH than without PH and correlated directly with the severity of PH and the degree of functional impairment. An NT-proBNP level of 160 pg/mL or greater had a 78% positive predictive value for finding an elevated TRV. In this and in other studies, an elevated NT-proBNP was an independent predictor of mortality.[97]

In contrast to patients with traditional forms of PH (e.g., idiopathic pulmonary arterial hypertension [PAH] or scleroderma-associated PAH) who may be symptomatic with mPAP in the range of 50 to 60 mm Hg, patients with SCD may be symptomatic with a mild to moderate degree of elevation in mPAP, in the range of 30 to 40 mm Hg. These patients may also have coexistent mild elevation in

PCWP, suggesting left heart failure (Table 127.3). Right heart catheterization data from multiple studies[21,23–26] show that the hemodynamic etiology of the PH in patients with SCD is multifactorial: precapillary PH (defined by a mPAP ≥25 mm Hg and a PCWP ≤15 mm Hg) is present in 50% of catheterized patients, whereas pulmonary venous hypertension secondary to left ventricular diastolic dysfunction disease (defined by a mPAP ≥25 mm Hg and a PCWP >15 mm Hg) is present in 50%.

Furthermore, using echocardiography in a cohort of 141 patients with SCD, Sachdev and associates[147] found that 47% of patients had PH, diastolic dysfunction, or both. PH and diastolic dysfunction were associated with a relative risk of death of 5.1 and 4.8, respectively, whereas the relative risk of death when both were present was 12.0.[147] These data suggest that both PH and diastolic dysfunction independently carry mortality risk.

Regardless of the hemodynamic etiology, SCD patients with chronic anemia, who maintain a high compensatory resting cardiac output to ensure adequate oxygen delivery, normally have a reduced PVR and appear to be poorly tolerant of even small increases in PVR. When compared with age-, gender-, and hemoglobin-matched patients with SCD without PH, individuals with PH exhibited a lower 6MWD, lower peak oxygen consumption on cardiopulmonary exercise testing, and higher ventilatory equivalent for carbon dioxide at anaerobic threshold on cardiopulmonary exercise testing.[113] Patients with SCD and PH appear to have worse functional capacity than is reported for patients with PH from other etiologies.[148] In addition, in patients with SCD, PVR sharply rises with exercise, suggesting that pulmonary vascular disease contributes to functional limitation in these patients.[139] Taken together, these data suggest that, in SCD patients with chronic anemia, mild to moderate PH has a severe adverse impact on functional and aerobic exercise capacity.

Table 127.3 Hemodynamic Profiles in Patients With Sickle Cell Disease

	Without PH	With PH
mPAP (mm Hg)	19 ± 0.7	36 ± 1
RAP (mm Hg)	6 ± 0.4	10 ± 1
PCWP (mm Hg)	11 ± 0.5	17 ± 1
CO (L/min)	10 ± 0.5	9 ± 0.3
PVR (dynes • s • cm^{-5})	59 ± 6	197 ± 14

CO, cardiac output; mPAP, mean pulmonary artery pressure; PH, pulmonary hypertension; PCWP, pulmonary wedge pressure; RAP, right atrial pressure; PVR, pulmonary vascular resistance.
Data from references 145, 264, and 265, except PVR, which comes from references 145 and 265.

Treatment. Data on the specific management of patients with SCD and PH are limited, although an increasing number of informative open-label intervention studies have been published. Most of the recommendations are based on expert opinion or extrapolated from data derived from observational intervention studies in patients with SCD or from other forms of PH and lack data from randomized controlled trials.[136,137] The general approach should include maximization of SCD-specific therapy (i.e., treatment of primary hemoglobinopathy), treatment of hypoxemia with chronic oxygen therapy, and treatment of associated conditions, such as iron overload, chronic liver disease, human immunodeficiency virus infection, nocturnal hypoxemia, and thromboembolic disorders. For patients with SCD with PH (mPAP ≥ 25 mm Hg and PCWP < 15 mm Hg with a relatively high PVR, > 160 dynes • s • cm^{-5}), targeted therapy with pulmonary vasodilator/antiremodeling agents can be considered. See Fig. 127.5 for an algorithm proposed by the American Thoracic Society for the diagnosis, risk stratification, and management of PH in SCD.[137]

Because chronic intravascular hemolysis is a central mechanism in the development of PH, it is likely that optimizing SCD therapy would be beneficial through amelioration of the principal mechanism involved in the pathogenesis of PH. Hydroxyurea has been shown to decrease the incidence of pain episodes and ACS, reduce the need for transfusions, and lower overall mortality.[47,75] It is possible that some of

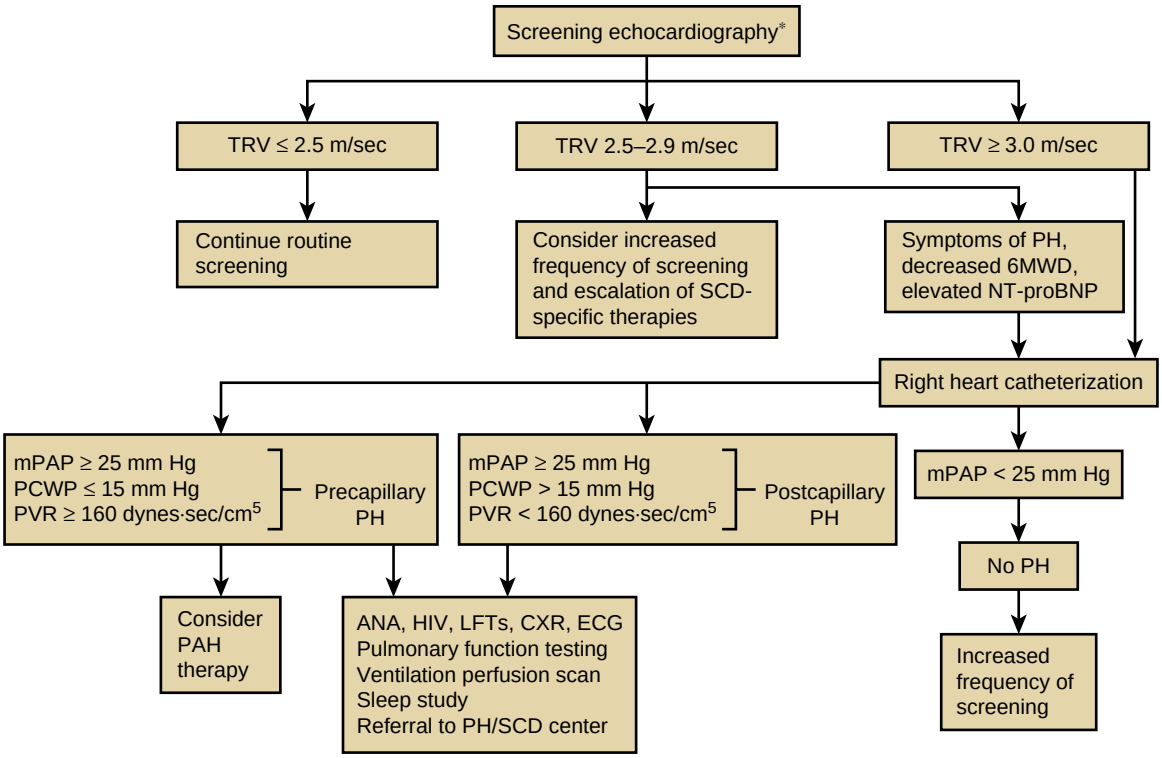

Figure 127.5 Proposed algorithm for evaluation of pulmonary hypertension related to sickle cell disease. Echocardiography should be performed while patients are clinically stable. Patients with an mPAP between 20 and 25 mm Hg need further study because they may be at increased mortality risk. *The use of the term *screening* refers to mortality risk assessment. ANA, antinuclear antibody; CXR, chest radiograph; ECG, electrocardiogram; HIV, human immunodeficiency virus; LFTs, liver function tests; mPAP mean pulmonary artery pressure; 6MWD, 6-minute walk distance; NT-proBNP, N-terminal pro–brain natriuretic peptide; PCWP, pulmonary capillary wedge pressure; PH, pulmonary hypertension; PVR, pulmonary vascular resistance; SCD, sickle cell disease; TRV, tricuspid regurgitant jet velocity. (From Klings ES, Machado RF, Barst RJ, et al; American Thoracic Society Ad Hoc Committee on Pulmonary Hypertension of Sickle Cell Disease. An official American Thoracic Society clinical practice guideline: diagnosis, risk stratification, and management of pulmonary hypertension of sickle cell disease. *Am J Respir Crit Care Med.* 2014;189[6]):727–740.)

the decreases in pulmonary and cardiovascular deaths seen in hydroxyurea-treated patients could be related to an improvement in PH. For patients with creatinine levels less than 1 mg/dL, hydroxyurea is started at a dose of 15 mg/kg/day and titrated up to a maximum of 35 mg/kg/day. Detailed treatment guidelines have been published.[76,149] Patients with renal dysfunction tend not to tolerate the myelosuppressant effects of hydroxyurea and, in those cases, we recommend adding erythropoietin to the regimen. Long-term transfusion therapy lowers the risk of most complications of the disease, including the risks of pulmonary events and central nervous system vasculopathy,[150–152] and might improve cardiopulmonary function and prevent the progression of PH. For example, in a small series of 13 patients with SCD and precapillary PH, chronic exchange transfusion therapy improved functional capacity (improved 6MWD and New York Heart Association functional class) and decreased PVR.[153] A large multicenter randomized trial of erythrocytapheresis on top of standard of care is currently sponsored by NHLBI, with randomization starting in 2020 (SCD CARRE trial). Haploidentical peripheral blood stem-cell transplantation and lung transplantation have also been shown to normalize pulmonary pressures and to improve short-term outcome measures in these patients.[154,155]

The potential benefits of warfarin therapy observed in patients with idiopathic PAH (group 1, see Chapter 84) have to be weighed against the risk of hemorrhagic stroke in adults with SCD or hemorrhage in chronically anemic individuals. We believe that the relatively low risk of hemorrhagic stroke (0.21 events per 100 patient-years[156]), compared with the high risk of death in patients with severe PH, supports anticoagulation in patients without a specific contraindication who have hemodynamic evidence of PH or chronic thromboembolic PH.

There are limited data on the specific treatment of PH in SCD, and the choice of agents (prostacyclin analogues, phosphodiesterase inhibitors, or endothelin receptor antagonists) is largely empirical and based on the safety profile of the drugs and physician preference. In general, randomized multicenter placebo-controlled studies evaluating the role of PH therapy in patients with SCD have not yet provided clear guidance.[157,158]

Prostacyclin-based therapy has been shown to reduce pulmonary pressures and increase 6MWD and functional class in patients with SCD and PH.[159,160] This study demonstrated dose-response relationships between subcutaneous, inhaled, and IV prostacyclin analogues and improvements in estimated pulmonary pressures and 6MWD. However, there are specific treatment concerns regarding the use of these drugs in patients with hemolytic diseases. For example, the use of prostanoids can produce systemic vasodilation and increases in cardiac output, raising the concern for the potential development of high-output heart failure in anemic patients. In addition, the risk of chronic IV-line–related complications, such as thrombosis and sepsis, is likely higher in patients with SCD.

Sildenafil and other phosphodiesterase inhibitors function by inhibiting the metabolism of cyclic guanosine monophosphate, the second messenger that mediates the effects of NO. In a series of seven patients with either thalassemia or sickle-thalassemia and severe PH, treatment with sildenafil from 4 weeks to 48 months resulted in an improvement in TRV, New York Heart Association functional class, and 6MWD.[161] In another case series of 12 patients with SCD treated with sildenafil for a mean of 6 months, mean pulmonary artery systolic pressure decreased by 9 mm Hg, 6MWD improved, and mean NT-proBNP decreased.[162] The main concern related to the use of sildenafil is the potential for the development of priapism in men with SCD.

Endothelin antagonists have limited evidence to support their use for PH. Minniti and colleagues[163] reported on the use of bosentan and ambrisentan in a cohort of 14 patients with SCD and PH documented by right heart catheterization. Endothelin antagonist therapy either as monotherapy or in combination with sildenafil was well tolerated and resulted in a modest improvement in 6MWD. The main toxicity of endothelin-1 receptor antagonists is hepatocellular injury, which could limit their applicability in patients with SCD at risk for liver dysfunction (e.g., iron overload, hepatitis C). Another class effect of these agents is a dose-related decrease in hemoglobin levels, usually by approximately 1 g/dL.[148]

Chronic Lung Disease

Sickle cell chronic lung disease has been used as a broad term to encompass pulmonary fibrosis resulting from recurrent ACS and PH.[46] Current understanding of sickle cell chronic lung disease suggests that pulmonary fibrosis is quite mild and that PH is a more important cause of chronic pulmonary disease. For this reason, we believe that this older terminology should be replaced with a more specific diagnostic classification.

In patients with SCD, repetitive episodes of acute injury to the lung related to ACS can result in parenchymal damage and typically mild restrictive lung disease (eFig. 127.7). In a study of 310 patients with homozygous SCD, pulmonary function was abnormal in 90% of adult patients; the most common abnormalities included mild restrictive physiology and decreased diffusing capacity.[164] These abnormalities worsen with age and are associated with increases in mPAP.[145,164]

In patients with SCD, airway hyperactivity is much more common in children than in adults.[165] Data are conflicting on whether children with SCD have a much higher prevalence of asthma and airway hyperactivity, when compared with ethnically and aged-matched control subjects.[53,166] Studies also suggest that wheezing and obstructive lung disease may arise independently of asthma and are markers of disease severity or a high-output state.[167,168] Compared to children with SCD who do not have asthma, children with SCD and asthma appear to have a higher incidence of ACS, cerebral vascular accidents, and need for blood transfusions, arguing for aggressive diagnosis and treatment of asthma in this population.[53,54,169] Similarly, adults with SCD who have asthma or recurrent episodes of wheezing have increased SCD-related morbidity, such as more episodes of pain, higher likelihood of development of recurrent ACS,[170] decreased lung function, and increased risk of death compared to adults with SCD without asthma symptoms.[171–176]

Sleep-disordered breathing has been reported in children and adults with SCD. In children, sleep-related upper airway obstruction and hypoxemia are the most common disturbances. In an uncontrolled study, adenotonsillectomy led to symptomatic improvement and amelioration of oxygen desaturation.[177,178] Evidence suggest that nocturnal hypoxemia contributes to the development of neurologic events and vaso-occlusive crisis via mechanisms that could involve upregulation of several inflammatory endothelial cell adhesion molecules.[179–181]

THALASSEMIA

Thalassemia refers to a spectrum of diseases characterized by reduced or absent production of one or more α or β globin chains. β-Thalassemia results from impaired production of β globin chains, which leads to a relative excess of α globin chains.[182] These excess α globin chains are unstable, incapable of forming soluble tetramers on their own, and precipitate within the cell, leading to ineffective erythropoiesis and hemolytic anemia.[182] Thalassemia major, or homozygous β-thalassemia, is a severe disorder due to the inheritance of two β-thalassemia alleles. Starting during the first year of life, patients develop severe and lifelong transfusion-dependent anemia, hepatosplenomegaly, and skeletal deformities due to bone marrow expansion; they are also prone to infection and skeletal fractures.

β-Thalassemia minor, also called β-thalassemia trait, arises in heterozygotes who have inherited a single gene leading to reduced β globin chain production. Such patients are asymptomatic, may be only mildly anemic, and are usually discovered when a blood count has been obtained for other reasons. β-Thalassemia intermedia is seen in patients with disease of intermediate severity, such as those who are compound heterozygotes of two thalassemic variants. Such patients may have the skeletal abnormalities and hepatosplenomegaly seen in thalassemia major. However, their hemoglobin concentrations usually range from 5 to 10 g/dL, and they usually require transfusions only when they have an intercurrent event, such as an infection, that impairs erythropoiesis. Their clinical symptoms may not be apparent until well after the first year of life. Another related condition is due to hemoglobin E, the most common hemoglobin variant in the world, which has a point mutation in the β-globin gene. In the heterozygous or homozygous states, patients with hemoglobin E are mostly asymptomatic or have a mild microcytic anemia. When hemoglobin E is present along with β-thalassemia, the condition is called hemoglobin E–thalassemia; about half of these patients are phenotypically similar to patients with thalassemia major and require regular transfusion therapy, with the other half having courses similar to patients with thalassemia intermedia.

Several cardiopulmonary abnormalities arise in patients with β-thalassemia, including restrictive and obstructive defects, hyperinflation, abnormal diffusing capacity, and decreases in aerobic exercise capacity.[183–185] However, in the majority of cases, these pulmonary function abnormalities are not associated with clinical symptoms. Several clinical complications are related to complications of therapy, such as transfusion-related iron overload, infection, thrombosis, possible acute deterioration in pulmonary function associated with the use of the iron chelator deferoxamine,

and PH related to splenectomy. In patients who are poorly transfused, extramedullary erythropoiesis can rarely cause pulmonary parenchymal masses, mediastinal masses (see eFigs. 115.44 and 115.45), and pleural effusions.

Similar to what is seen with SCD, PH is a common complication of thalassemia. Approximately 40–50% of patients with thalassemia intermedia[186] and 10–75% of patients with thalassemia major have echocardiographic evidence of PH.[187–189] In a multicenter cross-sectional study of β-thalassemia patients, those with a TRV of 3.2 m/sec or more (3.6% of the study group) underwent right heart catheterization. The prevalence of PH on right heart catheterization was 2.1% (4.8% in patients with thalassemia intermedia and 1.1% in patients with thalassemia major).[190]

PH in patients with thalassemia appears to be amenable to therapy. In spite of its potential complications, chronic transfusion therapy in severe thalassemia has changed the clinical course of the disease and is likely to have a favorable impact in individuals with PH. This idea is supported by a report that, in well-transfused, iron-chelated patients with thalassemia major, PH was completely prevented.[191] A favorable response to sildenafil has been reported in patients with thalassemia major and intermedia.[161,192] In a recent open-label study of 10 patients with β-thalassemia and a TRV greater than 2.5 m/sec, sildenafil decreased the TRV and improved left ventricular end-systolic/diastolic volume but did not improve 6MWD.[193] There are also case reports of favorable response to bosentan[194] and epoprostenol[195] in patients with right heart catheterization–confirmed precapillary PH. However, there are no studies evaluating either the specific hemodynamic derangements associated with PH or the impact of PH on survival in this patient population.

OTHER HEMOGLOBIN DISORDERS

Hemoglobin gene mutations can result in functional abnormalities in the globin chains that alter gas ligand affinity and oxygen uptake and delivery. Remarkably, there are more than 120 human hemoglobin gene mutations that have been associated with abnormal hemoglobin oxygen affinity.[196] Patients with moderately high-affinity hemoglobins usually present with erythrocytosis and are typically asymptomatic, but patients with variants associated with high oxygen affinity can present with cyanosis or symptoms related to increased RBC mass (polycythemia). In addition, whereas patients with low oxygen affinity hemoglobin variants are usually asymptomatic, some can present with cyanosis. The initial step in the workup of patients suspected of having a hemoglobinopathy affecting oxygen affinity is to evaluate the red cell oxygen equilibrium curve, whereby both the oxygen saturation of hemoglobin and P_{O_2} are directly measured to obtain a p50, the P_{O_2} at which hemoglobin is 50% saturated. This initial step should obviate the need for unnecessary and potentially invasive diagnostic procedures.

Methemoglobin is a nonfunctional state of hemoglobin in which the irons of heme are oxidized to the ferric (Fe^{3+}) state and are unable to bind oxygen. In addition, the oxygen affinity of any accompanying ferrous (Fe^{2+}) hemes in the hemoglobin tetramer is increased so that the oxygen dissociation curve is "left shifted," and oxygen delivery to the tissues is impaired.[153] Three mechanisms are associated with the development of methemoglobinemia: a genetic mutation resulting in abnormal hemoglobin (hemoglobin M), a congenital deficiency of methemoglobin reductase enzyme (cytochrome b_5 or cytochrome b_5 reductase deficiency), and a drug/toxin-induced oxidation of hemoglobin. Drugs that can induce methemoglobinemia include nitrates, nitrites, sulfonamides, dapsone, and several others. Most individuals with congenital methemoglobinemia are asymptomatic, and their primary complaint is "cyanosis" presenting as a slate-blue color of the skin and mucous membranes.

Cyanosis is clinically apparent when the absolute concentration of methemoglobin exceeds 1.5 g/dL, equivalent to approximately 10% methemoglobin.[197] In cases associated with drugs and toxins, the severity of the methemoglobinemia depends on the dose of the agent and the individual's susceptibility. At methemoglobin levels greater than 35%, patients can complain of headaches, weakness, and dyspnea; levels greater than 80% are typically incompatible with life.[196] Symptomatic patients should be treated with methylene blue (given IV at a dose of 1–2 mg/kg), which acts as a cofactor for the enzyme *reduced nicotinamide adenine dinucleotide phosphate* (NADPH)-methemoglobin reductase. Electrons are transferred from NADPH to methylene blue, which leads to a reduction of the heme iron.[198] Methylene blue should not be administered to individuals with glucose-6-phosphate dehydrogenase deficiency because it may precipitate hemolysis.[199]

Carbon monoxide (CO) binds to hemoglobin to form *carboxyhemoglobin* (COHb). CO has a much greater affinity for hemoglobin than does oxygen. The binding of CO to heme creates an allosteric change that diminishes the ability of hemoglobin to release oxygen to peripheral tissues, resulting in impaired oxygen transport and utilization. As such, CO poisoning is a major cause of morbidity and mortality. The clinical effects of CO poisoning are nonspecific and easily confused with other illnesses, such as viral illness, benign headache, and various cardiovascular and neurologic syndromes.[200] As the severity of exposure increases, patients develop more pronounced symptoms, with oxygen-dependent organs (the brain and the heart) showing the earliest signs of injury. Oxygen therapy improves tissue hypoxia and accelerates elimination of CO. Hyperbaric oxygen therapy should be considered in patients with severe CO poisoning (e.g., COHb > 25%, evidence of tissue ischemia, and loss of consciousness) and may reduce the incidence of the late neurocognitive deficits associated with severe CO intoxication.[201,202]

Cyanide binds the Fe^{3+} ion of cytochrome oxidase a3, inhibiting this final enzyme in the mitochondrial cytochrome complex and thereby preventing oxygen use by tissues. A small amount of cyanide can also bind to the Fe^{2+} iron ion of hemoglobin to form cyanhemoglobin, which is unable to transport oxygen and thus further exacerbates tissue hypoxia.[203]

WHITE BLOOD CELL DISORDERS

LEUKEMIAS

Although the majority of clinical pulmonary manifestations in patients with leukemia are not directly related to the disease, autopsy studies show that thoracic involvement is common in all types. Overall, the most common finding is

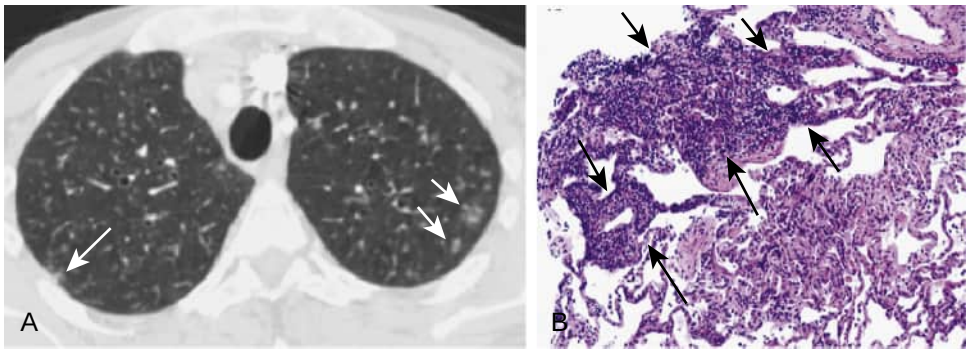

Figure 127.6 Leukemic infiltrates in a patient with chronic lymphocytic leukemia. (A) Diffuse nodular opacities *(arrows)*. (B) Transbronchial biopsy specimen demonstrating diffuse infiltration of lung interstitium by leukemic cells (especially *between arrows*). (Hematoxylin and eosin stain, ×20 magnification.)

mediastinal and lymph node involvement, but pleural and pulmonary infiltration is found in 20–65% of those who die with leukemia in autopsy series.[204–206]

The mediastinum is the most commonly affected intrathoracic site. This often manifests as a focal mass (eFig. 127.8) or as generalized mediastinal involvement. Hilar adenopathy is seen in 15–25% of patients.[207,208] Pleural effusion, usually unilateral, can present in up to 25% of cases and is seen more frequently in myeloid leukemias.[209] In the majority of cases, the effusion is related to lymphatic obstruction, congestive heart failure, or infections, with only approximately 5% of cases caused by leukemic infiltration.[209]

Leukemic pulmonary infiltrates are clinically significant in approximately 10% of patients (Fig. 127.6).[204] The usual radiographic pattern of involvement is a bilateral reticular pattern with septal lines resembling interstitial edema or lymphangitic carcinomatosis (eFig. 127.9). Interlobular smooth or nodular septal thickening is the most common high-resolution CT finding, followed by thickening of bronchovascular bundles. Other manifestations include peribronchovascular or random nodules, which can coalesce into masslike consolidation, focal areas of air space disease, and ground-glass opacities.[209–212] The diagnosis of leukemic infiltrates is one of exclusion because most of the pulmonary parenchymal abnormalities in these patients are associated with processes other than the hematologic disease, such as infections, hemorrhage, or pulmonary edema.

Pulmonary leukostasis or hyperleukocytosis is characterized by the distention of small pulmonary vessels by leukemic blast cells. It is most commonly seen in patients with acute leukemias and WBC counts greater than 100,000 cells/μL, with a predominance of blast cells.[213] Clinical and radiographic findings include dyspnea and hypoxemia associated with a bilateral reticular pattern with septal lines or air space consolidation.[213,214] Symptomatic leukostasis is a medical emergency, and efforts should be made to lower the WBC count rapidly. In most patients, rapid cytoreduction can be achieved by chemotherapy, but leukapheresis should be considered in severe cases or in patients who cannot receive chemotherapy immediately. Finally, patients can present with presumed acute spurious hypoxemia caused by an ex vivo decrease in arterial Po_2 mediated by the enhanced metabolism of the malignant cells; this process has been referred to as "leukocyte larceny." Pulse oximetry provides a more accurate assessment of arterial oxygen saturation in such circumstances.

Leukemic cell lysis lung disease arises in patients with high leukocyte counts undergoing chemotherapy and is part of the spectrum of tumor lysis syndrome. Severe hypoxia and diffuse bilateral opacities develop within 48 hours after the initiation of chemotherapy, resembling the clinical and pathologic presentation of ARDS.[215] In patients at intermediate or high risk for the development of tumor lysis syndrome, preventive measures are recommended, such as aggressive IV hydration, urine alkalinization in selected patients, and the use of agents to decrease uric acid levels, such as allopurinol and rasburicase.[216] These therapeutic strategies also apply to patients with established tumor lysis syndrome.

PLASMA CELL DISORDERS

Thoracic involvement in multiple myeloma is common, seen in 46% of patients, with the majority of cases related to neoplastic infiltration of the skeleton.[217] Pleural effusion caused by malignant infiltration has been reported and, for unclear reasons, the effusion appears to involve the left lung more frequently.[218] Pulmonary parenchymal or airway involvement is also rare, taking the form of single or multiple masses, diffuse parenchymal opacities, or endobronchial lesions.[217] Pulmonary amyloidosis can also result from systemic amyloid deposition, which can be a complication of different forms of plasma cell disorders (eFig. 127.10).[219]

Plasmacytoma is a circumscribed proliferation of plasma cells not associated with a plasma cell disorder. The vast majority of plasmacytomas involving the respiratory tract arise in the pharynx, followed by the trachea and, much less commonly, the lower airways and the pulmonary parenchyma.[220,221] Pulmonary parenchymal plasmocytomas present as a nodule or mass that is indistinguishable from bronchogenic carcinoma and may rarely present as a mass in the chest wall (eFigs. 127.11 and 127.12) or in the mediastinum (eFig. 127.13).

THROMBOSIS AND DISORDERS OF COAGULATION

INHERITED THROMBOPHILIA

Inherited thrombophilia encompasses the various mutations associated with venous thromboembolism (see Chapters 81 and 82 for further details). The most frequent causes of an inherited thrombophilia are the factor V Leiden mutation and a prothrombin gene (G20210A) mutation, which together account for 50–60% of cases. Mutations in

Table 127.4 Inherited Thrombophilic Disorders

Disorder	Prevalence in Healthy Individuals (%)	Frequency in Patients With VTE (%)	Relative Risk of First Episode of DVT	Relative Risk of Recurrence of VTE
Factor V Leiden (heterozygous)	0.05–4.8	18.8	7	1.4
Factor V Leiden (homozygous)	0.02	1.5	80	N/A
Prothrombin G20210A allele	0.06–2.7	7.1	2.8	1.7
Protein C deficiency	0.2–0.4	3.7	6.5	1.8
Protein S deficiency	0.16–0.21	2.3	5.0	1.0
Antithrombin III deficiency	0.02	1.9	20	2.6
Hyperhomocysteinemia	5–7	10	3.0	0.9

DVT, deep venous thrombosis; N/A, not available; VTE, venous thromboembolism.
Modified from Whitlatch NL, Ortel TL. Thrombophilias: when should we test and how does it help? *Semin Respir Crit Care Med*. 2008;29:25–39; and Dalen JE. Should patients with venous thromboembolism be screened for thrombophilia? *Am J Med*. 2008;121:458–463.

the genes coding for protein S, protein C, and antithrombin account for most of the remaining cases, although dysfibrinogenemias are rare causes of hypercoagulability (Table 127.4).[222,223] Patients with these disorders usually present with recurrent thromboembolism at a young age, typically younger than 50 years.

Several of these disorders are associated with an increased risk of initial and recurrent thromboembolism (see Table 127.4). There is, however, controversy about whether screening of individuals with venous thromboembolism for these inherited defects is warranted. Expert opinion suggests that evaluation for inherited thrombophilic disorders should be pursued in individuals with idiopathic thrombosis who are younger than 50 years, with a history of recurrent thrombosis, or with thrombosis in an unusual site; in those with a first-degree relative with thrombosis at a young age; or in women with thrombotic events during pregnancy or while taking oral contraceptives.[224,225] These recommendations must be contrasted with the results of epidemiologic studies, suggesting that a thrombophilic workup after a first thrombotic event is unlikely to confer clinical benefit.[226–228] The presence of a thrombophilic disorder does not impact the acute management of a thromboembolic event but could have an impact on the duration of chronic anticoagulant therapy.[229] Patients with antithrombin, protein C, or protein S deficiency should be considered for lifelong anticoagulation. Patients with heterozygous factor V Leiden or prothrombin gene mutations generally do not need lifelong anticoagulation but will likely benefit from extended anticoagulant therapy to reduce the risk of recurrence, as shown in other patients with idiopathic thromboembolism.[230,231] Patients with more than one allelic abnormality should also be considered for lifelong anticoagulation.

COAGULOPATHIES AND PLATELET DISORDERS

Spontaneous pulmonary hemorrhage does not appear to be a common complication of disorders of coagulation, such as the hemophilias, von Willebrand disease, or thrombocytopenia. The risk of bleeding appears to increase in individuals with preexisting pulmonary lesions or after physical or procedural trauma to the respiratory system. However, episodes of pulmonary hemorrhage, hemomediastinum, and tracheal and pleural hematomas have been described in patients with hemophilias.[232] Radiographic abnormalities, such as scarring, fibrosis, pleural thickening, abnormalities in pulmonary vessels, and hyperinflation and cases of PH, have also been described in patients with hemophilia.[196]

COMPLICATIONS OF TRANSFUSION

TRANSFUSION-ASSOCIATED ACUTE LUNG INJURY

Transfusion-related acute lung injury (TRALI) is an acute lung injury syndrome resulting from the transfusion of blood products containing plasma, most commonly whole blood, fresh frozen plasma, platelets, and packed RBCs. TRALI is currently the leading cause of transfusion-related morbidity and mortality.[233] Recently, the TRALI Delphi panel proposed a new consensus TRALI definition.[234] TRALI type I includes patients without risk factors for ARDS who meet the following criteria: acute onset of hypoxemia (arterial P_{O_2}/*fractional concentration of oxygen in inspired gas* [F_{IO_2}] ≤ 300 or oxygen saturation on room air < 90%), bilateral pulmonary opacities on imaging, no evidence of left atrial hypertension (LAH, or if LAH is present, it is not judged to be the main contributor to hypoxemia), and within 6 hours of infusion of a blood product. TRALI type II includes patients who have risk factors for ARDS but who have not been diagnosed with ARDS or who have existing mild ARDS (arterial P_{O_2}/F_{IO_2} of 200–300) but whose respiratory status deteriorates and is judged to be due to transfusion based on findings described in TRALI type I, and stable respiratory status in the 12 hours before transfusion.

Epidemiology

The incidence of TRALI is not well established but appears to be one episode for every 5000 blood component transfusions.[235] This likely underestimates the true incidence of the disease. Studies using systematic methods to identify

TRALI cases suggest that the incidence may be 5 to 50 times higher than previously thought.[236–239] A TRALI study group determined the incidence of TRALI by prospective, active surveillance in a case-control design in two academic medical centers.[240] The annual TRALI incidence decreased from 2.6 per 10,000 units transfused in 2006 to 0.8 per 10,000 units transfused in 2009, most likely related to TRALI mitigation strategies implemented in these centers.

TRALI has been reported in all age groups and with equal incidence in men and women. A single-center study suggested that patients with hematologic malignancies or cardiovascular disease requiring cardiopulmonary bypass operations are at a higher risk of developing this complication.[236] Administration of fresh frozen plasma, prolonged storage of blood products, and acute underlying conditions, such as recent surgery, massive transfusion, cytokine therapy, sepsis, and thrombocytopenia have also been implicated as risk factors for TRALI.[236,238,241–245] Multiparous women are the donors most commonly associated with cases of TRALI, which probably reflects the role of the antibodies formed due to exposure to fetal leukocyte antigens during pregnancy (see next section, "Pathogenesis").[235,246,247]

In the TRALI study group report, recipient factors associated with increased risk of TRALI included chronic alcohol abuse, shock, higher serum interleukin-8 levels, liver surgery, current smoking, higher peak airway pressure on mechanical ventilation, and positive fluid balance. Features of transfused blood products associated with increased risk of TRALI in the recipient were receipt of plasma or whole blood from female donors, high levels of human leukocyte antigen class II antibody, and anti–human neutrophil antigen–positive granulocytes. Little or no risk was associated with older RBC units, noncognate or weak cognate class II antibody, or class I antibody.[240]

Pathogenesis

Two leading hypotheses have been put forth to explain the mechanisms underlying the pathogenesis of TRALI. One theory proposes that transfused leukocyte antigens interact with antibodies to cause granulocyte activation and lung injury. An alternative "two-hit" hypothesis proposes that active substances accumulate as the blood product is stored and are transferred to a susceptible host, priming granulocytes that secondarily produce lung injury in the setting of systemic inflammation from another insult, such as sepsis.

The antileukocyte antibody hypothesis has support from several lines of evidence. Antileukocyte antibodies are found in donors or recipients after clinical episodes of TRALI, and infusion of antileukocyte antibodies in animals causes a similar form of lung injury.[248,249] In three case reports, TRALI was produced in healthy volunteers by infusions of plasma containing strong leukocyte antibodies.[250] Antibodies against human leukocyte antigen class I and II antigens are also found in patients with TRALI.[251]

The other two-hit hypothesis is also supported by several studies. The age of transfused blood has been reported as a risk factor for multiorgan failure in trauma patients.[252] The presence of bioactive lipids implicated in the pathogenesis of lung injury, such as lysophosphatidyl choline, is higher in blood products given to patients who develop TRALI.[238,244] CD40 ligand, which induces injury to activated microvascular endothelial cells, accumulates in stored blood products, and significantly higher levels have been found in blood products given to patients who develop TRALI.[253]

Clinical Features and Evaluation

Patients typically present with the sudden onset of respiratory distress 1 to 2 hours after the transfusion of blood products. Clinical signs include fever, tachypnea, tachycardia, and occasionally hypotension.[242] The patients may cough pink frothy secretions with a high albumin content indicative of increased permeability (noncardiogenic) pulmonary edema. Chest radiography classically reveals bilateral alveolar opacities with a normal cardiac silhouette and without pleural effusion. The finding of granulocyte, leukoagglutinating, or lymphotoxic antibodies in the serum from either the donor or recipient supports the diagnosis of TRALI, but these abnormalities are not found in all patients. The main differential diagnosis in these patients is transfusion-associated circulatory overload, and the differentiation of these two conditions can be difficult. The measurement of brain natriuretic peptide levels has been described as a helpful tool to differentiate these two entities.[254]

Approximately 70% of patients require mechanical ventilation at the time of presentation.[251] The illness tends to resolve within the first 48 hours, and with few exceptions, chest radiographs typically return to normal in 4 days. The estimated mortality associated with TRALI is 5%.[251]

Treatment

Because patients usually improve spontaneously, the management of TRALI is supportive. In patients requiring mechanical ventilation, the approach should be the same as recommended for patients with ARDS (see Chapter 134). There is no convincing evidence to support the use of corticosteroids in patients with TRALI. Individuals developing TRALI should not receive further blood products from the implicated donor but do not appear to be at increased risk for recurrent episodes with products from other donors.[255] Finally, in the TRALI study group case-control study, the incidence of TRALI decreased after the reduction of transfusion of plasma from female donors.[240]

Transfusion-Associated Circulatory Overload

Transfusion-associated circulatory overload (TACO) is likely the most common transfusion reaction affecting the respiratory system. It is characterized by pulmonary edema that develops due to volume excess or circulatory overload, primarily in patients who receive large volumes of transfusions over a short period of time, or in patients with underlying cardiac or renal disease. TACO can be typically differentiated from TRALI based on a combination of clinical, laboratory, and imaging characteristics, and response to diuretic therapy. These components have been incorporated in a recently revised international surveillance case definition.[256]

Given the variability in clinical definitions, the incidence of TACO is reported to range from 1–12%.[257] Patient-related risk factors for TACO include increasing age, female sex, white race, small body weight and stature, and a history of cardiac, renal, or lung disease.[257–261] Transfusion-related risk factors include number of units transfused,

faster infusion rate, and possibly plasma transfusion.[257,260] Approximately 70% of patients with TACO require mechanical ventilation.[260,261] TACO is associated with increased hospital length of stay, in-hospital mortality, and 1-year mortality.[260,262,263]

Several preventive strategies, including strict adherence to restrictive transfusion strategies, identification and close monitoring of at-risk patients, infusion of blood products at a low rate, and possibly preemptive diuretics in at-risk patients, would likely be effective in reducing the incidence of TACO.[257] The acute management of TACO is mostly supportive and includes discontinuation of the infusion of blood products if possible, oxygen therapy, ventilatory support, and most important, administration of diuretics.

Key Points

- Primary polycythemia is caused by either an acquired or inherited genetic abnormality; secondary polycythemia is mainly related to excess erythropoietin production from chronic hypoxia. Pulmonary complications include an increased risk of thromboembolism, pulmonary parenchymal disease, and *pulmonary hypertension* (PH).
- The acute chest syndrome and PH are leading causes of recurrent disability and premature death in *sickle cell disease* (SCD). Acute chest syndrome is thought to result from infection, bone marrow fat embolization, and/or direct red cell intravascular sequestration causing lung injury and infarction. PH is thought to result from hemolysis that alters nitric oxide activity and endothelial function.
- American Thoracic Society guidelines recommend yearly screening of adults with SCD for PH using Doppler-echocardiographic assessment of the tricuspid regurgitant jet velocity and plasma levels of *N-terminal pro–brain natriuretic peptide* (NT-proBNP). A tricuspid regurgitant jet velocity value of 2.5 m/sec or greater, especially with a plasma NT-proBNP level of 160 ng/pL or greater, suggests a high risk of PH and death and warrants intensification of SCD-specific care and evaluation for PH by sickle cell disease and PH specialists. Patients with PH are at high risk of having groups 1, 2, and 4 forms of PH and should be evaluated for hypoxemia, pulmonary arterial hypertension, right heart failure, and chronic thromboembolic PH, and managed accordingly.
- Thalassemia major is a severe heritable lifelong, multisystem disease owing to the presence of two β-thalassemia alleles; by contrast, thalassemia minor patients inherit just a single gene and may be asymptomatic with only mild anemia. PH is the most common pulmonary complication of this disorder.
- Leukemias and plasma cell disorders involve the pulmonary parenchyma uncommonly, although mediastinal involvement, lymphadenopathy, and pleural infiltration are common at autopsy.
- There is controversy about whether screening of individuals with venous thromboembolism for the presence of inherited thrombophilic defects is warranted; criteria for diagnosis have been suggested, but epidemiologic studies show little clinical benefit. Optimal chronic management of patients with inherited thrombophilia is not well established.
- Transfusion-related acute lung injury and transfusion-related circulatory overload are common causes of transfusion-related morbidity and mortality. Several risk factors have been identified, and multiple causes may play a role. The overall incidence appears to be diminishing, and clinical management remains supportive.

eFigure 127.4 Molecular pathophysiology of sickle cell disease. (A) A single nucleotide polymorphism in the β-globin gene leads to substitution of valine for glutamic acid at the sixth position in the β-globin chain. After deoxygenation, the mutated hemoglobin S (Hb S) molecules polymerize to form bundles. The polymer bundles result in erythrocyte sickling *(clockwise),* which in turn results in impaired rheology of the blood and aggregation of sickle erythrocytes with neutrophils, platelets, and endothelial cells to promote stasis of blood flow, referred to as vaso-occlusion (B). Vaso-occlusion promotes ischemia-reperfusion (I-R) injury *(clockwise).* (A) Hemoglobin (Hb) polymer bundles also promote hemolysis or lysis of erythrocytes *(counterclockwise),* which releases cell-free Hb into the blood circulation (C). Oxygenated Hb (ferrous iron [Fe^{2+}]) promotes endothelial dysfunction by depleting endothelial nitric oxide (NO) reserves to form nitrate (NO_3^-) and methemoglobin (ferric iron [Fe^{3+}]). Alternatively, Hb can also react with hydrogen peroxide (H_2O_2) through the Fenton reaction to form hydroxyl free radical (OH•) and methemoglobin (Fe^{3+}). Also, reduced nicotinamide adenine dinucleotide phosphate, xanthine oxidase (XO), and uncoupled endothelial NO synthase (eNOS) generate oxygen free radicals to promote endothelial dysfunction. Methemoglobin (Fe^{3+}) degrades to release cell-free heme *(counterclockwise),* which is a major erythrocyte damage-associated molecular pattern (DAMP). (D) Reactive oxygen species (ROS) generation, toll-like receptor 4 (TLR4) activation, neutrophil extracellular trap (NET) generation, release of tissue or cell–derived DAMPs, DNA, and other unknown factors (?) triggered by cell-free heme or I-R injury can contribute to sterile inflammation by activating the inflammasome pathway in vascular and inflammatory cells to release interleukin (IL)-1β. Finally, sterile inflammation further promotes vaso-occlusion through a feedback loop by promoting adhesiveness of neutrophils, platelets, and endothelial cells. GAG, guanine-adenine-guanine; Glu, glutamic acid; GTG, guanine-thymine-guanine; Val, valine. (From Sundd P, Gladwin MT, Novelli EM. Pathophysiology of sickle cell disease. *Annu Rev Pathol.* 2019;14:263–292.)

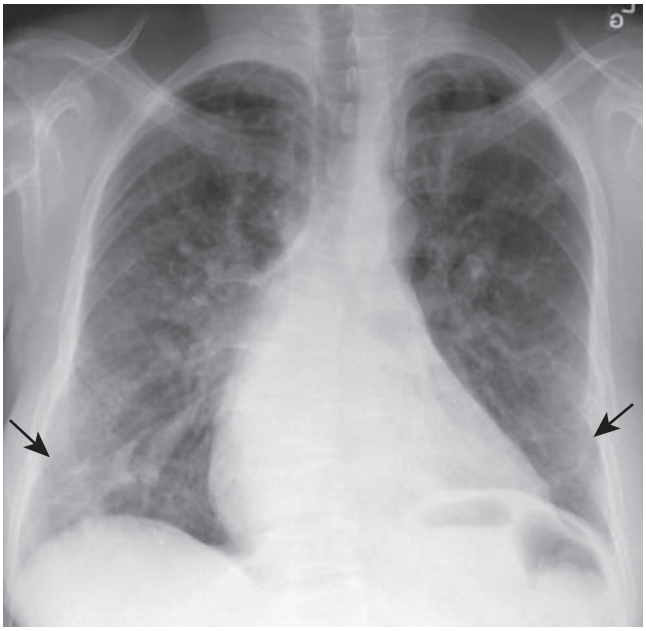
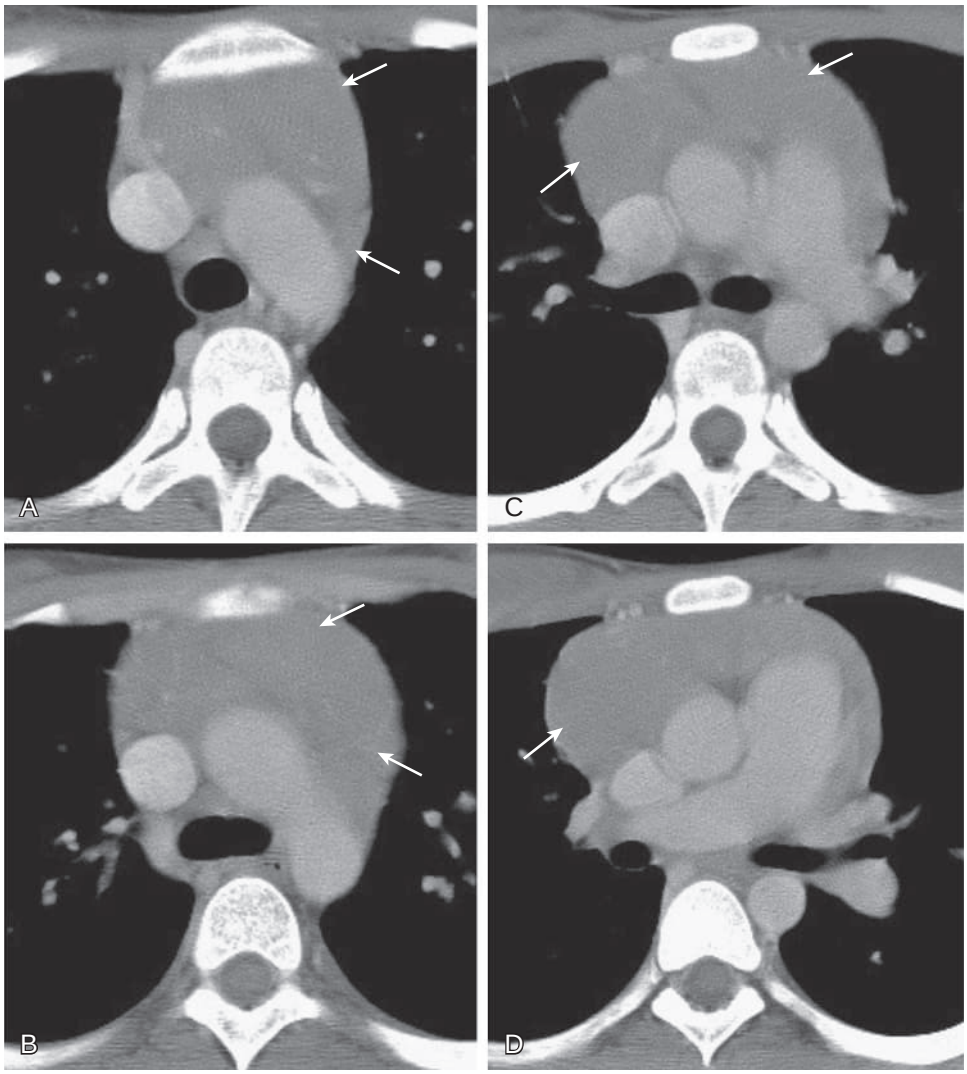
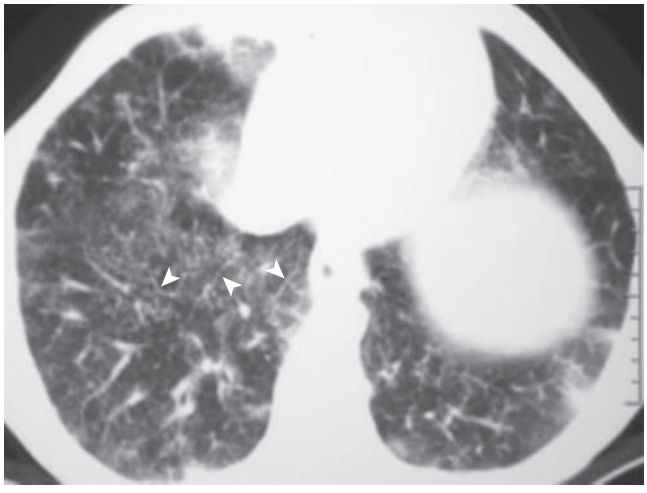
eFigure 127.6 Multifactorial pathogenesis of pulmonary hypertension in sickle cell disease, focusing on changes at a small pulmonary artery. Pulmonary hypertension is thought to arise from multifactorial effects of hemolysis and from the anemia, leading to increased cardiac output and multiorgan damage from iron overload, renal failure, and asplenia. EPO, erythropoietin; ET-1, endothelin-1; HIF-1α, hypoxia inducible factor-1α; NO, nitric oxide; PS, phosphatidylserine; Q̇, cardiac output; RBC, red blood cell; TF, tissue factor; VEGF, vascular endothelial growth factor; V/Q, ventilation-perfusion.



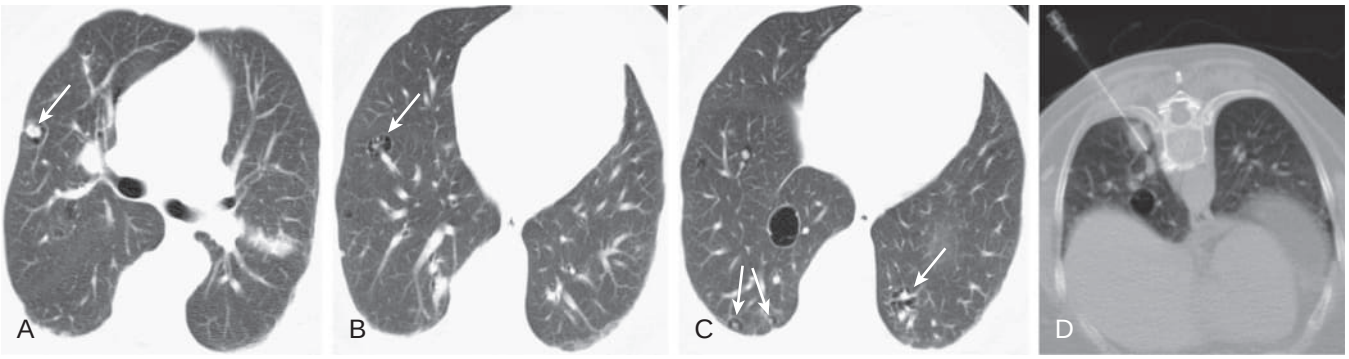
eFigure 127.7 Pulmonary fibrosis complicating multiple episodes of acute chest syndrome. Bibasilar (right greater than left) reticular opacities *(arrows)* are seen in the chest radiograph.



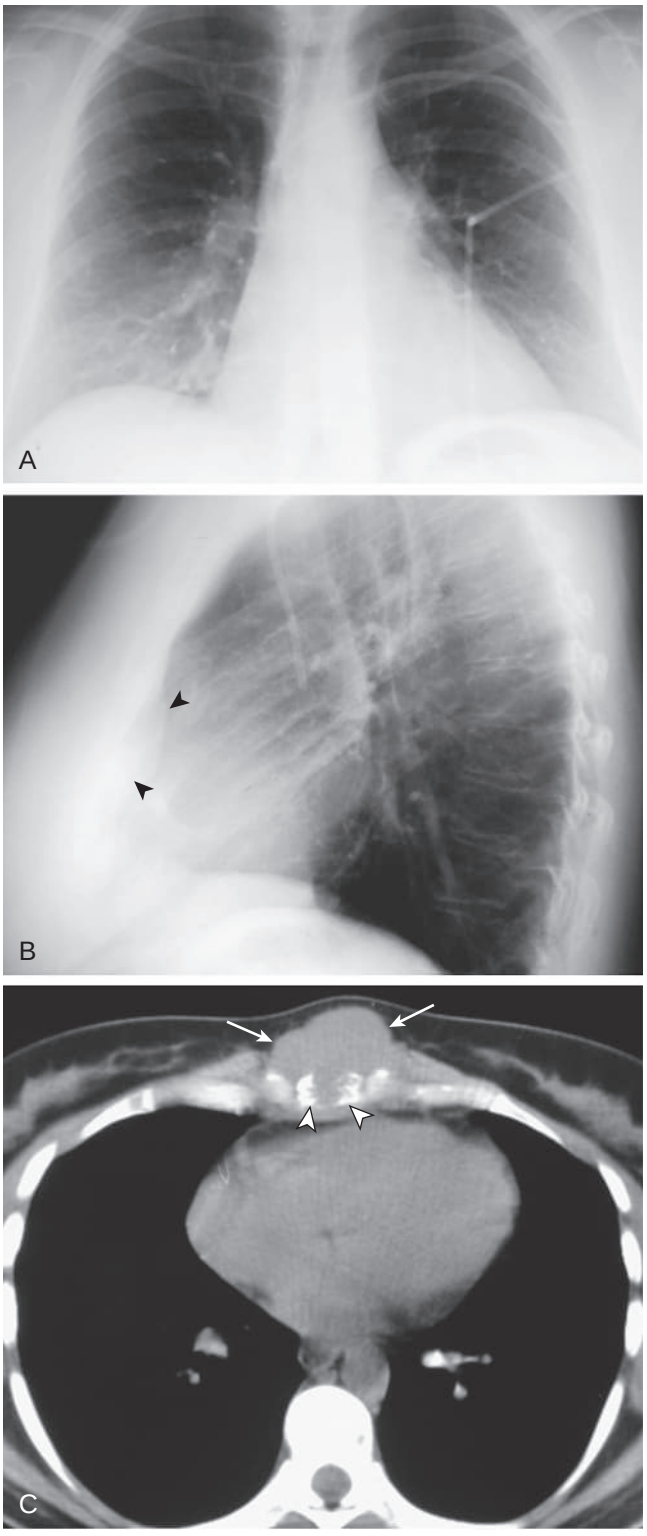
eFigure 127.8 Thoracic leukemia: mediastinal mass. (A–D) Axial enhanced chest computed tomography shows a soft tissue mass *(arrows)* in the anterior mediastinum proven to represent leukemic infiltration. (Courtesy Michael B. Gotway, MD.)



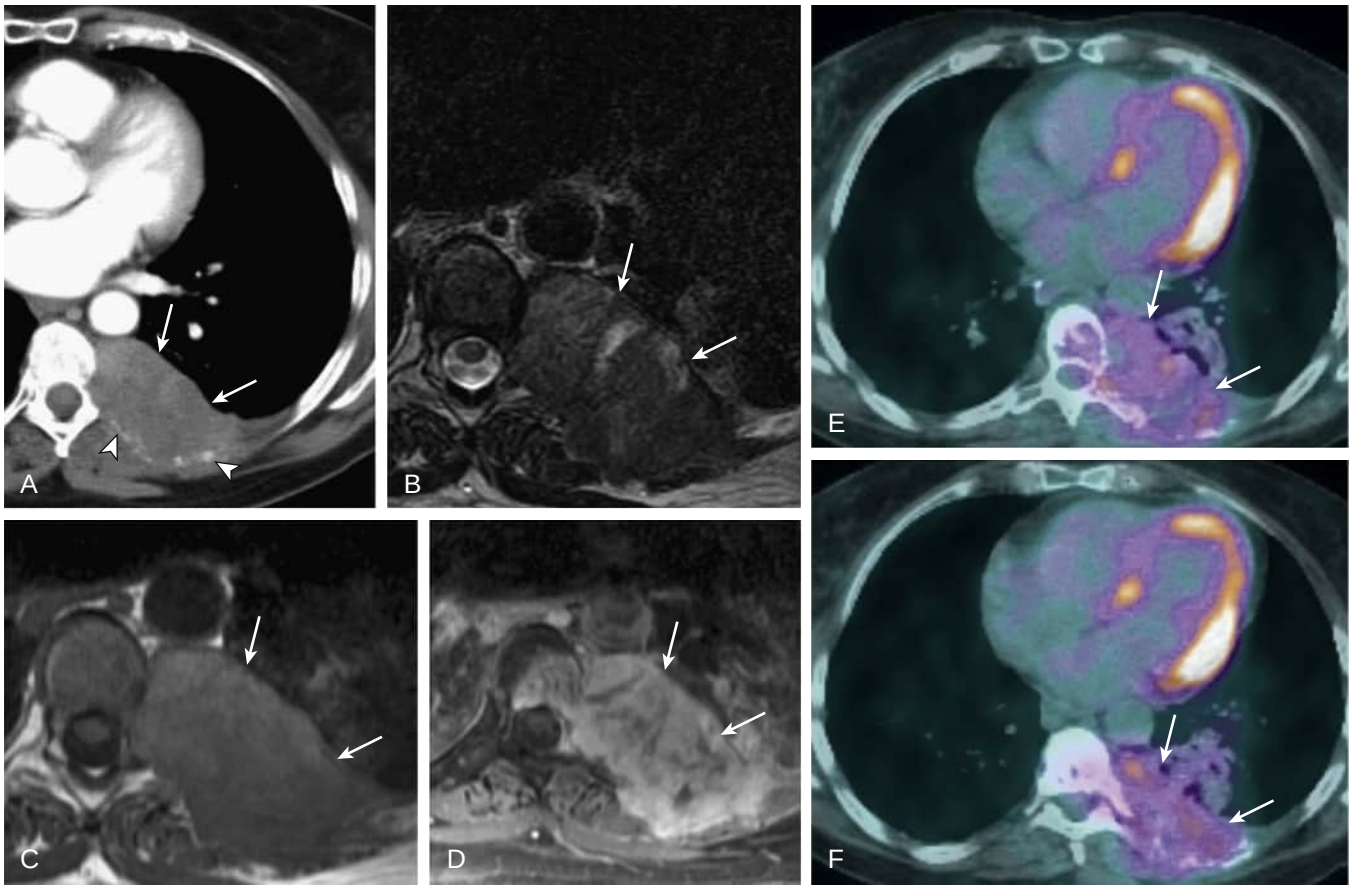
eFigure 127.9 Thoracic leukemia: pulmonary parenchymal infiltration. Axial chest computed tomography shows small nodules in the lung bases bilaterally associated with interlobular septal thickening *(arrowheads);* biopsy revealed pulmonary leukemic infiltration. (Courtesy Michael B. Gotway, MD.)



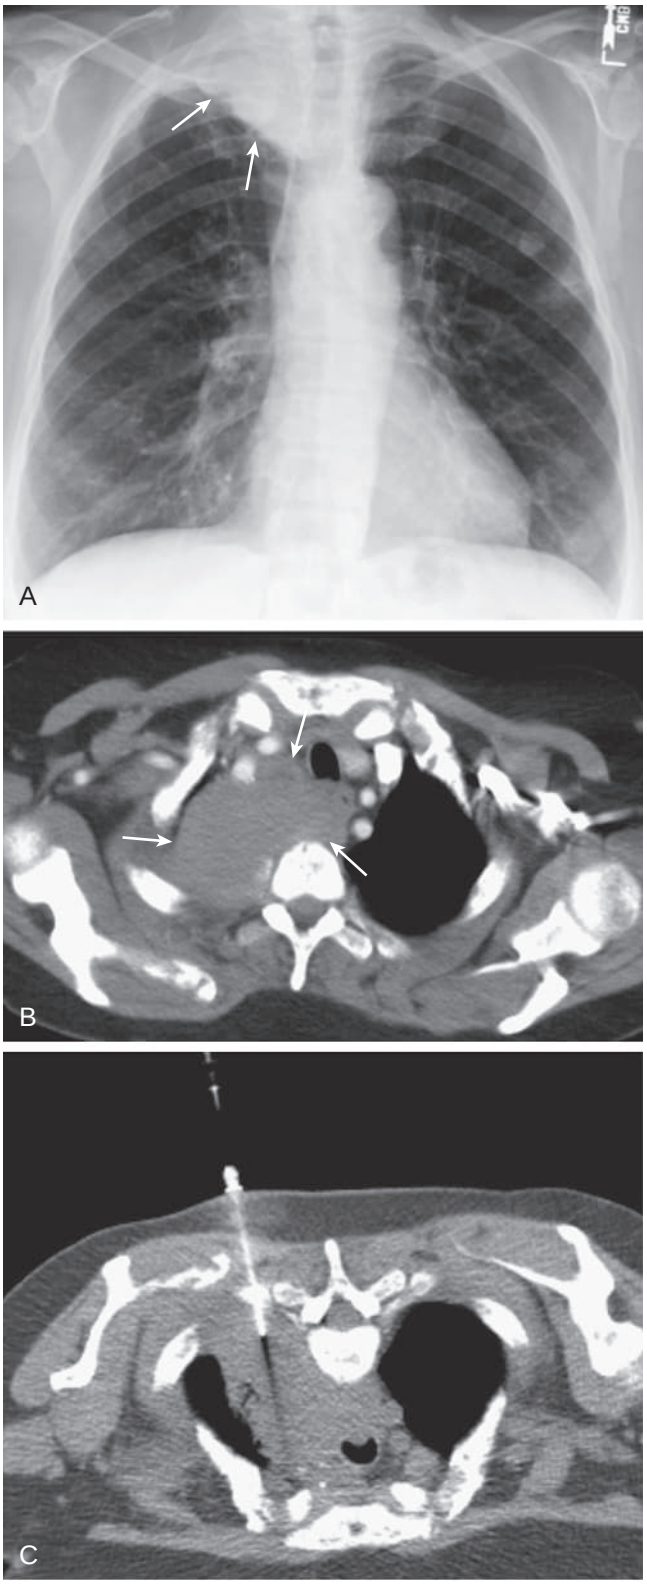
eFigure 127.10 Amyloidosis. (A–C) Axial chest computed tomography shows multiple pulmonary nodules associated with cystic change *(arrows),* proven on biopsy (D) to represent pulmonary amyloidosis. (Courtesy Michael B. Gotway, MD.)



eFigure 127.11 Thoracic plasmacytoma: chest wall origin. (A) Frontal and (B) lateral chest radiographs show a substernal contour deformity *(arrowheads).* (C) Axial unenhanced chest computed tomography shows sternal destruction *(arrowheads)* associated with a soft tissue mass *(arrows).* (Courtesy Michael B. Gotway, MD.)



eFigure 127.12 Thoracic plasmacytoma: chest wall origin. (A) Enhanced chest computed tomography. (B) T2-weighted, (C) unenhanced, and (D) enhanced fat saturation T1-weighted magnetic resonance imaging shows a mass *(arrows)* arising from the posterior medial chest wall, proven to represent plasmacytoma. Note the extensive rib destruction seen with computed tomography (*arrowheads,* A) and profound enhancement best seen at enhanced magnetic resonance (D). (E–F) ^{18}F-fluorodeoxyglucose positron emission tomography shows intense metabolic activity within the lesion *(arrows).* (Courtesy Michael B. Gotway, MD.)



eFigure 127.13 Thoracic plasmacytoma: mediastinal origin. (A) Frontal chest radiograph shows a superior thoracic mass *(arrows)*. (B) Axial chest computed tomography shows the mass *(arrows)*. The extensive contact with mediastinal structures (posterior wall of the trachea, esophagus, and great vessels) indicates a mediastinal origin for the lesion. (C) Percutaneous transthoracic biopsy-proved plasmacytoma. (Courtesy Michael B. Gotway, MD.)

IMMUNE CHECKPOINT INHIBITORS
KEY POINTS

INTRODUCTION

The endocrine system consists of various glands and their hormones that circulate and mechanistically interact with all physiologic systems. This chapter provides an overview of how the major endocrine disorders affect the respiratory system; these disorders include diabetes mellitus, hypothyroidism and hyperthyroidism, growth hormone deficiency and excess, calcium dysregulation, including hyperparathyroidism, adrenal gland disorders, and hypophysitis from immune checkpoint inhibitors. An understanding of these endocrinopathies will assist the pulmonologist in the prevention, recognition, and management of the associated respiratory complications.

DIABETES

The global prevalence of diabetes mellitus continues to increase (422 million, or 8.5% of the adult population).[1] Type 1 and type 2 diabetes mellitus afflict 30.3 million Americans (9.4% of the population). Approximately 1.5 million new cases are diagnosed each year in the United States, and prediabetes afflicts 84.1 million American adults.[2] Type 1 diabetes results from autoimmune destruction of pancreatic beta cells in genetically susceptible patients and may be triggered by environmental factors. *Type 2 diabetes mellitus* (T2DM) results from insulin resistance associated with genetic predisposition, obesity, leptin resistance, diet, smoking, and a host of inflammatory mediators causing beta cell loss or dysfunction. The pathophysiologic hallmark of chronic hyperglycemia, nonenzymatic protein glycosylation, leads to accumulation of advanced glycation end products and heightened binding to and activation of their receptors,[3] lipo-oxidative stress, especially when associated with obesity, a chronic low-grade proinflammatory state, deranged connective tissue metabolism, generalized irreversible collagen cross-linking in tissue,[4,5] autonomic neuropathy, and macroangiopathy and microangiopathy,[6–8] which resemble the phenotype of accelerated aging.

These generalized pathophysiologic features affect the respiratory system, making diabetic patients vulnerable to pulmonary dysfunction. Lungs from diabetic subjects show qualitative abnormalities, including collagen and elastin accumulation and retarded connective tissue breakdown.[9] Parenchymal congestion, histiocytosis, prominent alveolar septal interstitium, smooth muscle hypertrophy, hyperplasia of alveolar type 2 epithelium, thickened basement membrane, fibrosis, and septal obliteration have been noted at autopsy in the lungs of diabetic subjects.[10] Given that the lung is the largest microvascular organ in the body and the only organ receiving the entire right ventricular cardiac output, it is not surprising that microvascular complications of diabetes adversely affect nearly all aspects of respiratory structure and function (Table 128.1). The major abnormalities are discussed below and in eFigure 128.1.

VENTILATORY IMPAIRMENT

Diabetes may impair ventilatory responses to hypoxia, hypercapnia, or exercise due to autonomic neuropathy,[11] abnormal cholinergic bronchomotor tone, and/or thoracopulmonary restriction. Tidal volume may increase excessively upon exertion resembling changes seen after vagotomy. Maximal ventilation and ventilatory response during exercise[12] and isocapnic hypoxia[13] may be reduced. Perception of inspiratory resistive loading may be diminished,[14] while perception of dyspnea is

Table 128.1 Pulmonary Complications of Diabetes Mellitus

Pathophysiologic Processes	Clinical Consequences
Autonomic neuropathy, control of breathing	▪ Increased parasympathetic tone ▪ Increased inspiratory effort ▪ Increased perception of dyspnea ▪ Impaired response to ventilatory challenges ▪ Sleep-disordered breathing ▪ Nocturnal hypoxemia
Thoracopulmonary restriction	▪ Increased chest wall stiffness ▪ Reduced lung volumes and compliance ▪ Reduced maximal ventilation ▪ Increased work of breathing
Airway dysfunction	▪ Airway hyperresponsiveness ▪ Aggravates coexisting COPD and cystic fibrosis
Lung microangiopathy	▪ Loss of alveolar microvascular reserves ▪ Reduced D_{LCO} at a given pulmonary blood flow
Respiratory muscle dysfunction	▪ Reduced respiratory muscle strength and endurance
Impaired immune defenses	▪ Impaired cytokine response and macrophage function ▪ Susceptibility to infections—bacterial, viral, mycobacterial, fungal, mucormycosis, aspiration pneumonitis
Major comorbidities that accentuate pulmonary impairment	▪ Obesity and the metabolic syndrome, cystic fibrosis, asthma, COPD, pulmonary fibrosis

accentuated with a disproportionately greater inspiratory effort and a smaller increase in tidal volume during hypoxia challenge.[15,16] Obesity further exaggerates ventilatory abnormalities and could impede acclimatization to high altitude or ventilatory compensation in response to lung disease. T2DM is also an independent risk factor for sleep-disordered breathing and nocturnal hypoxemia by altering sleep architecture.[17]

LUNG AND CHEST WALL RESTRICTION

Otherwise healthy diabetic nonsmokers commonly exhibit mild-to-moderate ventilatory restriction at rest, including 8–20% reductions in spirometry,[18–24] lung volumes, elastic recoil, dynamic compliance,[22] and *diffusing capacity for carbon monoxide* (D_{LCO}); impairment directly correlates with glycemic control[21,25] and extrapulmonary microangiopathy (e.g., proteinuria).[26,27] Diminished lung recoil and parenchymal tethering of peripheral airways may lead to gas trapping.[28–30] Connective tissue stiffness of the chest wall and limited joint mobility[23] can exacerbate thoracopulmonary restriction, leading to elevated work of breathing and respiratory muscle oxygen requirements during exercise.[21] These increased respiratory muscle requirements eventually usurp a disproportionately large fraction of total body oxygen delivery, leaving insufficient oxygen delivery to locomotive muscles; exercise ability can then be curtailed by subjective leg fatigue (i.e., the so-called respiratory muscle "steal" phenomenon).[31]

Chronic hyperglycemia, insulin resistance, and prediabetes are independently associated with ventilatory restriction.[25,32–34] In type 1 diabetes, a low peak expiratory flow rate predicts clinical complications and mortality.[35] Poor glycemic control directly correlates with lower spirometry indices and lung volume. In T2DM, a low FEV_1 predicts mortality in some, but not all, studies.[24,32] Subclinical pulmonary dysfunction in prediabetes[36–38] independently predicts subsequent development of overt diabetes.[39–41]

LOSS OF ALVEOLAR MICROVASCULAR RESERVES

D_{LCO} reflects the rate of gas transfer across the alveolar barrier (consisting of tissue membrane, plasma, and erythrocyte membrane), the volume of pulmonary capillary blood, hemoglobin mass, and the gas binding affinity to hemoglobin. The vast alveolar-capillary surface areas and microvascular volume are underutilized at rest (i.e., apical capillaries may be perfused by plasma but not erythrocytes while epithelial surface folds reduce the *effective* gas exchange area). Upon exertion, increasing ventilation and perfusion unfold alveolar surfaces and recruit capillaries, respectively, while erythrocytes become more uniformly distributed within and among capillaries (eFig. 128.2); the recruitment of anatomic and physiologic reserves leads to an increase in D_{LCO}, an essential mechanism for maintaining a normal arterial oxygen saturation.

Chronic hyperglycemia is associated with thickened alveolar basement membrane and together with lung restriction leads to a modest reduction of D_{LCO} (10–30%) at a given pulmonary blood flow[18,20,21,42]; the reduction correlates with disease duration and extrapulmonary end-organ complications.[21,43–45] The normal sitting-to-supine postural increase in D_{LCO} may be absent,[46] an early sign of impaired microvascular recruitment. Nonsegmental pulmonary perfusion defects have been observed in diabetes correlating with a lower D_{LCO}[47]; these defects may be reversible, reflecting heterogeneous perfusion distribution. On quantitative perfusion chest *computed tomography* (CT), diabetic subjects show higher pulmonary blood flow, pulmonary blood volume, and the permeability-surface product, suggesting increased alveolar permeability.[48] Upon exercise, D_{LCO} at a given cardiac output in T2DM subjects is modestly (10–25%) below normal (see eFig. 128.2). Chronically, hyperglycemic T2DM subjects exhibit a lower D_{LCO} at a given cardiac output than T2DM subjects who maintained near-normoglycema.[26]

RESPIRATORY MUSCLE DYSFUNCTION

Respiratory muscle strength and endurance may be reduced, reflecting generalized diabetic myopathy.[49] Impairment in insulin-stimulated glucose transport activity reduces muscle glycogen synthesis, promotes intramyocellular lipid accumulation, and impedes insulin signaling.[50,51] Perfusion heterogeneity and a reduced microvascular surface area in diabetic muscle lead to diffusion impairment (low permeability-surface area product for small solutes)[52]

in parallel to the pathophysiology of diabetic diffusion impairment in the lung.

IMPAIRED IMMUNE DEFENSES

Both innate and adaptive immune factors are implicated in the pathogenesis of obesity-associated complications including insulin resistance,[53] T2DM, hyperlipidemia, hypertension, atherosclerosis, and even cancers. Obesity-induced lipo-oxidative toxicity leads to activation of immune cells (M1 macrophages and $CD4^+$ T lymphocytes), infiltration of adipose and other tissue causing low-grade inflammation,[54–56] as well as accelerated senescence of immune cells. Macrophages obtained from diabetic mice show reduced bacterial internalization and killing and altered cytokine responses.[57] Impaired immunity in diabetes predisposes to airway inflammation and hyperreactivity, pulmonary infections, and pulmonary edema.[58] T2DM is a risk factor for infections due to *M. tuberculosis*, atypical mycobacterial, and certain fungal species such as molds from the Mucorales order that cause mucormycosis.[59,60] Diabetic *cystic fibrosis* (CF) patients are more susceptible to coinfection with *S. aureus* and *P. aeruginosa* than normoglycemic CF patients; coinfection in turn worsens lung function and predisposes to pulmonary exacerbations. Glycemia-related alterations of the lung microbiome may contribute to the accelerated pulmonary decline.[61]

COMORBIDITIES

Subclinical loss of pulmonary reserves in otherwise healthy diabetic subjects is inconsequential but may become overtly debilitating under conditions of pulmonary stress (e.g., aging or high altitude exposure) and exacerbate clinical pulmonary dysfunction in the presence of comorbid conditions such as pneumonitis, emphysema, pulmonary fibrosis, acute respiratory distress syndrome, and extrapulmonary organ failure in critically ill patients. The presence of diabetes also increases risks for developing asthma, chronic obstructive pulmonary disease, pulmonary fibrosis, and pneumonia.[62]

By 35 years of age, up to 50% of CF patients develop pancreatic insufficiency with impaired insulin secretion and response to carbohydrate loading, or overt diabetes while basal insulin secretion may be preserved, leading to normal fasting glycemia, postprandial hyperglycemia,[63] and accelerated lung function decline, poor growth and nutritional status, and increased mortality.[64] Diabetes is the most common extrapulmonary complication of CF, and is primarily related to insulin insufficiency. Because patients with CF-related diabetes may remain asymptomatic for years, screening is recommended at an early age. Insulin treatment improves glycemia, nutritional status, and lung function.[65]

Diabetes is more prevalent among asthmatic youths[66] and in patients with COPD hospitalized for acute exacerbation compared to the general population[67,68]; the association is partly attributed to corticosteroid use.[69] Inhaled corticosteroid use also modestly increases the risks of diabetes onset and progression.[70,71] Recent evidence suggests additional connections between diabetes and COPD. Poor glycemic control is associated with higher mortality in patients hospitalized for acute COPD exacerbation even long after discharge.[72] In the Framingham Offspring Cohort,[25] both fasting hyperglycemia and diabetes predict pulmonary dysfunction, with a stronger relationship among ever-smokers than never-smokers, suggesting interactions between glycemia and tobacco use. Systemic inflammation is a direct measure of COPD severity; inflammatory mediators that are elevated in COPD are also elevated in diabetes.[73] Cumulative evidence suggests that pulmonary inflammation and oxidative stress in COPD predispose to development of other proinflammatory conditions, including metabolic syndrome, cardiovascular, hematologic, musculoskeletal, and malignant diseases.[74] Systemic inflammation in turn exacerbates COPD pulmonary inflammation in a reciprocal manner.[75,76] Both diabetes and cardiovascular disease are more prevalent in Global Initiative for Chronic Obstructive Lung Disease stage 3 or 4 COPD (odds ratio 1.5 and 2.4, respectively) after adjusting for confounding variables, and both comorbidities increase the risks of COPD-related hospitalization and mortality.[77] Therefore, patients with moderate to severe COPD should be screened for possible diabetes.

Limited literature suggests diabetes is a risk factor for idiopathic pulmonary fibrosis. In 65 Japanese idiopathic pulmonary fibrosis patients, the adjusted odds ratios were 5.40 for cigarette smoking and 4.06 for diabetes.[78] The association between idiopathic pulmonary fibrosis and diabetes may be related to autonomic neuropathy causing gastroesophageal reflux.[79]

ROLE OF ADIPOCYTE-DERIVED MEDIATORS

Type 2 diabetes mellitus may be associated with obesity and insulin resistance as part of the metabolic syndrome. Insulin resistance alters lung function directly or via adipocyte-derived mediators such as leptin and adiponectin. Leptin signals via its receptor to modulate energy balance, thermoregulation, bone metabolism, lung cell growth,[80] central respiratory control,[81] and proinflammatory immune responses.[82] Leptin promotes fibroproliferative acute respiratory distress syndrome via inhibition of peroxisome proliferator-activated receptor-gamma[83] and leptin resistance protects from experimental acute lung injury.[84] Serum leptin levels are variably elevated in morbid obesity,[81] associated with small lung volumes, abnormal respiratory mechanics, and sleep apnea. In nonobese normal subjects, serum leptin levels are inversely related to FEV_1,[85] suggesting that leptin plays a role in the pathogenesis of diabetic pulmonary dysfunction.

In contrast, adiponectin exhibits anti-inflammatory, antioxidative, and anti-apoptotic activities[86]; these tissue-protective effects are eliminated in experimental T2DM. In clinical T2DM, serum adiponectin levels inversely correlate with some, but not all, of the hallmarks of metabolic syndrome.[87,88] Mice lacking adiponectin spontaneously develop COPD-like phenotype with extrapulmonary inflammation, body weight loss, and osteoporosis, suggesting crosstalk between the lung and adipose tissue.[89]

PULMONARY RESPONSE TO GLYCEMIC CONTROL

Prospective interventional studies show that intense glycemic control in T2DM significantly improves spirometry;

the changes in glycosylated hemoglobin correlate inversely with spirometry.[90] In CF-related diabetes, glycemic control also improves lung function, retards pulmonary function decline, and reduces short- and long-term complications.[91,92] Diabetes medications possessing anti-inflammatory properties (e.g., metformin),[93] confer a survival benefit in T2DM[94] and, in conjunction with gliptin class medication,[95] have been reported to improve pulmonary function; improvement is positively correlated with blood antioxidants and negatively correlated with oxidative stress markers.[95]

THYROID DISORDERS

THE HYPOTHALAMIC-PITUITARY-THYROID AXIS

The hypothalamic-pituitary-thyroid axis for synthesizing the thyroid hormones thyroxine and 3,5,3′-triiodothyronine is tightly regulated. Thyroid hormone receptors are ubiquitous DNA-binding proteins that function as transcriptional factors.[96] In the nucleus, the thyroid hormone receptor complex binds to promoter regions of responsive genes to modulate gene expression. Thyroid hormones stimulate lipid metabolism, leading to fatty acid mobilization and oxidation and reductions in blood cholesterol and triglycerides. Thyroid hormones stimulate gluconeogenesis and glycogenolysis accompanied by enhanced insulin-dependent glucose entry into cells. In the cardiovascular system, thyroid hormones increase heart rate and cardiac contractility and promote vasodilation. The broad metabolic stimulation increases basal metabolic rate, thermogenesis, and oxygen consumption, which in turn increase the work of breathing. Thyroid hormones are essential for normal organ development and growth, including in the lung.

Thyroid dysfunction, both hypothyroidism and hyperthyroidism, is common, afflicting nearly 7% of the population and comprising up to 40% of endocrine practices.[97,98] Diagnosis and monitoring depend on measurements of circulating *thyroid stimulating hormone* (TSH) and free thyroid hormones. Depending on the degree of biochemical dysfunction, thyroid hormone deficiency or excess may lead to a variety of anatomic and physiologic respiratory disorders.[99–101]

HYPOTHYROIDISM

Hypothyroidism may result from failure of the hypothalamus, the pituitary gland, or the thyroid gland leading to thyroid hormone deficiency. Congenital thyroid deficiency causes cretinism, a form of severe somatic and mental retardation. Postnatal hypothyroidism is most commonly caused by autoimmunity, iodine deficiency, or thyroidectomy.[100] Hypothyroidism affects up to 3.7% of the U.S. population and up to 5.3% in European studies.[97,98,100] Hypothyroidism often presents with nonspecific symptoms such as fatigue, dyspnea on exertion, diminished exercise capacity, and even respiratory failure due to a variety of complications (Table 128.2). Although numerous studies describe hypothyroidism adversely impacting the respiratory system, most include small cohorts of patients with limited follow-up and subject to potentially biased methodology.[102]

Table 128.2 Adverse Impact of Thyroid Disorders on the Respiratory System

Hypothyroidism	Hyperthyroidism
Goiter-related airway obstruction or laryngeal dysfunction	Hyperventilation
Alveolar hypoventilation and sleep-disordered breathing	Pulmonary hypertension
Pulmonary dysfunction	Thyrotoxicosis and respiratory failure
Myopathy of respiratory muscles	Increased risk of lung cancer
Pleural effusion	

Airway Obstruction or Laryngeal Dysfunction

Anatomic complications of an enlarged thyroid gland include upper airway compression (Fig. 128.1), resulting in dyspnea, stridor, and cough,[103,104] and reduction of inspiratory flow on pulmonary function tests[105] (see Fig. 39.4A–B). Tracheal compression is slightly more common with substernal than cervical goiters and can significantly improve with goiter volume reduction.[106–108] After thyroid surgery, there can be laryngeal dysfunction due to vocal cord dysfunction following intubation or due to recurrent laryngeal nerve injury, leading to dysphonia, ineffective cough, and dyspnea.[109,110]

Pulmonary Dysfunction

In hypothyroidism, spirometry and D_{LCO} negatively correlate with serum TSH level and positively correlate with serum free thyroid hormone 4 (T4) level,[111] even when chest radiography and arterial blood gases are normal. Thyroid hormones modulate mitochondrial respiration and the production of adenosine triphosphate. Hypothyroidism impairs skeletal muscle capacity for oxidative phosphorylation and alters muscle structure and energetics,[112] leading to exercise impairment evidenced by reduced aerobic capacity, slow kinetics of oxygen uptake upon exercise, and delayed recovery after exercise. These abnormalities increase the metabolic cost of performing daily living activities and manifest as fatigue, lethargy, and dyspnea.[111]

Alveolar Hypoventilation

In patients with myxedema, a severe form of hypothyroidism, hypoxic ventilatory drive is significantly depressed despite alveolar hypoxia and markedly improved when euthyroid states are achieved.[113] Similarly, hypercapnic ventilatory response can be depressed but not improve with thyroid replacement.[113] Depressed ventilatory effort is also observed in response to hypercapnia and hypoxia in 39% of patients with hypothyroidism, particularly in women with markedly elevated serum TSH concentrations[114]; thyroid hormone replacement resulted in improvement of ventilatory response.[114] Myxedema can lead to life-threatening hypothermia, drowsiness, confusion, coma, and respiratory failure requiring mechanical ventilatory support.[115] Prompt clinical recognition and thyroid hormone replacement leads to resolution of such derangements, including the recovery of hypoxic ventilatory drive.[113] Hypothyroidism should be considered in the difficult to wean patient in the intensive care unit.[116]

Sleep-Disordered Breathing

Earlier studies reported an increased prevalence of sleep-disordered breathing in patients with hypothyroidism.[117,118]

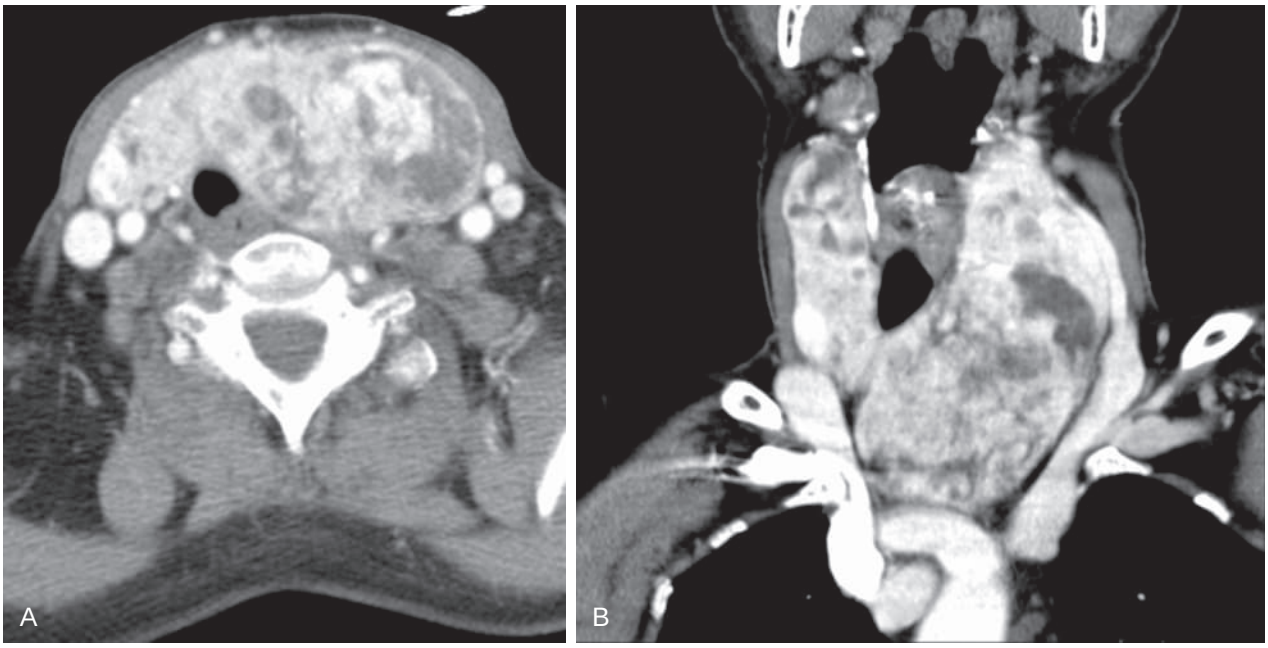

Figure 128.1 Multinodular goiter causing dyspnea. A 71-year-old woman with a large multinodular goiter experienced increasing dyspnea and required a total thyroidectomy. Note the displaced trachea. Axial (A) and coronal (B) views. (Courtesy Michael Landay, MD.)

Accumulation and soft tissue infiltration of matrix glycosaminoglycans are thought to cause macroglossia and pathologic narrowing of the pharyngeal space potentially leading to *obstructive sleep apnea* (OSA).[117,119] Thyroid replacement therapy may reduce connective tissue accumulation and, in some studies, improve or even cure sleep apnea in nonobese patients.[119–121] However, where obesity or skeletal defects are present, OSA may persist despite correction of the metabolic disorder.[117] Recent studies also suggest that thyroxine replacement in hypothyroid patients may not improve OSA without concurrent treatment with continuous positive airway pressure, suggesting persistent anatomic abnormalities.[122] A large study of thyroid function in 813 obese patients with severe OSA and daytime somnolence found a similar prevalence of hypothyroidism as in the general population, and no significant correlations between TSH, free thyroid hormones 3 or 4, and polysomnography results of breathing disorders during sleep.[123] Thus, the complex hormonal and anatomic relationship between thyroid hormone imbalance and prevalence of sleep-disordered breathing remains to be clarified. In addition to hypothyroidism, other endocrine and metabolic conditions (obesity, acromegaly, and polycystic ovary disease) may also be associated with OSA.

Respiratory Muscle Dysfunction

Thyroid hormone transcriptionally regulates the expression of myosin heavy chains, adenosine triphosphatase and other skeletal muscle proteins, and is a major determinant of muscle fiber composition and cell membrane permeability. Thyroxine deficiency impairs muscle glycogenolysis, oxidative respiration, lipid turnover,[124] repair, and myogenesis, associated with atrophy of type II (fast oxidative) fibers, compensatory hypertrophy of type I (slow oxidative) fibers, accumulation of muscle connective tissue, and decrease in muscle carnitine level.[125] These abnormalities predispose to muscle injury with elevated serum creatine kinase, myalgia, generalized muscle weakness, and, rarely, rhabdomyolysis.[125] According to the American Thyroid Association,[126] elevated serum muscle creatine kinase and/or lactic dehydrogenase persisting for at least 2 weeks justify serum TSH measurement to screen for hypothyroidism. Diaphragmatic muscle dysfunction may be a manifestation of hypothyroidism-related myopathy.[102,103] Pulmonary function tests may reveal reduced inspiratory and expiratory muscle strength in severe hypothyroidism and can lead to dyspnea and hypercapnia and contribute to respiratory failure.[103,127,128] In some studies, thyroid hormone replacement resulted in improved diaphragm and expiratory muscle strength.[127,128]

Pleural Effusion

Hypothyroidism-associated serous effusions, including ascites, pericardial effusion, and pleural effusion, are thought to develop as a result of increased capillary permeability and decreased lymphatic drainage of albumin.[129,130] Pleural effusion as a result of hypothyroidism alone is uncommon. In 128 patients with thyroid dysfunction, the majority of effusions were primarily due to other associated conditions such as pneumonia, congestive heart failure, or malignancy.[131] In these cases, although not a primary cause, the hypothyroidism may have contributed to their formation. When attributed to hypothyroidism alone, pleural effusions are small and asymptomatic due to slow fluid accumulation and may require no therapeutic intervention other than thyroid hormone replacement.[131] Management includes thoracentesis to exclude an exudative effusion caused by other conditions such as an underlying thyroid carcinoma or other malignancy,[129] thyroid hormone replacement therapy, and drainage of large effusions for symptomatic relief.

HYPERTHYROIDISM

Excess thyroxine production leads to accelerated metabolism and a spectrum of clinical disorders ranging from

asymptomatic mild elevations in thyroid hormones to nervousness, tremors, sweating, weight loss, fatigue, sleep disorders, tachycardia, arrhythmias, and life-threatening systemic thyrotoxicosis (thyroid storm).[101,132] In the respiratory system, hyperthyroidism can cause dyspnea, tachypnea, pulmonary hypertension, and extreme respiratory distress during thyroid storm. Tachypnea results from increased oxygen consumption and carbon dioxide production,[103] and hyperventilation due to heightened ventilatory responses to hypercapnia and hypoxia[133] associated with beta-adrenergic stimulation.[134] Vital capacity is reduced due to respiratory muscle asthenia, indicated by reductions in maximum inspiratory and expiratory pressures.[103]

Pulmonary Hypertension

Both hyperthyroidism and hypothyroidism may be associated with elevated pulmonary pressures[135,136] and increased morbidity and mortality from cardiovascular disease.[137] Recent data indicate a 24% prevalence of thyroid disorder in patients with *pulmonary hypertension* (PH),[136] and having an untreated thyroid disorder is a negative prognostic factor for worse survival in patients with PH.[138] Conversely, the prevalence of PH in patients with hyperthyroidism ranges from 41–65%.[135,139,140] In an echocardiographic study of patients with hyperthyroidism and normal left ventricular systolic function,[141] up to 45% had PH due to either pulmonary arterial hypertension with increased cardiac output (70%) or pulmonary venous hypertension with elevated left ventricular filling pressure (30%). Furthermore, PH in these hyperthyroid patients was largely asymptomatic and reversible following treatment with radioactive iodine and normalization of thyroid status. Proposed pathogenic mechanisms include autoimmunity, endothelial injury, and pulmonary vascular remodeling.[142]

Thyrotoxicosis

Excessive thyroid hormone activity can be asymptomatic or can lead to subclinical or life-threatening thyrotoxicosis or thyroid storm, with pulmonary hypertension, atrial fibrillation, embolism, cardiovascular collapse, and death.[132] The most common etiology of thyrotoxicosis is Graves disease, followed by toxic multinodular goiter, toxic adenoma, various forms of thyroiditis, drug-induced thyrotoxicosis from amiodarone and iodinated contrast, and rare causes such as struma ovarii, gestational trophoblastic neoplasia, exogenous thyroid hormone ingestion, activation mutations of the TSH receptor, and functional thyroid cancer metastases.[143] Multiorgan dysfunction can develop requiring intensive care unit support.[132] In its extreme form, thyroid storm has a mortality rate up to 25% and requires prompt recognition and a multidisciplinary treatment approach to reduce excess thyroid hormone while providing critical care support.[101]

Lung Cancers

In addition to mediating growth, development, and metabolism, thyroid hormone receptors also act as suppressors of tumor transformation. There is cumulative evidence that aberrant thyroid hormone receptor genes or expression are common in human cancers. Hyperthyroidism has been associated with inactivating mutations in thyroid hormone receptors that impede thyroid hormone action and increase the risk of developing prostate, breast, and lung cancers, whereas hypothyroidism is associated with a lower risk of prostate cancer and variable effects on the risk of breast cancer.[144] In the prospective, population-based Rotterdam Study, a higher free thyroxine level was associated with an increased risk of any solid cancer, including lung (1.79-fold) and breast (1.14-fold) cancers. In contrast, TSH level is not associated with cancer risk.[144]

Besides measuring thyroid hormone status, investigation of thyroid disorders commonly includes imaging by ultrasound or CT. It should be noted that, by introducing an iodine load, iodinated contrast agents can delay performance of whole-body radioiodine scans or ablation. Current water-soluble iodinated contrast agents are typically eliminated in 4 to 8 weeks, so radioiodine scanning and therapy can be performed within 1 month of contrast-enhanced CT (see also Chapter 20).

GROWTH HORMONE DISORDERS

ACROMEGALY

Primary *growth hormone* (GH) excess is a rare condition usually associated with pituitary hyperplasia or adenomas. Secondary GH excess may be due to dysregulated hypothalamic secretion of GH-releasing hormone or GH/GH-releasing hormone–secreting tumors (typically in the hypothalamus, lung, or pancreas). Excess GH stimulates *insulin-like growth factor 1* (IGF-1) production, leading to accelerated somatic growth (gigantism or acromegaly) with multiorgan manifestations.[145] Acromegaly is associated with vascular, neoplastic, and respiratory complications[146]; respiratory complications account for 25% of deaths, threefold higher than in normal subjects[147,148] (Table 128.3).

Anatomy and Respiratory Physiology

In a large cohort of acromegaly patients, pulmonary function showed larger lung volumes (forced vital capacity, total lung capacity, and residual volume) and small airway obstruction.[149] In active acromegaly (elevated GH and IGF-1 levels), CT pulmonary densitovolumetry revealed air trapping (60% of cases), airway calcification (40% of cases), and bronchiectasis (35% of cases) along with pulmonary function test findings of increased forced vital capacity, total lung capacity, and residual volume.[150] An increase in density of lung parenchyma has been attributed to GH and IGF-1 effects on smooth muscle cells and the lungs, increasing the synthesis of type I and type II collagen fibers and mucopolysaccharides.[150,151] Other proposed explanations for the increases in total lung capacity and residual volume include alveolar hyperplasia or increased number of alveoli.[152] Subclinical hypoxemia has been reported and is thought to result from ventilation-perfusion derangements.[153]

Obstructive Sleep Apnea

OSA is highly prevalent in acromegaly[117] due to skeletal and soft tissue alterations in the face, pharynx, and tongue that increase upper airway resistance and narrowing.[147,154] CT and magnetic resonance imaging reveal larger and thicker soft palates and thicker lateral pharyngeal walls in acromegaly patients with OSA, correlating

with both severity of sleep apnea and acromegaly.[155,156] Both obstructive and central sleep apnea[157] have been described,[158] and biochemical control of acromegaly improves sleep-disordered breathing.[159] Whereas OSA is prevalent in acromegaly, routine screening for acromegaly in OSA patients is not warranted due to the low prevalence of acromegaly.[160,161]

Association with Neoplasm

Excess IGF-I can increase the risk of tumor development and progression.[162] Untreated acromegaly with chronically elevated GH/IGF-1 levels has been associated with various neoplasms, including sporadic reports of lung cancer.[163] Conversely, acromegaly may be a rare paraneoplastic manifestation of GH/IGF-1-secreting pulmonary neuroendocrine tumor.[164]

Table 128.3 Pathology and Clinical Respiratory Abnormalities in Acromegaly

Pathologic Abnormalities	Clinical Conditions
UPPER AIRWAY	
Macroglossia	Obstructive sleep apnea
Soft palate and pharyngeal wall narrowing	Snoring
Mandibular protrusion	Daytime sleepiness
Vocal cord thickening	
LUNG PARENCHYMA	
Increased size of alveoli	Airflow obstruction
Increased lung volume and lung compliance	Obstructive lung disease
Cellular derangement	Ventilation-perfusion mismatch
	Mild hypoxemia
THORAX	
Kyphoscoliosis	Impaired breathing movement
Vertebral body enlargement	Rib cage stiffness
Intervertebral disc thickening	Respiratory muscle impairment
SYSTEMIC	
Chronic IGF-1 stimulation	Possible increased risk of cancers, including in the lung

IGF-1, insulin-like growth factor-1.
From Colao A, Auriemma RS, Pivonello R, Galdiero M, Lombardi G. Medical consequences of acromegaly: what are the effects of biochemical control? *Rev Endocr Metab Disord*. 2008;9(1):21-31.

Treatment

Prompt recognition and treatment of acromegaly via surgery, medication, or radiation therapy aims to control hormone excess and attenuate or reverse complications. Somatostatin analogs such as octreotide and lanreotide, or GH receptor antagonists alleviate sleep apnea in many patients (Fig. 128.2), although individual responses to therapy may vary[165] and OSA persists in 40% of patients.[117,165] Respiratory complications, represented mainly by sleep-related breathing disorders and respiratory insufficiency, are frequent at an early stage of the disease. Finally, although control of hormonal excess (surgically or medically) may improve associated respiratory conditions resulting from acromegaly, permanent irreversible anatomic changes often require persistent therapy to mitigate respiratory impairment.[166]

GROWTH HORMONE DEFICIENCY

GH deficiency has been associated with central and obstructive ventilatory defects. For example, Prader-Willi syndrome, a rare genetic disorder of loss of function in a specific region of chromosome 15, is associated with hypothalamic dysfunction and deficient GH secretion. Patients exhibit short stature, insatiable appetite, morbid obesity, hypogonadism, abnormal thermal control, sleep disturbances, and ventilatory restriction due to respiratory muscle weakness[167] and abnormal control of breathing (central hypoventilation and decreased peripheral chemoreceptor sensitivity) leading to depressed ventilatory responses to hypoxia or hypercapnia.[168] GH treatment increases ventilatory drive and activity.[169] Children with Prader-Willi syndrome exhibit abnormal sleep and arousal with increased apnea events, oxygen desaturation, increased maximum heart rate, abnormal arousal responses,[170] and daytime somnolence. In a randomized,

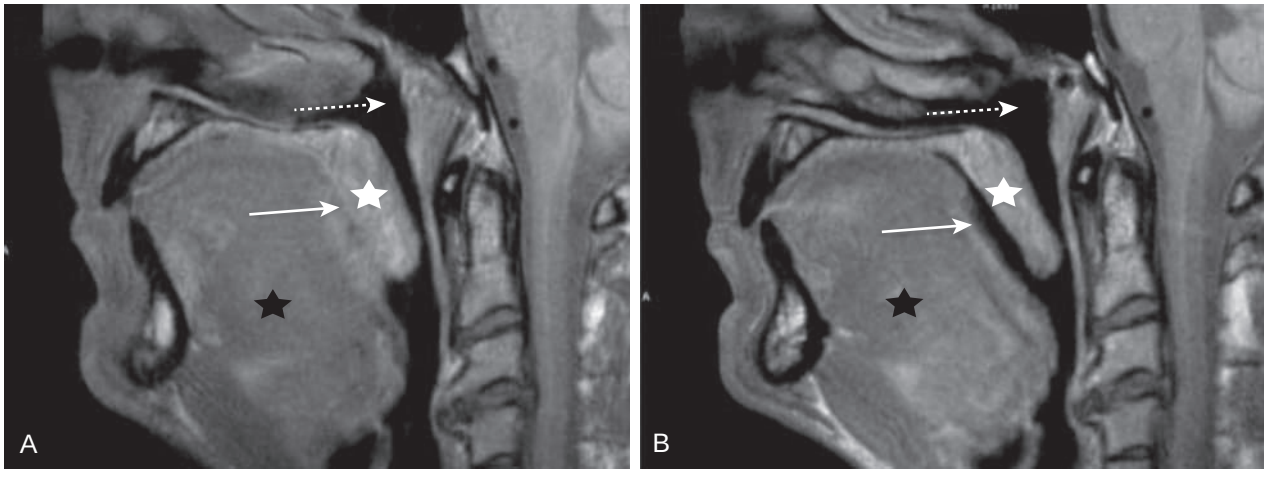

Figure 128.2 Sagittal T1-weighted magnetic resonance imaging sequences of the neck before (A) and after (B) effective treatment of acromegaly in a male patient with *obstructive sleep apnea* (OSA). The treatment of acromegaly allowed a clear decrease in thickness of the tongue (*black star*), soft palate (*white star*), and pharyngeal walls and an increase in the opening of the oropharynx space (*solid arrow*) between the tongue and soft palate and of the posterior nasopharyngeal area (*dashed arrow*), which were associated with the cure of OSA in this patient. (From Attal P, Chanson P. Endocrine aspects of obstructive sleep apnea. *J Clin Endocrinol Metab*. 2010;95[2]:483-495.)

double-blind, placebo-controlled, crossover study of GH treatment in children with Prader-Willi syndrome, peak flow rate, vital capacity, and forced expiratory flow rate improved and the number of hypopnea and apnea events and duration of apnea events tended to improve after treatment. Treatment improved linear growth velocity, resting energy expenditure, and lean body mass; optimization of body composition may have contributed to better sleep quality and pulmonary function.[171]

Pediatric snoring affects 10% of preschool-age children, while OSA affects 0.7–3.4% of all children.[172] In children with sleep-disordered breathing, depressed nocturnal GH secretion and excessive energy expenditure due to increased work of breathing during sleep are thought to contribute to growth retardation and failure to thrive.[172] Adenotonsillectomy in these children results in restored GH secretion, respiratory improvement, and catch-up weight gain.[172,173] Diminished GH secretion has also been shown in adults with primary sleep abnormalities.[174]

CALCIUM DYSREGULATION AND PULMONARY CALCIFICATION

PARATHYROID HORMONE

Parathyroid hormone (PTH) is rapidly produced by the parathyroid gland in response to a fall in serum calcium ion concentration and targets calcium-phosphorus homeostasis in bone and kidney cells. The short-acting PTH increases extracellular fluid calcium concentration by (1) stimulating osteoclast bone resorption, (2) directly promoting small intestine calcium absorption, (3) enhancing renal production of active vitamin D metabolites to up-regulate a calcium-binding protein in intestinal epithelium to facilitate calcium absorption, and (4) suppressing urinary calcium loss by simultaneously stimulating renal tubular calcium reabsorption and excretion of inorganic phosphate.[175] As serum calcium concentration increases, serum phosphate ion concentration falls; the calcium-phosphate product is maintained within normal limits, thereby preventing tissue calcium deposition.

Primary hyperparathyroidism is characterized by PTH oversecretion, commonly due to parathyroid adenoma and less commonly (≈1%) due to parathyroid carcinoma or hyperplasia in rare familial genetic abnormalities (e.g., multiple endocrine neoplasia).[176] Secondary hyperparathyroidism develops in response to low serum calcium concentration caused by chronic renal failure, intestinal malabsorption, inadequate calcium intake, or vitamin D deficiency.[176] Tertiary hyperparathyroidism develops when secondary PTH hypersecretion becomes autonomous and resistant to pharmacologic suppression and is sometimes seen after renal transplantation. Symptoms of hypercalcemia include thirst, polyuria, constipation, bone pain, fatigue, depression, and renal stones. Primary and tertiary hyperparathyroidism is usually treated by parathyroidectomy. Pharmacologic suppression of PTH involves administration of phosphate binder, vitamin D, and calcium-sensing receptor agonists.

PULMONARY CAUSES OF HYPERCALCEMIA

Hypercalcemia accompanied by appropriately suppressed PTH levels raises suspicion of metastatic cancer to the bone. Various cancers, including pulmonary carcinoma and neuroendocrine tumors, may also secrete PTH-related protein, a separate and widely expressed protein that binds to the PTH receptor and mimics PTH function. Autonomous nonrenal conversion of 25-hydroxy-vitamin D to the active metabolite 1,25-dihydroxy-vitamin D may induce hypercalciuria and hypercalcemia, typically seen in lymphoma and granulomatous lung diseases such as *M. tuberculosis*, fungal infections, and sarcoidosis.

DYSTROPHIC AND METASTATIC PULMONARY CALCIFICATION

Pulmonary calcification can result from calcium salt deposition in the lung.[177] There are two distinct types: dystrophic calcification and metastatic pulmonary calcification.[178] *Dystrophic* calcification refers to calcium deposition in previously injured, damaged lung such as previously infected or inflamed lung tissue, and takes place in the setting of *normal* serum calcium and phosphorus values. Classic examples include localized scars or granulomatous processes such as mycobacterial, fungal, viral, or parasitic disorders or other noninfectious disorders such as amyloidosis or sarcoidosis, where calcium deposits in injured or necrotic lung tissue. Histologically, calcium aggregates are seen in background fibrosis, chronic granulomatous changes, or areas with evidence of repair.[178]

Metastatic pulmonary calcification (MPC) (Fig. 128.3) refers to calcium deposition in otherwise normal lung tissue,

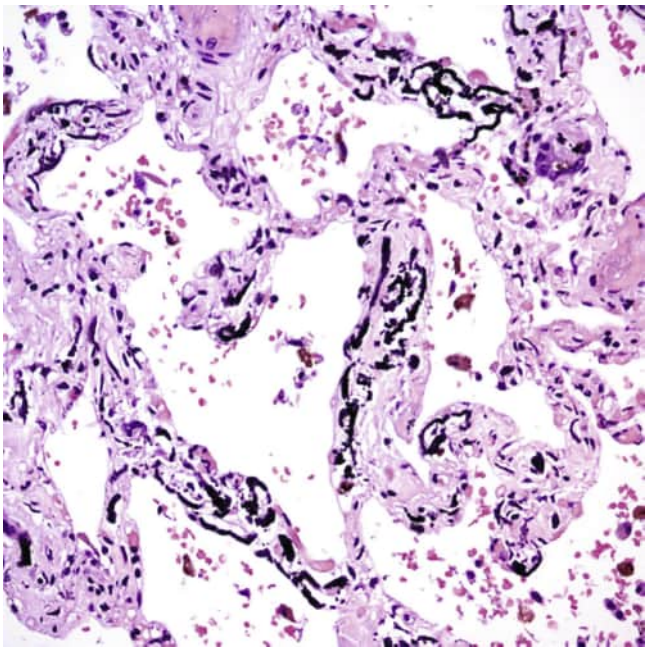

Figure 128.3 Metastatic calcification. Calcium is present as dark, basophilic fibrils within the alveolar walls and vessels in this lung. (From Zander DS, Farver CF. *Pulmonary pathology*. 2nd ed. Philadelphia: Elsevier; 2018.)

particularly in alveolar epithelial basement membrane and interstitium, and is usually the result of altered serum calcium and phosphorus metabolism. Nonmalignant causes of MPC include chronic renal failure, hyperparathyroidism, and primary bone disease.[177] Malignant causes of MPC are cancers associated with hypercalcemia such as parathyroid-related malignancies, multiple myeloma, leukemia, and small cell lung carcinoma.[177] Microscopic findings include calcium deposits within alveolar septal and vessel walls and may involve the airways in advanced cases.

Most patients with MPC are asymptomatic, reflecting the typical benign course, with up to 70% of cases diagnosed only at autopsy. Some patients may present with cough, dyspnea and, uncommonly, respiratory failure.[179,180] Clues to diagnosis include relative stability of pulmonary infiltrates in the clinical context of hypercalcemia; most patients show an elevated calcium-phosphate product above 70 mg^2/dL^2 (normal is ~40 mg^2/dL^2).[177] Depending on the burden of calcium deposition, pulmonary function tests can be normal or may reveal a restrictive pattern, decreased diffusing capacity, and hypoxemia.[179]

Radiographic Features

Chest imaging of MPC often reveals an upper lobe propensity due to a higher local ventilation-perfusion ratio there, leading to a lower arterial CO_2 tension and higher pH that encourage deposition of calcium salts.[177] However, all lung regions may be involved. Radiographic patterns include (1) multiple localized or diffuse calcified nodules, (2) diffuse or patchy areas of ground-glass opacity or consolidation, and (3) confluent high-attenuation parenchymal consolidations[179,181,182] (Fig. 128.4). Bone scintigraphy, such as with technetium-99m-methylene diphosphate, can usually diagnose MPC without the need for lung tissue biopsy[177] (Fig. 128.5).

Treatment

Pulmonary calcification may stabilize with medical strategies to reduce the serum calcium-phosphorus product.[177] In

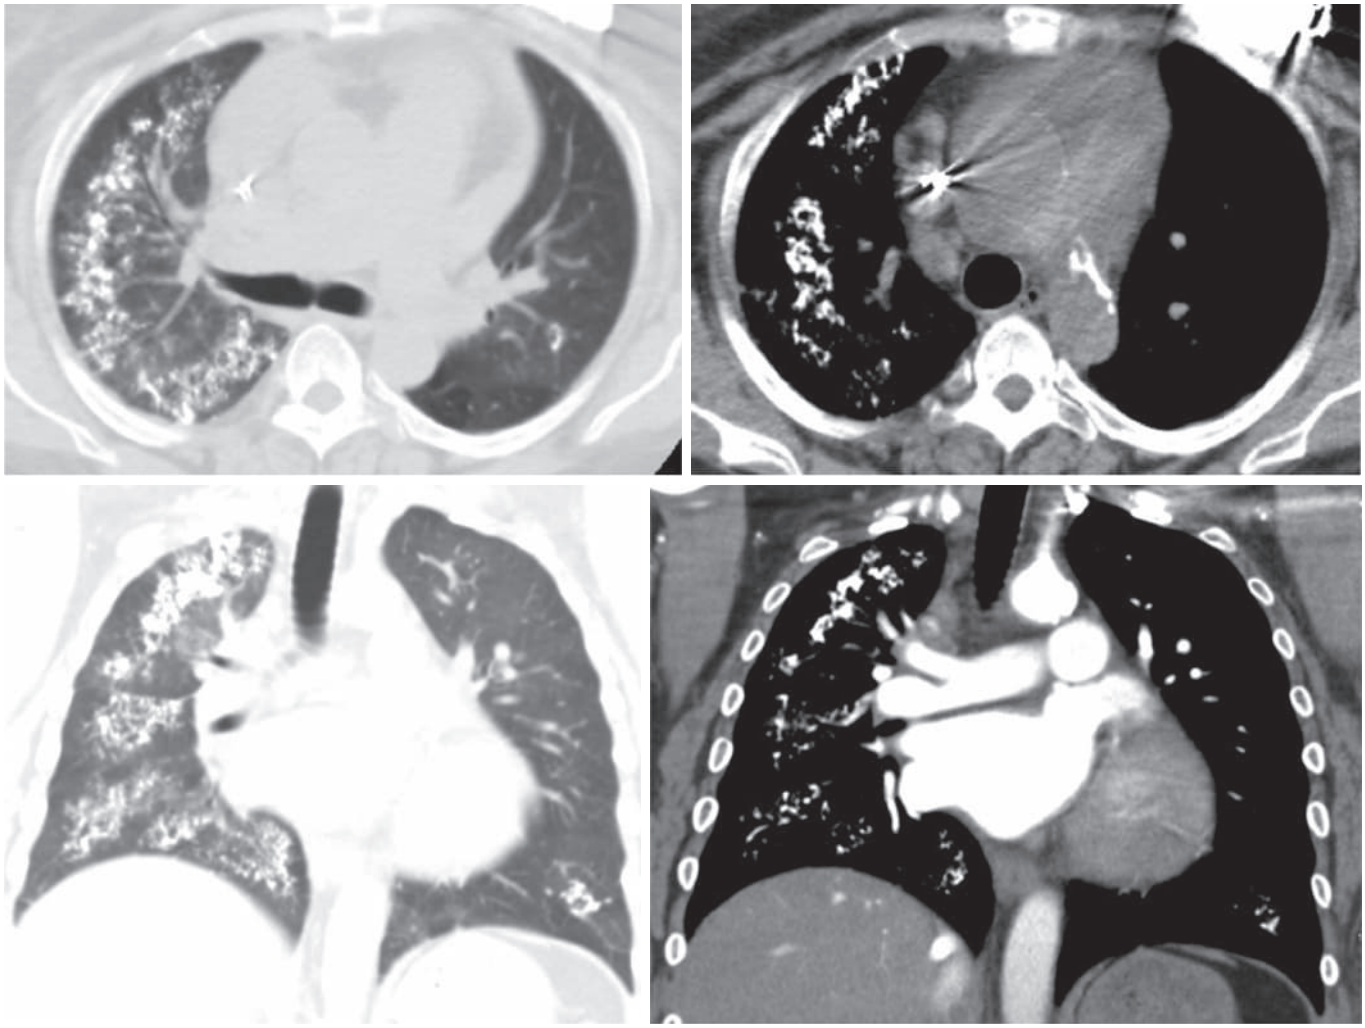

Figure 128.4 Metastatic calcification. Computed tomography in a patient with renal failure showing bilateral metastatic pulmonary calcification. There is right-sided predominance, but calcification is also seen in the left lung. There is also some apical predominance. Lung window (*left*) and soft tissue window (*right*) in axial (*top*) and coronal (*lower*) images. (Courtesy Michael Landay, MD.)

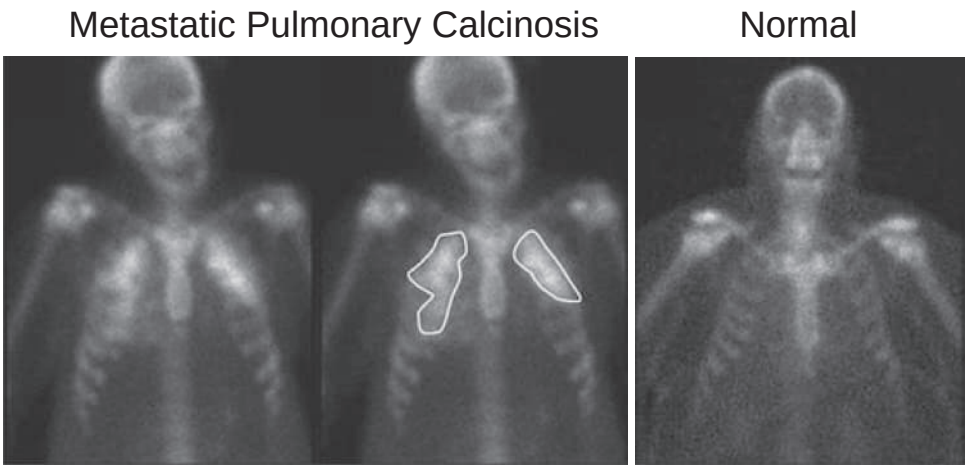

Figure 128.5 Metastatic pulmonary calcification in a patient with renal failure. *Left,* A coronal image of technetium-99m methylene diphosphonate scan shows extensive tracer uptake in both upper lungs (with and without the pulmonary uptake outlined). *Right,* A normal scan is shown for comparison. (Courtesy Michael Landay, MD, and Michael B. Gotway, MD.)

chronic renal failure, renal transplantation or dialysis may be effective but, in some cases, calcification continues to progress and may require parathyroidectomy.[183,184]

ADRENAL DISORDERS

ADRENOCORTICAL HORMONES AND LUNG DEVELOPMENT

Hypothalamic corticotropin-releasing hormone stimulates pituitary *adrenocorticotropic hormone* (ACTH) release, which in turn regulates adrenocortical production of *glucocorticosteroids* (GCs) including cortisol,[185] which mediates catabolism, blood pressure maintenance, neuronal function, stress response, and inhibitory actions on the immune system.[185] GCs mediate lung development by stimulating surfactant-associated protein production, phospholipid synthesis, cell maturation and differentiation, antioxidant enzymes, and lung fluid metabolism.[186] In neonates, serum cortisol response to ACTH stimulation increases with increasing birth weight. Antenatal dexamethasone administration during late gestation accelerates surfactant maturation and can ameliorate the development of respiratory distress syndrome in preterm infants.[187,188] Low-birthweight neonates who develop bronchopulmonary dysplasia show significantly lower ACTH-stimulated cortisol secretion than infants who recover without bronchopulmonary dysplasia, suggesting that adrenal insufficiency in low-birthweight infants may impede surfactant function and predispose to lung injury.[189] Early low-dose GC treatment improves survival of very preterm infants without bronchopulmonary dysplasia,[190] especially in the presence of added neonatal stress such as chorioamniotic.[191] In very preterm infants with severe respiratory failure supported by mechanical ventilation, GC treatment attenuates inflammatory cells and mediators and increases the alveolar desaturated phosphatidylcholine pool.[192] However, short-term benefits from GC use must be weighed against possible long-term adverse effects because high dose or repeated administration may impair somatic, brain, and lung growth and precipitate diabetes mellitus.

ADRENAL INSUFFICIENCY

Primary adrenal insufficiency resulting from disease of the adrenal cortex is accompanied by elevated corticotropin-releasing hormone and *adrenocorticotropic hormone* (ACTH) secretion. Causes include adrenalitis due to autoimmune reaction (Addison disease with antibodies against 21-hydroxylase that may be part of polyendocrinopathy syndromes)[193]; mycobacterial, fungal, and HIV-associated viral infections[194,195]; infiltrative diseases (metastatic lung cancer[196] or sarcoidosis[197]); medications (ketoconazole and etomidate[198]); and various genetic conditions.[199] *Secondary* adrenal insufficiency is caused by disorder of the anterior pituitary gland accompanied by elevated corticotropin-releasing hormone and reduced ACTH secretion. *Tertiary* adrenal insufficiency is caused by disorder of the hypothalamus accompanied by reduced corticotropin-releasing hormone and ACTH secretion. Clinical presentations include fatigue, anorexia, nausea, abdominal pain, weight loss, and orthostatic hypotension. Primary adrenal insufficiency may also present with salt craving due to mineralocorticosteroid deficit and skin hyperpigmentation due to binding of abundant circulating ACTH to the melanocortin-1 receptor in melanocytes. Chronic exogenous *glucocorticosteroid* (GC) use suppresses the hypothalamic-pituitary-adrenal axis and is the most common cause of tertiary adrenal insufficiency, which becomes manifest when the medication is rapidly tapered or abruptly discontinued.[199]

CUSHING SYNDROME

Glucocorticoid excess, or Cushing syndrome, can present with hypertension, hypokalemia, hyponatremia, and metabolic alkalosis in addition to physical exam features of buffalo hump, abdominal striae, and obesity.[200] Cushing syndrome is most commonly caused by exogenous GC use. Systemic and inhaled GC are frequently prescribed for asthma, COPD, and other pulmonary inflammatory conditions, and pulmonologists should be vigilant for this potential complication. HIV patients treated with ritonavir and inhaled corticosteroids may develop Cushing syndrome due to elevated levels of steroids from ritonavir's inhibition of the cytochrome P450 system.[201,202] In children, long-term use of oral corticosteroids results in weight gain, growth retardation, and Cushingoid

features.[203] Cushing syndrome can also arise from pituitary tumors or ectopic ACTH production by small cell lung cancer[204] and pulmonary carcinoid tumorlets.[205,206] Elevated cortisol levels predispose to pulmonary infections by various pathogens such as *Cryptococcus, Aspergillus, Nocardia, Pneumocystis*, and *Mycobacterium tuberculosis*.[207–210]

IMMUNE CHECKPOINT INHIBITORS

Immune checkpoint inhibitors block immune checkpoint proteins (CTLA-4, PD-1, and PD-L1) leading to activated T lymphocytes against various solid tumor and hematologic malignancies, including non–small cell lung cancer.[211–213] In up to 10% of patients,[212] immune checkpoint inhibitors can lead to complex immune-related endocrinopathies such as pituitary gland inflammation (i.e., hypophysitis), thyroid dysfunction, adrenal insufficiency, and, rarely, type 1 diabetes, central diabetes insipidus, and hypoparathyroidism.[211,214] Different immune checkpoint inhibitors modulate T cell response differently and exhibit distinct toxicity patterns; complications may be life-threatening if not recognized. Clinical manifestations of hypophysitis are widespread and include headache, hypotension, hypoglycemia, nausea, and multiple lab derangements including hyponatremia, low cortisol levels, low thyroid levels, and low gonadal hormonal and hypothalamic levels.[211,213] Management of immune-related endocrinopathies includes hormone level testing, supportive care, consultation with an endocrinologist, additional immunosuppression and, in some cases, withholding immune checkpoint inhibitors.[213,215]

Key Points

- The respiratory system is a target affected by multiple endocrine disorders. Conversely, primary respiratory disease may lead to endocrine abnormalities.
- Insulin resistance, diabetes mellitus, and obesity broadly impair immune defenses, ventilatory control, and respiratory structure, leading to a variety of anatomic, microvascular, mechanical, and gas-exchange abnormalities.
- Hypothyroidism can cause airway obstruction, alveolar hypoventilation, and pulmonary parenchymal and respiratory muscle abnormalities. Hyperthyroidism increases oxygen consumption, ventilation, and may lead to pulmonary hypertension and respiratory failure.
- Growth hormone deficiency retards somatic growth, whereas acromegaly predisposes to obstructive sleep apnea and malignancy, including in the lung.
- Calcium disequilibrium from parathyroid or other systemic or pulmonary diseases may lead to metastatic pulmonary calcification. Conversely, granuloma-forming pulmonary diseases such as lymphoma, fungal infections, and sarcoidosis can cause hypercalciuria and/or hypercalcemia.
- Adrenal hormone insufficiency or excess impacts fetal and postnatal lung development and may develop as a complication of exogenous glucocorticosteroid use or pulmonary malignancy.
- Immune checkpoint inhibitors used in the treatment of lung cancer can trigger complex endocrinopathies that in turn impact lung structure and function.

KEY POINTS

INTRODUCTION

Both respiratory physiology and the respiratory tract's susceptibility to disease are uniquely altered in gynecologic and obstetric conditions, including normal pregnancy. This chapter summarizes normal physiologic alterations during pregnancy and considers pathologic diseases and disorders that arise during pregnancy. Airway disorders, infectious diseases, pulmonary vascular and embolic disorders, and acute lung injury are discussed. Finally, pleural and parenchymal diseases that arise as a consequence of gynecologic conditions are addressed.

PHYSIOLOGIC ALTERATIONS DURING NORMAL PREGNANCY

Profound alterations of respiratory function and cardiovascular physiology accompany normal pregnancy in healthy women; these conditions contribute to many of the disorders of the lungs during pregnancy. The adaptive changes during the gravid period are designed to support maternal and fetal well-being during the special stresses of fetal growth and parturition, but they may exacerbate some underlying disorders and confuse interpretation of laboratory and imaging studies used to assess many other common conditions.

ALTERATIONS IN RESPIRATORY PHYSIOLOGY

Upper Airway

Upper airway, particularly nasal, mucosal edema is common in normal pregnancy. About 20% of gravid women report rhinitis symptoms, now attributed at least partially to placental growth hormone's effects on mucosal congestion.[1] The symptoms begin in the first trimester and persist throughout gestation. Many patients thought to have rhinitis of pregnancy may actually have other or coincident causes of rhinitis.[2] An important implication of nasal mucosal edema in pregnancy is that it predisposes to nosebleeds, including from nasal intubations, so an oral approach is favored if intubation is required at the time of delivery.

Chest Wall

Chest wall configuration is also altered, due to both a 50% increase in the average costal angle[3] and an increase in the circumference of the lower chest wall. Diaphragmatic position is elevated 4 to 5 cm, but excursion does not diminish.[3] Muscle strength, as measured by maximum transdiaphragmatic pressure, does not appear to be diminished from its usual mean value of about 95 cm H_2O,[4] allowing reserve for both the augmented minute ventilation of normal pregnancy and the stresses of delivery.

Lung Function

Important changes take place in lung function and lung volumes. The loss of lung volume resulting from elevation of the diaphragm is only partially offset by the increase in chest wall diameter, and therefore *functional residual capacity* (FRC) is diminished by about 18%, or 300 to 500 mL.[5] This reduction in FRC comprises an equal reduction in both the expiratory reserve volume and the residual volume.[3,5] The loss of FRC at term is made worse by recumbency, when diaphragm elevation is greatest because of the higher intra-abdominal pressure. Increased pulmonary blood volume in pregnancy may also serve to lower the FRC due to volume displacement by vascular engorgement.[6] This reduction in FRC is associated clinically with increased uptake and elimination of inhalational anesthetics and with rapid

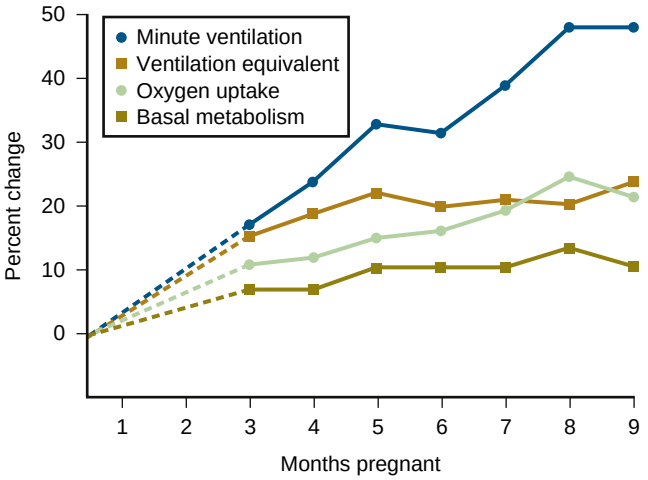

Figure 129.1 The physiology of pregnancy. The expected values for minute ventilation, the ventilatory equivalent for oxygen, oxygen uptake, and basal metabolism are shown at monthly intervals throughout pregnancy. (From Prowse CM, Gaensler EA: Respiratory and acid-base changes during pregnancy. *Anesthesiology.* 1965;26:381.)

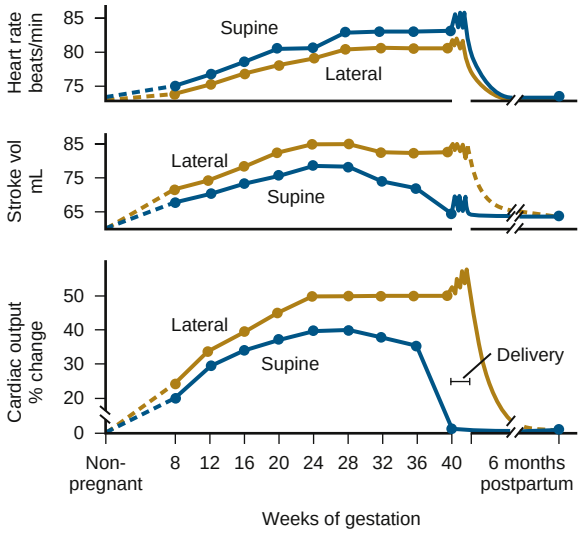

Figure 129.2 Changes in physiology in the supine position. Because the gravid uterus compromises venous return, there are characteristic changes in maternal heart rate, stroke volume, and cardiac output during pregnancy with the pregnant subject in the supine compared to the lateral position. (From Cheek TG, Gutsche BB. Maternal physiologic alterations during pregnancy. In: Shnider SM, Levinson G, editors. *Anesthesia for Obstetrics* Baltimore, MD: Williams & Wilkins; 1993.)

desaturation during hypopnea, as a result of the loss of the oxygen reservoir function of end-expiratory lung volume.[7] Endotracheal intubation at term is thus substantially more hazardous than in nongravid patients.

Airway function is largely unchanged during pregnancy.[3] Airway resistance may actually decrease slightly. Routine measurements of airflow, such as *forced expiratory volume in 1 second* (FEV_1), are thus valuable in assessing dyspnea during pregnancy.

Ventilation

The most striking changes are in respiratory drive and minute ventilation. Central drive, as assessed by the inspiratory pressure measured 100 msec after airway occlusion at the onset of inspiration ($P_{0.1}$), is increased by 13 weeks and continues to increase to week 37 of gestation, returning to normal by 24 weeks after delivery.[4] These serial changes in respiratory drive appear to correlate with changes in serum progesterone levels.[4,8] Carbon dioxide production itself increases one-third to one-half by the last trimester, related to the increased metabolic rate; however, this is more than made up for by the greatly augmented ventilation, so primary respiratory alkalosis with renal bicarbonate wasting as compensation is a normal finding.[9] Arterial blood gas measurements typically show the pH ranging from 7.40 to 7.47, with P_{CO_2} reaching as low as 28 to 32 mm Hg. P_{O_2} rises slightly as a result of the increase in alveolar ventilation.

Most of the increase in minute ventilation is due to a 30–35% increase in tidal volume. Respiratory rate is unchanged early and rises only about 10% later in pregnancy. Oxygen consumption increases 20–33% in pregnancy, owing to both maternal and fetal metabolic demands. Changes in some of these parameters are shown in Figure 129.1.

ALTERATIONS IN CARDIOVASCULAR PHYSIOLOGY

Adaptive cardiovascular changes are designed to support both maternal and fetal circulations but contribute to the risk for hydrostatic pulmonary edema; accordingly, cardiac disorders during pregnancy often present as respiratory failure. During normal pregnancy, maternal blood volume increases by about 2 L, or 40%.[10,11] Red blood cell mass increases as well, but only by 20–30%, accounting for the normal 10–12% decrease in hematocrit.[11,12] Plasma osmotic pressure also drops as intravascular volume expands, increasing the risk for pulmonary edema at lower intravascular hydrostatic pressures. During the 24 hours after parturition, osmotic pressure falls further because of blood loss and mobilization of extravascular fluid.

The enlarged intravascular volume of pregnancy is accommodated chiefly by venous capacitance vessels. Central venous pressure and pulmonary capillary occlusion (wedge) pressure are unchanged, reflecting an increase in left ventricular compliance, as evidenced by the enlarged cardiac silhouette seen on chest radiograph. The increased left ventricular end-diastolic volume results in an augmented stroke volume (ejection fraction is little changed), but systemic vascular resistance diminishes.[12,13] These changes account for the 30–45% increase in cardiac output reached by 25 to 32 weeks of gestation. After 5 weeks, heart rate increases as well,[14] but less so than stroke volume. Some of these changes, as well as the effects of supine versus lateral positioning, are depicted in Figure 129.2.

LUNG DISORDERS IN OBSTETRICS

Gravid and newly postpartum patients may develop pregnancy-specific disorders but also continue to experience common disorders that arise outside of pregnancy; the natural history or frequency of coexisting disorders is sometimes altered by the gravid state. Even for diseases not

altered by pregnancy, management requires special knowledge of the safety of therapies. Specific diseases are considered here with these principles in mind.

OBSTRUCTIVE AIRWAY DISEASE

Asthma

Asthma affects 4–8% of the general population and is the most common pulmonary disorder in pregnancy. The *National Asthma Education and Prevention Program* (NAEPP) Working Group on Asthma and Pregnancy estimated that 3.7–8.4% of pregnancies are complicated by asthma.[15] Poorly controlled maternal asthma increases the risk of preeclampsia, preterm birth, infants with low birth weight, intrauterine growth restriction, and perinatal death.[16]

Studies examining the hormonal milieu have suggested that progesterone might diminish smooth muscle contractility in the lung, as it does in the uterus and gut. Juniper and colleagues[17] performed serial measurements of bronchial reactivity to methacholine challenge in 16 women before and during pregnancy and found a decrease in airway hyperresponsiveness. Clinical and epidemiologic studies, however, have failed to provide convincing evidence of any consistent change in the natural history of asthma during pregnancy. Turner and coworkers,[18] for example, compiled the results of nine studies of asthma symptoms reported by pregnant women. Among them, 22% reported worsening, 29% reported improvement, and 49% reported no change. Other studies have reported similar figures, with about 23–42% worsening, 18–36% improving, and 40% exhibiting no change.[19,20] The differences reported in the natural history probably reflect differences in study populations, smoking history, ethnicity, or other variables.[21]

Fetal and maternal outcome for asthma and pregnancy have also been examined in a variety of studies since 1980. Adverse outcomes, including an increased incidence of preterm labor, low neonatal birth weight, increased perinatal mortality, preeclampsia, vaginal hemorrhage, chronic hypertension, and complicated labor, have been reported.[15,21] A large epidemiologic study from Sweden confirmed an association of asthma with perinatal mortality and low birth weight.[22] Nonetheless, adequate asthma therapy during pregnancy tailored to disease severity is associated with improved outcomes.[23] Therapy should be individualized according to severity of disease and frequency of symptoms, as outlined by the NAEPP and British Thoracic Society/Scottish Intercollegiate Guidelines Network.[15,24] Objective measurement of lung volumes and flow should be part of the regimen. Initial office spirometry is recommended, and home peak flow monitoring should be considered. For women who have asthma attacks during labor, which is extremely rare, fetal monitoring is considered essential by the NAEPP.

Therapy should be based on a step approach.[15] Mild intermittent asthma is best managed with inhaled short-acting β_2-agonists for symptomatic relief. Asthma that causes more than occasional symptoms should be treated daily with anti-inflammatory therapy, preferably inhaled corticosteroids. Budesonide is the best-studied and hence preferred, although substantive safety data exist for beclomethasone and fluticasone as well. Alternative therapies include cromolyn, sustained-release theophylline, or a leukotriene antagonist.[15] Frequent need for short-acting β_2-agonists should prompt institution of, or an increase in, the use of anti-inflammatory agents to treat, rather than to mask, a deteriorating clinical course. Long-acting β-agonists should only be used concurrently with long-acting inhaled corticosteroids.[21] Finally, the addition of rapidly tapered courses of oral corticosteroids should be considered for those with acute severe asthma or patients with active symptoms who are already using inhaled steroids and β-agonists. Daily or alternate-day oral steroid administration (e.g., prednisone 40 mg/day) is sometimes required.[15] Extensive practice algorithms have been made available by the NAEPP Working Group on Asthma and Pregnancy and the British Thoracic Society/Scottish Intercollegiate Guidelines Network.[15,24]

A large body of literature has examined the topic of possible teratogenicity of agents used in the pharmacotherapy of asthma in pregnancy. In general, the risks of poorly controlled asthma far outweigh the possible hazards of drug therapy. Both animal and human studies of β_2-agonists, administered either by inhalation or systemically, have indicated an acceptable safety profile for the fetus. They are also safe for use during lactation. Nonselective β-agonists, such as epinephrine, carry a risk of uterine vasoconstriction in animal models[25] and are probably best avoided. Acceptable β_2-agonists in pregnancy include metaproterenol, albuterol, pirbuterol, bitolterol, and terbutaline. Because the toxicology and pharmacology of the long-acting β-agonists salmeterol and formoterol are expected to be similar to shorter-acting β_2-agonists, these drugs have been recommended in patients with poor control on a combination of inhaled long-acting corticosteroids and short-acting β-agonists.[23,26] Limited data suggest that these drugs are safe in pregnancy.[27]

Theophylline is currently seldom used, but it passes freely to the fetus, and newborns occasionally show signs of theophylline toxicity, particularly when maternal blood levels are high. Animal studies suggest that the leukotriene inhibitors montelukast and zafirlukast are safe in pregnancy, and they can be continued in patients who have previously responded.[25,28,29] A large Danish cohort study demonstrated no increased incidence of congenital abnormalities after exposure to montelukast.[30] Zileuton has little human safety data, and animal studies have raised questions about its safety in pregnancy.[28]

Animal studies have shown an increased incidence of cleft palate with use of corticosteroids, but a very large Danish database study demonstrated no association of cleft lip/palate with first-trimester exposure to corticosteroids via either the oral, inhaled or intravenous route of administration.[31] Systemic corticosteroids have also been reported to cause intrauterine growth restriction but of a relatively modest degree. Fluorinated synthetic steroids such as betamethasone and dexamethasone cross the placenta, but nonhalogenated corticosteroids (hydrocortisone, prenisolone) are largely metabolized by the placenta and so fetal effects are not a major concern.[15] Overall, risk-benefit considerations nonetheless favor their use in persistent severe asthma with exacerbations unresponsive to other measures. A meta-analysis of the use of inhaled steroids during pregnancy demonstrated that these drugs do not increase the incidence of congenital abnormalities or

Table 129.1 Potential Fetal Risk of Drug Therapy in Pregnancy

Group	Drug	Pregnancy Risk
Inhaled β_2-agonist bronchodilators		Although data are limited, studies do not suggest an increased chance for birth defects with the use of inhaled albuterol during pregnancy.
Inhaled anticholinergic bronchodilators		Data are more limited than for inhaled β_2-agonist bronchodilators, but there is no evidence to suggest these drugs cause problems in pregnancy.
Long-acting β-agonists		Data are more limited than for short-acting bronchodilators, but there is no evidence to suggest these drugs cause problems in pregnancy.
ICSs	As a group	Studies of ICS have found no overall increased chance for birth defects. High doses of ICSs (doses similar to systemic steroid use) have not been well studied during pregnancy.
	Fluticasone and budesonide	As older, more established ICSs, these drugs have more published data to support their safety during pregnancy.
Leukotriene antagonists	Montelukast	Several large cohort studies of pregnant women exposed to montelukast have not shown an increased incidence of birth defects.
	Zafirlukast	Although data are more limited than for montelukast, an increased incidence of birth defects has not been demonstrated.
	Zileuton	Adverse fetal effects have been documented in animal studies, and there are no adequate human data to support safety in pregnancy.
Biologics	Omalizumab	No adverse fetal effects have been noted in limited early studies. For this IgG antibody, the risk of anaphylaxis must be considered and placental transfer increases as pregnancy progresses.
	Mepolizumab	No adequate data exist to assess safety, but similar concerns as an IgG antibody.
Other agents for asthma	Theophylline	Although animal studies suggest an increased risk of birth defects, this has not been demonstrated in limited human data.
	Inhaled cromolyn	No increased risk of birth defect has been demonstrated.
	Systemic steroids	Older studies suggest a small increased risk of cleft lip/palate, although this is not supported by newer data. The benefit of steroids in the management of a severe asthma attack outweighs these very small risks.
Antibiotics	β-lactams	No significant fetal risks have been identified.
	Macrolides	Several large studies have demonstrated no fetal risks from macrolide therapy. Erythromycin estolate may produce reversible hepatotoxicity in the pregnant woman.
	Quinolones	No birth defects have been demonstrated in human studies, although older animal studies did suggest some concerns.
	Tetracyclines	Tetracyclines accumulate in developing teeth and bones, and permanent discoloration of teeth can result from utero exposure.
Anticoagulants	Heparin	Heparin does not cross the placenta and is not associated with birth defects, but long-term heparin therapy during pregnancy may cause maternal osteopenia.
	LMWHs	LMWHs are not associated with adverse effects in pregnancy.
	Warfarin	Use should be avoided during the first trimester because it carries a significant risk to the fetus. Towards term, the risks of bleeding need to be considered.

In every pregnancy, the background risk for having a baby with a birth defect is 3–5%. This table describes whether exposure drugs may increase the risk for birth defects over that background risk.
ICSs, inhaled corticosteroids; Ig, immunoglobulin; LMWHs, low-molecular-weight heparins.

other adverse pregnancy outcomes.[32] A recent UK administrative database study demonstrated no adverse effects to exposure to fluticasone during pregnancy.[33] One study suggests that higher doses of inhaled corticosteroids (i.e., beclomethasone > 1000 μg/day) may be associated with a small increased risk of congenital abnormalities, although the confounding effect of increased asthma severity cannot be excluded.[34] There are limited data to confirm the safety of newer inhaled corticosteroids.[27] Table 129.1 summarizes the safety profile of commonly used asthma therapy in pregnant patients. Self-monitoring and self-management are important components of asthma care, and a telephone monitoring system using the Asthma Control Test[35] and a smartphone application[36] have been found helpful in this regard.

Labor and delivery can be especially hazardous for asthmatic patients, partly because of the drugs commonly administered. Narcotics other than fentanyl release histamine, which may worsen bronchospasm. Lumbar epidural analgesia is generally preferred but, if general anesthesia is to be used, pretreatment with atropine or glycopyrrolate assists bronchodilation. Ketamine is the preferred anesthetic, although halogenated anesthetics at low concentrations may provide bronchodilation as well.[15] Preterm labor may be safely treated with nifedipine or magnesium sulfate. Oxytocin is the optimal labor induction agent and is useful for postpartum hemorrhage, but 15-methyl prostaglandin F_{2a}, methylergonovine, and ergonovine may cause bronchospasm and should be avoided if possible.

Cystic Fibrosis

Cystic fibrosis (CF), present in about 1 in 1500 whites and 1 in 17,000 African Americans, is a common genetic disease. With improved therapy, median survival has now increased to 37 years.[37] Up to 4% of female CF patients between the ages of 17 and 37 may be pregnant at any time,[38] despite the frequent infertility of women due to delayed sexual development from nutritional deficiencies and chronic disease. Pregnancy in CF patients, as might be anticipated, has been associated with adverse fetal and maternal outcomes,[39,40] although several recent small case series have demonstrated good maternal and neonatal outcome in women with CF.[41–43] Premature delivery was more common in women with worse baseline FEV_1, and gestational diabetes was common. In a large U.S. review of 680 gravid women with CF enrolled in the U.S. Cystic Fibrosis Foundation National Patient Registry from 1985 to 1997, survival was actually better in the gravid group than in the matched 3327 control patients with CF.[44] Women with CF who became pregnant had higher predicted percentages of FEV_1 and higher weights. Pregnancy was not clearly harmful in any subgroup, after severity adjustment for age, *Pseudomonas aeruginosa* colonization, pancreatic function, and FEV_1. In another case-control study, pregnancy had little effect on patients with stable CF, although poor outcomes were seen in those with severe disease.[45] An analysis of a U.S. database documented the linear increase in CF pregnancies from 2000 to 2010, with more than 1000 deliveries from 2008 to 2010.[39] As might be anticipated, most studies suggest that risk stratifies according to severity of illness.[40,45] Declines in pulmonary function tend to mirror severity-adjusted control subjects, and clearly CF patients require substantially more care and have more visits to physicians when pregnant than when not.[41] Prepregnancy counseling, particularly for women with more severe disease, is essential in limiting excessive maternal and fetal risk. New therapies aimed at improving the function of the CF transmembrane conductance regulator are now available and provide significant clinical benefits to patients with CF (see Chapter 68). Isolated reports suggest that these may be safe during pregnancy.[46]

INFECTIOUS DISEASES

A woman's immune system changes during pregnancy to allow tolerance to paternally derived fetal antigens. This involves predominantly a down-regulation of cell-mediated immunity, balanced by an up-regulated humoral immune response. The pregnant woman is therefore at risk of more severe manifestations of certain infections, particularly viral and fungal infections, as described further in this section.

Bacterial Pneumonia

Pneumonia is a leading cause of maternal and fetal morbidity and mortality. The reported incidence varies widely, from 0.4 to 2.7 per 1000 deliveries,[47] but may not be higher than that in the general population. Some recent studies suggest an increased incidence of pneumonia in pregnant women with chronic disease and those with HIV.[47] Postpartum pneumonia may develop in the first 6 weeks after delivery and is more common after cesarean section.[48] Pneumonia accounted for 40% of pregnant women admitted to the ICU with severe sepsis in a large UK cohort study.[49]

Pregnancy increases the risk of major complications of pneumonia. In the series by Madinger and colleagues,[50] of 25 women with pneumonia from 25,000 deliveries, 40% had major complications, including five intubations, two empyemas, one pneumothorax, and one pericardial tamponade. Similarly, in the series by Briggs and associates,[51] 7 of 34 patients required mechanical ventilation, and two died. The Pneumonia Severity Index[52] used to identify severity of pneumonia for hospital admission does not appear to perform well in the obstetric population, underestimating the need for hospital admission.[53] Pneumonia (and other infections) increase the risk of preterm labor. Underlying chronic illness in the mother is a powerful predictor of adverse outcomes in both fetus and mother.

Pneumonia in pregnancy is most commonly bacterial in origin; the microbiologic spectrum mirrors community-acquired pneumonia, with *Streptococcus pneumoniae* and *Haemophilus influenzae* the most common organisms.[43,47] Other common organisms include *Mycoplasma pneumoniae* and *Chlamydia pneumoniae.* As in other community-acquired pneumonias, the causative agent is identified in only about half of the cases. Unfortunately, the diagnosis of pneumonia is frequently delayed because of reluctance to obtain a chest radiograph, due to inappropriate concerns for the effect of radiation on the fetus. A plain chest radiograph exposes the fetus to an extremely low radiation dose (<0.01 mGy) (see Chapter 20).[54] The hazard to both fetus and mother of delaying the diagnosis greatly exceeds the risk of this small radiation dose. Antibacterial therapy is similar to treatment in the nonpregnant patient, although tetracyclines and quinolones should be avoided if possible.[55] Erythromycin, clarithromycin, azithromycin, and β-lactam antibiotics are preferred because of their favorable safety profile (see Table 129.1).

Viral Pneumonia

Viral pneumonia remains a serious concern in pregnancy. In the influenza pandemic of 1918, the maternal rate of mortality from pneumonia was as high as 50%. In the epidemic of 1957, pregnant women accounted for 10% of fatalities, and about half of the women of childbearing age who died were pregnant.[56] Since then the maternal mortality rate from influenza A and B pneumonia has been relatively low but still much higher than that in the general population. Because of this, the Centers for Disease Control and Prevention recommends inactivated influenza vaccine in otherwise healthy women during any trimester of pregnancy.[57] Although influenza virus does cross the placenta, current opinion is that it is not likely to be teratogenic, despite isolated reports that link influenza with neural tube and other malformations. Amantadine has been used in pregnancy successfully, both as treatment and as prophylaxis, although there have been case reports of cardiovascular defects noted with first-trimester use, and there is considerable influenza viral resistance to the drug.

In 2009, the influenza A (H1N1) pandemic again confirmed the high risk of serious disease and appreciable mortality among pregnant women.[58,59] Surveillance by the Centers for Disease Control and Prevention in the United States identified influenza infection in 788 pregnant women, of whom 35% were admitted to the ICU and 7% died.[60] Early treatment of pregnant women and women up to 2 weeks

postpartum with oseltamivir or zanamivir appears to be beneficial.[61] Pregnant women are strongly urged to be vaccinated with the monovalent *inactivated* injectable influenza vaccine—not with the live attenuated vaccine.[62]

Varicella pneumonia, caused by a virus of the DNA herpesvirus group, has also been linked to particularly adverse outcomes during pregnancy. Haake and coworkers[63] report an increased incidence of pneumonitis in pregnant women with primary varicella infection and a 35% mortality rate in this group (over a period dating back to 1964), compared with 10% in other adults. Data are conflicting, and not all prospective studies have confirmed an increased incidence of mortality in pregnancy.[55] Treatment with acyclovir does appear to reduce mortality in gravid patients and should be used as therapy for active disease.[64] Use of varicella-zoster immune globulin should be considered within 96 hours for susceptible pregnant women who have been exposed to varicella. Administration of varicella-zoster immune globulin reduces but does not abolish risk for fetal infection or congenital varicella syndrome, and it is effective in preventing complications of varicella in the mother. Patients should be evaluated similarly to other adults, and a decision made to administer the immune globulin on the basis of immune status, type of exposure, and health status. The current licensed attenuated live vaccine against varicella is contraindicated in pregnancy.

The novel coronavirus, SARS-CoV-2, and its infection, COVID-19, is also linked to adverse outcomes during pregnancy. A pregnant woman is less likely to develop symptoms of fever and myalgia when infected.[65] Although infection is usually mild, the incidence of ICU admission and mechanical ventilation is higher than in the general population.[65–67] Risk factors for severe disease are similar to those in the nonpregnant patient and include obesity, ethnic minority status, asthma, hypertension, and age over 35 years.[65,67] Because both pregnancy and COVID are prothrombotic, the risk of thromboembolic disease is increased. The absolute risk of a poor outcome is low, but an increased mortality risk has been suggested.[65,67] Treatment is not very different than for the nonpregnant patient, although steroid dosing needs to be altered. In women at a preterm gestation, steroids are often given for fetal lung maturity and a higher dose of dexamethasone is required (e.g., dexamethasone 6 mg twice a day for 48 hours). Otherwise, a steroid that does not cross the placenta is preferably used (e.g., prednisolone). Iatrogenic preterm births are increased,[67] but the rate of spontaneous preterm labor does not appear to be increased.[65] The risk of stillbirth or neonatal death is not significantly increased, and the risk of vertical transmission and neonatal infection is very low.

Fungal Pneumonias

Fungal pneumonias are uncommon in pregnancy. Although there is no evidence that blastomycosis and histoplasmosis are more severe during pregnancy, it does appear that coccidioidomycosis is more likely to disseminate in pregnancy.[68] In the southwestern United States about 1 in 5000 pregnancies is complicated by *Coccidioides immitis* (see eFig. 56.7).[69] Dissemination is highly probable during the third trimester and is likely caused by both subtle impairment of cell-mediated immunity and a stimulatory effect of progesterone and 17-β-estradiols on fungal proliferation.[70] Amphotericin is the accepted therapy for disseminated coccidioidomycosis; azoles administered in the first trimester have been associated with branchial cleft abnormalities and should be used only after delivery.

Tuberculosis

Tuberculosis is an important cause of maternal morbidity and mortality, particularly in HIV-infected women, and in developing countries. Data from the United States have demonstrated an increasing incidence of tuberculosis in pregnant women,[71] and a study from the UK found that the incidence is significantly higher than in the nonpregnant population, particularly related to postpartum diagnoses.[72] Presentation may be atypical and disease is often extrapulmonary.[73] Diagnosis may be delayed by a reluctance to perform appropriate imaging studies. Pregnancy does not alter reactivity to tuberculin skin testing, and hence the test should be performed in the recommended groups during pregnancy. Interferon-γ-release assays are also an acceptable means of testing for tuberculous infection (see Chapters 42 and 53). Asymptomatic patients with positive skin tests should have their chest radiograph deferred until after 16 weeks of gestation. Treatment of latent infection is deferred until 2 months postpartum, except in the case of a known recent tuberculosis contact. Symptomatic patients with positive skin tests merit chest radiographs regardless of gestational stage. Isoniazid, rifampin, and ethambutol have acceptable safety profiles in pregnancy and are part of the standard treatment regimens advised by the Centers for Disease Control and Prevention and American Thoracic Society for pregnant women.[74] There is less collective experience with pyrazinamide, but this drug is recommended for use in pregnancy by the World Health Organization.[74] Worldwide data are accumulating, and pyrazinamide appears to be emerging as a drug that can be considered for treating multidrug-resistant tuberculosis and for HIV-infected women. Streptomycin, in contrast, is clearly associated with congenital deafness and is contraindicated during pregnancy.

PULMONARY EDEMA AND PULMONARY VASCULAR DISEASE

Gravid women are at special risk for pulmonary edema for a variety of reasons, including the hypervolemia and high cardiac output of pregnancy, the occasional need for tocolytic drugs that affect the vascular bed, and the unique vascular and endothelial disorders of pregnancy.

Among these effects, it is noteworthy that colloid osmotic pressure diminishes during pregnancy, although the effect on transcapillary pressure gradients is partially offset by a decrease in interstitial fluid colloid osmotic pressure (as explained in Chapter 133).[75] Etiologically, underlying cardiac disease, preexisting hypertension, use of tocolytic drugs, fluid overload, and preeclampsia are the most common causes for acute pulmonary edema in pregnancy.[75]

Increased Pressure (Cardiogenic) Pulmonary Edema

The cardiovascular adaptations to pregnancy have already been summarized. Their effects on underlying cardiac disorders are predictable. Stenotic valvular lesions are particularly poorly tolerated.[76] Of these, mitral stenosis is the

most common symptomatic valvular disease in pregnancy and frequently presents with pulmonary edema, not only during gestation but also immediately postpartum, because of the large shifts in intravascular volume associated with delivery. The gradient across a stenotic mitral valve is augmented by the increases in blood volume, cardiac output, and heart rate that take place during gestation and the puerperium. In aortic stenosis, the increase in cardiac output required for pregnancy worsens the gradient across the valve. As a compensatory mechanism, the left ventricular end-diastolic volume increases, but the low systemic vascular resistance impairs coronary artery filling during diastole and can precipitate ischemic syndromes. The reduction in systemic vascular resistance of pregnancy mitigates the consequences of mitral and aortic regurgitation and of the left-to-right intracardiac shunts of endocardial cushion defects but worsens the consequences of Eisenmenger syndrome and uncorrected tetralogy of Fallot. Depending on the cardiac disorder, perturbations induced by pregnancy can alter shunting, induce hypoxemia, or precipitate pulmonary edema.

A special problem of pregnancy is peripartum cardiomyopathy, a disorder that develops in 1 of 1300 to 15,000 deliveries, may present with congestive heart failure, and is associated with a special propensity for both pulmonary and systemic embolization toward the end of pregnancy or in the months following delivery.[77] Standard therapy for heart failure, including β-blockers, diuretics, and angiotensin-converting enzyme inhibitors (to be used only postpartum), are usually effective, but sometimes implantable defibrillators and even left ventricular assist devices, extracorporeal membrane oxygenation, and heart transplantation are required.[77,78]

Tocolysis-Associated Pulmonary Edema

The use of drugs such as β_2-sympathomimetic agents to retard premature labor is uncommon in current obstetric practice but, in the past, was associated with a 0–4% incidence of pulmonary edema.[79] A similar clinical picture has been reported during tocolysis with calcium antagonists[80] and atosiban, an inhibitor of oxytocin and vasopressin. The etiology of this disorder is controversial and likely multifactorial in nature, related to myocardial effects, vascular permeability impairment, and fluid retention. It usually presents after at least 24 hours of β-adrenergic therapy, with relatively acute onset of dyspnea and pulmonary edema seen on chest radiographs. Simple discontinuation of β-adrenergic therapy often results in rapid improvement; whether diuretics need to be given is unresolved, but furosemide is usually administered.

Pulmonary Edema Associated with Preeclampsia

About 2.9% of patients with preeclampsia or eclampsia develop pulmonary edema.[81] The spectrum of hemodynamic findings associated with pregnancy-induced hypertension and preeclampsia is wide and both hypodynamic and hyperdynamic patterns have been described (Table 129.2).[82] Systolic and diastolic function may also be impaired. The pulmonary edema commonly first presents in the postpartum period,[81] probably reflecting the effects of fluid administration at delivery. Low colloid osmotic pressure and abnormal vascular permeability are likely contributors. Hemodynamic monitoring of these patients is probably warranted if oliguria complicates the picture.

Table 129.2 Pregnancy-Induced Hypertension

	Hypodynamic	Hyperdynamic
Cardiac output	↓	↑
SVR	↑	↓
Timing	Early	Late
Fetal size	SGA	AGA
Other associations	-	Obesity

Possible hemodynamic subgroups and their clinical correlates.
AGA, appropriate for gestational age; SGA, small for gestational age; SVR, systemic vascular resistance.
Data from Ferrazzi E, Stampalija T, Monasta L, et al. Maternal hemodynamics: a method to classify hypertensive disorders of pregnancy. *Am J Obstet Gynecol*. 2018;218(1):124.e1–124.e11.

Pulmonary Embolism

Pulmonary embolism (PE; see also Chapters 81 and 82) is a leading cause of maternal mortality,[83] accounting for 15% of maternal deaths in the United States between 2003 and 2011.[83] Even though the risk for venous thromboembolism in pregnant women is about five times as great as in age-matched female nongravid controls, it is still relatively infrequent at about 0.5 to 1.2 per 1000 pregnancies.[84] The risk for thrombosis is increased in pregnancy because of an increase in coagulation factors, particularly V, VIII, X, and von Willebrand factor antigen, and also a marked fall in protein S.[85] Venous stasis, an important contributor to thrombosis, is caused by uterine compression of the inferior vena cava and the left iliac vein. Local trauma to pelvic veins at the time of delivery probably accounts for the peak incidence of thromboembolism in the postpartum period, especially after cesarean section. Specific risk factors for thromboembolism include previous thromboembolism, prolonged bed rest, a complicated or cesarean delivery, age greater than 35 years, thrombophilia, obesity, and smoking. The inherited defects include deficiencies of antithrombin, protein S, protein C, factor V Leiden, and prothrombin G20210A.[85] Antiphospholipid syndrome is an acquired thrombophilia. Previous thromboembolism or multiple risk factors warrant prophylactic heparin administration throughout pregnancy with low-molecular-weight heparins.

Clinical diagnosis of deep venous thrombosis during pregnancy and the puerperium is even more difficult than in the nonpregnant patient because of the peripheral edema associated with pregnancy, and the asymmetrical compression of the left-sided common iliac vein by the gravid uterus. The initial diagnostic test should be duplex ultrasonography (combined real-time B-mode compression ultrasonography plus Doppler venous ultrasonography). In the patient with high clinical suspicion but a negative test, a repeat examination at 5 to 7 days or magnetic resonance venography may be valuable. When venous thrombosis of the lower extremity is documented, it is usually left sided, as it was in 84 of 96 (88%) cases reported by Chan and colleagues.[86]

The diagnosis of PE in pregnant women is complicated by the overlap of some symptoms with normal findings in pregnancy (e.g., dyspnea) and the lack of validation of

many clinical prediction rules in pregnancy. Although biomarkers such as D-dimer are traditionally not considered valuable in the pregnant patient, a recent study evaluated a pregnancy-adapted YEARS algorithm incorporating three clinical criteria (clinical signs of deep vein thrombosis, hemoptysis, and PE as the most likely diagnosis) and D-dimer level.[87] This study suggested that PE could be safely ruled out by the absence of all three clinical features with a D-dimer less than 1000 ng/mL or D-dimer less than 500 ng/mL (if one to three clinical criteria are present).[87] Although these findings are supported by another study,[88] the lack of adverse events in these studies may reflect limited power to detect uncommon but important outcomes (i.e., the fact that there were very few PEs in the two studies does not necessarily mean that the proposed strategies reliably ruled out PE). The potentially catastrophic consequences of a missed diagnosis of PE means that these strategies cannot be considered safe, given that there is a certain risk of missing PE with each of these approaches. Another UK study assessing D-dimers and clinical decision rules to exclude PE in pregnancy (Diagnosis of PE in Pregnancy study) concluded that neither test could be used to exclude PE.[89,90]

Both ventilation-perfusion scanning and *computed tomography* (CT) pulmonary angiography can be performed during pregnancy in a modified fashion, and each raises issues of radiation exposure and relative accuracy. Perfusion scanning exposes the fetus to about 0.011 to 0.022 cGy (11 to 22 mrad), and simply halving the perfusion dose is standard practice in pregnancy, without greatly impairing resolution.[91] If the perfusion scan is normal, there is no need for the ventilation portion of the study. CT pulmonary angiography is associated with similarly low radiation doses to the fetus (Fig. 129.3).[91,92] However, a risk to consider is the potential carcinogenic effect of radiation exposure to the mother's breasts,[91,93] although the use of modern CT scanners has resulted in significant decreases in patient radiation exposures compared to even 10 years ago. Typical modern CT scanner radiation exposures are unlikely to result in teratogenicity, which is associated with exposure of greater than 5 to 10 cGy (5 to 10 rad). However, an increased incidence of childhood leukemia has been documented with lower fetal radiation exposure, in the range of 1 to 5 cGy (1 to 5 rad). A comparison of ventilation-perfusion scanning and pulmonary CT angiography concluded that the former method was more accurate than the latter for diagnosing PE during pregnancy.[94] Ventilation-perfusion scanning in pregnancy, due to the patient's younger age and lack of comorbidity, is associated with a low incidence of intermediate scans and high rate of normal scans.[95] Compared to its use in the nongravid woman, CT angiography may more often be technically suboptimal in the pregnant woman, due to her increased cardiac output.[96] For the same reason, CT angiography at early gestation is more likely to be technically successful than in later gestations.[97] Magnetic resonance imaging with gadolinium contrast also has promise because it can image pelvic and lower extremity veins, as well as the pulmonary arteries, and it has little contrast-associated toxicity. Its widespread use will require increased availability of ultrafast scanners and more evaluation of its accuracy.

Venous thromboembolism in pregnancy is treated with LMWH because warfarin crosses the placenta and causes nasal, ophthalmologic, and central nervous system abnormalities in the fetus. Direct oral anticoagulants should be avoided in pregnancy.[98] LMWH is preferred over unfractionated heparin in pregnancy, using a weight-adjusted dosing regimen.[99] Weight gain in pregnancy makes formulaic dosing less reliable, and some authors also advocate titrating the dose to achieve anti–factor X levels of 0.5 to 1.24 units/mL 4 hours after injection.[100] However, the lack of robust data and lack of correlation of anti–factor X levels with efficacy or complications make routine monitoring difficult to justify.[99] LMWH treatment is usually given for at least 6 weeks postpartum (for a minimum total duration of therapy of 3 months). LMWH should be held 24 hours before cesarean section or neuraxial (e.g., spinal, caudal,

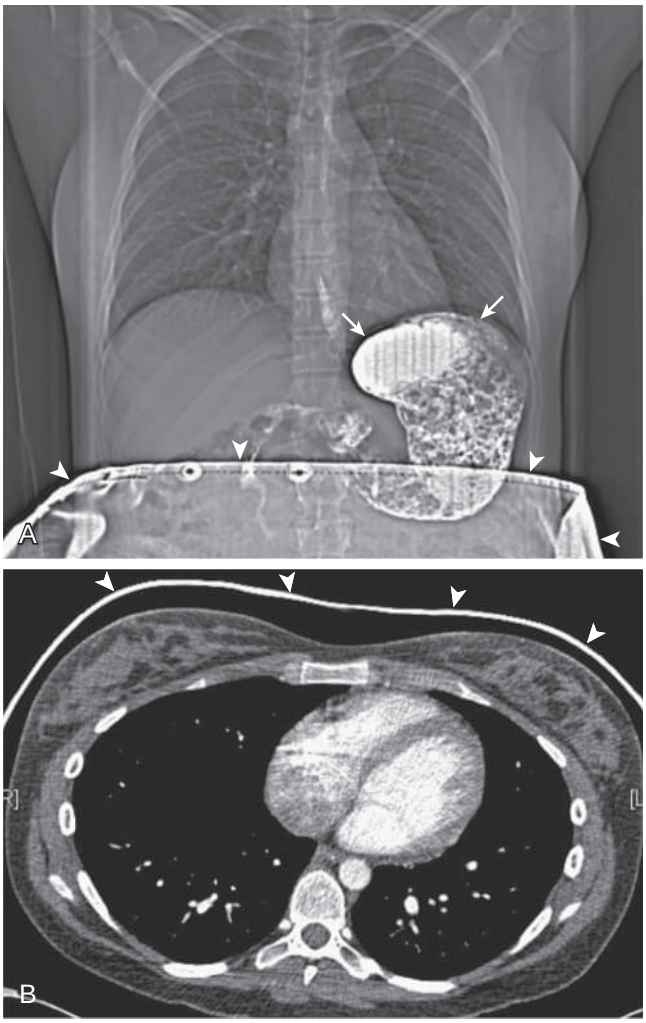

Figure 129.3 Dose-reduction methods for chest *computed tomography* (CT) in the pregnant patient. (A) Scout view before the CT acquisition shows an "internal barium shield" (*arrows*) created by having the patient swallow a dilute mixture of barium and water several minutes before CT scanning. The barium distributes within the stomach and proximal small bowel and attenuates internal maternal radiation that may otherwise expose the fetus. A lead apron (*arrowheads*) also reduces fetal radiation exposure. (B) Axial chest CT pulmonary angiogram obtained with manual reduction of both the tube current and tube voltage shows excellent vascular opacification, providing high-quality assessment for pulmonary embolism and other thoracic disorders. A maternal breast shield (*arrowheads*) has also been placed; these shields selectively filter low-energy x-ray photons that would otherwise deposit preferentially in maternal breast tissue, significantly contributing to maternal breast radiation exposure. (Courtesy Michael B. Gotway, MD.)

or epidural) anesthesia (for twice-daily dosing) or after a 50% dose the morning before delivery for daily dosing regimens.[99] In the postpartum period, warfarin can be given safely during lactation.

Thrombolytic therapy has been used successfully in life-threatening thromboembolism during pregnancy, with a complication rate similar to that in nonpregnant women.[101]

Amniotic Fluid Embolism

Small amounts of amniotic fluid may enter the circulation during uncomplicated pregnancy but rarely cause the catastrophic syndrome of amniotic fluid embolism. The reported incidence varies from 2 to 6 per 100,000 pregnancies, the variation being largely dependent on the method of case identification.[102] The onset is usually during labor and delivery or immediately after uterine manipulation, and amniotic fluid embolism should be considered in any pregnant or immediately postpartum woman with sudden cardiac arrest or cardiovascular collapse, seizures, respiratory distress or hypoxia, particularly in the context of associated coagulopathy.[103] Risk factors include older maternal age, induction of labor, high parity, cesarean section, low uterine segment laceration, and meconium staining of amniotic fluid.[101–103] Abruptio placentae is present in 50% of cases, and fetal demise in 40%.[103] The maternal mortality rate has been as high as 86%,[104] but a later report suggests a mortality rate of 11–43%.[102] Overall, amniotic fluid embolism may account for 4.9% of all maternal deaths.[83]

In a U.S. registry of cases, 78% of the patients with amniotic fluid embolism had ruptured membranes, and several had just undergone intrauterine procedures,[105] clearly implicating traumatic opening of uterine vessels in the pathogenesis. The exact quantity or constituents of amniotic fluid required to initiate the syndrome is unknown. Pathologically, fetal squamous cells are found in the maternal pulmonary circulation at autopsy (Fig. 129.4), but even in symptom-free patients, fetal cells may be aspirated from pulmonary artery catheters placed for other reasons.[106] Hemodynamically, the process is often biphasic, with pulmonary hypertension initially, followed by left ventricular failure.[107,108] These changes may be caused by leukotrienes and arachidonic acid metabolites, particularly prostaglandin F_{2a}, which appear in amniotic fluid during labor. An immunologic basis for some of the changes seems likely because women with male fetuses are more likely to acquire the disorder.[102] Clark and associates[105] seized on the similarities to anaphylaxis and suggested that the disorder be renamed *anaphylactoid syndrome of pregnancy*. A small study did not demonstrate evidence of mast cell degranulation but suggested a role for complement activation.[109] C1-esterase inhibitor activity has been shown to be depressed in patients with amniotic fluid embolism, the level correlating with severity.[110] On imaging studies, affected patients usually develop bilateral parenchymal opacities consistent with pulmonary edema associated with increased permeability lung injury (Fig. 129.5). Treatment consists of supportive

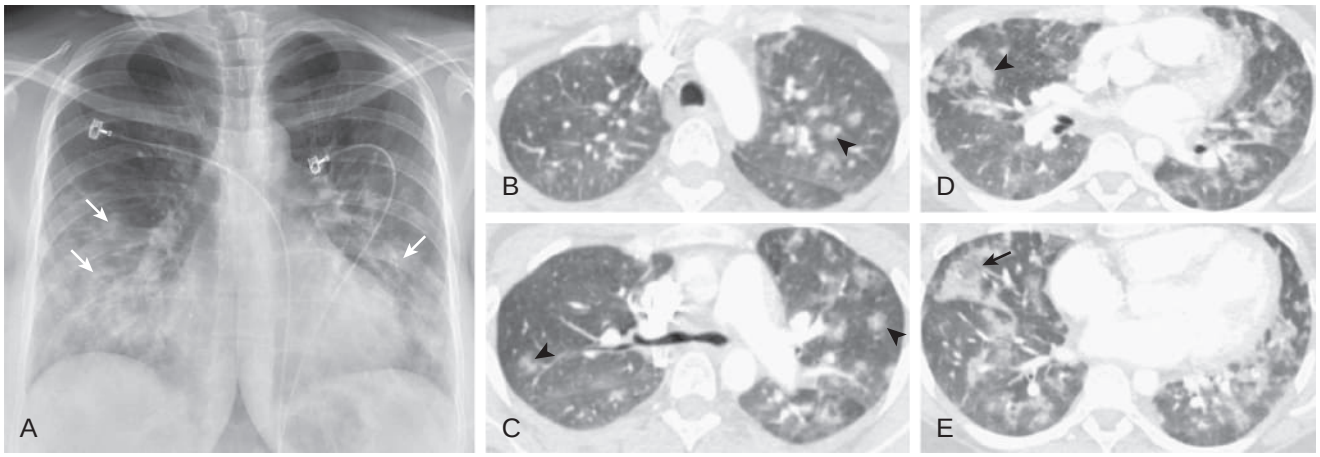

Figure 129.5 Amniotic fluid embolism. (A) Frontal chest radiograph in a patient who developed shortness of breath and cardiovascular instability during delivery shows multifocal, poorly defined opacities (*arrows*) along the bronchovascular bundles, distributed in the mid and lower lungs bilaterally. (B–E) Axial chest *computed tomography* (CT) pulmonary angiogram obtained for pulmonary embolism evaluation, displayed in lung windows, shows multifocal nodular appearing ground-glass opacities (*arrowheads*), somewhat more confluent in the right middle lobe (*arrow*). No features to suggest increased pressure edema, such as pleural effusion or interlobular septal thickening, are present, and no pulmonary embolism was detected. The CT features are consistent with an acute lung injury pattern. (Courtesy Michael B. Gotway, MD.)

care for the associated disseminated intravascular coagulation and left ventricular and respiratory failure. Isolated case reports have suggested a benefit of administration of recombinant C1-esterase inhibitor.[111] The fetus should be promptly delivered. In cases of maternal demise, emergency postmortem or periresuscitative cesarean section is warranted, as it is in other instances of cardiopulmonary resuscitation in pregnancy.[112]

Arteriovenous Malformations

Pulmonary arteriovenous malformations may expand during pregnancy because of hormonal changes, the increase in blood volume, and venous distensibility.[113] This increases the likelihood of bleeding, with life-threatening complications in about 1% of pregnant women with hereditary hemorrhagic telangiectasia.[114,115] Embolization and surgical management have been utilized successfully during pregnancy.

Air Embolism

Occasionally, venous air embolism can happen during pregnancy, presumably through the subplacental venous sinuses.[116] This disorder has been clearly documented during labor and delivery, during cesarean sections and abortions, in patients with placenta previa, and in those engaging in orogenital sex during pregnancy or the early puerperium. The patient presents with dyspnea, chest pain, and presyncope, which may progress to hemodynamic collapse. Differentiation from other similar catastrophic events may be difficult and involves exclusion of other causes. Management involves the usual resuscitative measures and administration of a high concentration of oxygen. Moving the patient into the left lateral decubitus position or Trendelenburg position will prevent air from being ejected from the right ventricle until it is absorbed.

ACUTE LUNG INJURY IN PREGNANCY

Aspiration Pneumonitis

Since Mendelson's[117] original report of 66 cases of gastric aspiration in 44,016 deliveries between 1932 and 1945 (an incidence of 0.15%), aspiration has continued to be a major cause of maternal morbidity and mortality. Increased intra-abdominal pressure due to the gravid uterus, the inhibitory effect of progesterone on the tone of the esophageal sphincter, and the assumption of the supine position for delivery all contribute. Eating during or just before labor increases the volume of emesis.[118] Aspiration of gastric contents with pH 2.5 or lower is known to cause chemical pneumonitis and increased permeability pulmonary edema. Both in Mendelson's original report and today, about two-thirds of cases of aspiration take place in the delivery suite. Emergency endotracheal intubation of patients with obstetric crises is particularly difficult,[119] and intubation in the delivery suite fails at a rate eight times that in the general surgical population.[120] To minimize the chance of acid aspiration at intubation, oral administration of histamine-2 blockers with antacids before intubation,[120] in conjunction with a formal airway assessment, is desirable. Identified risk factors in intubation include a high Mallampati class indicating poor visibility of the posterior pharynx, a short neck, protruding maxillary incisors, and a receding mandible.[121]

Acute Respiratory Distress Syndrome

ARDS is more common in pregnancy than in the general population, with an incidence of 1 in 6000 deliveries.[122] In one obstetric intensive care unit, ARDS was the leading cause of maternal death during a 6-year period.[123] The three most common nonobstetric causes are pneumonia, sepsis, and aspiration. The 2009 influenza A (H1N1) epidemic resulted in a significant increase in the incidence of ARDS in pregnancy, generating numerous publications on the epidemiologic and management issues. Australian investigators described a series of pregnant women treated with extracorporeal membrane oxygenation, with reasonable outcome.[124] Common obstetric causes of ARDS include chorioamnionitis, amniotic fluid embolism (see Fig. 129.5), and trophoblastic embolism.[125] Transfusion-related acute lung injury is an often unrecognized, potentially life-threatening complication of blood or blood product transfusion.

Ventilator management is unaltered in pregnancy and, although pregnancy was an exclusion criterion in the ARDS Network studies, the clear benefit in nonpregnant patients supports the use of low-volume ventilatory strategies in pregnant patients, with tidal volume (6 mL/kg) based on the patient's ideal weight.[125,126] Delivery does not necessarily improve the maternal respiratory condition, and should usually be reserved for situations where benefit for the fetus is also anticipated.[127] The prognosis also appears to be similar to the nonpregnant patient,[128] although ARDS outcome is dependent on the underlying etiology.

OTHER RESPIRATORY DISEASES IN PREGNANCY

Obstructive Sleep Apnea

Pregnancy may be complicated by *obstructive sleep apnea* (OSA), potentially adversely affecting both mother and fetus.[129] Although upper airway edema may potentiate obstructive events, apnea and hypopnea are uncommon in pregnancy because of the respiratory stimulatory effect of progesterone.[130] OSA usually develops in obese patients, precipitated by the airway mucosal edema and vascular congestion that accompany pregnancy. OSA is associated with preeclampsia and gestational diabetes.[130,131] Nocturnal hypoxemia may produce poor fetal growth, although snoring alone is not associated with fetal risk.[132] Pregnant women with documented OSA are at increased risk of developing preeclampsia and preterm birth, as well as other pregnancy complications[133]; in this group, treatment with continuous positive airway pressure is safe and effective.[130]

Interstitial Lung Disease

Interstitial lung disease is usually seen in patients older than those in their childbearing years.[134] When interstitial disease exists in pregnant women, the reduced diffusing capacity may cause difficulty in meeting the increased oxygen consumption requirements of pregnancy, sometimes necessitating ambulatory oxygen therapy. Associated pulmonary hypertension, regardless of its causes, carries significant risks because cardiac output increases during pregnancy. Few data exist on the management and outcome in these patients, but restrictive lung disease appears reasonably well tolerated in pregnancy.[135,136] Labor and delivery can

increase oxygen and ventilation requirements, which may be ameliorated by regional anesthesia and supported with noninvasive ventilation.

Lymphangioleiomyomatosis and systemic lupus erythematosus may worsen as a result of pregnancy.[134] Some drug therapy used for interstitial lung disease may be acceptable during pregnancy (e.g., prednisone, azathioprine), but other therapies (e.g., cyclophosphamide, rituximab, mycophenolate mofetil) are usually avoided.[134]

Pleural Disease

Pleural effusions may accompany obstetric complications such as preeclampsia and choriocarcinoma, but many women with normal pregnancies develop small, asymptomatic pleural effusions in the postpartum period.[137] These probably develop as a result of the increased blood volume and reduced colloid osmotic pressure in pregnancy, as well as from impaired lymphatic drainage due to repeated Valsalva maneuvers during labor. Moderate-size effusions or the presence of symptoms should prompt a full clinical evaluation. The Valsalva maneuvers of labor may also produce spontaneous pneumothorax and pneumomediastinum, particularly in patients with predisposing conditions such as asthma. This diagnosis should be considered in women who develop chest discomfort and dyspnea during, or immediately following, delivery.

Lung Transplantation

Improved survival after lung transplantation has resulted in women considering pregnancy in this situation, most commonly in women with lung transplantation for cystic fibrosis. The knowledge base is increasing, and registries have been established to collect data on these patients. Prepregnancy counseling is essential, and pregnancy should ideally be avoided for a minimum of 1 year and preferably 2 years posttransplant.[138] This time will allow immunosuppressive drugs to be weaned to the lowest possible doses and reduce the likelihood of requiring increased immunosuppressive therapy for early posttransplant rejection. Immunosuppression with prednisolone, azathioprine, and calcineurin inhibitors is considered acceptable during pregnancy. Pregnancy is not associated with an increased risk of rejection in stable patients, but compared with other solid organ transplants, rejection during or soon after pregnancy is more common after lung transplantation.[139] There is a high risk of spontaneous or therapeutic abortion, but the frequency of congenital malformation is not higher than in the general population. The incidence of diabetes and preeclampsia during pregnancy posttransplant is higher than in the general population.

LUNG DISORDERS IN GYNECOLOGY

CATAMENIAL PNEUMOTHORAX

Lillington and colleagues[140] introduced in 1972 the term *catamenial pneumothorax* to describe the already reported phenomenon of spontaneous pneumothorax within 24 to 72 hours after onset of menses. It appears to account for about 2.8–5.6% of spontaneous pneumothoraces in women,[141,142] most often affecting women in the third or fourth decade of life. About 30–60% of cases are attributable to thoracic endometriosis, as judged by inspection at thoracotomy (Fig. 129.6)[143]; other cases have a more obscure etiology, however, so a number of theories have been advanced. The first theory is that, during menstruation, the absence of the normal cervical mucus plug permits an open connection between ambient air and the abdominal cavity through the uterus and fallopian tubes.[142] Air can move transdiaphragmatically through right-sided diaphragmatic fenestrations into the pleural space, as it sometimes does during abdominal laparoscopy,[140] accounting for the condition's right-sided predominance.[142] A second theory is that high levels of prostaglandin F_{2a} during menstruation cause bronchospasm with attendant air trapping and pneumothorax; however, wheezing is not a common symptom of this disorder. A third theory is that pleural blebs or bullae are more susceptible to rupture during menstruation because of hormonal changes[142,143]; however, visceral pleural leaks are rarely found at surgery (see also Chapter 110 for a full discussion).

For cases of endometriosis-associated pneumothorax, a trial of gonadotropin-releasing hormones is warranted if the phenomenon is repetitive but not life-threatening. Oral contraceptives, other progestational agents, and tubal ligation have also been used with some success. For cases not clearly associated with systemic endometriosis, thoracoscopy during menstruation serves to define the etiology and can be used to achieve pleurodesis.[140]

ENDOMETRIOSIS

Endometriosis probably affects about 10% of women, shows no clear ethnic differences in prevalence, and is most commonly diagnosed at 30 to 34 years of age.[144] Although pelvic pain, dysmenorrhea, and infertility are its predominant manifestations, atypical locations, including diaphragmatic, pleural, and endobronchial sites, have been

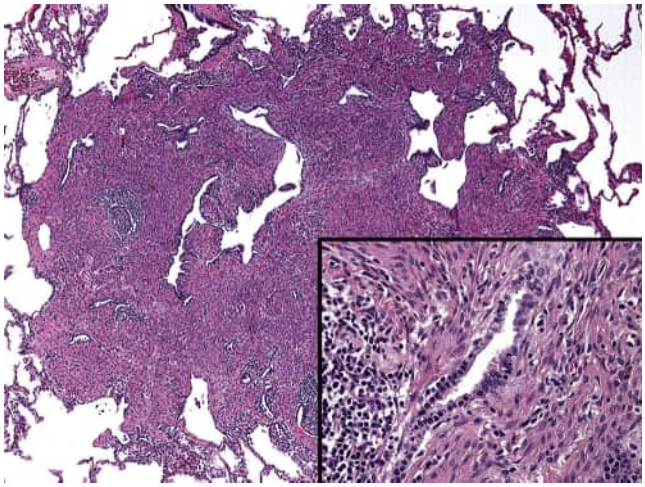

Figure 129.6 Pulmonary endometriosis. Wedge resection of right upper lobe subpleural nonencapsulated lesion in a 43-year-old woman with a history of pelvic endometriosis and recurrent pneumothoraces with menstrual cycles. (H&E stain; original magnification ×40.) *Inset,* The discrete nodule is composed of endometrial stromal cells admixed with endometrial glands. (H&E; original magnification ×200.) (Courtesy Dr. Gerald Berry, Stanford University.)

documented. As described previously, endometriosis can result in recurrent catamenial pneumothorax, which is its most common thoracic presentation (see Fig. 129.6). In one review of 110 cases with thoracic endometriosis, catamenial pneumothorax was the presenting symptom in 73% of cases, followed by hemothorax in 14% and hemoptysis in 7%.[144] Thoracic endometriosis has also been associated with right-sided pleuritic chest pain and pleural effusions. Inspection at thoracotomy or thoracoscopy typically reveals blue-brown nodules on the pleural surface, sometimes described as "gunshot" lesions.[145] The absence of known pelvic endometriosis does not exclude the diagnosis because only 20–70% of patients have associated pelvic disease. The diagnosis is suspected on clinical grounds because CT is not specific. Thoracoscopy can be diagnostic, although it may need to be performed during menses for maximum sensitivity.[146] Rarely, the endometriosis deposits are found in lung parenchyma, accounting for the catamenial hemoptysis. Most pleural and diaphragmatic disease is thought to arise from transdiaphragmatic spread from retrograde menses, even when abdominal disease is not evident. Massive ascites is sometimes related, although only 27 cases have been reported.[147] Pneumothoraces may be attributed to cyclical sloughing of tissue on key surfaces, such as the visceral pleura,[148] or to air trapping from airway involvement or compression.[149] Pulmonary parenchymal disease may be embolic in origin, as is presumed in the case of rare cases of central nervous system endometriosis.[149a] The diagnosis can be established only by biopsy showing the characteristic ectopic endometrial glands in involved sites. Medical therapy consists of progestational agents or gonadotropin-releasing hormones; surgical approaches include excision, local laser ablation, or pleurodesis.

LYMPHANGIOLEIOMYOMATOSIS

Lymphangioleiomyomatosis is a rare disorder that afflicts predominantly premenopausal women.[150] The most common presenting event is a pneumothorax, reported in 86.5% of patients in the National Heart, Lung, and Blood Institute registry.[150] It is fundamentally a low-grade neoplasm of smooth muscle cells that results in functional obstruction of vessels, lymphatics, and airways. (See Chapter 97 for a complete discussion of lymphangioleiomyomatosis.) Involvement of pulmonary vascular structures is responsible for the hemoptysis, whereas lymphatic obstruction accounts for the chylous effusions. Mediastinal and retroperitoneal lymphatic proliferation may be a feature of the disease as well. Lymphangioleiomyomatosis is also associated with renal angiomyolipomas, another hamartomatous disorder, and with tuberous sclerosis. The pathogenesis involves activation of the mTOR pathway acting synergistically with the estrogen-stimulated extracellular-signal-regulated kinase pathway.[151] Conventional therapy has included oophorectomy or progestational agents, mainly medroxyprogesterone acetate. Lung transplantation has been performed in more than 60 patients with this disorder, but it has clearly recurred in some of them. Sirolimus, an mTOR inhibitor, has been shown to improve lung function and symptoms, presumably by suppressing signaling pathways involved.[152] Data regarding the use of sirolimus in pregnancy are limited, but case reports have been published with successful outcome.[153]

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic disease is a group of intrauterine tumors arising from nonviable fertilized tissue. These tumors may be benign (hydatidiform mole) or malignant (choriocarcinoma). The major pulmonary complication of this entity is trophoblastic embolism. In one series, however, only 2.6% of 189 patients with hydatidiform mole had an embolic event, so most episodes of respiratory distress in such patients are not caused by embolism but, rather, pulmonary edema, anemia, or another complicating event.[154] Embolization, when it happens, is most common at the time of evacuation of the mole.

OVARIAN HYPERSTIMULATION SYNDROME

The ovarian hyperstimulation syndrome can result from the use of exogenous gonadotrophins to stimulate ovulation for in vitro fertilization. This entity has been associated with complications,[155] including ovarian cysts, bilateral pleural effusions, ascites, and intravascular volume depletion. Hypovolemic shock, renal failure, and ARDS may result. PE and upper limb or superior venal caval thrombosis may result from the hypercoagulable state induced by estrogens and intravascular volume depletion. Upper limb predominance may be related to higher concentrations of estrogens drained from ascites through lymphatic ducts.[156] Women with medical comorbidities who are older than 40 years are at most risk of developing life-threatening complications.[157] The mechanism of the effusions is unclear but is likely related to increased permeability due to release of vasoactive mediators, of which vascular endothelial growth factor appears to be the most important.[158] Evidence points to mutations in the follicle-stimulating hormone receptor as etiologic in at least some cases.[159] Treatment is supportive and involves maintaining intravascular volume, thoracentesis when required for respiratory compromise from abundant pleural effusion(s), and thromboprophylaxis.

Key Points

- Normal pregnancy is associated with profound alterations in respiratory and cardiovascular physiology, which—although designed for maternal and fetal well-being—may exacerbate underlying cardiopulmonary conditions or cause new ones.
- Major physiologic perturbations found in normal pregnancies include (1) an increase in central drive to breathe, with resulting changes in P_{CO_2} (28 to 32 mm Hg) and pH (7.40 to 7.47) and (2) an increase in both maternal blood volume, of about 2 L (40%), and cardiac output, after 25 to 32 weeks of gestation, of 30–45%.
- The most common pulmonary disorder of pregnancy is asthma, but the effects of pregnancy on asthma are variable, with about 40% remaining unchanged and the rest either worsening or improving.
- The risks of poorly controlled asthma for both mother and fetus during pregnancy far outweigh the risks of drug therapy. Some standard drugs are safer than others (see Table 129.1) and should be selected whenever possible.

- Cystic fibrosis and infectious pneumonias have all been linked with adverse fetal and maternal outcomes, the risk of which depends largely on the severity of the complicating disorder. Prepregnancy counseling and avoidance of certain antimicrobial drugs (as noted in Table 129.1) are strongly recommended.
- Pulmonary edema may develop during pregnancy in women with underlying heart disease, especially valvular stenosis, cardiomyopathy, and preeclampsia. Because the causative mechanisms differ, so does specific therapy.
- Pulmonary embolism is a leading cause of maternal mortality. When indicated during pregnancy, low-molecular-weight heparins are safe for both treatment and prevention; warfarin is contraindicated. Ventilation-perfusion imaging, computed tomography pulmonary angiography, and magnetic resonance imaging can be used as needed.

INTRODUCTION

Gas exchange between the atmosphere and the human body depends not only on the lungs but also in large part on the function of the "ventilatory pump," which consists of the respiratory control centers located in the brain, the bony rib cage, diaphragm, and intercostal, accessory, and abdominal muscles. A wide variety of neuromuscular disorders can result in dysfunction of the ventilatory pump that in turn can lead to respiratory failure, pneumonia, and even death. Breathing disorders are recognized as the leading cause of mortality in neuromuscular disease,[1,2] and appropriate interventions can prevent complications and prolong life in individuals with neuromuscular disease affecting the respiratory system.[3] Diseases of the chest wall are discussed in Chapter 131.

FUNCTIONAL ANATOMY OF THE RESPIRATORY SYSTEM

The ventilatory pump is designed to bring oxygen into the body to fuel energy generation and remove carbon dioxide as a waste product of cellular metabolism. The system is made up of the cortex of the brain that controls voluntary breathing; the brainstem, which is involved with automatic breathing; the spinal cord and motor neurons that transmit nerve impulses; the respiratory muscles that are the effectors of the system; and a complex system of feedback[4] receptors and nerves that regulate ventilation (Fig. 130.1). The system is remarkably flexible and can precisely maintain carbon dioxide and acid-base balance despite encountering large variations in metabolic demands that result from the activities of daily living. The following is a discussion of each of the components of this complex network.

CENTRAL NERVOUS SYSTEM

Voluntary Breathing Controllers

Voluntary breathing is controlled by signals from the cerebral cortex. Centers located within the parietal cortex send volitional signals that initiate inspiration and expiration.[4] These cortical areas project to the motor neurons in the spinal cord via the corticospinal tracts. The corticospinal tracts are separate pathways from the reticulospinal pathways that connect the central automatic breathing centers to the motor neurons.

Automatic Breathing Controllers

Automatic breathing is controlled by a complex system that includes respiratory centers in the pons and medulla, nerve tracts in the lower brainstem, the reticulospinal pathways in the spinal cord, and the feedback mechanisms that are both chemical and mechanical in nature. There are thought to be three centers that generate the rhythm and drive to breathe, one located in the pons and two in the medulla. More detailed reviews of this topic are available.[5]

Spinal Cord

The spinal cord and motor nerves conduct nerve impulses from the cortex and brainstem to the anterior horn cells of the motor neurons supplying the respiratory muscles. As noted previously, the nerve fiber tracts in the spinal cord responsible for voluntary (corticospinal tract) and automatic (reticulospinal tract) breathing are separate within the spinal cord.[6] The fibers in both of these tracts travel through the spinal cord to synapse with the lower motor neurons.

PERIPHERAL NERVOUS SYSTEM

Lower Motor Neurons

The lower motor neurons have their cell bodies in the spinal cord (anterior horn cell) and exit the spinal cord to become

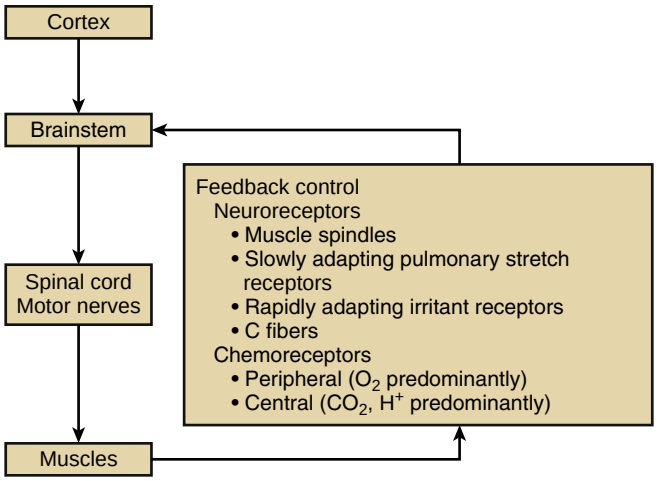

Figure 130.1 Respiratory system feedback control. Neuromechanical respiratory system flowchart indicates the neuromuscular pathways and sites of feedback control.

the spinal nerve roots and the nerves that supply the respiratory muscles. When the nerves arrive at the muscle, they divide into branches known as *twigs* that, upon reaching the muscle fiber, further divide into bulbous projections called *boutons* that apply themselves to the muscle membrane at a specialized anatomic junction called the *motor end plate.* These boutons contain acetylcholine, which is the chemical transmitter that serves to excite the muscle to contract. With nerve firing, there is release of acetylcholine at the motor end plate into the cleft between the nerve and the muscle. The acetylcholine binds to receptors on the muscle side of the motor end plate, which results in a *suprathreshold excitatory end plate potential* and depolarization of the muscle membrane muscle action potential then results in contraction of the muscle fiber.

Total Lung Capacity

Respiratory Muscles. The respiratory muscles are the mechanical effectors of the breathing system. They are often divided into three major groups: (1) the inspiratory muscles, (2) the expiratory muscles, and (3) the accessory muscles of respiration. The muscles that maintain patency of the upper airway during the respiratory cycle are sometimes also considered muscles of respiration because of their close interaction with the other respiratory muscles.

The diaphragm is the major muscle of inspiration and accounts for approximately 70% of the inhaled tidal volume in the normal individual (Fig. 130.2). Contraction of the diaphragm results in a downward piston motion of the muscle. The resultant increase in abdominal pressure pushes the lower ribs up and out along the *zone of apposition,* further expanding the thoracic cage.[7] The innervation of the diaphragm is via the phrenic nerve that originates from cervical nerve roots 3 through 5.

The intercostal muscles are thin sheets of muscular fibers that run between the ribs in the costal spaces.[8] There are two sheets of muscle fibers, the external and internal intercostals. (Fig. 130.3). The external intercostals, which are on the outside (external) of the other muscles, function to expand the rib cage during inspiration. The internal

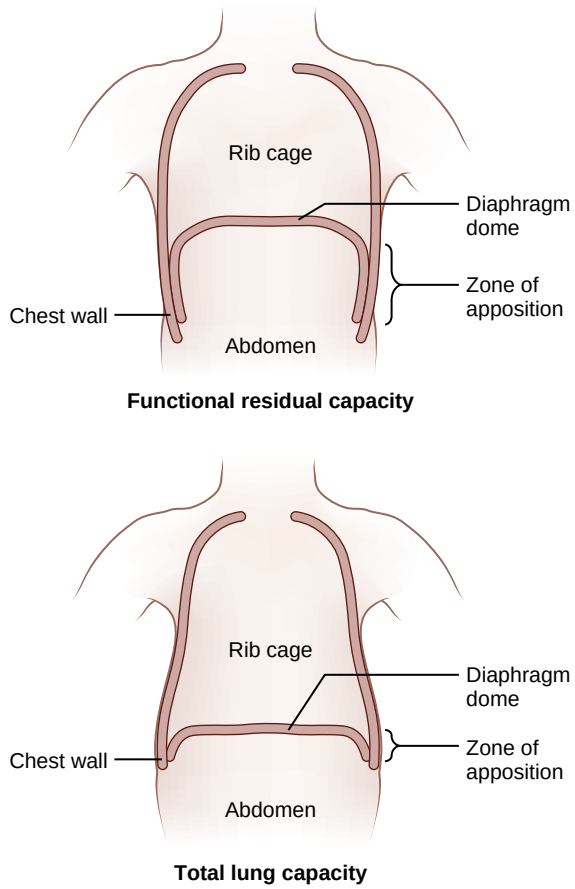

Figure 130.2 Diaphragmatic positions at rest *(top)* and at full contraction *(bottom).* At functional residual capacity *(top),* the diaphragm lies within the chest with a zone of apposition along the chest wall. At total lung capacity (*bottom),* the contracted diaphragm has displaced abdominal contents and, via the increase in abdominal pressure, has expanded the chest wall outward.

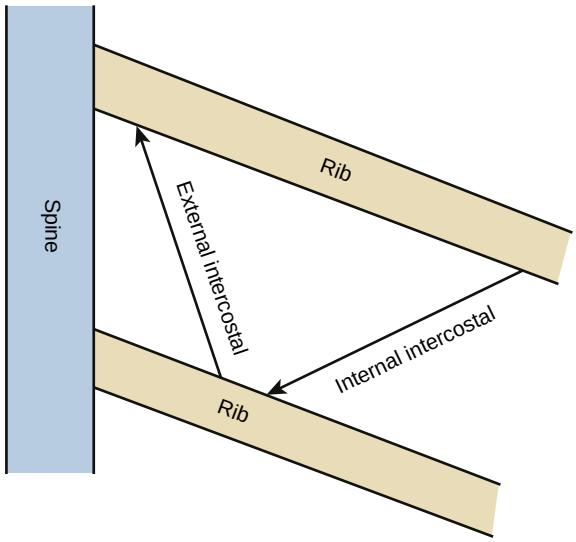

Figure 130.3 Actions of the intercostal muscles on the ribs. Contraction of the external intercostals results in an upward and outward movement of the ribs during inhalation. Contraction of the internal intercostals results in a downward and inward movement of the ribs during exhalation.

intercostals are deeper (internal) and function to decrease rib cage size during expiration. The orientation of the muscle fibers with respect to the ribs and the spinal column where the rib rotates up or down at the costovertebral joint results in the increase or decrease in the size of the rib cage; as the muscles contract, the greater torque is applied to the point more distal from costovertebral rotating joint at the spine. In the case of the external (inspiratory) intercostal muscles, the distal attachment is at the outside portion of the lower rib compared to the upper rib, so contraction tends to pull the lower rib upward and outward thereby expanding the chest. Although there is a torque on the upper rib, it is smaller so that the overall effect is to expand the chest wall. For the internal (expiratory) intercostal muscles, the distal attachment is at the inner portion of the upper rib and thus contraction of the muscle tends to pull the upper rib down and in, thereby decreasing the chest. Innervation of the intercostals is via the intercostal nerves originating from the thoracic spinal nerve roots.

The abdominal muscles (rectus abdominis, internal oblique, external oblique, and transversus abdominis) serve a number of functions in respiration that mainly assist expiration but can also function in inspiration. The internal and external obliques and the transversus abdominis result in an inward movement of the abdominal wall that displaces the diaphragm upward into the thoracic cavity and assists exhalation. The rectus abdominis as well as the internal and external obliques pull the lower rib cage caudally and thereby increase pleural pressure and exhalation. The abdominal muscles also may play a minor role in inspiration[9]; if their contraction reduces lung volume below function residual capacity, abdominal muscles can store elastic recoil energy in the chest wall that then assists expansion of the chest wall during the next inspiration. This "inspiratory assist" may be seen during exercise when expiration becomes active.

The accessory muscles of respiration (sternocleidomastoid, scalenes, trapezii, latissimus dorsi, platysma, and pectoralis major and minor muscles) can expand the rib cage and assist inspiration during situations of increased ventilatory demand such as during exercise or when other inspiratory muscles are impaired as in tetraplegia or COPD. Some of these accessory muscles function during minimal exertion and during quiet tidal breathing, even in normal persons.[10]

The muscles of the upper airway are also considered to be muscles of respiration because they maintain patency of the upper airway and allow air to flow into and out of the lungs without interruption. Some of these also participate in protection of the lower airway during swallowing, a key function in the defense of the respiratory system. The upper airway muscles include the abductors of the vocal cords, the palatal elevators, retractors of the tongue, and dilators of the nares. These muscles are innervated by cranial nerves V, VII, and IX through XII. The central control centers for these muscles are the same as those described previously for the more commonly considered ventilatory muscles.

CONTROLLER FEEDBACK

The respiratory control mechanisms depend on both neural and chemical receptors found in peripheral and central sites. The automatic respiratory centers in the brainstem respond to feedback from these receptors and adjust neural output to the ventilatory and upper airway muscles that expand the chest wall and maintain upper airway patency (see Fig. 130.1).

Neural receptors are present in the upper airway, respiratory muscles, lungs, and pulmonary vessels. Once stimulated, these receptors project signals to the central respiratory controller via the vagus nerve. The respiratory centers then adjust their output to the respiratory muscles to alter ventilation and modulate reflexes such as cough and sneeze. There are several different types of neural receptors. *Muscle spindles* and *slowly adapting pulmonary stretch receptors* predominantly respond to changes in thoracic cage and lung volume, respectively. As the chest wall and lung inflate, these receptors are stretched and dampen the output from the inspiratory centers in the medulla. These receptors are involved in the Hering-Breuer reflex in which inspiration is halted as lung volume increases.[11] They are also essential for initiating cough. *Rapidly adapting irritant receptors* respond to changes in lung volume, to chemical stimuli such as histamines and prostaglandins, and to noxious stimuli. *C fibers* in the airways and lung are stimulated by chemical stimuli in the local environment. The C fibers likely mediate the hyperventilation seen in normoxic circumstances in a number of pulmonary disorders such as asthma, pulmonary embolism, pneumonia, and pulmonary edema.

Chemical receptors or *chemoreceptors* are located both peripherally as well as in the central nervous system. The *peripheral chemoreceptors*, which include the carotid and aortic bodies, are the primary site for sensing low levels of *arterial oxygen pressure* (arterial P_{O_2}) but also respond to a lesser extent to changes in *arterial carbon dioxide pressure* (arterial P_{CO_2}) and pH. They are stimulated when the arterial P_{O_2} falls below 75 mm Hg as well as when the arterial P_{CO_2} increases and pH decreases. Whereas both receptors stimulate ventilation in hypoxia, the aortic chemoreceptors are more important in infants and the carotid receptors are more important in adults.[12] Once stimulated, the carotid bodies send impulses via cranial nerve IX to the nucleus tractus solitarius where neurotransmitters are released that increase ventilation.[13] Although the control of ventilation during exercise is not completely understood, the predominant stimulus for increased ventilation is thought to arise from the peripheral receptors. It is postulated that additional peripheral receptors exist that are yet to be identified because the hyperventilatory response of exercise cannot be fully accounted for by the carotid bodies.[14] The *central chemoreceptors* are crucial in the adjustments of ventilation to acid-base disturbances and arterial P_{CO_2}. There are four groups of chemosensitive neurons in the brainstem: the locus ceruleus, the nucleus tractus solitarius, the midline raphe, and the ventrolateral quadrant of the medulla. The central chemoreceptors are responsible for most of the response to carbon dioxide. They respond to increases in arterial P_{CO_2} by their detection of the fall in pH of the cerebrospinal fluid associated with an increase in cerebrospinal fluid arterial P_{CO_2}, which closely follows an increase in serum arterial P_{CO_2}. Of note, once the drop in pH is detected, it appears that

Table 130.1 Diseases of the Central Nervous System Associated With Respiratory Dysfunction

Cerebral Cortex	Brainstem/Basal Ganglia	Spinal Cord
Stroke	Stroke	Trauma
Neoplasm	Neoplasm	Infarction or hemorrhage
Cerebral degeneration	Poliomyelitis	Demyelinating disease
Seizures	Central alveolar hypoventilation	Disc compression
	Progressive bulbar palsy	Syringomyelia
	Multiple system atrophy	Tumor
	Anoxic encephalopathy	Epidural abscess
	Encephalitis	
	Multiple sclerosis	
	Parkinson disease	
	Chorea	
	Dyskinesias	

Table 130.2 Diseases of the Peripheral Nervous System Associated With Respiratory Dysfunction

Motor Nerves/ Anterior Horn Cell	Neuromuscular Junction	Myopathies
Acute idiopathic polyneuropathy (Guillain-Barré syndrome)	Myasthenia gravis	Muscular dystrophies
Motor neuron disease	Lambert-Eaton myasthenic syndrome	Myotonic dystrophy
Amyotrophic lateral sclerosis	Toxins	Dermatomyositis
Spinal muscular atrophy	Botulism	Polymyositis
Primary lateral sclerosis	Snake venoms	Inclusion body myositis
Critical illness neuropathy	Scorpion bites	Glycogen storage diseases
Vasculitides	Shellfish	Pompe disease
Toxins (e.g., lithium, arsenic, gold)	Crab poisoning	Forbes-Cori disease
Metabolic	Drugs	Thick filament myopathy
Diabetes	Antibiotics	Mitochondrial myopathy
Porphyria	Neuromuscular junction blockers	Nemaline body myopathy
Uremia	Anticholinesterase inhibitors	Severe hypokalemia
Diphtheria	Corticosteroids	Hypophosphatemia
	Lidocaine	
	Quinidine	
	Lithium	
	Antirheumatics	

the parasympathetic nervous system is important in the response to cerebrospinal fluid pH changes because inhibition of acetylcholine transmission can abolish the central pH response in animals.

DISEASES AFFECTING THE RESPIRATORY SYSTEM

The diseases of the neurorespiratory system can be organized most logically in the framework of functional anatomy. Diseases of the central nervous system known to affect the respiratory system are listed in Table 130.1 and those affecting the peripheral nervous system are listed in Table 130.2.

CENTRAL NERVOUS SYSTEM DISEASES

Cortical and Brainstem Disorders

Diseases of Voluntary Breathing. The pathways that connect the voluntary respiratory centers of the cortex with spinal motor neurons (corticospinal tracts) can be affected in a number of disorders. Midpontine strokes can damage the corticospinal tracts and cause what is known as the *locked-in syndrome,*[15] a syndrome with total paralysis with the exception of eye movement. Because injury to the reticulospinal tracts causes loss of volitional but not automatic breathing, the response to automatic breathing is preserved. This syndrome is most commonly due to ischemic stroke but can be due to pontine tumor, central pontine myelinolysis, high cervical demyelination, syphilitic arteritis, and head injury. Extrapyramidal disorders such as parkinsonism can also affect voluntary breathing.[16] In these disorders, patients have less ability to alter their breathing pattern voluntarily. They also may demonstrate periodic breathing or a Cheyne-Stokes respiratory pattern.

Diseases of Automatic Breathing. Automatic breathing but not voluntary breathing is classically disrupted in central alveolar hypoventilation, otherwise known as *Ondine's curse,*[17] caused by injury to the automatic respiratory centers in the brainstem. Because automatic triggering controls breathing during sleep, individuals with central alveolar hypoventilation develop central sleep apnea. Congenital central alveolar hypoventilation is a rare genetic disorder affecting infants and children, although it has now been described in adults as well.[17] Acquired central alveolar hypoventilation can result from unilateral or bilateral medullary infarction, bulbar poliomyelitis, or bilateral cervical tractotomy performed to control chronic pain. Although disorders of the neurorespiratory system generally lead to hypoventilation and the need for ventilatory support, diseases of the automatic respiratory centers in the brainstem can also lead to hyperventilation. This may be caused by diseases such as central nervous system infection or tumor[18] or by stimulation of an otherwise normal autonomic respiratory center by fever, sepsis, pain, pregnancy, medications such as progesterone or salicylates, or high altitude. A variety of irregular breathing patterns has also been associated with central nervous system disease including Cheyne-Stokes respiration and ataxic breathing.

Diseases of the Spinal Cord

Spinal Cord Injury. *Spinal cord injury* (SCI) is most commonly due to traumatic injury caused by motor vehicle accidents, falls, sports accidents, and gunshot wounds. In the United States, an estimated 250,000 individuals have suffered significant SCI; the incidence is approximately 12,000 incident cases per year with 78% of the injuries seen in males (National Spinal Cord Injury Statistical Center: http://www.spinalcord.uab.edu). Respiratory complications including atelectasis, pneumonia, and respiratory failure are the leading cause of morbidity and mortality for individuals with SCI.[19] Immediately following acute SCI, a number of physiologic changes can affect the respiratory system and predispose to respiratory complications. These aberrations include (1) cough inefficiency due to expiratory

muscle weakness, (2) ciliary dysfunction and mucous hypersecretion possibly due to impairment of the peripheral autonomic nervous system, (3) glottic dysfunction or gastric hypomotility increasing the risk of aspiration, (4) bronchial hyperreactivity due to sympathectomy, and (5) loss of consciousness at the time of the injury, increasing the risk of aspiration.[20,21]

Acute respiratory failure immediately after the injury may be due to direct disruption of respiratory muscle innervation (cervical cord injury), aspiration at the scene due to loss of consciousness, pulmonary edema, or other traumatic injuries to the chest or head. Many individuals with SCI are intubated at the scene of the accident or shortly thereafter, a valuable step that can reduce the likelihood of massive aspiration and other complications as long as care is taken to stabilize the C-spine. Further preventive measures include encouragement of deep breathing and cough, frequent changes of position, postural drainage, assisted cough (manual or mechanical), and bronchoscopy when other measures fail to clear the airways. Patients with SCI are at high risk for venous thromboembolism, with the greatest risk 3 days to 2 weeks after injury. Prophylaxis for deep venous thrombosis is highly recommended during the initial hospitalization.

The extent of respiratory muscle impairment following SCI mainly depends on the level and severity of the spinal injury because the function of respiratory muscles innervated below the level of the cord injury is lost. The innervation of the respiratory muscles is shown in Table 130.3. The overall pattern of pulmonary function abnormality is one of restriction.[22] In the first few months to a year following the initial SCI, there is a significant improvement in lung volumes and maximal inspiratory and expiratory pressures,[23] possibly due to resolution of spinal cord edema and/or strengthening of the diaphragm and accessory muscles of inspiration.

In general, the higher the SCI, the more likely that ventilatory assistance will be needed.[24] Treatment of ventilatory failure following SCI can be accomplished by invasive (tracheostomy) or noninvasive (mask or mouthpiece) methods.[25] Many individuals are ventilated through a tracheostomy tube for some time after their injury; however, transfer to noninvasive means can often be achieved even for those requiring full-time ventilatory support. The choice of invasive versus noninvasive ventilation is determined by the degree of local expertise with these forms of ventilation as well as by patient preference. For those with high cervical SCI (C1–2) and intact phrenic nerve function, diaphragm pacing with electrodes directly placed on the phrenic nerve by video-assisted thoracoscopic surgery can provide ventilatory support. Placing pacing wires directly in the diaphragmatic muscle via a laparoscopic approach is also a means of providing ventilatory support. It should be noted that those with diaphragm pacemakers implanted still need a tracheostomy in place to avoid airway obstruction during sleep owing to the absence of the normal neurologic coordination of diaphragm contraction and upper airway dilation during inspiration. Although traumatic SCI is the major cause of spinal cord pathology, other causes include vascular accidents, demyelinating diseases (multiple sclerosis, transverse myelitis), syringomyelia, tumors, and epidural abscess (see Table 130.1).

Table 130.3 Respiratory Muscles and Their Innervation

Muscle Group	Spinal Cord Level	Nerve(s)
INSPIRATORY MUSCLES		
Diaphragm	C3–5	Phrenic
Parasternal intercostals	T1–7	Intercostal
Lateral external intercostals	T1–12	Intercostal
Scalenes	C4–8	Cervical (deep branches)
Sternocleidomastoids	Above spinal cord	Spinal accessory
EXPIRATORY MUSCLES		
Lateral internal intercostals	T1–12	Intercostal
Rectus abdominis	T7–L1	Lumbar
External and internal obliques	T7–L1	Lumbar
Transversus abdominis	T7–L1	Lumbar
UPPER AIRWAY MUSCLES		
Muscles of mastication	–	CN V, VII
Laryngeal and pharyngeal	–	–
Abductors	–	CN IX–XII
Adductors	–	CN IX–XII

CN, cranial nerve.

Ventilator dependence in patients with SCI is more common with high (cervical) SCI. Because the diaphragm is the major muscle of inspiration (C3–5 spinal nerve roots), those with lesions at C3 and above invariably require ventilatory support and are at the highest risk of respiratory complications.[24] Those with injuries between C3 and C5 vary in their requirements for ventilatory support. Even if they require ventilation initially, these individuals may become independent of ventilatory support eventually. The risk for ventilator dependence in this group of patients is greatest for those with injury close to C3 or age older than 50 years.[26] Individuals with lesions below C5 almost always become independent of continuous ventilator support. In contrast to inspiratory muscle function, expiratory muscle function is impaired after all levels of cervical cord injury resulting in expiratory muscle weakness and ineffective cough. Because an effective cough depends in large part on abdominal and intercostal muscle function (spinal nerve roots T1–L1), cervical, thoracic, and even some high lumbar SCIs can impair the ability to cough and clear secretions. Therefore, measurement of cough function in these patients is very important, as is described later.

Other Respiratory Effects of Spinal Cord Injury. For unknown reasons, the frequency of sleep apnea appears to be increased by as much as fourfold in patients with SCI compared to a normal population of similar age.[20] A sleep study should be considered when symptoms of nocturnal hypoventilation such as morning headache, daytime hypersomnolence, or unexplained nocturnal awakenings are present or when daytime hypercarbia (arterial P_{CO_2} >

45 mm Hg), unexplained right heart dysfunction, or *forced vital capacity* (FVC) less than 50% predicted are present.[27] Bronchial hyperreactivity and bronchial hypersecretion are also present in some individuals following SCI, likely due to interference with normal autonomic control of the airways after injury.[28]

PERIPHERAL NERVOUS SYSTEM DISEASES

Diseases of Motor Nerves or Anterior Horn Cells and Diseases of the Neuromuscular Junction

Disorders of the motor nerves and the *neuromuscular junction* (NMJ) can arise acutely as in acute inflammatory polyneuropathy (Guillain-Barré syndrome) or botulinum toxicity or can arise more chronically as in motor neuron disease (e.g., *amyotrophic lateral sclerosis* [ALS]) or myasthenia gravis (see Table 130.2). The level of motor nerve root involvement dictates the effects of the disorder on the respiratory system.

Acute Diseases Affecting Motor Nerves

Acute Immune-Mediated Polyneuropathy. Acute immune-mediated polyneuropathy, also referred to as Guillain-Barré syndrome, is a heterogeneous group of diseases now thought to be caused by antiglycolipid antibodies.[29] Acute idiopathic demyelinating polyneuropathy is the most common form, making up about 85–90% of cases. It is an acute progressive process characterized by symmetrical, ascending muscle weakness progressing over a 2-week period and associated with loss of deep tendon reflexes. It is thought that an antecedent viral infection induces an immune response to viral epitopes that then cross-react with lipid components of the peripheral nerve.[30] The process usually starts in the lower extremities but may start primarily in the arms or the face, head, and neck (Miller-Fisher variant).[31] Acute idiopathic demyelinating polyneuropathy affects the respiratory system by causing (1) weakness of the upper airway muscles, (2) weakness of the inspiratory and expiratory muscles, and (3) secondary complications such as pneumonia or pulmonary embolism.[32] Approximately 25–50% of patients develop respiratory insufficiency severe enough to necessitate intubation and mechanical ventilation.[33] A number of variables used to predict impending respiratory failure and the need for mechanical ventilatory support have been used, including FVC, *maximal inspiratory pressure* (MIP), *maximal expiratory pressure* (MEP), and nocturnal desaturation. Generally accepted guidelines for intubation and mechanical ventilation include an FVC less than 15 mL/kg, an FVC less than 1 L, a decline in FVC to 50% or less of the normal predicted value for that individual, or an MIP of 30 cm H_2O or less.[32] FVC and MIP should be monitored frequently (multiple times per day depending on rapidity of progression). With rapidly progressive disease, the *intensive care unit* (ICU) is considered the best location for monitoring. Absolute indications for intubation include impaired consciousness, respiratory or cardiac arrest, shock, arrhythmias, blood gas alterations, or bulbar dysfunction with confirmed aspiration.[32] Noninvasive ventilation is generally not an option for these individuals because they are at a high risk for aspiration due to bulbar muscle involvement. Successful extubation may be achieved once treatment such as steroids, immune globulin, and plasmapheresis is begun and respiratory muscle strength returns.[33] Until respiratory muscle strength returns, scrupulous supportive ICU care including tracheostomy for prolonged mechanical ventilation and prophylaxis to prevent deep venous thrombosis is required to prevent complications such as ventilator-associated pneumonia, sepsis, and pulmonary embolism.

Poliomyelitis. Poliomyelitis is a viral disease affecting the anterior horn cell and motor nerve caused by a human enterovirus. Significant epidemics with frequent respiratory complications began to appear in the United States and Western Europe during the 20th century. Owing to improved sanitation and vaccine development, polio is no longer a major public health issue in the developed world. However, in the developing world, acute infections still happen.

In the developed world, the major health issue arising from polio currently is the postpolio syndrome, in which new weakness develops in survivors of the polio epidemics of the mid-20th century.[34,35] The cause of progressive neurologic deterioration in postpolio syndrome is unknown. Theories of pathogenesis suggested include (1) progressive degeneration of reinnervated motor units, (2) persistence of poliovirus in neural tissue, or (3) induction of autoimmunity with subsequent destruction of neural structures.[36] The average time to onset from the time of the initial infection is 35 years but ranges from 8 to 71 years. A high percentage of polio survivors, between 20% and 60% of individuals, complain of new muscle weakness.[36] Although the exact incidence of respiratory system involvement in the postpolio syndrome is not known, sleep-disordered breathing is common and noninvasive nocturnal ventilation can be highly effective.[37] Fortunately it appears that frank hypoventilation associated with the postpolio syndrome is unusual.[38]

Chronic Diseases Affecting Motor Nerves

Amyotrophic Lateral Sclerosis. ALS is a progressive neurodegenerative disease with no known cure. The usual clinical presentation is that of an individual with gradually progressive asymmetrical weakness associated with hyperreflexia due to upper motor nerve involvement and muscle fasciculations due to lower motor nerve involvement. Like most neurologic diseases, ALS has no direct effect on the lung; however, it significantly affects the upper airway, chest wall, and diaphragm, thereby impairing respiratory muscle function. Indeed, ALS affects all of the major muscle groups of the respiratory system, including (1) upper airway muscles leading to abnormal swallowing and inadequate cough, (2) expiratory muscles leading to inadequate cough, and (3) inspiratory muscles leading to inadequate ventilation. Therefore, all patients with ALS are at significant risk for respiratory complications. Respiratory failure, the leading cause of death in this population, has also been reported as the initial clinical presentation of ALS. Patients may complain of dyspnea, difficulty managing secretions, or inability to cough effectively. Monitoring pulmonary function in the outpatient setting is crucial. The FVC is the most commonly used measurement and has prognostic significance.[39] MIP and MEP, as well as sniff nasal inspiratory pressure, have also been used. Attention must be given to

glottic and cough function as well because aspiration and pneumonia are significant contributors to morbidity and mortality.[39] Sleep-disordered breathing is very common in ALS, and *noninvasive positive-pressure ventilation* (NPPV) has been used both at night and, as the disease progresses, during the day to improve quality and duration of life.[40–43] Patients often have difficulty managing secretions owing to swallowing dysfunction. Secretions can be reduced by using anticholinergic agents,[43] by low-dose irradiation of salivary glands,[44] or by injecting the glands with botulinum toxin.[45] As ALS progresses, NPPV ceases to be effective and a decision needs to be made concerning the appropriateness of tracheostomy and long-term invasive ventilation. Although tracheostomy can prolong survival substantially,[46] it does not alter the progression of the disease and patients ultimately become completely paretic. Due to different cultural approaches, rates of invasive ventilation vary substantially among countries.[47]

Neuromuscular Junction Diseases

Myasthenia Gravis. Myasthenia gravis is the most common disease affecting neuromuscular transmission. It is an autoimmune disease characterized by an antibody-mediated immune attack directed at acetylcholine receptors and/or receptor-associated proteins in the postsynaptic membrane of the NMJ. It causes weakness of several muscle groups, including the respiratory muscles. The respiratory muscles are particularly susceptible to fatigue during the severe, potentially life-threatening exacerbations known as *myasthenic crises*.[48] The clinical considerations during myasthenic crisis are very similar to those for acute idiopathic demyelinating polyneuropathy noted earlier, and the indications for intubation are the same.[32] Acute treatment of myasthenic crisis focuses on rapid therapies including intravenous immunoglobulin as well as plasmapheresis and corticosteroid therapy.[49,50] Assiduous attention to respiratory care provides support of the patient, allowing time for therapy of the underlying myasthenia to be effective.

Myasthenia gravis can also arise as a paraneoplastic syndrome in association with thymoma. It has been estimated that approximately 15% of all patients with thymoma will exhibit myasthenia gravis. Removal of the thymoma may result in amelioration of the myasthenia symptoms. Predictors of improvement after thymectomy have been reported to be age younger than 35 years, duration of symptoms less than 24 months, and absence of perioperative steroid use.[51]

Lambert-Eaton myasthenic syndrome (LEMS) is a myasthenic syndrome associated with small cell lung cancer; the myasthenia can affect the respiratory muscles in a fashion similar to that of myasthenia gravis. In patients with small cell lung cancer, LEMS may be present in approximately 3% of cases.[52] However, in patients with LEMS, as many as 50–60% will have a tumor, almost always a small cell lung cancer. The small cell lung cancer may be occult and should be sought for up to 5 years after the diagnosis of LEMS. LEMS is thought to be due to autoantibodies directed against presynaptic voltage-gated calcium channels,[53] thereby interfering with synaptic function. These voltage-gated calcium channels may be shared by the neuroendocrine cells of the small cell lung cancer, thus explaining the association of the two conditions. Although respiratory involvement is often a late finding, frank respiratory failure can be a manifestation of LEMS,[54] and this disorder should be considered in individuals with unexplained neuromuscular weakness. Although LEMS shares a similar pathophysiologic mechanism with myasthenia gravis, the clinical presentation is different; LEMS is characterized by (1) an increase in the compound muscle action potential with repetitive nerve stimulation, a feature not seen in myasthenia, (2) more frequent presence of proximal leg weakness, which is worse in the morning, (3) greater autonomic dysfunction, and (4) frequent association with malignancy.[55]

Botulism. Botulism is a neuroparalytic syndrome caused by a toxin produced by the gram-positive bacterium *Clostridium botulinum*, which blocks acetylcholine release at the NMJ. It can be acquired by humans in one of five ways: (1) food-borne botulism, in which there is ingestion of food contaminated with preformed toxin, (2) wound botulism, in which the bacteria growing in the wound produce toxin in vivo, (3) infant botulism, in which there is ingestion of clostridial spores allowing colonization of the host's gastrointestinal tract by the bacteria and production of the toxin in vivo, (4) adult enteric infectious botulism, which is similar to infant botulism, and (5) inhalational botulism, which follows inhalation of aerosolized toxin released in an act of bioterrorism.[56]

C. botulinum produces a number of toxins that can produce paralysis by binding to synaptotagmin I and II receptors, which then mediate toxin entry into the nerve cell cytoplasm.[57] Once intracellular, the toxin produces *irreversible* disruption in stimulation-induced acetylcholine release. The botulinum toxin is one of the most potent toxins known. Recovery from the injury requires regrowth of new synapses, a process that can take 6 months. The clinical syndrome is one of progressive paralysis with early cranial nerve involvement causing blurred vision, dysphagia, dysarthria, and facial weakness. Descending muscle weakness is the usual course, and involvement of the upper airway, diaphragm, and intercostal muscles often leads to the requirement for intubation and mechanical ventilation.[58] All patients should be monitored in the ICU and intubation should be undertaken for those who cannot protect their airway or who have an FVC of less than 30% predicted. Botulism antitoxin (intravenous botulinum immune globulin) is available for use in the United States and is given to affected infants younger than 1 year.[58] For adults in the United States, an investigational equine serum heptavalent botulism antitoxin is available through the Centers for Disease Control and Prevention.[59] For all patients, supportive care is the mainstay of therapy and, when necessary, intubation and mechanical ventilation are critical to improved survival. Prolonged hospitalization is common.

Other Neuromuscular Junction Toxins. A number of other toxins can affect the NMJ. The insecticides organophosphates and carbamates are potent inhibitors of acetylcholinesterase, leading to high levels of acetylcholine in the NMJ and resulting in parasympathetic and sympathetic overstimulation, skeletal muscle paralysis, and sometimes respiratory failure.[60] Several species of tick produce toxins that can inhibit NMJ neurotransmission (tick paralysis) by inhibiting the influx of sodium ions and preventing

presynaptic terminal axon depolarization and the release of acetylcholine at the nerve terminal.[61] Venom from a number of families of snakes produces neurotoxins that can cause paralysis, respiratory failure, and death owing to inhibition of neurotransmission.[62] Finally, a wide range of medications can cause NMJ blockade even at therapeutic doses, including D-penicillamine, aminoglycoside antibiotics, fluoroquinolone antibiotics, phenytoin and other anticonvulsants, lithium, β-blockers, glucocorticoids, and magnesium sulfate.[63,64]

Diseases of the Respiratory Muscles

A large number of disorders, both acute and chronic, can directly affect the respiratory muscles (see Table 130.2). Many causes of chronic muscle disease result in respiratory muscle dysfunction including genetic muscular dystrophies, myopathies, and myotonias as well as inflammatory myopathies and those associated with systemic diseases.

Duchenne and Becker Muscular Dystrophies. Duchenne muscular dystrophy and Becker muscular dystrophy are the most common inherited muscle diseases found in childhood, affecting 8.3 and 7.3 children per 100,000.[65] They are both progressive myopathic disorders caused by mutations of the dystrophin gene on the X chromosome (Xp21).[66] Dystrophins are glycoproteins that coat sarcolemmal, sarcomeric, and cytosolic muscle proteins. With Duchenne muscular dystrophy, dystrophin is absent whereas, in Becker dystrophy, dystrophin is reduced in quantity or quality. Both disorders are inherited as X-linked recessive traits and are characterized by progressive muscle wasting and weakness.[67] Typically, weakness of limb muscles is more severe in Duchenne than in Becker muscular dystrophy. Both diseases can involve the respiratory muscles. The diaphragm, however, may be less susceptible than limb muscle because of different gene transcription patterns.[68]

In Duchenne muscular dystrophy, weakness of proximal muscle groups usually manifests by age 2 to 3 years, while weakness of the respiratory muscles becomes evident later in childhood.[69] In Becker muscular dystrophy, weakness manifests later in childhood and individuals can remain ambulatory often into adult life. Because limb muscles are more affected than the respiratory muscles, exercise is initially limited by limb muscle weakness rather than dyspnea due to respiratory muscle weakness. However, the respiratory muscles may progressively weaken and dyspnea may appear with minimal exertion or at rest. Inspiratory muscle weakness can be assessed by measuring MIP. In children unable to perform this maneuver, maximal sniff nasal inspiratory pressures may provide a useful surrogate.[70] With severe inspiratory muscle weakness (MIP < 50% predicted), lung volumes are reduced and FVC may decline at a rate of 6–11% per year. This restrictive process is worsened by concurrent scoliosis or kyphosis, which can develop as a result of muscle dysfunction (see Chapter 131).

Glucocorticoids have been used with limited success to slow the rate of decline of lung function and delay the need for scoliosis surgery.[71–73] Idebenone, a quinone-like drug that targets mitochondrial oxidative phosphorylation, may enhance energy production at the mitochondria and mitigate the decline in respiratory function.[74] Therapies based on genetic manipulation to increase dystrophin production have evolved to include ataluren, which can act to minimize the effect of a stop codon mutation, and eteplirsen, which can help restore the proper reading frame.[75,76]

The diagnosis is often suspected by noting an elevated serum creatine kinase. However, this finding is not specific for these disorders. Analysis for deletions in the dystrophin gene and gene sequencing, if needed, will detect the majority of cases of Duchenne muscular dystrophy.[77,78] A muscle biopsy can be obtained if the diagnosis remains in doubt after genetic testing. With muscular dystrophy, there is degeneration and regeneration of muscle fibers as well as replacement of muscle by fat and connective tissue. Immunoblots for dystrophin can aid in distinguishing Duchenne from Becker muscular dystrophy. Female siblings of individuals with Duchenne or Becker muscular dystrophy should be tested to determine whether they are carriers of the disease. It is important to identify carriers not only for genetic counseling but also because they may be at higher than average risk for development of cardiomyopathy.

The combination of a restrictive pulmonary deficit and expiratory muscle weakness impairs cough and therefore predisposes these individuals to development of respiratory complications such as atelectasis and pneumonia. Methods for preventing atelectasis and infection are discussed later in this chapter.

Once- or twice-yearly measurements of FVC, MIP, and MEP provide useful markers of inspiratory muscle weakness.[79] As the inspiratory muscles weaken, the restrictive lung dysfunction worsens, with total lung capacity and FVC dropping to less than 60% predicted. At this stage, atelectasis can be reduced with lung volume recruitment maneuvers delivered by an in-exsufflation device.[80,81] Individuals with an FVC less than 30% predicted are at high risk for nocturnal hypoventilation and may complain of nonrefreshing sleep and daytime fatigue. These symptoms can present early, before muscle weakness becomes evident.[82,83] Nocturnal ventilation is usually initiated if symptoms develop related to hypoventilation, right heart failure, or elevated arterial P_{CO_2} (>45 mm Hg) either at night or during the day. In general, daytime measures of respiratory muscle strength or lung volumes are poor predictors of nocturnal hypoventilation and overnight oximetry or a sleep study should be considered in high-risk individuals. Noninvasive ventilation is a therapeutic intervention that typically can be delivered with a positive-pressure device using an interface such as a nasal mask, nasal-oral mask, or mouthpiece (discussed later). Noninvasive ventilation is likely to improve quality of life, physical activity, and hemodynamics and to normalize arterial blood gases.[84] Extension of noninvasive ventilation into waking hours may provide relief of dyspnea in more severely affected patients.[85,86] Individuals with Duchenne or Becker muscular dystrophy who require surgery may be at higher risk for respiratory complications.[87] A consensus statement has been published addressing the respiratory and other risks of anesthesia and suggesting methods for avoiding excessive morbidity and mortality.[88] Other muscular dystrophies such as limb-girdle muscular dystrophy, facioscapulohumeral dystrophy, and myotonic dystrophy can affect the respiratory muscles but do not generally cause respiratory impairment until later in the course of the disease.

Chronic Inflammatory Myopathies. *Dermatomyositis* (DM), *polymyositis* (PM), and *inclusion body myositis* (IBM) are systemic inflammatory diseases of unknown etiology that cause profound skeletal muscle weakness.[89,90] DM and PM, with a prevalence of roughly 1:100,000, affect females more than males.[91] DM, PM, and IBM have been associated with genetic abnormalities.

The myopathies have characteristic pathologic changes. Both DM and PM are characterized by muscle fiber inflammation and necrosis. With DM, the inflammatory process may be due to complement-mediated microangiopathy or related to type 1 interferons, and the locus of inflammation is the perifascicular fibers and blood vessels. With PM, the inflammatory response is cell mediated and involves the muscle fascicles themselves. With IBM, in addition to the perivascular inflammation involving the perimysium, the sheath of connective tissue surrounding groups of skeletal muscle fibers, there is also evidence of vacuoles and degenerative deposits. In IBM, tau protein and β-amyloid precursor protein may contribute to muscle injury.[92]

Inflammatory myopathies generally cause symmetrical proximal muscle weakness with insidious onset of symptoms due to slowly progressive muscle weakness. DM and PM involve proximal muscle groups, whereas IBM is typically characterized by asymmetric atrophy of distal muscles and lack of peripheral reflexes. DM can be seen in children and adults, whereas PM and IBM are generally seen only in adults, with IBM involving those older than 50 years with a male predominance. DM may be associated with a rash or underlying carcinoma.

Inflammatory myopathies can involve the diaphragm, intercostal muscles, and accessory muscles, but other peripheral muscle groups are usually more severely affected than the respiratory muscles. Thus, symptoms related to respiratory muscle weakness usually are not the presenting complaints. However, respiratory muscle weakness can develop in 5–10% of the patients with DM and PM and may be found in as many as 75% of individuals when respiratory muscle function is carefully evaluated.[93] Diaphragm dysfunction can be associated with dyspnea, nocturnal hypoventilation and, if the MIP is less than 30% of predicted, respiratory failure. Respiratory muscle weakness can also impair cough, which, in concert with esophageal dysfunction and lymphopenia, can predispose these patients to pneumonia. Aspiration due to pharyngeal muscle weakness can result in chronic interstitial changes.[94]

Individuals with DM or PM should be evaluated for the presence of restrictive pulmonary disease, which may be due to respiratory muscle weakness as well as underlying *interstitial lung disease* (ILD). ILD may develop in up to 70% of patients with DM or PM[95] and may be especially aggressive in the presence of antisynthetase antibodies.[96] ILD may be found more frequently in patients with anti-Jo antibodies.

Diagnostic workup includes measuring muscle enzymes and autoantibodies, magnetic resonance imaging, and muscle biopsy. Muscle enzymes (creatine kinase, aldolase, and lactate dehydrogenase) can be elevated in all inflammatory myopathies but more so in DM and PM than in IBM. ANA titers are significantly elevated in 80% of patients with DM and PM.[90] Serologic markers that are specific for DM and PM include autoantibodies such as anti-Jo-1 (seen in up to 50% of patients with PM); antibodies to signal recognition particle (anti-SRP antibodies); and antibodies to Mi-2, a nuclear helicase (found more frequently in DM).[97] Anti-TIF1-γ antibodies are frequently found in patients with paraneoplastic DM.[98,99] Type 1 interferon-inducible transcripts can be detected in DM and PM and may play a pathogenic role.[100] Magnetic resonance imaging provides a broad overview of muscle and is helpful in distinguishing between PM and IBM and in selecting a biopsy site. In IBM, abnormal changes can be seen throughout the muscle with inclusion body vacuoles of β-amyloid and ubiquitin, whereas, in PM, changes are noted only along fascial planes.[101] Muscle biopsy findings, described above, can be confirmatory.

Treatment of DM and PM includes the use of corticosteroids and immunosuppressive agents such as azathioprine, methotrexate, and mycophenolate mofetil. High-dose intravenous immunoglobulins can be used in patients who are refractory to corticosteroids.[102] Tumor necrosis factor-α blockers and antireceptor antibodies (rituximab, eculizumab) may be used as second-line therapy.[103,104] Aminoquinolone antimalarials have been used as steroid-sparing agents. IBM is typically more refractory to treatment.

Metabolic Myopathies

Glycogen Storage Disease. A number of enzyme deficiencies can lead to glycogen storage diseases characterized by the accumulation of glycogen in tissue, including skeletal and cardiac muscle. There are 12 types of glycogen storage diseases, seen approximately once in 40,000 live births.[105] Glycogen storage diseases are generally inherited as autosomal recessive conditions. The glycogen storage diseases most likely to affect the respiratory system are acid maltase deficiency (type II—Pompe disease) and myophosphorylase deficiency (type V—McArdle disease). These disorders usually present in childhood, but some, such as Pompe disease, have separate adult-onset forms. McArdle disease does not involve cardiac muscle and can lead to exercise intolerance without the production of lactic acid.[106] In Pompe disease, because of the deficiency of acid α-glucosidase, an enzyme that degrades glycogen to glucose, glycogen accumulates within cardiac and skeletal muscle lysosomes, resulting in myopathy. Complete enzyme deficiency results in cardiorespiratory failure and death, usually in the first year of life.[107,108] When the onset of weakness begins after age 1 year, the disease is less severe and does not involve the heart. Those with a later onset of symptoms have a better prognosis. With diaphragm involvement, there is intolerance of the supine position and the development of restrictive lung disease with reductions in MIP.[109,110] Respiratory failure can develop in most severe cases.[111] Nonpharmacologic therapies include utilization of airway clearance techniques, NPPV, inspiratory muscle training, and dietary supplements.[112] Enzyme replacement therapy with recombinant acid α-glucosidase has shown promising results, with stabilization of pulmonary function and increased survival.[113–116]

Other Metabolic Myopathies. Disorders of lipid metabolism or defects directly involving the mitochondria can result in myopathy. Disorders of lipid metabolism may be caused by an abnormal carnitine transporter protein

("primary" carnitine deficiency) or a deficiency of carnitine palmitoyltransferase (CPT1 or CPT2).[117] These disorders usually do not cause respiratory disability but involve other skeletal muscle groups (arms and legs) and may involve cardiac muscle.[118] High carbohydrate diets have had limited success in improving exercise tolerance.[119]

Mitochondrial disorders include those due to deficiencies of enzymes in the mitochondrial respiratory chain complexes and to defects of phosphorylation-respiration coupling. Disorders of mitochondrial metabolism involving complexes I, II, III, IV, and V cause multiple respiratory chain defects[120] and alter the kinetics of oxygen metabolism during exercise.[121] The main consequences of mitochondrial myopathy are muscle weakness, muscle wasting, and exercise intolerance. Dyspnea that accompanies exercise may be due to an exaggerated ventilatory response to metabolic demands.[121] Occasionally, mitochondrial myopathies cause significant respiratory muscle weakness resulting in nocturnal hypoventilation and the need for assisted ventilation.[122] Treatments that focus on bypassing the defective mitochondria include dietary supplements such as creatine, carnitine, and coenzyme Q10.[123,124]

CRITICAL ILLNESS NEUROPATHY AND MYOPATHY

Neuromuscular weakness is common and develops for a variety of reasons in mechanically ventilated patients.[125] One cause of neuromuscular weakness is critical illness neuropathy and myopathy (critical illness polyneuromyopathy), which can result in diaphragm and limb muscle weakness in up to 80% of individuals receiving mechanical ventilation.[126–129] Two major risk factors for developing critical illness polyneuromyopathy are mechanical ventilation and sepsis. Other risk factors include multiorgan failure, renal failure, hyperosmolality, systemic inflammatory response syndrome, hyperglycemia, and treatment with corticosteroids, neuromuscular blocking agents, aminoglycosides, or catecholamines.[130]

The pathology of the myopathy has been well described and includes two major patterns of disease: (1) myocyte atrophy with thick filament (myosin) destruction and (2) widespread myocyte necrosis with intracellular vacuolization and phagocytosis of muscle fibers.[131] The neuropathic changes described by electrophysiologic testing with nerve conduction studies reveal reduced motor and often sensory nerve action potentials and muscle fibrillation suggestive of denervation. Critical illness polyneuromyopathy should be distinguished from other neuromuscular diseases such as Guillain-Barré syndrome.

Pharmacologic therapy includes correcting hypophosphatemia,[132] the use of inhibitors of phosphodiesterase (PDE)3 and PDE4,[133] and the use of the calcium sensitizer levosimendan.[134]

VENTILATOR-INDUCED DIAPHRAGM DYSFUNCTION

Ventilator-induced diaphragm dysfunction is associated with atrophy of both fast and slow myofibers and begins after only 24 to 36 hours of mechanical ventilation.[135] Measurements of diaphragm thickness with ultrasound[136–140] or measurements of endotracheal pressure following stimulation of the diaphragm have been used to assess diaphragm function in ventilated patients.[128] Diaphragm pacing or using modes of mechanical ventilation that minimize patient-ventilator asynchrony are interventions that may prevent diaphragm atrophy.[136,141–143]

Unilateral Diaphragmatic Paralysis

The diaphragm is the major muscle of inspiration and is innervated by the phrenic nerve, which arises from C3 to C5 (see Fig. 130.2). Diaphragm weakness or paralysis can involve either one of the diaphragm leaflets (unilateral) or both (bilateral). Unilateral diaphragmatic paralysis is more common than bilateral diaphragmatic paralysis. The most frequent causes of unilateral paralysis include phrenic nerve injury related to cardiac or thoracic surgery, herpes zoster, cervical spinal disease, or invasive or compressive tumors (Table 130.4). With unilateral diaphragmatic paralysis, patients may be asymptomatic at rest but have dyspnea with exertion.[144] Orthopnea may be present but is not as common or severe as in bilateral paralysis. When dyspnea is present in patients with unilateral paralysis, comorbid conditions such as obesity and underlying heart or lung disease may be present. The patient also should be evaluated for other disorders that cause muscle weakness.[145] The diagnosis is often suggested by an elevated hemidiaphragm on chest radiograph and confirmed with a fluoroscopic sniff test or by diaphragm ultrasonography.[146–148] These tests are discussed in more detail in the evaluation of the patient with neuromuscular disease section later in this chapter. Diaphragm function may recover as the phrenic nerve heals. As many as half the patients who acquire acute paralysis may recover; however, it may take up to 2 to 3 years following the initial injury.[149]

Diaphragm eventration may be confused with unilateral paralysis. In eventration, a part of the diaphragm is replaced with fibroelastic tissue resulting in a localized area of diaphragm elevation, usually anteromedially. Eventration can be distinguished from unilateral paralysis by demonstrating diaphragm contraction by ultrasound or by measuring the transdiaphragmatic pressure while stimulating the phrenic nerve on the side in question.[150]

Diaphragm plication is a treatment that consists of oversewing the membranous central tendon and the muscular components of the diaphragm, thereby tightening the flaccid hemidiaphragm. Surgical plication may be indicated for unilateral paralysis when disabling symptoms are present and when there is significant elevation of the hemidiaphragm on chest radiography. By reducing the paradoxical motion of the paralyzed hemidiaphragm, surgical plication may reduce dyspnea and improve FVC, especially in the supine position.[151–153] This intervention has no role in bilateral diaphragmatic paralysis.

Bilateral Diaphragmatic Paralysis

Bilateral diaphragmatic paralysis is most often seen in the setting of a disease producing severe generalized muscle weakness. The most common causes are diffuse muscle diseases or motor neuron disease, such as ALS. However, bilateral paralysis may develop with a myriad of disorders that involve the cervical spinal cord, phrenic nerve, or

Table 130.4 Causes of Diaphragm Weakness and Paralysis.

Neuropathic Causes	Myopathic Causes
TRAUMA	**MUSCULAR DYSTROPHIES**
Cardiac surgery with cold cardioplegia	Limb-girdle
Blunt trauma	Duchenne and Becker
Spinal cord injury	**METABOLIC MYOPATHIES**
Radiation injury	Hyper- or hypothyroidism
Cervical manipulation	Acid maltase deficiency
Scalene and brachial nerve block	**RHEUMATOLOGIC**
Tumor compression	Systemic lupus erythematosus
Lung cancer	Dermatomyositis
Metastatic mediastinal tumor	Mixed connective disease
METABOLIC	**MISCELLANEOUS**
Diabetes	Amyloidosis
Vitamin deficiency (B_6,B_{12}, folate)	Malnutrition
Hypothyroidism	Idiopathic
INFLAMMATORY NEURITIS	
Idiopathic (neuralgic amyotrophy, Parsonage-Turner)	
Mononeuritis multiplex	
Vasculitis	
Paraneoplastic	
MISCELLANEOUS	
Cervical spondylosis	
Poliomyelitis	
Amyotrophic lateral sclerosis	

neuromuscular junction; examples include neuralgic amyotrophy (Parsonage-Turner syndrome) or complications following cardiac, thoracic, or neck surgery.[154]

Patients with bilateral paralysis primarily complain of dyspnea,[155] either at rest, during exercise, or during certain activities that increase abdominal pressure. These activities, such as bending, lifting, or becoming immersed in water, increase abdominal pressure and displace the paralyzed diaphragm cranially, thereby decreasing lung volume. A similar problem arises upon lying supine; thus orthopnea is a common symptom, and patients may need to use a recliner to sleep. Because sleep-disordered breathing with hypoventilation and hypoxemia is common,[156] these individuals generally respond well to NPPV.[157]

Bilateral diaphragmatic paralysis may be suspected by observing paradoxical rib cage and abdomen motion during inspiration. The gold standard diagnostic test is measuring transdiaphragmatic pressure (Fig. 130.4).[158] Alternatively, diaphragm ultrasound provides a noninvasive means of obtaining the diagnosis as discussed in the "Diaphragm Imaging" section. Once the diagnosis of bilateral diaphragmatic paralysis is confirmed, further diagnostic workup should include an evaluation for nocturnal hypoventilation and computed tomography of the chest to exclude a mediastinal mass, which may be compressing or invading the phrenic nerve. In addition, magnetic resonance imaging of the neck may be needed to evaluate the spinal cord and nerve roots.[145]

Bilateral diaphragmatic paralysis is usually not reversible unless the underlying disease is treatable. Spontaneous recovery of diaphragm function has been noted in some individuals with bilateral paralysis due to neuralgic amyotrophy (brachial plexus neuritis) with the recovery taking an average of 15 months from the onset of symptoms.[149,159] Phrenic nerve pacing requires intact phrenic nerves and has been used in patients with cervical cord injuries above C3 and in patients with congenital hypoventilation syndrome. Thus it is not applicable in most cases of diaphragmatic paralysis. Direct diaphragmatic pacing involves the implantation of electrodes in the diaphragm. Identification of the entrance points of the phrenic nerve into the diaphragm is a prerequisite for direct pacing because uniform diaphragm activation requires placing the intramuscular electrodes in these locations.[160] For unclear reasons, pacing has not been helpful in patients with ALS.[161] Interventions such as sural or intercostal nerve grafting and transfers may provide options in the future to restore diaphragm function.[160,162,163] Diaphragm dysfunction related to metabolic or hormonal imbalance (hypothyroid, hypokalemia, hypomagnesemia, hypophosphatemia, alcohol use, diabetic neuropathy) or parasitic infections may improve with treatment of the underlying disease.

APPROACH TO THE INDIVIDUAL WITH NEUROMUSCULAR DISEASE

EVALUATION

Background

Although each neuromuscular disease has a different etiology and clinical course as well as potential treatment, the respiratory effects of neuromuscular diseases can be approached in a systematic way that can be applied to any neuromuscular diagnosis. This approach uses the fact that the three major muscle groups involved in maintaining ventilation and protecting the airway and lungs are (1) the inspiratory muscles responsible predominantly for ventilation, (2) the expiratory muscles responsible predominantly for cough, and (3) the upper airway muscles responsible for cough, swallowing, and airway protection (Fig. 130.5). This section outlines a general approach for individuals with known or suspected neuromuscular disease.

Comprehensive disease-specific consensus guidelines for evaluation and management of patients with Duchenne muscular dystrophy,[164] congenital muscular dystrophies,[165] pediatric neuromuscular weakness,[166] ALS,[167–169] spinal muscular atrophy,[170] and late-onset Pompe disease[171,172] have been published. Other clinical guidelines address positive-pressure ventilation in patients with chronic respiratory failure including those with neuromuscular disease.[173–175] For patients with Duchenne muscular dystrophy, a consensus committee of the Centers for Disease Control and Prevention has recommended that clinic visits should include relevant evaluations of each of the three areas as appropriate for the stage of disease progression from ambulatory to late nonambulatory.[176]

Clinical Assessment

Individuals with respiratory muscle (particularly diaphragmatic) weakness may present with dyspnea that develops insidiously, but occasionally may be acute (e.g., as in neuralgic amyotrophy).[155,177] Dyspnea is typically exacerbated

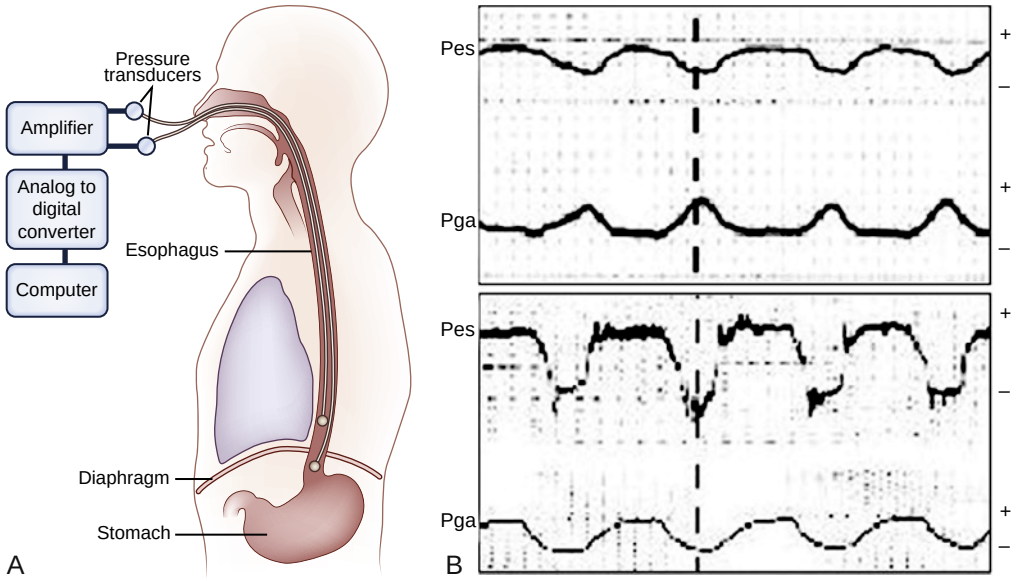

Figure 130.4 Apparatus used to measure transdiaphragmatic pressure and the pressure tracings for normal and paralyzed diaphragms. (A) Esophageal and gastric balloons placed through the nose into the esophagus and stomach, respectively, allow measurement of the pressures above and below the diaphragm simultaneously. (B) *Top*, Normal esophageal (Pes) and gastric (Pga) pressure tracings. Note Pes becomes more negative and Pga more positive during normal inspiration owing to the action of the diaphragm. *Bottom*, Diaphragmatic paralysis where Pes and Pga deflect in the same direction showing no muscular activity of the diaphragm.

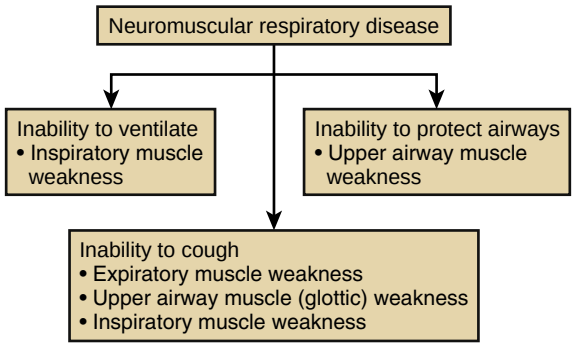

Figure 130.5 Clinical effects of weakness or dysfunction of inspiratory, expiratory, and upper airway muscles. Neuromuscular conditions lead to respiratory disease mainly via inability to ventilate, to cough, and to protect the upper airway from aspiration.

during exertion (especially if carrying heavy objects), and more specifically with recumbency, when bending forward, and when immersed in water[178] due to increased abdominal pressure and cranial displacement of the diaphragm. Frequent respiratory infections or slow recovery from respiratory infections may result from ineffective cough and secretion clearance. Sleep fragmentation, morning headache, daytime fatigue, and sleepiness may develop related to sleep-disordered breathing. A Sleep-Disordered Breathing in Neuromuscular Disease Questionnaire has been developed and validated in a small case series but has not been widely used.[179] Signs of respiratory muscle weakness may include tachypnea and paradoxical rib cage and abdomen motion during inspiration, especially when supine.

Cough Assessment. Effective cough requires a coordinated maneuver starting with adequate inspiration to high volumes, followed by glottic closure, effective expiratory muscle contraction, and rapid glottic opening.[180] Cough insufficiency may be suspected if the patient describes an inability to bring secretions to the mouth for expectoration or if there is a history of frequent respiratory infections. Cough function is best assessed by measuring *peak cough flow* (PCF) rate. This can be measured easily with an asthma peak flowmeter connected to a face mask or mouthpiece (Fig. 130.6). Normal values range from 360 to 960 L/min; a value below 160 L/min may place individuals at high risk for cough insufficiency and ventilator dependence.[181] A PCF below 270 L/min during a healthy period can drop below 160 L/min during infection. Therefore, once PCF drops below 270 L/min, cough augmentation techniques are recommended.

Bulbar Assessment. Patients with neuromuscular diseases such as ALS frequently develop bulbar muscle dysfunction due to motor neuron involvement in the brainstem. Dysfunction of the lips, tongue, and pharyngeal and laryngeal muscles can result in an increased risk of aspiration as well as difficulty generating adequate glottic closure for effective cough function. Choking is common and may even be triggered by aspiration of saliva. Swallowing may be impaired and ingesting adequate nutrition can be challenging for the patient, resulting in malnutrition or rapid weight loss.[182] Swallowing may be evaluated clinically[183] or by videofluoroscopic or fiberoptic evaluation of swallowing techniques.[184] Speech and swallowing consultation can be helpful in diagnosis and management.

Pulmonary Function Testing. Tests of pulmonary function are useful for initial assessment of and, often more important, follow-up of patients over time.[185] Spirometry classically shows a restrictive defect, but FVC may be preserved early on. A fall in FVC by more than 25% upon lying supine is more sensitive and specific than changes in upright FVC for detecting diaphragm weakness.[186] The flow-volume loop may show flow oscillations in patients with bulbar involvement.[187] Functional residual capacity, inspiratory capacity, and total lung capacity typically decline over time, while residual volume may be elevated due to expiratory muscle weakness. MIP and MEP are often both reduced but, in patients with isolated diaphragm weakness, MIP may decline while MEP is relatively preserved.[188] Tests of respiratory muscle strength may be difficult for

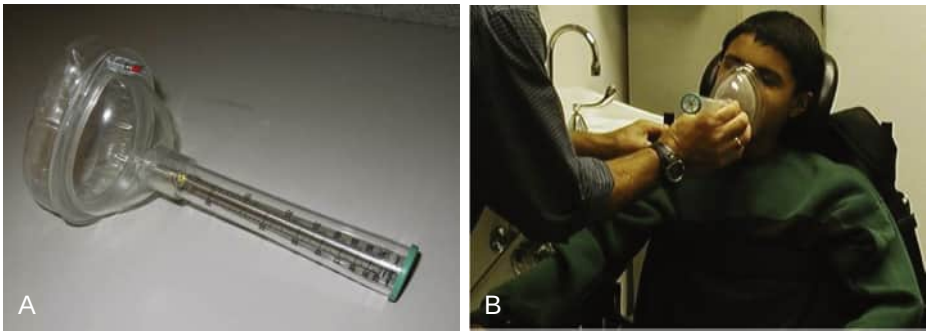

Figure 130.6 Device to measure peak cough flow and demonstration in patient with muscular dystrophy. (A) Device to measure peak cough flow consists of an asthma peak flowmeter connected to a face mask. (B) Peak cough flow device being used in a patient with muscular dystrophy.

patients with bulbar dysfunction to perform, and sniff nasal inspiratory pressure may be more reliable.[189,190] The 1999 National Association for Medical Direction of Respiratory Care National Consensus Conference, which ultimately informed the Centers for Medicare and Medicaid coverage decisions, developed guidelines for the initiation of NPPV and included MIP less than 60 cm H_2O and FVC less than 50% among the physiologic criteria to initiate NPPV in neuromuscular disease.[173]

Gas Exchange (see also Chapter 45). Carbon dioxide can be measured as arterial P_{CO_2}, the traditional measure of adequate ventilation, or as exhaled or end-tidal carbon dioxide (end-tidal P_{CO_2}), transcutaneous carbon dioxide (transcutaneous P_{CO_2}), or capillary P_{CO_2}. Arterial blood gas sampling is the most accurate means of assessing alveolar ventilation. Arterial P_{CO_2} of 45 mm Hg or greater is used to define hypoventilation for diagnostic and treatment purposes. End-tidal P_{CO_2} is an easy and accurate method of estimating arterial P_{CO_2},[191] but it may be inaccurate in patients with pulmonary disease, mouth breathing, high respiratory rates, or under specific technical conditions (e.g., moisture in tubing, use of supplemental oxygen). Transcutaneous P_{CO_2} technology is improving and may be more accurate than end-tidal P_{CO_2} in many common conditions,[192–194] including in patients with neuromuscular disease with weakness and reduced tidal volumes.[195]

Sleep Assessment. Sleep-disordered breathing in neuromuscular disease is common, precedes diurnal hypoventilation, and predicts the onset of diurnal respiratory failure.[196–198] Prevalence varies depending on the definition used.[199] The classic pattern is nocturnal hypoventilation, which is noted first in *rapid eye movement* (REM) sleep, then in both REM and non-REM sleep, and then finally in those who are awake.[200] However, some disorders may present with obstructive sleep apnea (e.g., classically a bimodal pattern in Duchenne muscular dystrophy with obstructive sleep apnea early and hypoventilation late), and with central sleep apnea in disorders associated with cardiomyopathy.[201]

Nocturnal pulse oximetry (Sp_{O_2}) monitoring, nocturnal P_{CO_2} monitoring, cardiorespiratory polygraphy, and polysomnography may be used for assessment.[198] Continuous Sp_{O_2} monitoring in the home is readily available, can detect desaturation (which is usually due to hypoventilation in neuromuscular disease),[202] and can be used to initiate NPPV because desaturation less than or equal to 88% for five minutes is one of the accepted criteria used to initiate NPPV.[173] However, nocturnal Sp_{O_2} is not as sensitive or specific for sleep-related hypoventilation as is transcutaneous P_{CO_2}.[199] Thus, transcutaneous P_{CO_2} monitoring, either alone, in combination with Sp_{O_2}, or as part of polysomnography, is a useful method for monitoring these patients during sleep. Polysomnography is the gold standard test to detect and characterize sleep-disordered breathing, can assess nocturnal oxygenation and ventilation (if continuous P_{CO_2} monitoring is used during the test), and can detect nonrespiratory sleep disorders. It is the recommended test in children with suspected sleep-disordered breathing and in adults with suspected complicated sleep-disordered breathing.[203–206] However, it is costly, labor-intensive, and not as readily available as other tests, and it may be difficult to obtain for patients with limited mobility. Current practice guidelines do not require formal sleep testing for the initiation of NPPV, although the American Academy of Sleep Medicine guidelines recommend polysomnography for titration of NPPV if possible.[207] Daytime positive airway pressure testing[208] and the use of advanced modes of NPPV with volume-assured pressure support have successfully facilitated managing NPPV without any need for formal polysomnography.[209]

Diaphragm Imaging. Chest radiography may show unilateral or bilateral diaphragm elevation suggesting diaphragmatic paralysis. This finding is moderately sensitive but nonspecific for diaphragm dysfunction[210] and diaphragm weakness must be confirmed by additional testing.[211] With unilateral diaphragmatic paralysis, fluoroscopy can be used to confirm the diagnosis by observing diaphragm motion during a sniff test. When the upright patient vigorously sniffs, there may be a cephalad or paradoxical movement of the paralyzed hemidiaphragm (see Video 20.1).[146] The paradoxical motion is due to the passive movement of a paralyzed hemidiaphragm in response to the increase in abdominal pressure (and decrease in pleural pressure) created by the contraction of the normal hemidiaphragm. However, unilateral diaphragmatic paralysis cannot be ruled out when the sniff test shows normal motion of the elevated hemidiaphragm. With bilateral diaphragmatic paralysis, there is no normal hemidiaphragm to use for comparison with an abnormal one, and chest radiography and sniff testing can yield false-negative and false-positive results in this situation.

Two-dimensional echocardiography of the diaphragm is increasingly available, with two general approaches: visualization of the dome of the diaphragm or visualization of the thickness of the diaphragm at the zone of apposition of the diaphragm to the rib cage.[147] Assessing movement of the

diaphragm dome can be diagnostic in unilateral diaphragmatic paralysis and requires less operator skill compared to the other ultrasonographic approach, but shares the same limitations as fluoroscopy.[212] Ultrasonographic imaging of the diaphragm in the zone of apposition provides an alternative means of diagnosing unilateral diaphragmatic paralysis by showing a thin diaphragm that fails to thicken with inspiration (Video 130.1).[148] It also can be diagnostic of bilateral diaphragmatic paralysis when no diaphragmatic thickening is seen on either side with inspiration.[147,148]

Specialized Testing of Diaphragm Function. The gold standard diagnostic test is measurement of *transdiaphragmatic pressure* (Pdi) using thin balloon-tipped polyethylene catheters placed in the esophagus and stomach (see Fig. 130.4A). The pressure is measured during a maximal inspiratory maneuver against an occluded airway (Pdi_{max}) or during a maximal sniff (Pdi_{sniff}) or it can be measured when the phrenic nerve is electrically or magnetically stimulated (Pdi_{twitch}). In diaphragm weakness, there is a lack of ability to generate a normal transdiaphragmatic pressure[158] (see Fig. 130.4B). Because measurement of Pdi is invasive and requires special expertise and because complementary methods of respiratory muscle strength are available, it is not used in routine clinical settings. Phrenic nerve conduction studies and diaphragmatic electromyography may be useful in distinguishing between a neuropathic or myopathic cause of diaphragmatic paralysis but can have technical limitations.[155]

MANAGEMENT

Ventilatory Support

Ventilatory support for patients with neuromuscular disease has been available for more than 60 years[213] (Table 130.5). Some of the first ventilators were known as body ventilators and included devices such as the iron lung, rocking bed, and pneumobelt.[213] With the advent of positive pressure via either invasive (tracheostomy) or noninvasive (face mask) ventilation, these body ventilators are used only rarely.

Invasive positive-pressure ventilation using an indwelling tracheostomy has been successfully employed in neuromuscular disease. Benefits of this type of ventilatory support include complete control of tidal volume and ease of access to the central airways for suctioning of secretions. The development of convenient, portable, positive-pressure generators has made this form of ventilation practical even in the home environment.[214] However, the cost of this care is significant, and the difficulty with obtaining trained caregivers reduces access to community-based living for those with a tracheostomy.[215] Invasive positive pressure should be considered in those with (1) coexisting lung disease, (2) copious secretions, (3) poor oropharyngeal muscle strength associated with ineffective clearing of secretions, (4) uncontrolled seizure disorders that can cause upper airway obstruction, (5) a preference for invasive rather than noninvasive methods, (6) orthopedic or other conditions that interfere with placement of noninvasive devices, and (7) limited access to individuals with expertise in noninvasive techniques.

Unfortunately, invasive long-term positive-pressure ventilation via a tracheostomy has been associated with several complications such as damage to the trachea from the indwelling tracheostomy tube leading to tracheal necrosis, stenosis, hemorrhage, or tracheoesophageal fistulas.[216] However, the development of low-pressure, high-volume cuffed plastic tracheostomy tubes has lowered the incidence of these complications. Tracheostomy tubes increase the risk of airway colonization with bacteria and lower respiratory tract infection. The use of a tracheostomy tube requires humidification. A number of devices and techniques have been designed to allow speech and communication while a patient has a tracheostomy and is being mechanically ventilated. These include techniques such as deflating the balloon to allow simple "leak speech," and devices such as one-way valves that allow gas to pass through the vocal cords during exhalation (Passy-Muir valve) or channels that direct compressed air through the vocal cords (Trach Talk tracheostomy tube). Unfortunately, not all individuals can use these approaches.[217]

NPPV is becoming the preferred method for treatment of patients with neuromuscular respiratory disease[218] (see also Chapter 136). NPPV was first used during the polio epidemics of the 1950s to allow patients to spend time outside the iron lung. Since the 1980s, there have been considerable refinements in the application of this technique. There are currently three ways in which NPPV may be delivered: (1) via full face mask, (2) via nasal mask, or (3) via mouthpiece with or without a lip seal (Fig. 130.7). Occasionally, more than one method may be used in the same patient; for instance, a mouthpiece may be used during the day and a nasal mask used at night.

The mouthpiece was the first interface to be used with a positive-pressure ventilator. Patients hold the mouthpiece devices between their teeth and often are able to use them while sleeping, especially when lip seal devices are added.[219] Since the late 1990s, nasal interfaces have been developed and used successfully.[220] Tidal volume is most effectively delivered when there are no leaks in the system. The use of a full face mask interface may reduce leaks but in selected patients may worsen apneas and hypopneas.[221] Pressure-cycled rather than volume-cycled devices are generally used for mask ventilation. With pressure-cycled machines, positive pressure can be delivered at two levels, a higher level during inspiration and a lower level during expiration (bi-level support). The positive-pressure

gradient during inspiration results in delivery of a tidal volume to the patient while exhalation is passive and is terminated when the airway pressure returns to the lower expiratory level. Maintenance of a positive expiratory pressure is important for two reasons. First, the gas flow needed to maintain end-expiratory positive airway pressure flushes the ventilator tubing of exhaled carbon dioxide and prevents rebreathing.[222] Second, because the expiratory pressure is positive and greater than atmospheric, the end-expiratory lung volume is increased, which may be associated with less atelectasis and fewer areas with low ventilation-perfusion ratios or shunt than seen with low end-expiratory lung volumes.

Data Supporting Noninvasive Positive-Pressure Ventilation in Neuromuscular Disease

Nocturnal Ventilatory Support. The use of nocturnal ventilation in patients with neuromuscular disease with sleep-disordered breathing has been shown to have a number of benefits, including (1) reduced arterial P_{CO_2} and increased arterial P_{O_2} on and off the ventilator, (2) decreased symptoms of sleep-disordered breathing such as morning headache, nocturnal awakenings, vivid nightmares, and night sweats, (3) improved quality of life, and (4) reduced morbidity and most likely reduced mortality.[174]

The mechanism by which nocturnal ventilation improves daytime symptoms and arterial blood gases in patients with neuromuscular disease is not entirely clear. A number of explanations have been suggested including (1) resting of chronically fatigued respiratory muscles, (2) reversal of mechanical problems associated with neuromuscular disease, such as reduced chest wall and lung compliance, and (3) a resetting of the central respiratory control centers with an increase in chemosensitivity to arterial P_{CO_2} during the daytime, thus maintaining blood gas homeostasis.[223,224] In addition to improvement in arterial blood gases, other measures of physiologic function have been shown to improve with intermittent ventilation; for example, nocturnal ventilation can increase FVC, improve right heart function, and reduce erythrocytosis.[225] The effects of mechanical ventilation have been best studied in ALS where the use of NPPV for more than 4 hours and early initiation of NPPV has been shown to improve survival.[226,227] It is therefore generally accepted that mechanical ventilation in the home leads to improved survival in most patients.

Full-Time Ventilatory Support

For those who require full-time ventilatory support, it is possible to provide NPPV for 24 hours per day.[228–230] There have been no randomized controlled trials of continuous ventilation. In one cohort study, 24 patients with Duchenne muscular dystrophy using NPPV were compared with 22 patients who received positive-pressure ventilation by tracheostomy.[231] The individuals who used NPPV had significantly fewer hospitalizations and hospital days per year. In another retrospective study by the same group, patients with Duchenne muscular dystrophy using a protocol consisting of mouthpiece positive-pressure ventilation and breath stacking plus mechanical insufflation-exsufflation to assist cough (see "Cough Support") had significantly lower mortality (3 of 34 patients) than a group that did not have access to the protocol and either received tracheostomy or used NPPV on a near-continuous basis (27 of 31 patients).[232] In the setting of ALS, the ability to use mouthpiece ventilation improves survival by approximately 20 months as opposed to those who are unable to use the device.[233] Multiple consensus statements on the respiratory care of patients with neuromuscular disease have suggested that NPPV be considered when expertise is available for initiation of appropriate protocols.[166,173,174,176]

Cough Support

Therapeutic interventions aimed at improving cough and airway clearance are equally if not more important than ventilatory support because pneumonia is one of the leading causes of morbidity and mortality in patients with neuromuscular disease.[218,234] Normally, the cough reflex is initiated by stimulation of cough receptors in the airways that activate brainstem centers that initiate inhalation, glottic closure, and forceful contraction of expiratory muscles during which intrathoracic air is

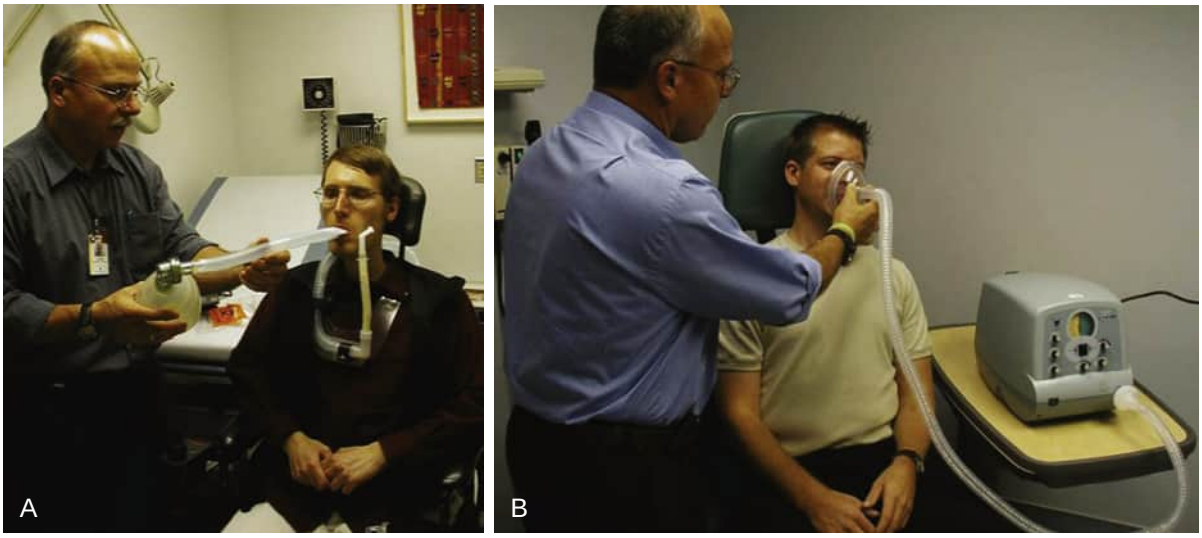

Figure 130.8 Methods to assist cough. (A) Resuscitator bag used to stack breaths to increase lung volume and thereby increase cough flow. (B) Mechanical insufflator-exsufflator being used to assist in secretion removal.

compressed under high pressures.[235] The glottis then rapidly opens, allowing an explosive release of air from the airways through the vocal cords. The high-velocity airflow shears secretions away from the airway walls and propels them out of the lung. Adequate cough is essential for airway hygiene and problems with cough sometimes lead to consideration of tracheostomy. Fortunately, there are a number of ways that an impaired cough can be augmented and pulmonary hygiene maintained without the use of a tracheostomy.

Manually assisted cough is a method of applying a rapid positive pressure to the abdomen. The increase in abdominal pressure is transmitted to the thorax and induces expiratory flow, leading to airway clearance and enhanced cough expiratory flow rates. A number of techniques are available for an attendant to apply rapid abdominal thrusts, resulting in effective clearance of secretions.[236] Increasing the volume of air in the respiratory system prior to the assisted cough increases the volume available for exhalation, optimizes the length-tension relationship of the expiratory muscles to increase potential intrathoracic pressure generation, and increases the inward elastic recoil pressure of the respiratory system, which can further increase the expiratory pressures. This maximal achievable inspired volume has been labeled the maximal insufflation capacity.[237] Inspired lung volume can be increased by patients using breath stacking or glossopharyngeal ("frog breathing") techniques[238] or by use of a resuscitator bag and mouthpiece (Fig. 130.8A). Breath stacking involves taking multiple breaths to increase lung volumes above the single breath volume and holding each successive breath in the lungs using a closed glottis. Glossopharyngeal breathing involves forcing air into the trachea using the tongue and pharyngeal muscles.[238] Increasing the lung volume to the greatest possible volume, known as lung volume recruitment, by using breath stacking or a mechanical device, may help both with improving cough function and with maintaining lung compliance and FVC in progressive neuromuscular disease.[239,240]

Mechanically assisted cough techniques are also available. A very effective secretion management device, available for more than 50 years but only recently used to any great extent, is the mechanical insufflator-exsufflator or CoughAssist (In-exsufflator) (see Fig. 130.8B). This device consists of an electric motor that can generate positive and negative pressures of up to 50 cm H_2O to insufflate and then rapidly exsufflate the lung. The pressure is applied to the patient's airway via a face mask or mouthpiece; a positive pressure of 30 to 50 cm H_2O is applied over a 1- to 3-second period followed immediately by a negative pressure of between 30 and 50 cm H_2O for a short duration. By simulating a cough, this technique moves secretions out of the airway noninvasively without violating airway integrity (Video 130.2).[241] Other noninvasive mechanical aids include devices that oscillate the chest wall or airway directly.[242] These have not been well studied in neuromuscular disease patients without tracheostomy and their role in support of secretion management of these disorders is unclear.

The decision to initiate cough assistance is determined by measurement of *peak cough flow* (PCF). Normal values for PCF range from 360 to 960 L/min. It is recommended that one or more of the previously discussed techniques should be made available to the patient when values of PCF fall below 270 L/min while the patient is well, because this correlates with a critical value of less than 160 L/min when the patient develops a respiratory tract infection.[181] This drop in cough function with respiratory illness may be due to increased muscle weakness or to the effects of the secretions themselves in reducing expiratory flow. In patients with bulbar muscle dysfunction, choking and vocal cord spasm may be triggered by aspiration of saliva. In these patients, the use of cough assist may worsen the episodes, and muscle relaxants may be more helpful.[243]

Aspiration can be a related problem for patients with neuromuscular disease (see also Chapter 43). Besides problems with cough, patients with neuromuscular disease often have problems with swallowing and airway protection.

However, treatments for swallowing muscle dysfunction are limited. The risk of aspiration and development of pneumonia in patients with ALS is due primarily to problems with upper airway function and cough. Pharyngeal and laryngeal muscle dysfunction can lead directly to aspiration of oral contents into the lungs. Other than surgical diversion of the airway,[244] no treatment directly aimed at laryngeal and glottic function is currently available. When patients develop significant dysphagia and aspiration of solids or liquids, many experts recommend placement of a percutaneous endoscopic gastrostomy tube.[245,246]

- Either nocturnal or full-time noninvasive ventilation is standard practice for patients with neuromuscular respiratory failure and likely prolongs survival.
- Cough can be aided noninvasively by manual or motorized means; cough support should be considered when the peak cough flow rate is less than 270 L/min in a patient without respiratory tract infection and definitely when the peak cough flow rate is less than 160 L/min.

Key Points

- Respiratory failure is a leading cause of morbidity and mortality in individuals with neuromuscular disease.
- Spinal cord injury to the cervical and upper thoracic spinal cord is associated with restrictive pulmonary dysfunction and respiratory muscle weakness. Diaphragm pacing is an effective means of providing long-term mechanical ventilation in patients with C1 or C2 lesions.
- Acute immune-mediated polyneuropathy (acute idiopathic demyelinating polyneuropathy or Guillain-Barré syndrome) is an ascending paralytic disease. Intubation can be life-saving and should be considered when the FVC is 15 mL/kg or less, the FVC is 1 L or less, or the maximal inspiratory pressure is 30 cm H_2O or less, or there is a lack of upper airway protection.
- Neuromuscular weakness arises commonly in individuals receiving mechanical ventilation and can result in diaphragm and limb muscle weakness.
- Unilateral diaphragmatic paralysis is most commonly due to injury to the phrenic nerve, whereas bilateral disease is most commonly due to diffuse muscle or motor neuron disease. The difference between upright and supine vital capacity can be used to screen for diaphragm dysfunction. The definitive diagnosis can be made by ultrasound measurements of diaphragm thickness or of diaphragm dome excursion.
- Respiratory assessment of the individual with neuromuscular respiratory impairment should include evaluation of muscle groups responsible for inspiration, expiration and cough, and airway protection.
