PATHOGENIC ASPECTS OF RESPIRATORY FAILURE IN CHEST WALL DISEASES
KEY POINTS

INTRODUCTION

Disorders of the soft tissue and bony structures of the chest wall generally cause restrictive dysfunction by limiting motion or causing disordered movement of the chest wall. Kyphoscoliosis and ankylosing spondylitis involve the spine and its articulations, pectus excavatum involves the sternum, flail chest affects the ribs, and obesity adds to the soft tissues of the rib cage and abdomen. Kyphoscoliosis has the most severe impact on respiratory function and pectus excavatum the least. Alterations in respiratory mechanics produced by these disorders are discussed in concert with the most recent developments in diagnosis and treatment. Neuromuscular diseases that affect the chest wall are reviewed in Chapter 130.

KYPHOSCOLIOSIS

DIAGNOSIS AND ETIOLOGY

Kyphoscoliosis refers to a group of disorders characterized by excessive spinal curvature in the lateral plane (scoliosis) and sagittal plane (kyphosis), as well as rotation of the spinal axis[1,2] (Fig. 131.1). Scoliosis, which is defined as a lateral spinal curvature greater than 10 degrees, is frequently associated with kyphosis and rotation of the spine around its long axis.[2] Kyphoscoliosis is a relatively common spinal abnormality, with an estimated prevalence for mild deformity of 1 in 1000 persons and for severe deformity of 1 in 10,000 persons in the United States.[1]

Kyphoscoliosis is classified as idiopathic (no known cause), paralytic or secondary (associated with neuromuscular disease), or congenital (associated with vertebral malformation present at birth)[2,3] (Table 131.1). Idiopathic kyphoscoliosis, accounting for 80% of all cases, usually manifests in late childhood or early adolescence and involves girls more often than boys, with a ratio of 4:1. Despite multiple theories linking idiopathic kyphoscoliosis to biomechanical, neuromuscular, environmental, or genetic causes, its precise etiology is largely unknown.[4] The most important sequelae of progressive kyphoscoliosis are back pain, psychosocial problems, and respiratory failure.[2]

The diagnosis of kyphoscoliosis is made by physical examination and confirmed radiographically. In severe cases, the examiner may readily notice the dorsal hump, which is caused by angulated ribs and shoulder asymmetry, and the hip tilt, which is related to spinal rotation. In mild cases with less apparent findings, it is important to inspect the spine for asymmetry and to perform the Adam forward bend test. With this test, the examiner inspects the spine for thoracic or lumbar asymmetry while the patient bends forward at the waist until the spine becomes parallel to the floor. When kyphoscoliosis is severe and complicated by right heart failure, clinical examination may reveal cyanosis, distended neck veins, peripheral edema, and hepatomegaly.[5]

Upright radiographs of the chest or spine are used to confirm the diagnosis and assess severity of the spinal deformity by measuring the Cobb angle[2] (Fig. 131.2). The greater the Cobb angle, the more severe the deformity. Angles greater than 100 degrees are usually associated with respiratory symptoms such as dyspnea on exertion, and angles greater than 120 degrees are associated with respiratory failure.[5–7]

PATHOPHYSIOLOGY

Pulmonary Function and Respiratory Mechanics

Kyphoscoliosis can produce severe restrictive impairment related to markedly decreased distensibility of the chest wall, especially with Cobb angles greater than 90

degrees[8–10] (Table 131.2). With such severe deformity, total lung capacity and *vital capacity* (VC) may be reduced to as low as 30% of predicted values.[6,9,10] In contrast, residual volume may be normal or slightly increased, resulting in an elevated ratio of residual volume to total lung capacity.[10,11] In children with severe spinal deformity, hypoplastic lung may result and contribute to reduced lung volumes.[12] Other factors contributing to the restrictive process include the number of vertebrae involved, the thoracic location of the curve, the patient's age, the presence of kyphosis, the degree of spinal rotation, and the presence of weak respiratory muscles.[13–15]

Associated abnormalities may increase the severity of restriction. For example, in the paralytic type of kyphoscoliosis, the degree of lung restriction is determined primarily by the degree of the respiratory muscle weakness rather than by the degree of the spinal curvature.[16,17] In addition, in congenital kyphoscoliosis, lung restriction may be worsened by associated rib deformities and underlying lung abnormalities.[17] For these reasons, compared with patients with idiopathic kyphoscoliosis, patients with paralytic or congenital kyphoscoliosis generally have a greater loss in VC for a given degree of spinal deformity.[17]

IDIOPATHIC DISORDER
■ Multigene disorder, developing by childhood or adolescence
PARALYTIC OR SECONDARY DISORDER
■ Neuromuscular (poliomyelitis, muscular dystrophy, cerebral palsy, Friedreich ataxia, Charcot-Marie-Tooth disease)
■ Disorders of connective tissue (Marfan syndrome, Ehlers-Danlos syndrome, Morquio syndrome)
■ Vertebral disease (osteoporosis, osteomalacia, vitamin D–resistant rickets, tuberculous spondylitis, spina bifida)
■ Post-thoracoplasty status
CONGENITAL DISORDER
■ Spinal or vertebral malformations at birth

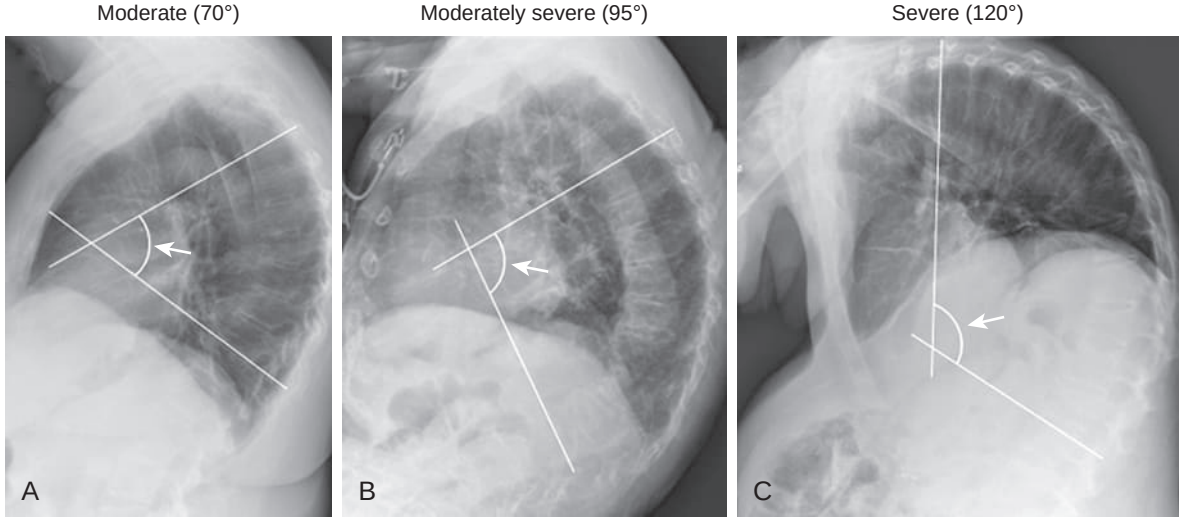

Figure 131.2 Lateral chest radiographs with different degrees of kyphoscoliosis showing calculation of the Cobb angle. Lines are drawn through the superior end plate of the vertebral body marking the cranial portion of the curve and the inferior end plate of the vertebral body marking the caudal portion of the curve. The angle of intersection between these two lines is the Cobb angle (*arrows*). Patients are shown with (A) moderate, (B) moderately severe, and (C) severe kyphoscoliosis along with their calculated Cobb angles. (Courtesy Michael B. Gotway, MD.)

Respiratory system compliance is reduced in kyphoscoliosis of any etiology, primarily because of the reduction in chest wall compliance and, to a lesser degree, a reduction in lung compliance as a result of microatelectasis.[9,18,19] Cobb angles up to 50 degrees have minimal impact on respiratory compliance, whereas angles greater than 100 degrees may reduce compliance to levels seen in the adult respiratory distress syndrome.[9,18,20] The stiff chest wall reduces the *functional residual capacity* (FRC). These factors combine to move the tidal breathing to a flatter, stiffer portion of the respiratory volume-pressure curve[8] (Fig. 131.3). This requires greater inspiratory effort for relatively small tidal breaths that increases the work and oxygen cost of breathing.[8] The increase in the oxygen cost of breathing may reach values three to five times those measured in healthy individuals[5,9,21] and thus may place patients at risk for respiratory muscle fatigue.[22]

Table 131.2 Representative Values for Pulmonary Function and Respiratory Mechanics in Chest Wall Diseases

Parameter	KS	Post-Thor	PE	AS
TLC (% pred)	45	65	90	85
VC (% pred)	30	50	90	80

AS, ankylosing spondylitis; Ccw, compliance of chest wall; CL, compliance of lungs; Crs, compliance of respiratory system; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; KS, kyphoscoliosis; MVV, maximum voluntary ventilation; PE, pectus excavatum; PI_{max}, maximum respiratory pressure; post-thor, post-thoracoplasty; pred, predicted; RV, residual volume; TLC, total lung capacity; VC, vital capacity.

Exercise Capacity

Individuals with mild idiopathic kyphoscoliosis usually have normal exercise capacity.[23–27] If exercise is limited, it is typically the result of deconditioning rather than diminished ventilatory reserve.[23,24,28] In contrast, individuals with *moderate* idiopathic kyphoscoliosis (Cobb angles of 25 to 70 degrees), *moderately severe* kyphoscoliosis (Cobb angles of 70 to 100 degrees), or *severe* kyphoscoliosis (Cobb angles greater than 100 degrees) may have exercise limitation related to ventilatory constraints.[23,29,30] With severe deformities (Cobb angles greater than 100 degrees), cardiovascular factors may further contribute to exercise limitation.[23,29] Supplemental oxygen may improve oxygenation during exercise but usually does not affect walk distance.

Control of Breathing and Sleep-Disordered Breathing

Patients with kyphoscoliosis compensate for the increased elastic loads on the inspiratory muscles by adopting a rapid shallow breathing pattern consisting of low tidal volumes and shortened inspiratory time.[11,31] Both parameters of rapid shallow breathing, tidal volumes and inspiratory time, decrease as the Cobb angle increases.[31] However, rapid shallow breathing has the negative consequence of increasing dead space ventilation and promoting microatelectasis. Another strategy to compensate for the increased elastic load is to increase neural drive to the respiratory muscles. Indirect evidence for this compensatory strategy is the elevated mouth occlusion pressure at 100 msec seen during quiet breathing, exercise, or breathing stimulated by hypercapnia.[31,32] As the degree of kyphoscoliosis increases, the neural output to the respiratory muscles increases; that is, occlusion pressure at 100 msec correlates positively with

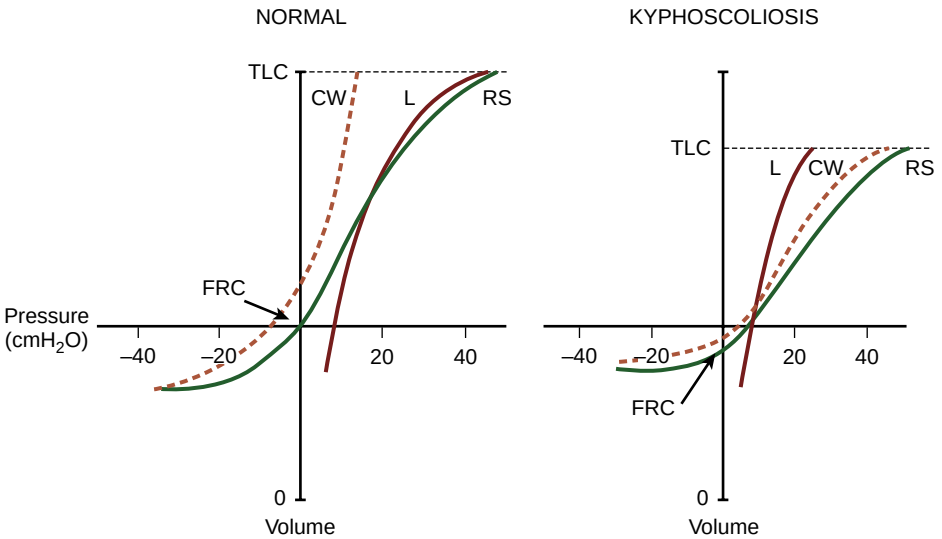

Figure 131.3 Schematic illustration of volume-pressure relationship of the *lung* (L), *chest wall* (CW), and *respiratory system* (RS) in a normal individual (left) and in kyphoscoliosis (right). Note that in kyphoscoliosis the chest wall is less compliant, leading to a reduction in *functional residual capacity* (FRC) and positioning of tidal breathing on a flatter portion of the respiratory system volume-pressure curve. TLC, total lung capacity.

the Cobb angle in these patients.[31] The increase in neural drive does not necessarily translate into increased minute ventilation because of the mechanical constraints imposed by the stiffened chest wall.

Hypoventilation is the most common breathing disorder affecting individuals with kyphoscoliosis (eFig. 131.1), and it can be particularly significant during sleep. Hypoventilation results in hypercapnia and hypoxemia and is most severe during rapid eye movement sleep when there is a reduction in neural drive to the respiratory muscles.[33,34] Of note, nocturnal hypoxemia typically predates the onset of respiratory failure, and the Cobb angle does not correlate with the magnitude of nocturnal oxyhemoglobin desaturation in these patients. Accordingly, it is important to screen for nocturnal hypoventilation with overnight oximetry even in patients with only moderate spinal deformity.[33,35,36] In addition, obstructive sleep apnea may be seen with a frequency similar to that in the general population and, if present, can further aggravate nocturnal hypoventilation.[37] (For the effects of sleep-related abnormalities on cardiorespiratory function, see "Pathogenic Aspects of Respiratory Failure in Chest Wall Diseases" later in this chapter.)

CLINICAL COURSE

Of all types of kyphoscoliosis, idiopathic kyphoscoliosis has the most benign clinical course.[2] Paralytic kyphoscoliosis may progress rapidly, largely depending on the underlying cause of neuromuscular weakness and the age of onset of the spinal deformity. An early age of onset with rapid curve progression during growth and progression after skeletal maturity increase the risk of serious respiratory complications.[38,39] Congenital kyphoscoliosis may also progress rapidly.[40]

In mild idiopathic kyphoscoliosis, the probability of developing respiratory failure with aging is similar to that in a healthy population.[2] However, the risk is higher for patients with moderate or severe deformities. Large spinal curves at presentation, skeletal immaturity, and thoracic location of the curve apex are generally considered risk factors for curve progression.[7,41] The presence of respiratory muscle weakness enhances the likelihood of developing respiratory failure.[11] In general, the spinal deformity worsens at a rate of about 1 degree of Cobb angle per year in individuals with thoracic deformities greater than 50 degrees at skeletal maturity.[41,42]

Individuals with severe idiopathic kyphoscoliosis (Cobb angles >100 degrees) should be monitored closely for respiratory complications, especially if they are middle-aged or older.[6] Initially, individuals may experience dyspnea only with exertion but, as they age and the spinal deformity progresses, dyspnea may develop even at rest.[5,6] In addition to the degree of chest wall deformity, other factors that contribute to ventilatory failure in patients with idiopathic kyphoscoliosis are inspiratory muscle weakness, sleep-disordered breathing, and airway compression caused by distortion of the lung parenchyma and twisting of airways.[5,36,43] When respiratory failure develops in a patient with kyphoscoliosis and a Cobb angle less than 100 degrees, other causes of respiratory failure should be sought, particularly treatable causes such as sleep-disordered breathing.

TREATMENT

Medical Treatment

General supportive care includes immunizations against influenza and pneumococci, smoking cessation, maintenance of a normal body weight, and physical activity to minimize deconditioning. Orthopedic braces have been used in skeletally immature individuals with idiopathic kyphoscoliosis in an effort to prevent or correct the spinal deformity. Although its efficacy is uncertain,[44,45] a brace is generally recommended for growing children with Cobb angles between 25 and 40 degrees.[2,46]

Home noninvasive mechanical ventilation is an effective treatment in individuals with severe kyphoscoliosis.[47–49] Indications for instituting noninvasive nocturnal ventilation include symptoms suggestive of nocturnal hypoventilation or signs of right heart dysfunction with either an elevated daytime arterial *partial pressure of carbon dioxide* (P_{CO_2}) or nocturnal oxygen saturation less than 88% for 5 consecutive minutes[50] (eTable 131.1). Either pressure or volume preset ventilators are effective in providing noninvasive ventilation.[51,52] Supplemental oxygen is indicated if hypoxemia persists despite correction of hypoventilation. In patients intolerant of noninvasive ventilation or unable to manage excessive bronchial secretions, tracheostomy is another option.[53]

The benefits of noninvasive ventilation are well established and include improvements in gas exchange, hemodynamic parameters, sleep architecture, number and duration of hospitalizations, quality of life, and perhaps survival[47,54–56] (eTable 131.2). Interestingly, noninvasive ventilation does not appear to improve respiratory muscle strength or endurance; instead, noninvasive ventilation may improve respiratory failure by enhancing central chemosensitivity to carbon dioxide.[57]

Surgical Treatment

In general, surgery involves fusion of the affected vertebral bodies through the posterior approach and the use of devices such as rods, wires, hooks, and pedicle screws to support the spine. This approach allows for multiplanar correction, stable fixation with less spinal fusion, and early postoperative mobilization without a cast or brace.[7] Newer techniques without spinal fusion include the use of growth-friendly rods such as expandable spinal rods, titanium rib implants, or remotely operated magnetic growth rods.[58,59] Surgery is currently recommended in individuals with skeletal immaturity and a Cobb angle greater than 45 degrees.[2] The benefits of spinal surgery on pulmonary function remain unclear.[60] Immediately following surgery, pulmonary function may be impaired as a result of rib cage trauma and changes in the chest wall caliber.[18] In the long-term, pulmonary function is more likely to improve in young children and adolescents than in adults.[6,61] In the absence of randomized controlled studies assessing the efficacy of surgery, the overall role of surgical management in restoring function and minimizing the possibility of respiratory failure is not clear.[2,7,62,63]

eTable 131.1 Indications for Instituting Long-Term Noninvasive Ventilation for Kyphoscoliosis (and Other Chest Wall Diseases)

Symptoms (e.g., fatigue, morning headaches, dyspnea) or signs of right heart dyfunction and one of the following:

- Daytime arterial P_{CO_2} ≥45 mm Hg
- Nocturnal oxygen saturation <88% for >5 consecutive minutes
- Progressive neuromuscular disease with $P_{I_{max}}$ <60 cm H_2O or FVC <50% of predicted

FVC, forced vital capacity; P_{CO_2}, partial pressure of carbon dioxide; $P_{I_{max}}$, maximal static inspiratory pressure.

Modified from Clinical indications for noninvasive positive pressure ventilation in chronic respiratory failure due to restrictive lung disease, COPD, and nocturnal hypoventilation—a consensus conference report. *Chest*. 1999;116:521–534.

eTable 131.2 Benefits of Noninvasive Nocturnal Ventilation in Chest Wall Diseases

GAS EXCHANGE
Increased arterial P_{O_2}
Decreased arterial P_{CO_2}
HEMODYNAMICS
Decreased pulmonary arterial pressure
Improved right ventricular function
MECHANICS
Reduced work of breathing
Increased maximal inspiratory pressure
SLEEP HYGIENE
Normalized sleep patterns
Fewer apneic episodes
OUTCOME
Fewer hospitalizations
Improved quality of life
Relief of dyspnea
Possible increased survival

P_{CO_2}, partial pressure of carbon dioxide; P_{O_2}, partial pressure of oxygen.

Figure 131.4 Frontal chest radiograph in a patient with a history of thoracoplasty for prior *Mycobacterium tuberculosis* infection. There is an extensive deformity of the right hemithorax consistent with prior thoracoplasty; this chest wall deformity is the likely cause of the scoliosis of the thoracic spine. L, left.

THORACOPLASTY

In the pre-antituberculous chemotherapy era, thoracoplasty was commonly used to reduce lung volume as a way to control pulmonary tuberculosis.[64] Thoracoplasty reduced lung volume by removing or fracturing ribs (Fig. 131.4), resecting the phrenic nerve, or filling the pleural space with foreign material (i.e., Lucite spheres [eFig. 131.2] oil [eFig. 131.3], and ping pong balls). Severe restrictive impairment may develop decades after the procedure, manifesting initially with dyspnea on exertion and then at rest and eventually with chronic respiratory failure.[65] The severity of the restrictive defect, which can be similar to that seen in kyphoscoliosis (see Table 131.2), may reflect a reduction in respiratory system compliance, fibrothorax, lung resection, phrenic nerve damage, scoliosis, and lung fibrosis related to prior underlying granulomatous disease.[65] Thoracoplasty is occasionally still performed to treat bronchopleural fistulas that have failed to close following decortication or persistent empyema in which decortication is not feasible or has not eradicated the infection.[64,66,67] Treatment consists of oxygen, antibiotics when appropriate, and noninvasive nocturnal mechanical ventilation.

PECTUS EXCAVATUM

DIAGNOSIS AND ETIOLOGY

Pectus excavatum is a common congenital chest wall deformity characterized by excessive depression of the sternum and its adjacent costal cartilages[68] (Fig. 131.5). It is the most common chest wall deformity, seen in approximately 0.5–2% of the population and more frequently in boys and men than in girls and women (4:1 ratio).[69] Approximately 5% of patients have a connective tissue disorder such as Marfan syndrome or Ehlers-Danlos syndrome, and 40–60% have scoliosis.[70,71] The pathogenesis of pectus excavatum is unknown.[72] A leading theory favors a developmental

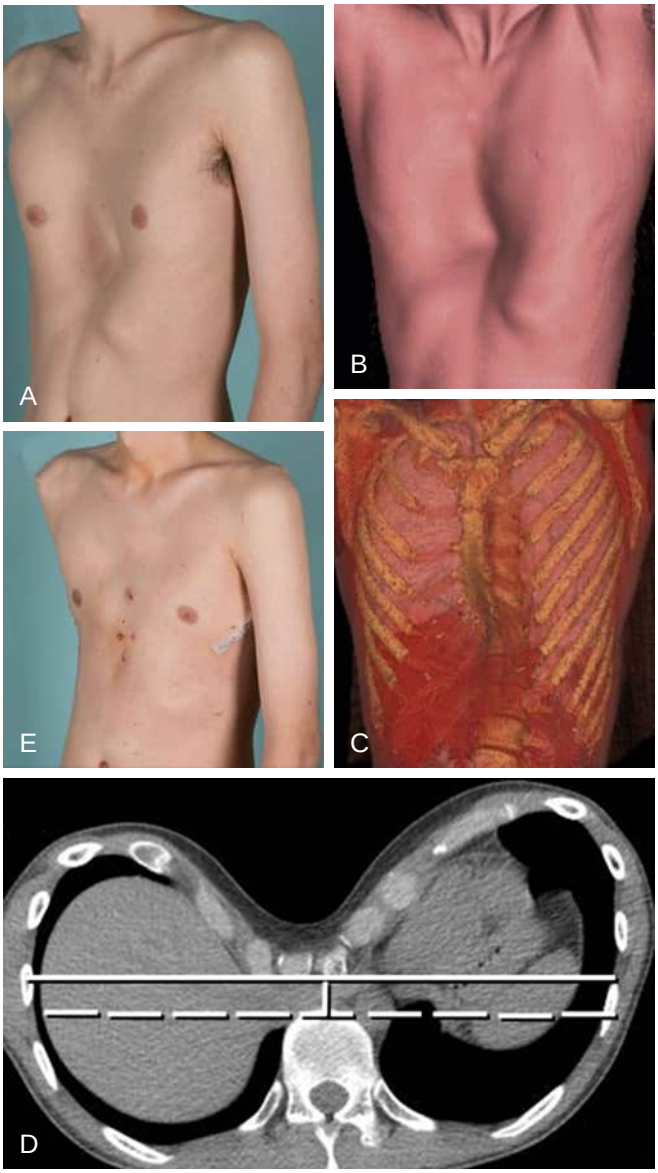

Figure 131.5 Severe pectus excavatum before and after surgery. (A) Severe pectus excavatum deformity in a 22-year-old man. (B–C) Volume-rendered computed tomography images tailored to show the cosmetic appearance of the pectus deformity (B) and to highlight the posterior sternal displacement (C). (D) Axial unenhanced chest computed tomography through the caudal sternum shows severe posterior displacement of the caudal sternum, consistent with severe pectus excavatum deformity. The pectus index, or Haller index, is calculated as the maximum transverse thoracic diameter (*solid horizontal white line*) divided by the minimum *anteroposterior* (AP) diameter (*vertical white line*). The minimum AP diameter is the distance from the posterior aspect of the pectus deformity, typically the caudal sternum or xiphoid process, to the anterior aspect of the vertebral body; the latter is typically determined by drawing a horizontal line across the anterior aspect of the vertebral body (*dashed line*), with the measurement of the minimum AP dimension intersecting this line. The calculated Haller index was 24.64; a Haller index of 3.25 or greater is considered significant. (E) The patient following surgical repair of the pectus deformity. (Courtesy D.E. Jaroszewski, MD, Consultant and Professor, Cardiothoracic Surgery, Mayo Clinic, Scottsdale, AZ.)

disorder with abnormal cartilage growth displacing the sternum inward.[72]

The magnitude of sternal deformity is best assessed by computed tomography of the chest. The transverse and anteroposterior diameters of the rib cage are measured at the level of the deepest sternal depression and are measured from the internal margins of the ribs, vertebra, and sternum. The normal ratio of the transverse to the anteroposterior diameter, also known as the Haller index, is 2.5 or less. A Haller index greater than 3.25 indicates a significant pectus deformity that may need surgical correction[73] (see Fig. 131.5).

Individuals with a significant deformity commonly have cosmetic complaints, and 30–70% of individuals may report exercise limitation or dyspnea with exertion, often out of proportion to recognized abnormalities in cardiopulmonary function.[68,74,75]

PATHOPHYSIOLOGY

Respiratory Mechanics and Exercise Capacity

Most patients with pectus excavatum have normal pulmonary function with normal mobility of the rib cage.[76] Occasionally, patients have a mild restrictive deficit, especially with concomitant scoliosis.[77,78]

Results of cardiopulmonary exercise testing are usually normal, although patients with the most severe deformities may exhibit a mild reduction in maximal work rate and oxygen consumption.[75,79,80] Although the concept is not widely accepted, right ventricular compression by the depressed sternum (Fig. 131.6 and Video 131.1) may be a mechanism contributing to exercise limitation in some individuals.[81,82]

TREATMENT

Surgical correction of pectus excavatum is usually considered for patients with a Haller index greater than 3.25 in conjunction with symptoms or evidence of cardiac or pulmonary impairment.[83,84] The modified Ravitch procedure consists of resection of costal cartilage and a sternal osteotomy, with or without fixation of the sternum by external or internal supports.[83] The Nuss procedure is currently the standard surgical practice for pectus excavatum repair in children and teenagers.[85,86] It entails placing a curved metal rod under the sternum through small incisions on each side of the rib cage. The rod is rotated under the sternum, thus forcing and holding it outward; the rod is removed after 2 to 4 years once the sternum is stabilized in its proper position.[87]

Other minimally invasive or noninvasive procedures under investigation use magnets or create a vacuum through a suction cup to pull the sternum outward and gradually correct the deformity.[88,89]

With corrective procedures, improvement of symptoms and function is difficult to predict. To date, there is no convincing evidence that correction of the deformity improves either cardiopulmonary function or exercise capacity.[75]

FLAIL CHEST

DIAGNOSIS AND ETIOLOGY

Flail chest results when double fractures of three or more contiguous ribs or combined sternal and rib fractures uncouple a segment of the rib cage from the chest wall. Consequently, the rib cage moves inward rather than outward during inspiration[90,91] (Video 131.2). Up to 25% of rib injuries result in flail chest.[92] By contrast, a "nonintegrated chest wall" refers to an unstable segment of the chest wall resulting from multiple single rib fractures to contiguous ribs that *partially* uncouples a segment of the rib cage from the chest wall.[93] Both types of rib injury may result in considerable respiratory morbidity, with 82% requiring intensive care unit admission and 59% mechanical ventilation.[92] The associated mortality can be as high as 33%.[94]

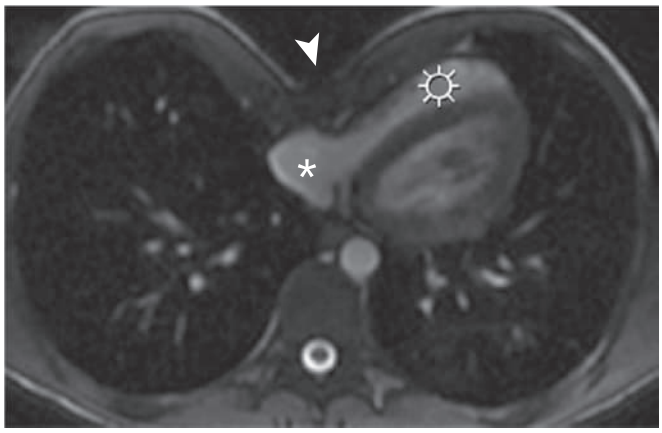

Figure 131.6 Pectus excavatum with right ventricular compression seen on magnetic resonance imaging. Steady-state free precession axial magnetic resonance images show right ventricular compression by the sternum (*arrowheads*) induced by the pectus deformity. Asterisks denote the right atrium; sunbursts denote the right ventricle. See also Video 131.1 for this patient showing cardiac motion.

The most common cause of flail chest is blunt chest trauma.[95] It is most commonly seen after automobile accidents and falls, although it may also develop after aggressive cardiopulmonary resuscitation or in patients with pathologic rib fractures.[96] Rarely, flail chest may complicate corrective rib resection or result from congenital rib abnormalities. In children, flail chest is infrequent because the chest wall is more compliant than an adult's chest wall; thus, flail chest in a child signifies a much greater degree of trauma.[97]

The diagnosis of flail chest is made by examining the rib cage and noting the characteristic paradoxical movement of a chest wall segment inward rather than outward during inspiration (Fig. 131.7 and see Video 131.2). In subtle cases, the paradoxical motion of the flail segment may be appreciated only by palpation of the chest wall, and the diagnosis of flail chest may be delayed for several days.[98] Chest radiographs can confirm the presence of multiple rib fractures; however, three-dimensional reconstruction of a chest computed tomography scan is a more sensitive technique for identifying rib fractures and the other related pulmonary injuries, such as pulmonary contusion or hemothorax.[99] In the mechanically ventilated trauma patient, the diagnosis of flail chest may not be evident until the withdrawal of sedation and resumption of spontaneous breathing.

TRAUMA AND FLAIL CHEST

The presence of flail chest following trauma signifies severe thoracic injury and is an independent risk factor for

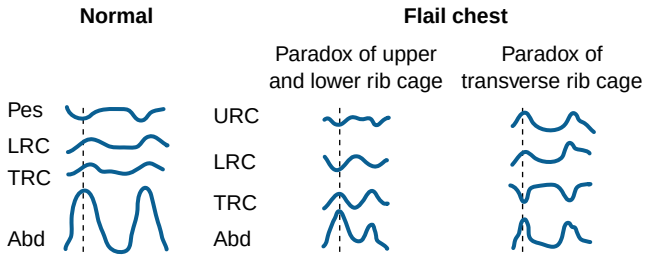

Figure 131.7 Magnetometer tracings of chest wall motion in a normal person and in two patients with flail chest. In each patient, at the point of maximal inspiration (*dashed line*), a portion of the rib cage moves paradoxically. In the patient with a paradox of the *upper rib cage* (URC) and *lower rib cage* (LRC), the upper and lower rib cage segments move inward (*downward tracing*) with outward movement of the *abdomen* (Abd) and *transverse rib cage* (TRC). In the patient with a paradox of the transverse rib cage, the transverse rib cage is the only segment moving inward with inspiration. Pes, esophageal pressure. (Modified from Tzelepis GE, McCool FD, Hoppin FG Jr. Chest wall distortion in patients with flail chest. *Am Rev Respir Dis.* 1989;140:31–37.)

respiratory failure and death.[92,100,101] In addition to flail chest, high-velocity chest injuries are associated with lung contusion, pneumothorax, hemothorax, and injuries to intrathoracic blood vessels.[92,100–102] Pain from fractured ribs can promote atelectasis, impair cough, and contribute to respiratory failure. Patients with flail chest are twice as likely to develop respiratory failure and require mechanical ventilation than patients with isolated lung contusion without flail chest.[97,101]

The presence of flail chest is a marker of increased mortality in patients with isolated chest wall trauma. Without flail chest, mortality from chest wall trauma ranges from 7–14%; with concomitant flail chest, mortality increases further.[97,101] Similarly, in patients with multiple sites of trauma, mortality is roughly 30% in those without flail chest and may be as high as 68% in those with flail chest.[97,101] The high mortality associated with flail chest is in part the result of the coexistence of other injuries such as fractures of long bones or vertebrae, head trauma, rupture of major vascular structures, or laceration of abdominal organs. Concomitant head injury and age older than 65 years are particularly poor prognostic factors in patients with traumatic flail chest.[100,103] In patients who survive the acute injury, chronic disability related to flail chest may develop. Symptoms include chest tightness, chest pain, or dyspnea on exertion. However, with operative fixation of the flail segment, even years after the injury, these symptoms can improve dramatically.[100,104]

PATHOPHYSIOLOGY

Respiratory Mechanics

Flail chest disrupts the anatomic and functional integrity of the chest wall. With flail chest, the uncoupled segment moves passively with the variations of pleural pressure. Thus, with inspiration, the decrease in pleural pressure pulls the flail segment inward; with expiration, the increase in pleural pressure pushes the flail segment outward. If the normal swings of pleural pressure are amplified by a decrease in lung compliance resulting from concomitant pulmonary contusion or atelectasis, the paradoxical motion of the flail segment becomes more pronounced.[105]

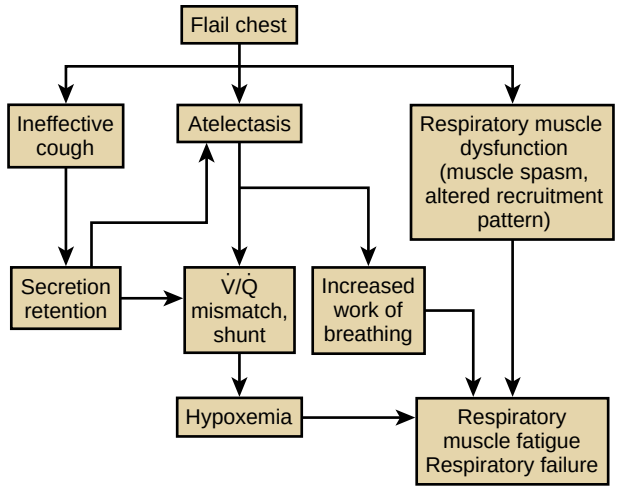

Figure 131.8 Algorithm of factors leading to respiratory failure in flail chest. Flail chest can impair cough and respiratory muscle function, which together with atelectasis and pain can lead to muscle fatigue and failure. V̇/Q̇, ventilation-perfusion.

The location of the flail segment is dependent on the site of rib fractures, with the most common location the lateral rib cage. The flail segment may move paradoxically within the rib cage itself or between the rib cage and the abdomen (see Fig. 131.7).[106] The degree of paradoxical motion also may differ at different locations. Posterior rib fractures exhibit less paradoxical motion because of splinting provided by the paraspinal muscles. Similarly, rib cage paradox may be reduced by intercostal muscle recruitment.[107,108] Different pain-induced respiratory muscle recruitment patterns may explain why some cases of flail chest remain unstable following prolonged mechanical ventilation and why lateral flail segments have a higher propensity for dislocation following surgical fixation.[109,110]

Respiratory Failure

The pathogenesis of respiratory failure in flail chest is multifactorial; hypoventilation resulting from pain, flail-induced impairment of respiratory muscle function, and concomitant lung injury all play a role. A flail segment has important physiologic consequences, even in the absence of lung contusion. First, pain impairs cough and promotes shallow tidal breathing, both of which may lead to atelectasis. Second, the flail segment impairs respiratory muscle performance by increasing the degree of muscle shortening needed for a given tidal volume and by increasing the work per breath.[106–108] Increased work of breathing, together with an inefficient use of respiratory muscles, increases the oxygen cost of breathing. When these factors are compounded by increases in elastic loads related to lung contusion or atelectasis along with hypoxemia, the respiratory muscles are predisposed to fatigue and respiratory failure or weaning difficulty ensues (Fig. 131.8).[105] Although the movement of air back and forth from the injured to the uninjured side of the chest (*pendelluft*) was once thought to be important, it is now recognized not to play a role in the pathogenesis of respiratory failure.[111]

Pulmonary Function Tests

VC and FRC are reduced immediately following the development of flail chest. VC may be reduced to 50% of

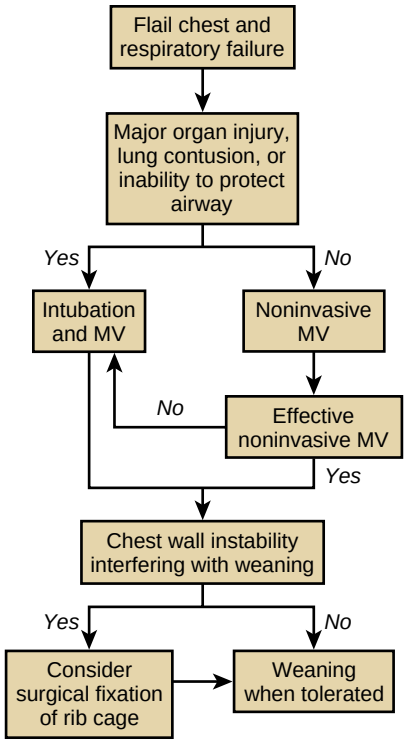

Figure 131.9 Algorithm for management of acute respiratory failure resulting from flail chest. MV, mechanical ventilation.

predicted.[98] These reductions are related to pain, disordered chest wall motion, and underlying lung contusion. In patients with flail chest without lung contusion, VC and FRC generally return to baseline values within 6 months of the acute injury.[112] In contrast, patients with flail chest complicated by lung contusion have impaired pulmonary function for up to 4 years after injury.[112] The reduced VC is likely the result of fibrosis of the contused area. Compared with conservative management, operative fixation of flail chest may be a better option to preserve pulmonary function.[110,113]

TREATMENT

General Aspects

The restoration of anatomic and functional integrity of the chest wall is key for avoiding complications related to flail chest. Surgical and nonsurgical approaches can be used to stabilize the flail segment (Fig. 131.9). Nonsurgical management is based on administration of adequate analgesia, clearing of bronchial secretions, and mechanical ventilatory assistance if needed.[114] Control of pain is crucial in averting atelectasis and achieving an effective cough. Adequate pain relief can be accomplished with oral medications, patient-controlled analgesia pumps, intercostal nerve blocks, or epidural anesthesia.[114] Adequate analgesia in combination with supplemental oxygen, effective tracheobronchial toilet, and cautious fluid replacement often results in successful treatment of flail chest and avoidance of respiratory failure. If needed, mechanical ventilation can act as a pneumatic splint to stabilize the flail segment by keeping pleural pressure positive. However, mechanical ventilation delivered through a tracheostomy or endotracheal tube solely for the purpose of providing stability to the chest wall is not recommended because of the increased morbidity and mortality associated with invasive ventilation. In contrast, positive-pressure ventilation delivered noninvasively through a nasal or face mask to patients who are spontaneously breathing and able to protect their upper airway provides an alternate means of stabilizing the flail segment.[114] Noninvasive ventilation, in conjunction with patient-controlled analgesia, improves gas exchange, allows for early patient mobilization and access for physiotherapy, and significantly reduces morbidity and mortality when compared with invasive mechanical ventilation.[115,116] If intubation and mechanical ventilation are needed, a low-impedance ventilator mode that minimizes the likelihood of generating subatmospheric pleural pressure is an optimal choice for stabilizing the flail segment and for weaning from ventilation.[106]

Surgical procedures used to stabilize a flail segment include mobilization of large chest wall flaps and insertion of devices such as medullary wires or nails, Judet struts, or titanium plates.[90,117] The few controlled studies available suggest that surgical fixation may be superior to conservative management by reducing the need for ventilatory support, reducing the length of hospital stay and days of mechanical ventilation, lowering the infection rate,[118–121] and possibly improving pulmonary function test results.[113] Although the indications are not defined, operative fixation of flail chest may be appropriate for patients who are unable to be weaned from mechanical ventilation because of chest wall instability; patients undergoing thoracotomy for concurrent injuries; or those with persistent pain, severe chest wall instability, a progressive decline in pulmonary function, or a deformity that can be repaired by fixing only one fracture per rib.[119,122,123]

ANKYLOSING SPONDYLITIS

DIAGNOSIS AND ETIOLOGY

Ankylosing spondylitis (AS) is a chronic progressive inflammatory disease involving the ligamentous structures of the spine, costovertebral, sacroiliac, and large peripheral joints.[124–126] It can be seen in 0.2–1.4% of the population and affects men more than women, whites persons more than Blacks, and up to 20% of human leukocyte antigen B27–positive persons.[127] The most common age of onset is between 15 and 25 years. Back pain, generally worse in the early morning, is a frequent symptom and may precede the diagnosis by years. Fever, malaise, and joint pain also may be present.[128,129] AS is associated with up-regulation of genes encoding the proinflammatory cytokine interleukin-17[130] and with overexpression of *tumor necrosis factor-α* (TNF-α).[131]

PATHOPHYSIOLOGY

Respiratory Mechanics

Chronic inflammation eventually leads to fibrosis and ossification of the spine (Fig. 131.10) and adjacent structures, as well as immobility of the costovertebral and sternoclavicular joints. This in concert with back pain limits rib cage mobility (Fig. 131.11).[102,126,132] Limited rib cage

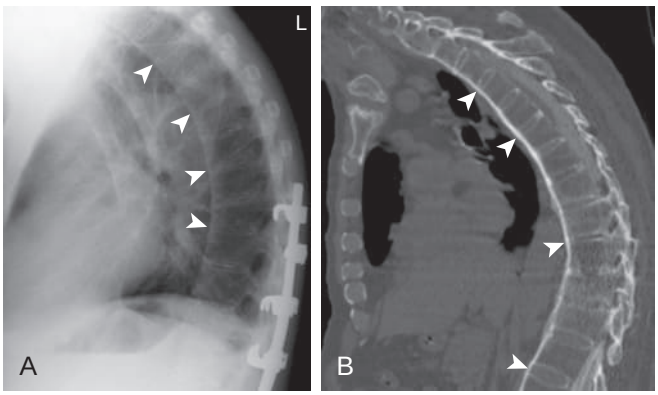

Figure 131.10 Lateral imaging of two patients with fused thoracic spine. (A) Lateral chest radiograph and (B) sagittal reformatted thoracic computed tomography myelogram from a different patient show flowing syndesmophytes (*arrowheads*) representing ossification of the outer fibers of the annulus fibrosis, bridging one vertebral body corner to another. When accompanied by longitudinal ligament ossification, fusion and kyphosis of the spine result.

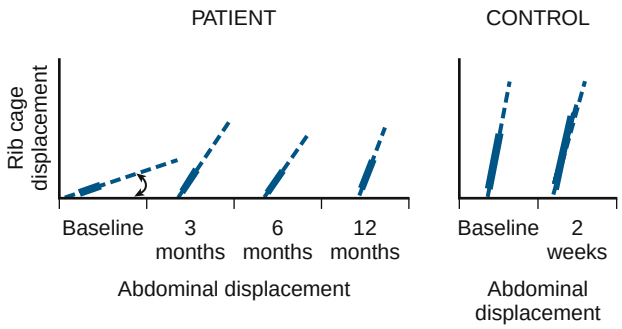

Figure 131.11 Representative plots of the rib cage and abdominal displacements during quiet breathing in a seated patient with ankylosing spondylitis, before and at various time points during therapy with anti–tumor necrosis factor-α. Note the diminished contribution of the rib cage to tidal volume at baseline and the progressive increase in the rib cage contribution to breathing with treatment, a contribution that becomes closer to the normal patterns obtained about 2 weeks apart in a healthy individual (control). (Modified from Tzelepis GE, Kalliakosta G, Tzioufas AG, et al. Thoraco-abdominal motion in ankylosing spondylitis: association with standardized clinical measures and response to therapy. *Ann Rheum Dis.* 2009;68:966–971.)

mobility, in turn, promotes lung inflation through the abdomen pathway (i.e., the lung expands along the "path of least resistance"),[133,134] resulting in a reduced contribution of rib cage expansion to breathing (from a normal contribution of 75% to tidal volume to ~50%)[135] (see Fig. 131.11). Thus, during quiet breathing, exercise, or speech, lung volume changes mostly by caudal displacement of the diaphragm and expansion of the anterior abdominal wall.[133,134,136] Consequently, transdiaphragmatic pressure increases by 2.4-fold in patients with AS at levels of ventilation at which healthy individuals increase transdiaphragmatic pressure by only 1.4-fold.[126] With advanced disease, limited rib cage mobility may lead to intercostal muscle atrophy.[126] Despite a pronounced reduction in rib cage mobility, lung compliance remains normal except in patients with fibrobullous (eFig. 131.4) or interstitial lung disease.[126,136,137]

Pulmonary and Respiratory Muscle Function

Mild restrictive lung disease may be seen in patients with AS.[138] This restriction may be caused by spinal and rib cage immobility, the presence of fibrobullous disease, or kyphosis, which may develop in up to 50% of patients with AS[139–141] and may be a consequence of osteoporosis or spinal fracture[142,143] (eFig. 131.5). Mild restriction may also be the result of back pain limiting patient performance.[144] Restriction is associated with disease activity and duration.[140]

Respiratory muscle strength may be reduced in AS, and respiratory muscle endurance may be impaired even in individuals with normal respiratory muscle strength.[126,145,146] Mild reductions in strength and endurance may be related to intercostal muscle atrophy[126] or to poor coordination or performance as a result of pain.[146,147] Patients with AS are also at risk for respiratory failure if cervical spine fractures (typically C6 or C7) cause tetraplegia.[148]

Gas Exchange and Exercise Capacity

Regional ventilation is usually normal despite the limited expansion of the rib cage.[149] A mild impairment in gas exchange may be seen (reduced diffusing capacity for carbon monoxide) in some patients, probably related to the mild reduction in lung volumes and total alveolar surface area.[139] However, when fibrobullous disease (see eFig. 131.4) is present, gas exchange may be severely compromised and arterial *partial pressure of oxygen* (Po_2) reduced.[150]

Exercise capacity may be reduced in patients with AS.[145,151] The reduction in exercise capacity may be related more to deconditioning or reduced cardiac preload than to a limitation of ventilation.[145,152] A progressive decline in exercise capacity may be significant enough to result in loss of employment.[153]

Interstitial Lung Disease

Fibrobullous upper lobe disease is present in 1–4% of patients with AS.[150] The cause of apical fibrobullous disease is unknown. Possible causes include diminished upper lobe ventilation and apical mechanical stress resulting from thoracic rigidity, as well as recurrent pulmonary infections from impaired cough. Fibrobullous disease may be unilateral or bilateral and affects male patients more than female patients. The spectrum of disease ranges from minimal upper lobe interstitial opacities to marked fibrosis, honeycombing, and cavitary lesions that may be mistaken for tuberculosis.[150] In a limited number of cases, histologic examination has revealed prominent interstitial fibrosis with hyaline and elastic degeneration of collagen and an absence of granulomas.[150] Patients are usually asymptomatic but, with severe disease, they may develop dyspnea and be at risk for spontaneous pneumothorax, aspergillosis (eFig. 131.6), or mycobacterial infection. In another 10–20% of patients with AS, nonapical interstitial lung disease develops and can be detected by high-resolution computed tomography scans of the chest.[154]

TREATMENT

Nonsteroidal anti-inflammatory drugs, together with exercise and physical therapy, are key components of

standard care.[124,155–158] Corticosteroids do not prevent progression of the disease.[159] However, the development of biologic agents represents a major advance in the treatment of AS.[160,161] The TNF-α antagonists (infliximab, etanercept, adalimumab, and golimumab) provide symptom relief, reduce spinal inflammation, and improve the quality of life in these patients.[160–162] Anti–TNF-α therapy improves rib cage mobility (see Fig. 131.11).[133] Anti–interleukin-17A monoclonal antibody has also been approved for the treatment of AS.[163] Tobacco use should be avoided. Patients should be monitored with baseline chest radiography and spirometry and should undergo repeat studies if respiratory symptoms develop. For patients treated with anti–TNF-α agents, a high index of suspicion for possible reactivation of latent tuberculosis is required.[164,165] Vertebral osteotomy may at times be performed to address spinal deformities.[166] If intubation is planned, it should be performed with caution because these patients are at increased risk for spinal cord injury given that hyperextension of a rigid cervical spine may lead to fracture and, rarely, upper airway compromise resulting from involvement with fixation of the cricoarytenoid joint. Because lung resection can be complicated by bronchopleural fistula in 50–60% of patients with fibrobullous disease,[150] this procedure is recommended only for treatment of major hemoptysis.[150]

OBESITY

DIAGNOSIS AND ETIOLOGY

The prevalence of obesity is increasing, and obesity is a recognized risk factor for many chronic diseases, including cancer and conditions affecting the lungs, heart, kidneys, and musculoskeletal system.[167] Worldwide, it is estimated that more than 600 million adults and more than 100 million children are obese, with the rate of increase of obesity in children surpassing that in adults in many countries.[167] In the United States alone, more than $300 billion in health care expenditures have been attributed to obesity, and this estimate continues to climb with time.[168] Body fat usually constitutes 15–20% of body mass in healthy men and 25–30% in healthy women. In obesity, the body fat content may increase by as much as 800% in men and 500% in women.[169] Fat-free mass also increases in obese individuals, accounting for 15–30% of the total weight gain.[170,171] Several parameters have been used to assess obesity, the most common being *body mass index* (BMI), which is calculated as the body weight in kilograms divided by the square of the height in meters (body weight/height^2). (BMI can also be calculated as the body weight in pounds multiplied by 703 and divided by the square of the height in inches.) Individuals with a BMI between 18.5 and 24.9 kg/m^2 are considered normal, persons with a BMI between 25 and 29.9 kg/m^2 are overweight, and persons with a BMI greater than 30 kg/m^2 are obese. When the BMI is greater than 40 kg/m^2, obesity is severe (morbid).[172]

When compared with persons with a normal BMI, overweight persons have a 20–40% higher risk for death, and obese persons have a 300–400% higher risk for death.[173,174] Morbidity also increases as BMI increases and is primarily related to cardiovascular and respiratory factors, with intra-abdominal fat constituting an independent risk factor for cardiovascular disease.[173,175–177]

The most frequent respiratory symptoms in obese individuals are dyspnea and exercise intolerance.[177] These symptoms may be related to abnormal pulmonary function, disordered respiratory control, and elevated levels of mediators of inflammation, such as those linking obesity to airway hyperresponsiveness[178,179] (see Chapter 61). The severity of the respiratory impairment may not correlate with the degree of obesity.

PATHOPHYSIOLOGY

Obese individuals with the same BMI may exhibit different abnormalities in respiratory function. In particular, in some obese individuals, the arterial P_{CO_2} may be normal, whereas in others with the same BMI, the P_{CO_2} may be elevated. Indeed, the level of arterial P_{CO_2} is used to distinguish obese individuals who have simple obesity (individuals who are eucapnic) from those who have the *obesity-hypoventilation syndrome* (OHS; individuals who retain carbon dioxide).[180] In addition, pulmonary function, respiratory mechanics, gas exchange, respiratory control, and exercise capacity may be significantly different in patients with simple obesity and OHS.

Pulmonary Function

In obesity, the most common abnormalities of pulmonary function are reductions in *expiratory reserve volume* (ERV) and FRC (Fig. 131.12).[181,182] For each unit increase in BMI from 20 to 30 kg/m^2, FRC and ERV decrease by approximately 3% and 5%, respectively; thereafter, for each unit increase in BMI, both FRC and ERV decrease approximately 1%.[181] Consequently, an individual with a BMI of 30 kg/m^2 can be expected to have an FRC of approximately 75% of predicted and an ERV of only 47% of predicted. The FRC is reduced by adipose tissue compressing the rib cage and abdomen, thereby reducing the outward elastic recoil of the chest wall and shifting the balance of recoil between the lung and chest wall to lower lung volumes. Because residual volume is affected to a lesser extent than FRC, ERV is preferentially reduced.[183–185] In patients with OHS, FRC and ERV may be reduced even further.[186,187]

Although total lung capacity, VC, and residual volume may be normal or only minimally reduced in individuals with simple obesity, these values may be significantly reduced (total lung capacity and VC <80% of predicted) in persons with OHS or morbid obesity (Table 131.3).[186,187] Because pulmonary function is more severely affected in OHS than in simple obesity, factors other than the BMI must be involved. The more substantial reductions in total lung capacity and VC in persons with OHS may reflect weakness of the respiratory muscles.[188] In addition, the distribution of fat may contribute to differences in lung volumes. For example, the distribution of body fat to the upper body (central fat distribution) impairs pulmonary function more than a distribution to the lower body (below the hips).[189–191] Upper body fat distribution is indicated by a waist circumference of 35 inches (89 cm) or more for women and 40 inches (102 cm) or more for men.[189–191] Diffusing capacity testing in obese patients can yield heterogeneous results; however, in general, the single-breath diffusing capacity is usually normal or increased in simple obesity (because of

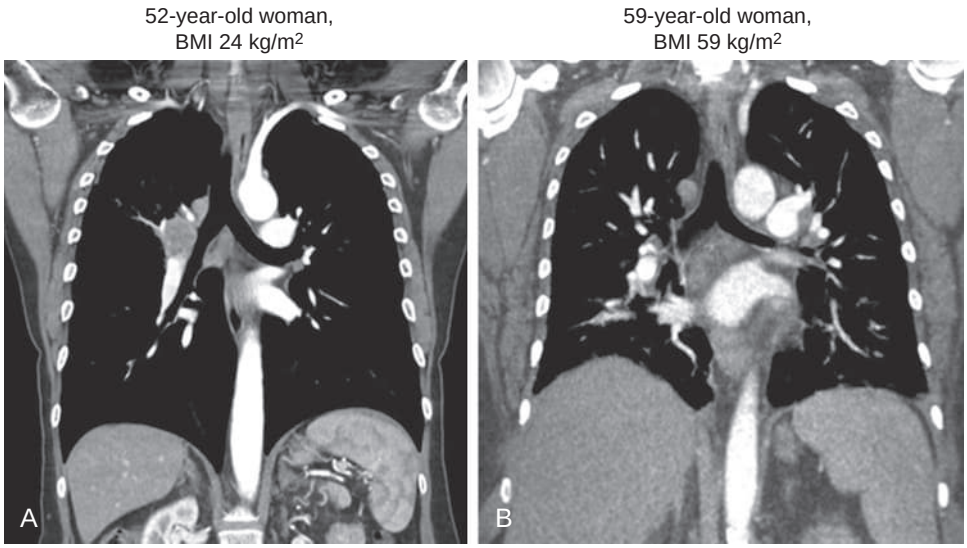

Figure 131.12 Lung volumes and obesity. Coronal computed tomography images of a nonobese person (A) and an obese individual of similar height, age and total lung capacity (B). The lung volume of the obese individual is noticeably less than that of the nonobese individual. The reason may be the added load of excess fatty tissue on the respiratory system that is most pronounced in the supine position. Typically, obesity has the greatest effect on functional residual capacity and expiratory reserve volume. BMI, body mass index.

Table 131.3 Representative Values of Respiratory Pathophysiology of Simple Obesity and Obesity Hypoventilation Syndrome

Parameter	Normal	Simple Obesity	Obesity Hypoventilation
BW (% ideal)	100	200	200
BMI (kg/m^2)	24	45	45
TLC (% pred)	100	95	80
Crs (L/cm H_2O)	0.10	0.05	0.06
Rrs (cm H_2O/L/sec)	1.2	4.0	7.8
Work of ventilation (J/L)	0.43	0.74	1.64
MVV (L/min)	160	130	90
PI_{max} (cm H_2O)	100	95	60

BMI, body mass index; BW, body weight; Crs, compliance of the respiratory system; J, joule; MVV, maximum ventilatory volume; PI_{max}, maximal static inspiratory pressure; pred, predicted; Rrs, respiratory system resistance; TLC, total lung capacity.

Modified from Rochester DF. Obesity and abdominal distention. In: Roussos C, editor. *The Thorax*. New York: Dekker; 1995:1950–1973.

increased pulmonary blood volume) and is slightly reduced in OHS. One pattern that can be seen in patients with morbid obesity–related restriction is a supranormal rate of carbon monoxide uptake from alveolar gas (also expressed as the ratio of diffusing capacity for carbon monoxide to alveolar volume), which results from a normal (or even increased) capillary blood volume passing through lungs that have incomplete alveolar expansion without compromised alveolar structure (similar to patients with other conditions limiting alveolar expansion, such as neuromuscular disease).[192,193] Results of other tests of pulmonary function, such as the ratio of forced expiratory volume in 1 second to forced VC (FEV_1/FVC ratio), maximal voluntary ventilation, and peak inspiratory flow rate, are usually normal.[186,187]

Respiratory Mechanics

Obesity reduces respiratory system compliance, primarily by lowering lung compliance (Fig. 131.13).[182,184,194–197] In simple obesity, values for respiratory system compliance are approximately 80–90% of normal and are further reduced as BMI increases or when changing from the upright to supine position.[182,194–197] In OHS, respiratory system compliance is generally less than 45% of normal.[198] The reduced compliance is likely multifactorial and depends on the degree of obesity. Studies in patients undergoing chest wall strapping (which is thought to mimic mild to moderate obesity) suggest a decreased alveolar surface compliance resulting from changes in surfactant function whereas, in more severe obesity, it is thought that the weight of adipose tissue forcing FRC and tidal breathing to low lung volumes, near residual volume, reduces lung compliance because of airway closure.[184,194,195,199] In addition, an increase in pulmonary blood volume leads to reduced lung compliance.[200] Conversely, chest wall compliance is generally normal in obesity, with a similar pressure-volume relationship as in normal individuals—only the curve is shifted to the right (see Fig. 131.13).[182,184,194] This shift is caused by excess chest wall adipose tissue and creates a threshold load by making pleural and alveolar pressure less subatmospheric or even positive at end-expiration (intrinsic positive end-expiratory pressure).[182,194] The inspiratory muscles must lower pleural pressure sufficiently to overcome intrinsic positive end-expiratory pressure before inspiratory flow ensues. The inspiratory threshold load is greater in the supine position and may account for much of the disordered chest wall mechanics in obesity.[183,194,201]

Airway resistance and total respiratory system resistance are increased in obesity primarily because of breathing at low lung volumes, where the airway diameter is lower and airway resistance is higher, with values usually twice as great as those in nonobese individuals.[197,202] However, given that airway resistance remains elevated even after normalizing for lung volume or after significant weight loss (e.g., specific airway conductance is reduced to 50–70% of normal), factors other than breathing at low lung volumes may account for some of the increase in resistance.[202–206] Increased levels of inflammation may be present in the airways of the obese patient and may promote a unique

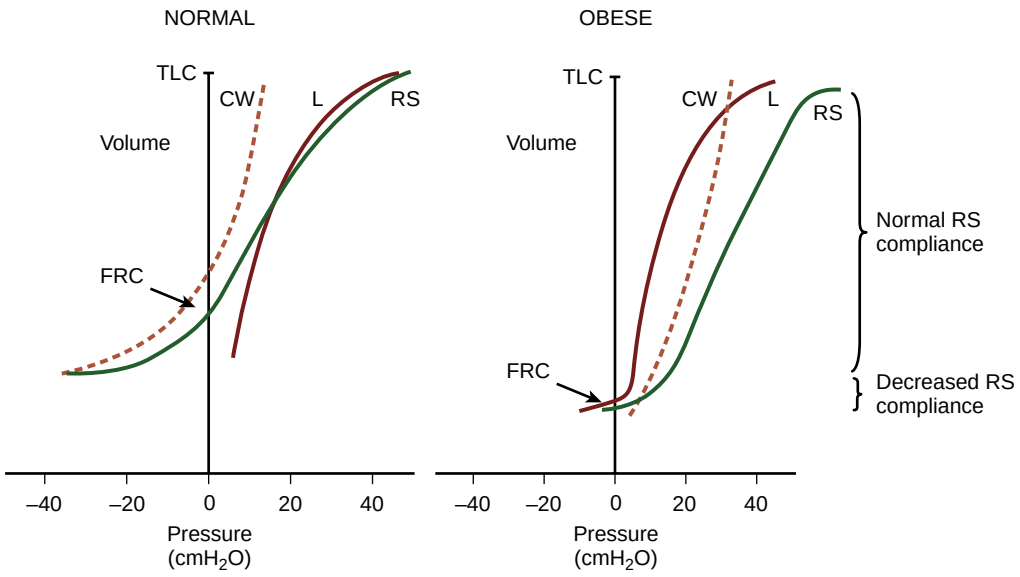

Figure 131.13 Theoretical volume-pressure curves in healthy and obese individuals. In obese persons, the *functional residual capacity* (FRC) is reset to a lower lung volume where the lung is less compliant, and tidal breathing takes place at the lower stiffer region of the respiratory system volume-pressure curve. CW, chest wall; L, lung; RS, total respiratory system; TLC, total lung capacity.

asthma phenotype, with additional airway dysfunction arising from possible proinflammatory properties of leptin (although this role remains undefined).[207–210] The normal FEV_1/FVC ratio suggests that the greatest resistance to airflow may be at the level of the small airways rather than the large airways; this view is supported by studies using impulse oscillometry.[205,211,212] The transition from the upright to the supine position may further increase airway resistance.[197] The increase in the intra-abdominal pressure when supine may further reduce FRC, thus resulting in expiratory flow limitation during tidal breathing and orthopnea in severe obesity.[182,201,213,214] The negative impact of the supine position on respiratory mechanics must be considered when evaluating obese patients for risks following general anesthesia.[215,216]

The work of breathing is increased in both simple obesity and OHS.[198,217,218] Three factors that contribute to the increase in work are increases in *elastic loads* (reductions in compliance), *threshold loads* (increases in the pressure needed to initiate inspiration), and *resistive loads* (increases in pressure needed to move air through the smaller airways).[195] The work of breathing can be up to 60% greater in simple obesity and as much as 250% higher in OHS.[198,217,218] The increased work together with a reduced efficiency of breathing increases the oxygen cost of breathing 5-fold in simple obesity and 10-fold in OHS.[192] The increased oxygen cost of breathing may place obese patients at risk for respiratory failure during states of increased ventilatory demands, such as during intercurrent illness.[218] To minimize the elastic load during inspiration and optimize the oxygen cost of breathing, obese patients adopt a rapid, shallow breathing pattern, which is more pronounced in OHS than in simple obesity.[219–222] In persons with simple obesity, the respiratory rate during quiet breathing is approximately 40% higher than in normal-weight subjects, with most of the lung volume change during tidal breathing accomplished by the rib cage rather than by abdominal displacement.[222] In OHS, however, breathing frequency is 25% higher and tidal volume 25% lower than in simple obesity.[221,223] The adverse effect of adopting a rapid, shallow breathing pattern is increased dead-space ventilation, which may contribute to carbon dioxide retention.[218,223]

Gas Exchange

In patients with simple obesity, the arterial P_{O_2} is usually normal or slightly reduced.[224] However, in patients with OHS or morbid obesity, hypoxemia is more pronounced.[186,187,224] Hypoventilation can account for hypoxemia in the setting of a normal alveolar-arterial P_{O_2} difference. Additionally, ventilation-perfusion mismatch and shunt resulting from premature airway closure can widen the alveolar-arterial P_{O_2} difference and contribute to hypoxemia.[224,225] Because of the physiologic changes described previously, hypoxemia worsens in the supine position.[182,197,225,226] The effects of these physiologic changes may be most profound in the setting of anesthesia, where the combination of these factors can lead to very rapid severe hypoxemia once the obese patient is apneic.[216,227,228] During exercise, oxygenation may improve in response to enhanced ventilation of the lung bases.[219,226] Weight loss will improve oxygenation by shifting FRC toward normal; an increase in FRC lessens the degree of airway closure during tidal breathing and improves arterial P_{O_2} roughly by 1 mm Hg for every 5 kg reduction in weight.[224] In the setting of mechanical ventilation, it has been demonstrated that appropriate adjustments in applied positive end-expiratory pressure and lung recruitment maneuvers can improve operating lung volumes, respiratory system elastance, and oxygenation.[229]

Control and Pattern of Breathing

Differences in the control of breathing may also explain why hypercapnia is found in some but not all obese individuals of similar BMI. In eucapnic obese individuals, central respiratory drive is intact. Respiratory drive—as measured by the occlusion pressure at 100 msec, ventilatory, or electromyographic responses to hypoxia or hypercapnia—is normal or even increased because of the elastic and threshold loads placed on the inspiratory muscles.[192,201,230] If the elastic and threshold loads are lessened by weight loss, the compensatory increase in ventilatory drive decreases.[231,232] In patients with OHS, however, respiratory drive is blunted, and the

occlusion pressure at 100 msec, ventilatory, or electromyographic response to hypoxia or hypercapnia is reduced.[230,233] The exact mechanism underlying the attenuated ventilatory drive in OHS is unknown. Mechanical disadvantage in OHS does not adequately explain the hypercapnia because most patients with OHS can normalize arterial P_{CO_2} through volitional hyperventilation.[234] A genetic predisposition is unlikely because ventilatory drive is intact in first-degree relatives of patients with OHS.[235] Instead, in persons with OHS, the central chemoreceptors may be "reset" because of chronic hypoxemia or hypercapnia or because of reduced leptin levels or leptin resistance. Leptin is a protein produced by adipose tissue that acts in the hypothalamus to decrease appetite, increase metabolic rate, and stimulate breathing. The development of a relative leptin deficiency or leptin resistance may contribute to diminished ventilatory responsiveness and hypercapnia in OHS.[186,236,237] Because serum leptin levels are generally increased in obesity, both in simple obesity and even more so in OHS, central resistance to leptin has been proposed.[236,237] Furthermore, these ventilatory control changes and resultant hypercapnia may be worsened by relative overproduction of carbon dioxide in patients with OHS.[238]

The increased respiratory drive in simple obesity may contribute to the sensation of dyspnea.[219,232,239] However, dyspnea is also a frequent and disabling symptom in OHS and may be related to airway disease or disordered respiratory mechanics (decreased compliance, increased airway resistance, or expiratory flow limitation).[217,219,239–242] Finally, dyspnea may result from cardiac disease, a frequent comorbid condition.

Respiratory Muscle Function

In patients with simple obesity, respiratory muscle strength is usually normal; in fact, strength may be maintained by the chronically higher elastic and threshold loads imposed on the inspiratory muscles.[197,201,242] In patients with OHS, respiratory muscle strength is usually decreased, perhaps because of deconditioning or other factors related to chronic disease.[186,242] In severely obese persons, especially those with dyspnea or OHS, diaphragm function may be impaired, especially in the supine position.[242,243] This may be related to increased intra-abdominal pressure and cranial displacement of the diaphragm.[243]

Exercise Capacity

At rest, obese persons have increased metabolic and ventilatory demands, and resting volume of oxygen inhaled per unit time can be approximately 25% higher than in nonobese subjects.[244] Given these increased demands, dyspnea scores at any submaximal work rate are higher in obese individuals.[219,245] In general, maximal work rates do not differ significantly between obese and nonobese persons, and the $\dot{V}_{O_2}$ work rate relationship is normal.[244–246] During maximal testing, a typical pattern seen in obese patients is a normal (or supranormal) peak volume of oxygen inhaled per unit time when adjusted for ideal body weight but a low peak volume of oxygen inhaled per unit time when adjusted to actual body weight (because of the increased unmeasured work being performed by an obese subject and accounting for the lower metabolic rate of adipose tissue, respectively).[246–248] In addition to the increased metabolic demands of moving relatively heavier limbs during exercise, there is evidence of a higher oxygen cost of breathing playing a small role as well.[249] The ventilatory response to exercise in obese individuals can be abnormal, and they have been shown to increase end-expiratory volume during exercise (rather than decrease it); this may serve to attenuate the expiratory flow limitation otherwise seen at lower operating lung volumes.[219] This breathing pattern may assist these persons in accommodating their higher metabolic demands and maintain relatively normal gas exchange.

TREATMENT

Weight loss is the optimal therapy but is not always attainable, and long-term weight loss maintenance is even more difficult.[250] Generally, weight loss programs emphasize diet, enhanced physical activity, and behavioral therapy as initial treatments in all obese individuals regardless of the severity of obesity. Bariatric surgery can produce not only a substantial weight loss but also long-term maintenance of weight loss.[251] It is indicated in obese individuals with a BMI of at least 40 kg/m^2 and in those with a BMI of at least 35 kg/m^2 with serious comorbidities.[250,252,253] Weight loss in obese individuals is associated with improved ERV and FRC[254,255]; however, there is no correlation between the magnitude of weight loss and the degree of improvement of lung volumes. Weight loss also may improve respiratory muscle performance,[188] resting gas exchange,[254,256] diffusing capacity (if previously morbidly obese),[224] dyspnea scores,[232,254,257] sleep apnea,[257–259] 6-minute walk test results,[254,260] airway responsiveness,[261] and respiratory drive.[232] Overall, weight reduction appears to be the most effective solution to OHS, with bariatric surgery providing the best option for managing the various comorbid conditions related to extreme obesity, such as hypertension, hyperlipidemia, cardiac dysfunction, and type 2 diabetes.[262–264]

PATHOGENIC ASPECTS OF RESPIRATORY FAILURE IN CHEST WALL DISEASES

Elastic loads imposed on the respiratory muscles are the primary causes of ventilatory failure in chest wall diseases.[105] Hypoventilation may develop acutely if the magnitude of load is excessive and there is loss of integrity of the rib cage, as in flail chest, or it may develop after a variable period of time if the load is chronic and progressive, as in kyphoscoliosis, thoracoplasty, or obesity.[105] Generally, in disorders with chronic elastic loading of the respiratory muscles, the development of respiratory failure depends on a balance between the magnitude of the elastic load and the functional status of respiratory muscles. Minimal decreases in chest wall compliance, as in pectus excavatum or in kyphoscoliosis with Cobb angles of less than 120 degrees, do not excessively overload the respiratory muscles and do not cause respiratory failure unless there is concomitant respiratory muscle weakness.[8] Similarly, when decreased distensibility of the chest wall is limited to only one of its compartments, for example, the rib cage in AS, the diaphragm adapts to accomplish lung inflation primarily through displacement of the abdomen and can thus sustain alveolar ventilation near normocapnic levels.[133,134] With excessive loads on the respiratory muscles, patients typically require a greater inspiratory

pressure to inflate the stiff chest wall with each breath.[9] In some instances, this pressure becomes a significant fraction of maximal inspiratory pressure (>50% of the maximal inspiratory pressure).[9] In this setting, the breathing pattern is altered by decreasing tidal volume and increasing respiratory frequency to decrease this greater inspiratory pressure and avoid fatigue of the respiratory muscles.[265,266] Consequently, the proportion of wasted (dead space) ventilation increases, alveolar ventilation decreases, and ultimately hypoventilation and hypercapnia ensue.[265]

Sleep-disordered breathing,[267,268] age-related decreases in chest wall compliance[269] and respiratory muscle function,[270] mechanical disadvantage of the diaphragm,[9,271,272] and underlying lung dysfunction resulting from microatelectasis[5] or, less frequently, from bronchial compression[43] by the deformed spine in severe kyphoscoliosis may significantly contribute to development of respiratory failure. The first signs of respiratory failure invariably manifest during sleep in these patients.[267,268] During wakefulness, patients with chest wall disorders typically depend on intercostal and accessory muscle activation to maintain alveolar ventilation.[11] During rapid eye movement sleep, intercostal and accessory muscle activation is inhibited and, in conjunction with a weakened diaphragm, may lead to hypoventilation.[33,34] Decreased intercostal muscle tone may further reduce FRC and in certain patients may cause chest wall instability. The supine sleep position also lowers tidal volume and worsens gas exchange because of cephalad movement of abdominal contents and displacement of the diaphragm into the thoracic cavity.[273] A mechanical disadvantage of the diaphragm can develop when the diaphragmatic muscle tension is not converted into effective pressure and when the muscle shortening is not converted into inspiratory flow; it can contribute to respiratory difficulties in patients with severe kyphoscoliosis and possibly in those with thoracoplasty and chronic flail chest.[9,271,272] This disturbance is probably related to the way the diaphragm is coupled to distorted thoracic cavity, regional differences in chest wall compliance, or rib cage muscle dysfunction. In patients with chest wall disorders, the increased work of breathing over time may lead to respiratory muscle fatigue, an altered breathing pattern with shallow and frequent breathing, and ultimately alveolar hypoventilation, development of pulmonary hypertension, right heart failure, and death.

Key Points

- Diseases that affect the chest wall, including obesity, primarily affect the respiratory system by reducing chest wall compliance. The degree to which the chest wall stiffens varies with the disease process. Individuals with kyphoscoliosis may have the greatest degree of chest wall stiffness, whereas individuals with pectus excavatum or ankylosing spondylitis may have normal chest wall compliance.
- The lung is usually an "innocent bystander" in the sense that it is usually not primarily affected by a pathologic process. When restrictive chest wall disorders limit full inflation of the lung, however, microatelectasis can lead to a reduction in lung compliance and impaired gas exchange.
- Of the chest wall disorders, flail chest is most likely to precipitate acute respiratory failure, whereas kyphoscoliosis and severe obesity are most likely to lead to chronic ventilatory failure, pulmonary hypertension, and right heart dysfunction. Coincident inspiratory muscle weakness in any of these disorders will further worsen restrictive pathophysiology and predispose persons to respiratory failure.
- Acute respiratory failure may complicate flail chest and can be treated initially with positive-pressure ventilation. In some patients with flail chest, surgical fixation of the flail segment may reduce the duration of mechanical ventilation and improve long-term pulmonary function.
- Chronic respiratory failure, which can be seen in kyphoscoliosis or with severe obesity, can be successfully managed with noninvasive nocturnal positive-pressure ventilation. This type of ventilation has markedly improved morbidity and mortality in this group of individuals.

Key Readings

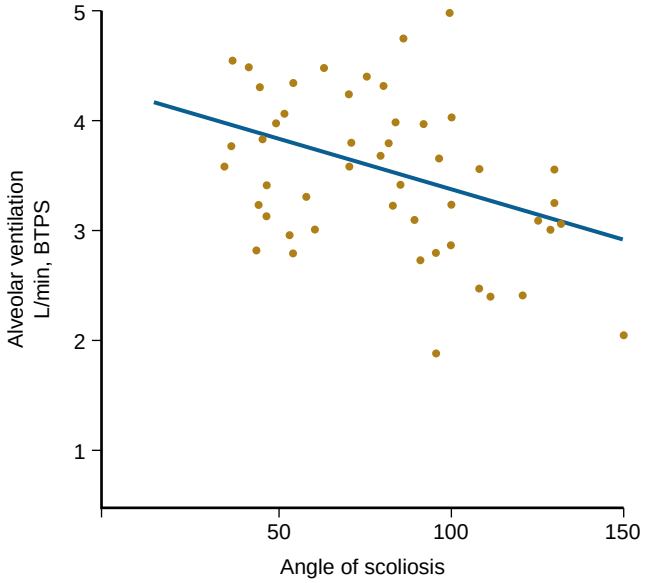
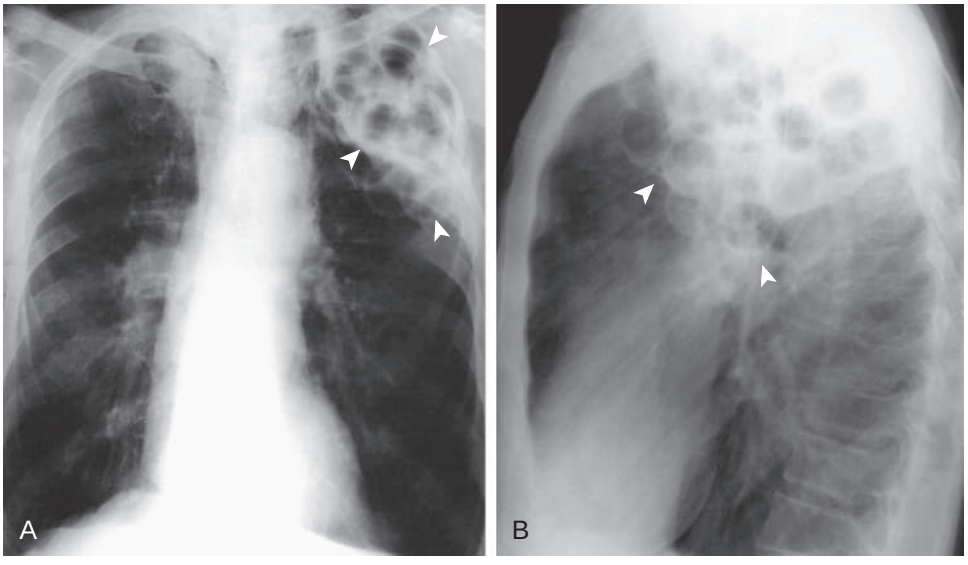
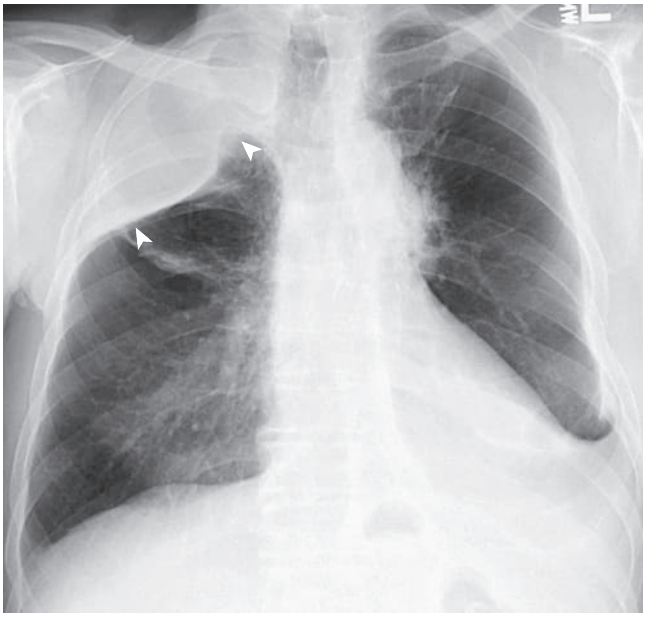
eFIGURE IMAGE GALLERY



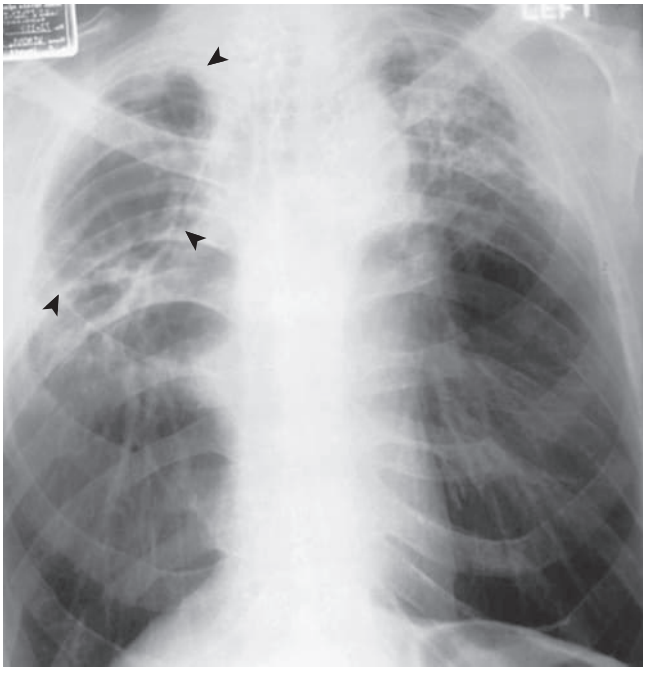
eFigure 131.1 The relationship between alveolar ventilation and angle of scoliosis in patients with idiopathic kyphoscoliosis. Note the decrease in alveolar minute ventilation below normal level (≈4.2 L/min) with the increasing angle of scoliosis. These measurements were made with the subjects awake. BTPS, body temperature, ambient pressure, saturated with water vapor. (Modified from Kafer ER. Idiopathic scoliosis. Gas exchange and the age dependence of arterial blood gases. *J Clin Invest.* 1976;58:825–833.)



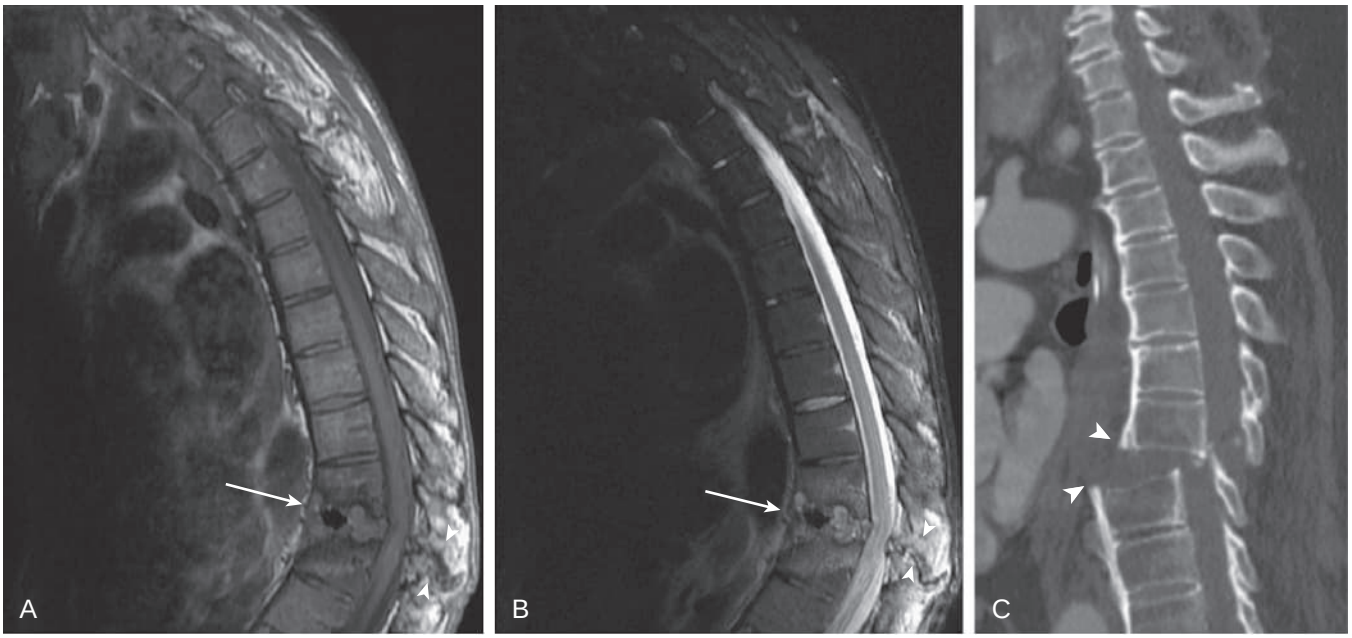
eFigure 131.2 Lucite sphere plombage seen on chest radiographs. (A) Frontal and (B) lateral chest radiographs show regular lucencies (*arrowheads*) representing Lucite sphere plombage in a patient with prior left upper lobe *Mycobacterium tuberculosis* infection.



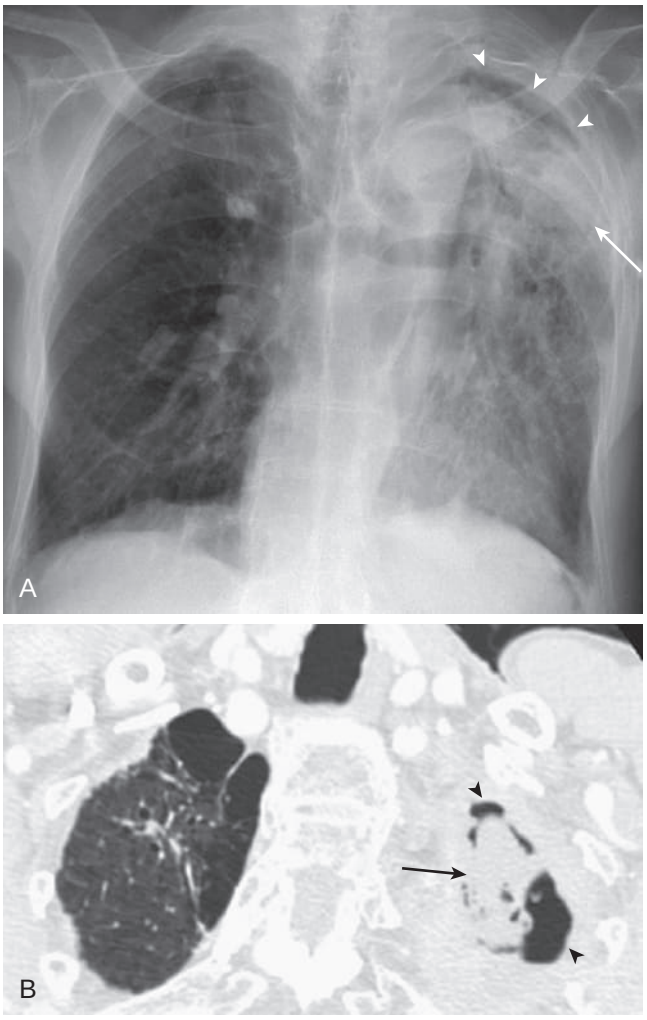
eFigure 131.3 Oleothorax seen on frontal chest radiograph. A homogeneous right upper thoracic opacity (*arrowheads*) represents extraparenchymal oil injection as a form of pulmonary collapse therapy in a patient with *Mycobacterium tuberculosis* infection.



eFigure 131.4 Ankylosing spondylitis: upper lobe fibrobullous disease on frontal chest radiograph. A thin-walled cystic structure in the right upper lobe (*arrowheads*) is associated with upper lobe fibrosis bilaterally, evidenced by bilateral hilar retraction and architectural distortion.



eFigure 131.5 Ankylosing spondylitis: fused thoracic spine complicated by fracture seen on sagittal magnetic resonance and computed tomography scans. Sagittal (A) T1-weighted and (B) T2-weighted magnetic resonance imaging shows an irregular intermediate and centrally low signal (*arrow*) extending transversely through the intervertebral disc space, associated with kyphosis centered at this level. Note that the injury extends into the posterior elements (*arrowheads*); this pattern of spinal fracture is common in ankylosing spondylitis. (B) The T2-weighted image shows increased signal in the involved vertebral bodies consistent with bone marrow edema, and it also reveals spinal cord compression. (C) Sagittal reformatted image from a thoracic computed tomography scan in a different patient shows a similar three-column fracture pattern, although more severe, complicated by distraction and displacement; note the anterior widening of the intervertebral disc space (*arrowheads*)



eFigure 131.6 Ankylosing spondylitis: fibrobullous disease complicated by mycetoma on chest radiograph and computed tomography. (A) Frontal chest radiograph in a patient with ankylosing spondylitis and upper lobe fibrobullous disease shows an irregular masslike opacity at the left lung apex (*arrow*), with lucency (*arrowheads*) along the cranial margin of the opacity. (B) Axial thoracic computed tomography displayed in lung window confirms the presence of the opacity (*arrow*) within the cavity (*arrowheads*) in the left apex, consistent with mycetoma.

INTRODUCTION

Respiratory failure exists when the respiratory system cannot maintain gas exchange, causing dysfunction in other organs or threatening life. Such impairment primarily affects oxygenation, manifested by hypoxemia, or ventilation, manifested by hypercapnia and respiratory acidosis. This chapter deals with this latter circumstance, commonly called ventilatory failure.

Carbon dioxide (CO_2) tension in the arterial blood (arterial P_{CO_2}) is a function of *alveolar ventilation* ($\dot{V}_A$) and CO_2 production, according to the following relationship:

$$\text{arterial } P_{CO_2} = (\dot{V}_{CO_2} \times k) / \dot{V}_A \qquad \text{(Eq. 1)}$$

Total minute ventilation is the sum of both $\dot{V}_A$ and dead space ventilation, shown as minute ventilation = $\dot{V}_A$ + dead space ventilation. Either a decrease in total minute ventilation or an increase in dead space ventilation can thus decrease $\dot{V}_A$. Any decrease in $\dot{V}_A$ or increase in $\dot{V}_{CO_2}$ relative to $\dot{V}_A$ results in an increase in arterial P_{CO_2}. Because bicarbonate retention by the kidneys in response to hypercapnia is slow, a sudden increase in arterial P_{CO_2} will not be buffered quickly by bicarbonate and thus will abruptly lower arterial pH. Ventilatory failure exists whenever arterial P_{CO_2} is substantially elevated, and acute ventilatory failure is present when the change from the patient's baseline state develops rapidly enough to produce a clinically important drop in arterial pH. Because patients with severe COPD, chronic neuromuscular disease, and other disorders may already have hypercapnia at baseline, the presence of a component of acute (acute-on-chronic) ventilatory failure is determined not so much by the arterial P_{CO_2} value as by the presence of acidemia, typically to an arterial pH of less than 7.35. The presence of acute ventilatory failure cannot be determined accurately by physical examination, pulse oximetry, exhaled CO_2, or other noninvasive tests. Thus, making the diagnosis requires arterial blood gas analysis.[1]

PATHOPHYSIOLOGY

Alveolar ventilation becomes inadequate in relation to CO_2 production either because of a failure of the patient's

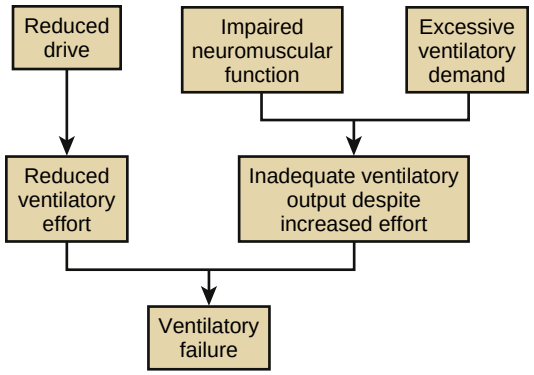

Figure 132.1 The physiologic mechanisms of acute ventilatory failure. The two major causes of acute ventilatory failure are either a reduced ventilatory effort or a reduced ventilatory output despite increased effort.

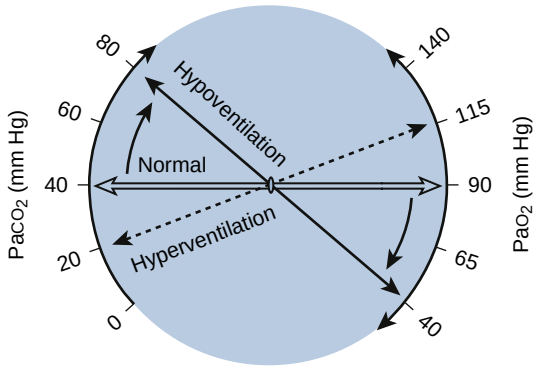

Figure 132.2 Relationship between arterial P_{O_2} and arterial P_{CO_2}. There is a reciprocal relationship between arterial oxygen pressure (arterial P_{O_2}) and arterial carbon dioxide pressure (arterial P_{CO_2}) as ventilation increases or decreases, assuming that the (A–a)P_{O_2} difference does not change and the respiratory exchange ratio is 0.8. (Modified from Pierson DJ, Kacmarek RM, eds. *Foundations of Respiratory Care*. New York: Churchill Livingstone; 1992:298.)

ventilatory capability (pump failure) or ventilatory effort (drive failure)[2,3] (Fig. 132.1). These two mechanisms are distinct in their clinical presentations. Patients with acute failure of the ventilatory pump are dyspneic and tachypneic with other signs of distress, whereas patients with failure of ventilatory drive are not short of breath and typically demonstrate bradypnea or apnea.

Although acute ventilatory failure is primarily a disorder of alveolar ventilation, hypoxemia is also usually present. Alveolar hypoventilation causes a proportional fall in *alveolar oxygen pressure* (alveolar P_{O_2}), according to the alveolar gas equation:

$$\text{alveolar } P_{O_2} = P_{I O_2} - (\text{arterial } P_{CO_2}/R) \quad \text{(Eq. 2)}$$

where arterial P_{CO_2} is assumed to be nearly the same as alveolar P_{CO_2}, P_{IO_2} is the inspired P_{O_2} (i.e., the inspired oxygen fraction multiplied by the difference of barometric pressure and 47 [water vapor pressure in mm Hg at body temperature]), and R is the respiratory exchange ratio. This relationship explains the fall in arterial P_{O_2} that accompanies alveolar hypoventilation, as shown in Figure 132.2.[2] Calculating alveolar P_{O_2} using Equation 2 permits determination of the *alveolar-arterial oxygen pressure difference* [(A−a)P_{O_2}] (commonly but imprecisely called the A–a gradient and, more precisely, the A–a oxygen tension difference). This calculation distinguishes between pure hypoventilation as an explanation for hypoxemia (in which case, (A−a)P_{O_2} is normal) and the presence of other mechanisms such as low *ventilation-perfusion* ($\dot{V}/\dot{Q}$) ratios and right-to-left shunt (in which case, (A−a)P_{O_2} is increased).

Finally, hypercapnia can be a feature of hypoxemic respiratory failure if the derangement in gas exchange is sufficiently severe. Both right-to-left shunt and low $\dot{V}/\dot{Q}$ ratios are present in *acute respiratory distress syndrome* (ARDS) and can increase dead space/tidal volume ratios,[4] thus impairing CO_2 elimination and contributing to hypercapnia.

Table 132.1 classifies the typical clinical presentations of acute ventilatory failure according to the site or type of defect and the physiologic mechanism or category of disorder responsible. Not every listed example is discussed here.

More than one mechanism may coexist in a given patient, producing a life-threatening condition even when the individual processes are only moderate in severity. For example, in decompensated obesity-hypoventilation syndrome, a patient whose underlying respiratory drive is reduced and whose obesity poses an increased elastic load on the ventilatory pump may develop acute-on-chronic ventilatory failure in the presence of a relatively modest increase in the work of breathing from an additional restrictive effect of cardiomegaly and pleural effusions.

INSUFFICIENT VENTILATORY DRIVE

CONGENITAL CAUSES

Congenital disorders associated with diminished hypoxic or hypercapnic ventilatory drive include primary alveolar hypoventilation (or Ondine's curse),[5] Prader-Willi syndrome,[6,7] hypogonadism treated with exogenous testosterone,[8] and Arnold-Chiari malformation.[9] These disorders contribute to the development of acute ventilatory failure through diminished ventilatory drive, often in combination with other contributing mechanisms (such as acute infection), and are most often seen in pediatric settings.

ACQUIRED CAUSES

Decreased ventilatory drive is a frequent contributor to the development of chronic ventilatory insufficiency but is typically not the sole mechanism for acute ventilatory failure, except for patients with drug-induced suppression.

PHARMACOLOGIC CAUSES

Depression of the drive to breathe by drugs is by far the most common circumstance of acquired acute ventilatory failure. Opioids are potent depressors of both hypoxic and hypercapnic ventilatory drive; however, most sedative, hypnotic, or anxiolytic agents cause respiratory depression if administered in sufficient quantity.[10] With the current epidemic of opiate overdoses, hospitals have seen a substantial increase in *intensive care unit* (ICU) admissions and deaths due to ventilatory failure. In one large database accrued from a consortium of 162 hospitals, ICU admissions due to opiate overdoses increased by 34% between 2009 and 2015, with a concomitant increase in ventilator use and mortality.[11] More recently, deaths due to opiate overdose have continued to rise, reaching almost 70,000 in 2018.[12] Two-thirds of these were due to synthetic opioids, and most of these were related to intravenous injection of

Table 132.1 Clinical Classification of Ventilatory Failure by Site

Site of Defect	Mechanism or Type	Clinical Examples
VENTILATORY DRIVE	Congenital	Primary alveolar ventilation (Ondine's curse)
	Acquired	Drug overdose (opioids, sedatives, alcohol); propofol; cerebrovascular accident; neoplasm; carotid body resection
	Combination	Obesity-hypoventilation syndrome; myxedema
NEURAL TRANSMISSION		
Spinal cord	Trauma	Cervical spinal cord injury
	Vascular	Vascular accident
	Tumor	Primary or metastatic
	Other	Poliomyelitis; amyotrophic lateral sclerosis
	Demyelinating	Acute idiopathic demyelinating polyneuropathy (Guillain-Barré syndrome)
Peripheral nerves	Phrenic nerve lesion	Trauma; cardiac surgery; neoplasm; idiopathic
Neuromuscular junction	Autoimmune	Myasthenia gravis
	Infectious/toxins	Botulism, tetanus, tick paralysis
	Pharmacologic	Neuromuscular blocking agents
Neuromuscular	Critical illness	ICU-acquired weakness, ventilator-induced diaphragmatic dysfunction
VENTILATORY MUSCLES	Congenital	Muscular dystrophy
	Autoimmune	Polymyositis; dermatomyositis
	Acquired	Hypophosphatemia; hypokalemia; hypomagnesemia; myxedema
THORACIC		
Vertebrae and rib cage	Decreased mobility	Kyphoscoliosis; tight casts or bandages; ankylosing spondylitis; flail chest
Soft tissues	Extrapulmonary restriction and decreased mobility	Severe obesity
Pleura	Extrapulmonary restriction	Pneumothorax; pleural effusion; pleural thickening; malignancy
AIRWAYS		
Upper	Obstruction	Epiglottitis, foreign body, tumor, vocal cord paralysis, tracheomalacia
Lower	Obstruction	COPD, acute severe asthma
PARENCHYMA	Increased dead space and very high $\dot{V}/\dot{Q}$	COPD
	Very low $\dot{V}/\dot{Q}$; shunt	Severe ARDS
PULMONARY CIRCULATION	General hypoperfusion	Hypovolemic or cardiogenic shock, CPR, pulmonary hyperinflation (intrinsic PEEP)
	Localized hypoperfusion	Pulmonary thromboembolism; venous air embolism
OTHER	Increased CO_2 production (inflammation; hypermetabolism; muscle activity)	Fever; sepsis; burns; severe trauma; shivering; tetany; seizures; malignant hyperthermia
	Exogenous CO_2 inhalation	Laboratory or industrial accident; therapeutic use; rebreathing

ARDS, acute respiratory distress syndrome; CPR, cardiopulmonary resuscitation; PEEP, positive end-expiratory pressure; $\dot{V}/\dot{Q}$, ventilation-perfusion ratio.

fentanyl synthesized illegally with a potency in reducing respiratory drive varying between 50 and 100 times that of morphine. This has led to an epidemic of opioid-related deaths that have risen rapidly during the past decade.

Propofol is another potent respiratory depressant used commonly for sedation during procedures or during mechanical ventilation that must be dosed with caution and monitored closely in patients breathing spontaneously.[13] Respiratory depression resolves as the drug is cleared from the body or is pharmacologically antagonized, as signaled by the return of spontaneous breathing efforts. Because the central nervous system effects of some agents may wax and wane due to the enterohepatic circulation, lipid storage, or other mechanisms, patients should be observed until it is clear that the respiratory drive has been reestablished before they are weaned from ventilatory support. In the case of drug overdoses and other poisoning, identifying the specific agent or agents involved and the use of any specific therapies available, such as antidotes or dialysis, is important to expedite the weaning process from ventilatory support.[10] With the current epidemic of opiate overdoses, community-based naloxone distribution and training in its administration is a public health priority aimed at early reversal of opiate-induced respiratory depression to avoid ICU admissions and deaths.[14] Patients who fail to wean from mechanical ventilation because of inadequate drive from depressant drugs breathe slowly or not at all when ventilatory support is briefly discontinued. The much more common reason for difficulty weaning after drug overdose is that other mechanisms (e.g., aspiration pneumonia or sepsis) intervene. In these circumstances, with a return of respiratory drive, patients become tachypneic and manifest signs of respiratory distress when ventilatory support is discontinued.[15]

OTHER ACQUIRED CAUSES

Myxedema[16,17] may present with hypercapnia related to acquired depression of ventilatory drive, and hypothyroidism may be a cofactor when patients present with

worsening hypercapnia. Thyroid function testing should be done routinely in patients with new or worsening hypercapnia, especially when a clear physiologic explanation is inapparent. Patients with underlying abnormalities of ventilatory drive who develop respiratory infections, congestive heart failure, or other acute illnesses are more likely to develop acute ventilatory failure compared with individuals without such defects.

Obesity hypoventilation syndrome, discussed in Chapters 121 and 136, is characterized by blunted responses to hypoxia and hypercapnia[18] and is one disorder in which patients may first present in acute ventilatory failure. Typically, such patients have a history of recent weight gain and are found to be markedly fluid overloaded, with features of right heart dysfunction. The increased work of breathing from decreased chest wall compliance, cardiomegaly, and often large pleural effusions, as well as worsening hypoxemia, all contribute to respiratory muscle fatigue and the development of severe hypercapnia and respiratory acidosis. Hypoventilation and acute ventilatory failure related to obesity are more common among hospitalized patients with severe obesity than has previously been reported.[19,20] As the prevalence of obesity increases, ventilatory failure from decompensation of the obesity-hypoventilation syndrome is likely to be encountered more frequently.[19]

Acute stroke is another setting in which disordered ventilatory drive may contribute to acute ventilatory failure, even though other processes are usually present, especially the inability to protect the airway and clear respiratory tract secretions.[21,22] The prognosis of patients with ischemic and hemorrhagic strokes who require intubation and mechanical ventilation is poor both in the short and long term, with a survival rate of 50% at 30 days and 30% after 1 year.[21,23,24] Prognosis is especially unfavorable after basilar artery occlusion due to the depressant effect on respiratory drive as well as the swallowing impairment and problems with secretion clearance seen with brainstem injury.[25]

As guidelines for the early management of patients with acute ischemic stroke continue to evolve with the development of improved pre-hospital care, in-hospital stroke teams, and advancing treatment options with intravenous and intra-arterial therapies, American Heart Association guidelines recommend mechanical ventilation for patients with acute stroke if needed.[26] This necessitates an ethical discussion with the patient and/or family to determine the patient's wishes regarding aggressive support (see Chapter 141).

PRINCIPLES OF MANAGEMENT

Because the underlying physiologic defect is inadequate ventilatory drive despite a presumably normal ventilatory pump, management focuses on restoring normal alveolar ventilation. Although *noninvasive ventilation* (NIV) is being applied in an increasing number of clinical settings to augment alveolar ventilation, its utility lies mainly in supporting ventilation in patients with normal or augmented respiratory drive and failure of the ventilatory pump, whereas endotracheal intubation is generally necessary following acute failure of respiratory drive. NIV can be quite effective in treating chronic congenital or acquired central hypoventilation in outpatients but, in the setting of acute loss of respiratory drive, invasive mechanical ventilation restores alveolar ventilation more rapidly and reliably and is more effective for airway protection and secretion clearance than is NIV.

Because of the patient's impaired ventilatory drive, a ventilator mode that provides full support with a backup rate, such as volume-targeted assist-control ventilation, should be chosen initially. In the absence of acute respiratory distress syndrome or severe airflow obstruction, ventilator settings should be chosen to aim for values of arterial pH and arterial P_{CO_2} in the normal range, and supplemental oxygen should be supplied (with *positive end-expiratory pressure* [PEEP] if necessary) to maintain normal arterial P_{O_2}. Unless there are serious coexisting pulmonary conditions, weaning should be carried out as soon as ventilatory drive is restored. Extubation is probably safe if the patient has a spontaneous cough, does not require frequent suctioning, and is judged to be able to protect the airway, even if alertness remains impaired.[27] This has been controversial, though, because extubation failure rates have been high in some studies,[28] and more sophisticated scoring systems have been proposed to determine what patients are candidates for extubation.[29]

NEURAL TRANSMISSION IMPAIRMENT (see Chapter 130)

CERVICAL SPINAL CORD INJURY

Injury to the upper cervical spinal cord may interrupt transmission of the stimulus to breathe from the respiratory centers in the brainstem to the diaphragm and other ventilatory muscles, depending on the injury level. Because the phrenic nerve roots supplying the diaphragm arise from spinal segments C3 to C5, patients with acute injury at this level or above usually require ventilatory assistance. Patients with C1–C2 spinal injury levels are permanently ventilator dependent, whereas those with C3–C4 injuries may eventually achieve at least partial ventilator independence. Lesions below C4 are usually compatible with unassisted ventilation unless there are complicating processes such as intrinsic lung disease or impaired mental status.

Adverse physiologic effects can happen within the first days or weeks after the injury, including loss of lung volumes and inability to take deep breaths (which predisposes to atelectasis), inability to cough normally (which predisposes to the development of pneumonia and complicates its management), and impaired hypoxic pulmonary vasoconstriction (which predisposes to severe and often refractory hypoxemia after atelectasis or pneumonia).[30] These effects depend on the level of injury, being more frequent with lesions above C4, and on the degree of injury, being more frequent with complete, than with incomplete, lesions.[31]

The short-term prognosis of spinal cord lesions is generally related to the level of the injury,[30] even though some retrospective studies have shown that both mortality[32,33] and ICU length of stay[30] are more strongly influenced by the development of pneumonia and other respiratory complications than by the specific cord injury level.

Although there are reports of initial management of patients with high cervical spinal cord injury (C3–C4 or higher) with NIV,[34] great expertise is required to avoid aspiration and other complications. Decisions about NIV should be made on a case-by-case basis[31]; in most centers, invasive ventilatory support is preferable, at least initially. Phrenic nerve[35–37] or diaphragm pacing,[38] permitting extubation or removal of the tracheostomy tube (decannulation), has also been reported in the later period following injury. The eventual ability to wean from ventilatory support and to undergo decannulation from tracheostomy are major determinants not only of survival but also of quality of life for patients with cervical spinal cord injury.[30,32]

MOTOR NEURON DISEASE

Amyotrophic lateral sclerosis (ALS) and other motor neuron diseases demonstrate a variable but progressive weakness of the bulbar and ventilatory muscles. This progression determines the course of ventilatory failure and pulmonary complications, which represent the most common cause of death in these patients.[39,40] Most often, ventilatory muscle weakness develops gradually after the diagnosis is already well established; therefore, repeated assessments during outpatient evaluation are useful to monitor the progression of ventilatory muscle impairment.[39–43] This permits intervention with NIV or, less often, tracheostomy before the onset of acute ventilatory failure. However, some cases present with acute ventilatory failure as the initial manifestation of the disease.[44]

Elective initiation of noninvasive ventilation has become a standard of care in motor neuron disease patients with progressive ventilatory impairment because it improves both quality of life and survival rate[42,43,45] in patients without significant bulbar involvement. NIV has been successful not only in the chronic, slowly progressive setting, but also in acute ventilatory failure complicating ALS.[46] However, bulbar weakness and a high risk of aspiration make invasive mechanical ventilation a preferred choice for ALS patients with acute ventilatory failure, at least initially. With appropriate counseling about end-of-life planning, only a small proportion of patients in the United States with ALS receive invasive mechanical ventilation, and presentation to an emergency department with acute ventilatory failure should be unusual.[47] Other cultures may take different approaches to use of tracheostomy for ALS. In a survey, 53% of Japanese caregivers favored tracheostomy compared to only 33% in the United States.[48]

INJURY OR DISEASE AFFECTING THE PHRENIC NERVE

Loss of diaphragm function leading to ventilatory failure is often due to spinal cord injury, immunologic diseases (such as Guillain-Barré syndrome or multiple sclerosis), or neuropathy (ALS, Charcot-Marie-Tooth). Unilateral paralysis of the diaphragm leading to ventilatory failure may be a result of phrenic nerve injury or disease. Its presentation ranges from an incidentally discovered radiographic abnormality without clinical impact to acute ventilatory failure requiring long-term mechanical ventilation, although the latter is quite unusual and generally due to multiple factors.[36,49] In the past, unilateral diaphragmatic palsy following phrenic nerve injury was most often caused by cold cardioplegia (phrenic frostbite) during open-heart surgery or direct injury during internal mammary artery harvesting.[50] Since routine use of insulation for the phrenic nerves during cardiac surgery, this complication is now rare, but unilateral or bilateral phrenic nerve palsies are still seen as a consequence of direct invasion by neoplasm, infectious diseases (such as herpes zoster and Lyme disease), metabolic peripheral neuropathy (diabetes or porphyria), and radiotherapy.[51] Although acute ventilatory failure as a consequence of bilateral diaphragmatic paralysis is unusual, these patients are much more symptomatic than those with unilateral paralysis and usually have severe orthopnea.

IMMUNOLOGIC NEUROPATHIES

Guillain-Barré syndrome, now known as *acute idiopathic demyelinating polyneuropathy* (AIDP), is an autoimmune polyneuropathy that accounts, together with myasthenia gravis, for the majority of admissions for ventilatory failure due to neuromuscular impairment.[52–57] Therapy with intravenous immunoglobulin and plasmapheresis improves outcomes in AIDP, although 2–10% still die, and up to 20% of individuals who survive remain seriously disabled.[58] Theoretically, death should be preventable in the vast majority of patients with this disease because mortality is primarily from potentially avoidable respiratory complications (see the discussion in Chapter 130). Although the 20/30/40 rule (FVC <20% predicted, maximum inspiratory pressure <30 cm H_2O, and maximum expiratory pressure <40 cm H_2O) is still commonly used, prediction of the need for mechanical ventilation can be challenging, especially in patients with swallowing difficulty, and close observation of these patients in an ICU is mandatory.[57,59,60]

NEUROMUSCULAR JUNCTION IMPAIRMENT

Immunologic Disease

Myasthenia gravis (MG) is less common than AIDP as a cause of acute ventilatory failure, although 15–20% of myasthenic patients experience a crisis during their lifetime. These events usually happen in patients with an established diagnosis of MG. With adequate therapy (plasmapheresis and intravenous immunoglobulin) and respiratory support through noninvasive or invasive mechanical ventilation, mortality is 5–10%.[61,62] Isolated ventilatory muscle weakness requiring mechanical ventilation has been reported as the initial manifestation of the disorder.[52]

Infectious Disease

Botulism remains an infrequent but important cause of acute ventilatory failure worldwide. In western countries, the incidence of ventilatory failure due to food-borne illness has been unusual but steady in recent decades, with about 23 cases per year in the United States.[63] The vast majority of patients with botulism manifest respiratory symptoms, and up to 75% of individuals develop clinically

significant respiratory failure due to progressive, symmetrical, descending flaccid paralysis, requiring mechanical ventilation.[64] Recovery may be prolonged, with residual ventilatory muscle weakness detectable as long as 2 years after presentation.[65] Recent reports from the Canadian Arctic associated with inadequately refrigerated seafood illustrate the importance of early recognition and treatment with botulinum antitoxin, which may speed recovery.[66]

Myopathies

Primary myopathies due to muscular dystrophies or other congenital myopathies are an uncommon cause of acute respiratory failure in most acute care hospitals but are more common in the pediatric setting. These patients usually develop ventilatory failure gradually and are begun on NIV in an outpatient setting. When they present with acute ventilatory failure, it is usually a precipitating factor, such as pneumonia or bronchitis, that causes problems with secretion retention. In such an event, they should be placed in an intensive care unit and treated with an aggressive regimen to assist with secretion clearance.[67] Endotracheal intubation may be necessary to control secretions, with weaning to NIV once the acute crisis subsides. Dermatomyositis may also cause respiratory muscle weakness severe enough to lead to acute ventilatory failure,[68,69] although not as an initial manifestation in the absence of other typical symptoms and signs of this condition. In these reported cases, ventilatory function recovered as the disease was brought under control with immunosuppressive therapy.

Pharmacologic Causes

Neuromuscular blocking drugs are sometimes administered to ventilated patients, in conjunction with sedation, to facilitate mechanical ventilation, reduce oxygen consumption, or control intracranial pressure. The clinical kinetics of these agents have been determined mainly in the context of short-term general anesthesia, and their effects on ventilatory muscle function in critically ill patients are much more variable. For example, most neuromuscular blocking drugs are cleared more slowly in the presence of hepatic or renal insufficiency. This is particularly true for pancuronium and vecuronium; the effects of these drugs can last days or even weeks in the presence of renal failure.[70] In contrast, atracurium and cisatracurium are metabolized in plasma and do not depend on renal or hepatic function for clearance; thus, they are not associated with prolonged muscle weakness as a result of delayed clearance.[71]

Train-of-four stimulation (i.e., a peripheral nerve stimulator monitoring the strength and number of impulses required for a muscular twitch) can be used to monitor the depth of neuromuscular blockade, avoiding excessive paralysis, reducing the quantity of drug used, and decreasing recovery time of neuromuscular function in critically ill patients.[72] The benefits of train-of-four monitoring may not be seen when atracurium and cisatracurium are used.[73] Furthermore, use of train-of-four testing has been controversial because it is influenced by the skill of caregivers, muscular site of monitoring, manufacturer of the device, edema, patient temperature, and other factors.[74] For this reason, the most recent Society of Critical Care Medicine guidelines suggest use of train-of-four for any of the non-depolarizing neuromuscular blockers only when combined with careful clinical assessment.[75] Minimizing the use and careful dosing of neuromuscular blocking drugs in ventilator management, a comprehensive monitoring plan, and a structured physiotherapy regimen may help reduce the incidence of prolonged paralysis.

NEUROMUSCULAR WEAKNESS ASSOCIATED WITH CRITICAL ILLNESS

Neuromuscular dysfunction associated with critical illness commonly contributes to the subsequent inability to wean such patients from mechanical ventilation.[71] Several forms of critical illness–associated neuromuscular dysfunction are recognized.

Intensive Care Unit–Acquired Weakness

Unexpected acute weakness and prolonged ventilatory failure were first reported in patients with status asthmaticus treated with corticosteroids and neuromuscular blocking drugs.[76,77] Subsequently, a similar syndrome was recognized in other groups of ICU patients, especially those with sepsis and systemic inflammation, even without corticosteroid administration or therapeutic paralysis.[71] Either muscle or nerve abnormalities can predominate, leading to a confusing array of diagnostic terms, such as critical illness myopathy, critical illness polyneuropathy, postparalytic myopathy, ICU-acquired paresis, acute quadriplegic myopathy, and the preferred term, *ICU-acquired weakness*.

The pathophysiology of ICU-acquired weakness is poorly understood but may involve elements of disuse and active muscle catabolism sparked by systemic inflammation. Electromyography reveals reduced compound muscle action potentials on motor nerve stimulation (with normal conduction velocity), increased action potential duration, and spontaneous electrical activity on muscle needle recording (e.g., fibrillation potentials, positive sharp waves).[78] Biopsy findings may include primary axonal degeneration, type II muscle fiber atrophy, thick filament (myosin) loss, and (occasionally) necrotizing myopathy.

One-quarter to nearly all patients who require more than 7 days of ICU care and the majority of patients who develop the systemic inflammatory response syndrome can be shown by neurophysiologic testing to have ICU-acquired weakness.[71] These neurophysiologic abnormalities arise early, accumulate during the course of illness, and usually affect both nerves and muscles.[79] Prospective studies have shown that about one-third of critically ill patients exhibit weakness on clinical evaluation.[71,80] The typical patient exhibits symmetrical extremity weakness in which proximal function is more impaired than distal function and the facial muscles are spared. Clinically, this disorder can produce severe neuromuscular weakness, often affects the respiratory muscles, and may prolong the need for ventilatory support.[80,81] This syndrome should be suspected in patients who are weak (Medical Research Council score <48[80]) in the context of critical illness, have the typical clinical examination, and in whom no better alternative cause for weakness can be identified. Handgrip strength may serve as a simple test

to identify ICU-acquired weakness.[82] Nerve conduction studies, electromyography, and muscle biopsy generally are not necessary to make a diagnosis, and clinical scoring systems assessing strength of multiple muscle groups can be helpful.[71] The prognosis for recovery of strength is variable, with many patients improving rapidly over days to weeks while others remain weak for many months or longer. The incidence of ICU-acquired weakness may be reduced by intensive insulin therapy,[81,83,84] although this has lost favor due to potential hypoglycemic complications. Avoiding neuromuscular blocking drugs and corticosteroids where possible and applying early mobilization[85,86] are other favored strategies to minimize ICU-acquired weakness. Because ICU-acquired weakness is so strongly associated with severity of illness, length of ICU stay, and the presence of multiple organ system dysfunction, prevention focuses on scrupulous attention to evidence-based supportive care and avoidance of iatrogenic complications.[71]

Ventilator-Induced Diaphragmatic Dysfunction

Many critically ill patients develop muscle weakness that impedes functional recovery and is associated with prolonged mechanical ventilation. Some component of this represents ICU-acquired weakness,[87] but mechanical ventilation itself (without systemic inflammation) can induce respiratory muscle weakness.[88–90] The lack of neural stimulation or associated contraction plays a role in the evolution of weakness because measures to keep muscles contracting can ameliorate weakness. The diaphragm, the muscle most responsible for sustaining the work of breathing, may be even more sensitive than other skeletal muscles to the effects of critical illness. In animal models, the diaphragm weakens and atrophies during the first 1 to 3 days of controlled mechanical ventilation thought to be related to disuse. This and excessive prolonged demands on the diaphragm are thought to induce myotrauma.[91]

Diaphragm dysfunction in these situations can be detected by ultrasound, showing diminished tidal excursions and decreased thickening corresponding to blunted contractility.[92] Using phrenic nerve stimulation, one study demonstrated weakness by measuring a reduction in maximal transdiaphragmatic pressure in a group of continuously ventilated patients in comparison with findings in normal volunteers.[93] As in studies of peripheral skeletal muscle, stimulating the diaphragm attenuates the loss of strength.[94] A transvenous bilateral phrenic nerve stimulator has been shown to preserve diaphragm function in experimentally ventilated rats and could see clinical application in the not too distant future.[95] An alternative approach proposed recently is to titrate ventilator settings so that diaphragm effort is optimized, avoiding insufficient or excessive demands,[96] and there may be a role for pharmacotherapy with theophylline, which has been shown to increase diaphragm contractility.[97]

ASSESSMENT OF NEED FOR MECHANICAL VENTILATION IN NEUROMUSCULAR WEAKNESS

Respiratory muscle weakness can be suspected when there is obvious peripheral muscle weakness, but neuromuscular abnormalities may not always be evident. Respiratory muscle weakness should also be suspected when dyspnea is out of proportion to radiographic and respiratory mechanical abnormalities. Orthopnea raises the possibility of diaphragmatic weakness or paralysis. Further, suspicion is raised when maximal inspiratory pressure is reduced or, in some instances, when ultrasound examination of the diaphragm is abnormal.

Early clinical indicators of the need for mechanical ventilation in patients with neuromuscular weakness remain controversial. In addition to subjective assessments of symptoms of dyspnea and respiratory distress, objective assessments of vital capacity and maximum inspiratory and expiratory pressures have been used to evaluate ventilatory muscle capability.

In AIDP, rapid disease progression, bulbar and bilateral facial weakness, and dysautonomia are highly correlated with the need for intubation and mechanical ventilation. Moreover, the 20/30/40 rule, mentioned above, is often invoked to assess risk for intubation.[56] However, no prospective randomized studies have assessed these variables, and predictors of the need for intubation may merely reflect the criteria in current use to determine when a patient should be intubated.

One study reported an association between electrophysiologic evidence of demyelination and the need for intubation and mechanical ventilation.[98] Another study on 44 AIDP patients who required mechanical ventilation showed greater cranial nerve involvement and immunoglobulin G anti-GQ1b antibody levels than 87 AIDP patients not requiring intubation.[99] These could also be markers of greater disease severity, thus explaining the higher intubation rates.

In MG, the criteria to predict the need for intubation are not as reliable as for AIDP, mostly due to the fluctuating nature of MG.[100] Nonetheless, serial assessments of vital capacity and the use of the same predictors as for AIDP are still recommended in MG as long as the patient is monitored closely in an ICU and caregivers are prepared for emergent intubation if necessary.[101,102]

In ALS, as previously noted, serial ventilatory muscle assessments during outpatient management are required for the timely initiation of NIV to avoid respiratory crises and the need for emergency intubation. Clinical signs of respiratory muscle weakness (such as use of accessory muscles and paradoxical or diminished excursion of the abdomen) and symptoms of diaphragm weakness (such as orthopnea) are important to assess. We recommend serial measurement of pulmonary function tests, particularly FVC, slow vital capacity, supine FVC, peak expiratory flow and peak expiratory cough flow, which have been shown to correlate with prognosis.[103,104] Sniff inspiratory pressure may also be useful as an index of diaphragm strength.[105]

In-lab sleep studies may be helpful earlier during the progression of disease if sleep apnea is suspected,[106] but these may be difficult in advanced disease due to patient unfamiliarity with the lab. Home sleep studies or nocturnal oximetry may be helpful in advanced disease to assess the efficacy of NIV. Recommendations for starting NIV in ALS patients vary widely from FVC less than 80% predicted, with the idea that deterioration in respiratory muscle function can be slowed, to less than 50% predicted in the United

States as per the threshold for Medicare reimbursement for NIV.[107,108] We believe that data are insufficient to make firm recommendations on any specific FVC threshold for NIV initiation but that, in association with pulmonary dysfunction and in keeping with its palliative role, NIV should be started when patients develop symptoms that are likely to respond to NIV. For example, dyspnea at rest or orthopnea can respond to NIV, as can symptoms attributable to poor sleep, such as daytime fatigue, hypersomnolence, or morning headaches.

Although the optimal means for monitoring respiratory muscle function remain uncertain, it is clear that initiation of NIV[109] or, if that fails, intubation and mechanical ventilation (if patients desire it), should be undertaken before the development of severe respiratory acidosis or respiratory arrest. For this reason, patients with neuromuscular disease who show signs of acute pulmonary compromise should be monitored in an ICU. Although the rate of progression may fluctuate, serial measurements of vital capacity and maximal inspiratory pressure along with repeated physical examinations focusing on bulbar function and ability to cough are advisable to avoid the need for emergent intubations (Fig. 132.3).[109]

PRINCIPLES OF VENTILATOR MANAGEMENT

Patients with acute ventilatory failure due to neuromuscular disease usually have normal underlying lung parenchyma. Although NIV is often used successfully in these patients, significant bulbar involvement is associated with a high likelihood of NIV failure and patients with these deficits should be intubated if the goal is prolongation of life. Intubated patients are usually supported with volume-targeted ventilators using tidal volumes of 6 to 8 mL/kg, rates slightly below spontaneous, and 5 to 10 cm H_2O PEEP to prevent atelectasis. These targets can also be achieved using portable pressure-limited ventilators with the pressure difference between inspiratory and expiratory pressure adjusted to achieve similar tidal volumes (pressure difference usually at least 8 to 10 cm H_2O) while avoiding respiratory alkalosis. In patients requiring continuous ventilatory assistance, settings should aim not only to maintain gas exchange but also comfort, considering that there is no convincing evidence that "exercising" respiratory muscles in neuromuscular disease speeds recovery. Some advocate a protocol using prophylactic NIV and mechanical cough assistance to facilitate extubation and avert the need for reintubation in patients with neuromuscular disease who are weaning from invasive mechanical ventilation.[67,111]

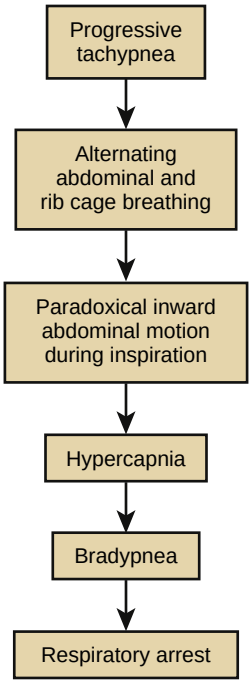

Figure 132.3 The sequence leading from ventilatory pump failure to respiratory arrest. Patients proceed through the steps at variable rates and may skip one or more stages. However, except for sudden events affecting the central nervous system or the administration of paralyzing drugs, respiratory arrest does not present abruptly without preceding physical manifestations. (Modified from Cohen CA, Zagelbaum G, Gross D, et al. Clinical manifestations of inspiratory muscle fatigue. *Am J Med.* 1982;73:308-316.)

CHEST WALL DEFECTS (see Chapter 131)

Many restrictive diseases of the lungs or chest wall progress insidiously over months or years. Critical illness in patients with restrictive disease may represent the natural history of the underlying condition but may also signal an acutely superimposed, potentially reversible crisis such as infection, pneumothorax, or thromboembolism.

CHEST WALL SKELETAL ABNORMALITIES

Thoracic restriction and ventilatory muscle dysfunction due to severe kyphoscoliosis typically lead to gradually progressive ventilatory insufficiency. Such patients can present with acute or acute-on-chronic ventilatory failure and require intensive care. Physiologic studies have shown that both lung and chest wall mechanics are impaired during acute respiratory failure in patients with kyphoscoliosis.[112] Chest trauma, especially when leading to flail chest due to rib fractures, may also cause acute hypercapnic respiratory failure. In either case, the ventilator pump fails because of inability to sustain ventilatory work due to abnormalities that compromise ventilatory function, such as increased chest wall stiffness in kyphoscoliosis and decreased ventilator efficiency due to paradoxical chest wall motion and pain in flail chest.

PLEURAL DISEASE

Primary disease of the pleura, such as asbestos-related diffuse pleural thickening or postinflammatory fibrothorax, could potentially present in a similar way as skeletal deformities, but dyspnea and hyperventilation are more common than hypoventilation with these chronic pleural diseases. Respiratory acidosis develops late in the course of these disorders, but earlier if ventilatory drive is depressed or there is concomitant lung involvement. Pleural effusion or pneumothorax can precipitate acute ventilatory failure if accumulation is rapid and large and usually in the presence

of underlying obstructive or restrictive pulmonary parenchymal disease.

PRINCIPLES OF MANAGEMENT

NIV has been shown to be beneficial in thoracic restriction due to severe kyphoscoliosis and other chest wall diseases[113] for both acute and acute-on-chronic ventilatory failure.[114–117] Some studies report that NIV reduces the need for intubation and leads to a shortened hospital stay in patients with chest trauma.[118,119]

Parenchymal Lung Disease

Idiopathic pulmonary fibrosis and other pulmonary parenchymal restrictive diseases are usually associated with hyperventilation rather than hypoventilation. However, acute ventilatory failure can arise in the late stages of these conditions, either as a manifestation of the primary disease process[120,121] or, more often, in conjunction with pneumonia, surgery, or other intercurrent illness.[122–124] Physiologic assessment has demonstrated marked increases in lung stiffness and airway resistance in patients with end-stage idiopathic pulmonary fibrosis requiring mechanical ventilation,[124] explaining the development of hypercapnia and acute ventilatory failure.

Several small case series have documented the poor prognosis of patients who present with acute respiratory failure in the setting of advanced interstitial fibrosis.[121,123,124] Outcomes appear equally poor regardless of whether ventilation is invasive or noninvasive.[125]

Principles of Ventilator Management

Due to increased lung stiffness, NIV for restrictive disease usually requires higher airway pressures than are used for COPD. Thus, avoiding gastric insufflation and air leaks around the mask can be challenging. Furthermore, considering that a superimposed condition such as a respiratory infection often precipitates the acute bout of respiratory failure, accompanied by increased work of breathing and secretion retention, invasive ventilatory support is often necessary. The best way to ventilate patients with acute respiratory failure in the setting of underlying restrictive thoracic or lung disease has not been determined by clinical trials. The potential for hemodynamic compromise, barotrauma, and ventilator-induced lung injury with the use of high pressures and the physiologic similarity to ARDS in patients with worsening pulmonary fibrosis make it reasonable to apply similar lung-protective ventilator strategies and management targets (see Chapter 135). Low tidal volumes (e.g., 6 mL/kg predicted body weight) should be applied, attempting to keep the end-inspiratory plateau pressure below 30 cm H_2O if possible. Patients with restrictive lung disease typically breathe rapidly and shallowly, so tachypnea may not be avoidable during the weaning process and should not be used as the sole reason for delaying extubation if gas exchange and other assessments are acceptable.

AIRWAY OBSTRUCTION

UPPER AIRWAY OBSTRUCTION

Upper airway obstruction is an occasional cause of acute ventilatory failure. The onset can be precipitous, as with occlusion of the glottis by an aspirated foreign body (i.e., "café coronary") or a swollen and edematous epiglottis due to acute epiglottitis.[126] The onset can also be insidious, progressing over months, as with a tracheal tumor. The severity and length of narrowing and airflow determine the airway resistance and thus the additional work of breathing imposed by the obstruction. Gradually progressive upper airway narrowing may be well tolerated, at least while breathing at rest, until a critical limit is reached, often when the airway diameter drops to the range of 5 to 6 mm.

The location and variability of the narrowing are also important in determining the clinical manifestations. Extrathoracic variable upper airway narrowing affects mainly inspiratory flow because the negative intraluminal pressure exacerbates the narrowing during inspiration. During expiration, the positive intraluminal pressure widens extrathoracic airways. Vocal cord paralysis is an excellent example of a variable extrathoracic upper airway obstruction, producing stridor and severe airway obstruction during inspiration but no significant obstruction during expiration. The opposite pertains to variable intrathoracic obstructions, with narrowing becoming less severe during inspiration because pressure gradients favor airway widening. During expiration, the airways narrow and the severity of the obstruction worsens. Tracheomalacia can cause variable intrathoracic airway obstruction. Fixed obstructions affect both inspiration and expiration regardless of their location.

Upper airway obstruction causes ventilatory failure by increasing airway resistance to the point where respiratory muscles can no longer sustain minute volume at a level adequate to maintain CO_2 homeostasis. Negative-pressure pulmonary edema caused by severe reductions in intrathoracic pressure occasionally created during upper airway obstruction can also contribute to the gas-exchange impairment.[127] Ideally, the therapeutic aim is to relieve the obstruction. This may be achieved by removal of a foreign body, laser therapy of an endotracheal tumor, placement of a stent in an area of tracheomalacia or stenosis, or tracheostomy to bypass an area of obstruction. Inhalation of heliox (to reduce airway resistance), *continuous positive airway pressure* (CPAP), or noninvasive ventilation using pressure support and PEEP can help reduce work of breathing and avoid intubation in patients who have reversible causes of their upper airway obstruction, such as postextubation stridor, or who are awaiting tracheostomy or surgical repair of an obstruction. However, these temporizing measures require close monitoring with the recognition that the patient can deteriorate abruptly.

COPD

COPD is the third leading cause of death among adults aged 65 to 84 in the United States, being the primary contributor to mortality caused by lower respiratory disease, and poses enormous costs to the U.S. health care system, mostly due to hospitalization.[128] The vast majority of hospitalizations are due to acute exacerbations of COPD, but other causes such as acute pneumonia, congestive heart failure, pulmonary embolism, and pneumothorax may contribute to the deterioration.

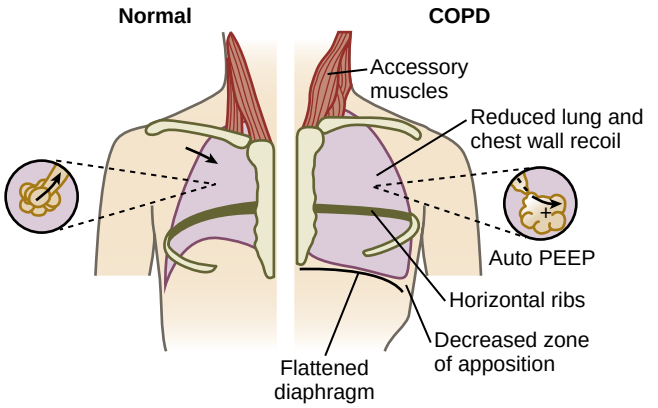

Figure 132.4 Schema depicting the chest wall configuration at functional residual capacity of a normal individual (*left*) and a patient with severe COPD (*right*). The COPD patient has a flattened diaphragm, which increases its radius of curvature and increases the tension for a given pressure. The COPD patient's ribs are horizontal, and the zone of apposition between the diaphragm and chest wall is reduced, greatly reducing the diaphragm's efficiency in expanding the chest wall. Also, *intrinsic positive end-expiratory pressure* (auto PEEP) poses an inspiratory load, adding further to the inspiratory work. Exhalation is slowed by airway collapse and the loss of elastic recoil. (Modified from Hill NS. Current concepts in mechanical ventilation for chronic obstructive pulmonary disease. *Semin Respir Crit Care Med.* 1999;20:375-395.)

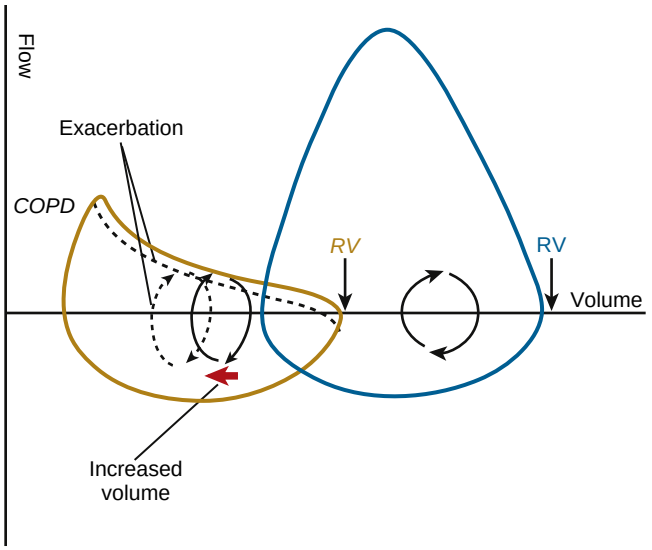

Figure 132.5 Flow-volume loops for a patient with a normal lung (*blue line*) and one with COPD (*brown line*) along with their respective tidal volume loops (*inner black loops with arrows*). Note that the expiratory flow during tidal breathing in the COPD patient reaches maximal expiratory flow. During an exacerbation (*dashed lines*), expiratory flow drops; because the flow during tidal breathing is already maximal, the only mechanism available for maintaining flow is to increase lung volume during tidal breathing (leftward shift of tidal breathing loop; *red arrow*). Although this strategy maintains expiratory flow, it increases the work of breathing and oxygen consumption, predisposing to inspiratory muscle fatigue and eventual respiratory failure. RV, residual volume. (Modified from Hill NS. Current concepts in mechanical ventilation for chronic obstructive pulmonary disease. *Semin Respir Crit Care Med.* 1999;20:375-393.)

Pathophysiology

Hyperinflation associated with severe COPD places the respiratory muscles at a mechanical disadvantage (Fig. 132.4). The loss of elastic structures is responsible for an increase in lung compliance leading to hyperinflation (with an increase in total lung capacity and functional residual capacity) and the collapse of small airways during expiration contributing to an increase of residual volume, often referred to as air trapping. The flattening of the diaphragm increases the radius of curvature, which, according to the Law of Laplace, also increases muscle tension and impedance to blood flow. In addition, ventilatory efficiency is reduced because the shortened diaphragm operates at a disadvantageous position on its length-tension curve and the horizontal orientation of the flattened diaphragm causes the lower rib cage to move paradoxically during inhalation, inward rather than outward (Hoover sign).

The hyperinflation and impairment in diaphragm function necessitate recruitment of accessory muscles to maintain ventilation at higher lung volumes, contributing to the already increased oxygen cost of breathing. Finally, the collapse of small airways predisposes to incomplete emptying and positive intrathoracic pressure at end-expiration (intrinsic or auto-PEEP). Auto-PEEP poses an inspiratory threshold load requiring inspiratory muscles to generate subatmospheric pressures from an elevated alveolar pressure in order to initiate airflow for the next breath.[129–131]

During an exacerbation of COPD, the combination of airway swelling, secretions, and bronchospasm caused by acute inflammation increases airway resistance, further worsening the expiratory flow limitation and increasing end-expiratory lung volume. As depicted in Figure 132.5, COPD patients adapt by attempting to maintain airflow by breathing at even higher lung volumes. In addition, they adopt a rapid, shallow breathing pattern further limiting the time available for expiration, aggravating intrinsic PEEP and adding further to work of breathing. The diaphragm flattens more and develops increased tension, further impeding diaphragmatic blood flow. The resulting limitation in substrate delivery to muscle is aggravated by progressive hypoxemia, caused by worsening hypoventilation and $\dot{V}/\dot{Q}$ imbalance related to secretion retention. Thus, as the demand for breathing increases, the capacity to supply breathing work diminishes. As respiratory drive increases in a futile attempt to reverse the worsening alveolar hypoventilation, muscular performance deteriorates and the diaphragm fatigues.[132] A vicious cycle ensues, leading inexorably to worsening respiratory muscle fatigue, ventilatory failure, and death unless therapeutic interventions interrupt the cycle.

Clinical Assessment

Patients with exacerbations of COPD must be carefully evaluated to identify those at risk of developing respiratory failure and to exclude other causes of respiratory failure. History and physical examination are useful. Although the Borg or visual analogue scales help gauge the level of dyspnea in clinical studies, a subjective assessment that dyspnea is worse than at baseline and of at least moderate severity suffices to identify patients who may be at risk for respiratory failure. Physical findings seen with severe exacerbations include tachypnea, accessory muscle use, abdominal paradox (inward paradoxical movement of the abdomen on inspiration demonstrating diaphragm dysfunction), Hoover sign (inspiratory inward motion of the lower lateral rib cage), cyanosis, and mental status alterations.

In addition to a sputum examination for purulence, a white blood cell count, electrocardiogram, chest radiograph, and arterial blood gas should be obtained to assess the severity of an exacerbation. The widespread use of continuous pulse oximetry and venous blood gases has decreased, but not eliminated, the need for arterial blood gases. Whereas venous pH values average 0.03 to 0.04 below arterial values, venous P_{CO_2} less closely reflects arterial P_{CO_2}, averaging 3 to 8 mm Hg above arterial[133]; nonetheless, a normal venous P_{CO_2} (in the range of 41 to 51 mm Hg) may be useful in excluding all but mild hypercapnia.[134] Arterial blood gases provide a rapid assessment of arterial P_{CO_2} and pH, information that is helpful when deciding to place patients in critical care units or to initiate mechanical ventilation and to assess response to therapy. During severe exacerbations, patients with chronic CO_2 retention develop acute-on-chronic hypercapnia, manifested by a drop in pH indicative of retained CO_2 uncompensated by bicarbonate, an important indicator of ventilatory failure that can be detected only by measurement of arterial blood gases.

Medical Therapy

Medical therapy, consisting of bronchodilators, corticosteroids, and antibiotics, should be promptly started in patients with severe exacerbations. Additional therapies, including diuretics, nitrates, or anticoagulation, should be started whenever comorbidities such as congestive heart failure or pulmonary embolism are suspected.

Oxygen should be supplemented routinely to improve hypoxemia, but it should be carefully titrated in patients with CO_2 retention to maintain a target oxygen saturation of 88–92%. Overzealous oxygen supplementation in such patients has long been known to aggravate CO_2 retention by either blunting the hypoxic ventilatory drive, increasing physiologic dead space (perhaps due to oxygen-induced bronchodilation in poorly perfused lung regions), or both.[135] Another mechanism may be the Haldane effect, in which the increased oxygen tension decreases the affinity of hemoglobin for CO_2.[136] Because hypoxemia in COPD patients is easily reversed, initial supplementation with nasal oxygen at 2 L/min is often adequate.[137] In patients with severe exacerbations, arterial blood gases should be repeated periodically (or followed with venous blood gases or noninvasive monitoring) to assess the effect of oxygen supplementation on arterial P_{CO_2}.

Noninvasive Ventilation (see Chapter 136)

Although initial medical therapy is usually effective in mild COPD exacerbations, it is often not sufficient in severe exacerbations. In severe exacerbations, tachypnea, dyspnea, and CO_2 retention may persist or worsen despite initial medical therapy. Until the mid- to late-1990s, patients in such a predicament would usually be intubated and mechanically ventilated. If they declined intubation, they were kept comfortable while medical therapy was continued, but they often died. Invasive mechanical ventilation was successful in the majority of cases, but hospital mortality rates were substantial, averaging 30% in several studies.[138] Complications of invasive mechanical ventilation were common, including upper airway trauma, pneumothorax, and nosocomial infection, all contributing to patient mortality.[139]

In 1990, Brochard and coworkers[140] demonstrated that the noninvasive delivery of pressurized air into the lungs via a face mask was effective in providing partial ventilatory assistance during COPD exacerbations. Shortly thereafter, Appendini and colleagues[141] showed that noninvasive extrinsic PEEP (to counterbalance the effects of intrinsic PEEP) combined with pressure support reduced diaphragmatic work of breathing even more effectively in COPD patients than either CPAP or pressure support alone. In this way, NIV restores the balance between supply and demand for the work of breathing, thereby serving as a "crutch" during COPD exacerbations and halting the progression of respiratory muscle fatigue while medical therapies are given time to work.

Since Brochard's study, multiple randomized controlled studies and meta-analyses have demonstrated the efficacy of NIV to treat exacerbations of COPD.[139] When compared with standard oxygen and medical therapy alone, NIV for severe exacerbations of COPD more rapidly improves dyspnea, respiratory and heart rates, arterial P_{CO_2}, and encephalopathy scores.[142–144] In addition, intubation and mortality rates drop precipitously (from roughly 75% and 30% in controls to 25% and 10%, respectively, in NIV-treated patie nts).[142,143,145] NIV also lowers complication rates and hospital lengths of stay compared with controls.[142–144] Such benefit has not been shown in milder exacerbations, when work of breathing is not substantially increased.[146,147]

Several meta-analyses[148,149] have concluded that NIV is effective in avoiding intubation (relative risk 0.42 and absolute risk reduction 28%, respectively), reducing mortality (relative risk 0.41 and absolute risk reduction 10%, respectively), and shortening hospital length of stay (by approximately 4 days). A more recent study on a large cohort of more than 25,000 patients with COPD exacerbations requiring mechanical ventilation showed reduced mortality, length of stay, and cost with NIV compared to invasive ventilation.[150] On the basis of this evidence, current guidelines,[148–155] including the most recent European Respiratory Society/American Thoracic Society guidelines from 2017,[156] have recommended that NIV be used in patients with a COPD exacerbation and acute or acute-on-chronic ventilatory failure (pH <7.35) and should be started early in the course of moderate to severe COPD exacerbations. The European Respiratory Society/American Thoracic Society guideline also recommends against NIV use in patients with mild exacerbations (with pH ≥7.35) because of the studies showing lack of efficacy in this setting.[146,147]

NIV may also be considered in patients with COPD developing acute ventilatory failure in a number of different settings. Patients with acute exacerbations of COPD complicated by pneumonia have more severe COPD exacerbations than those without pneumonia[157] but still respond favorably to NIV, with reduced intubation and mortality rates and ICU lengths of stay compared to conventional therapy in one controlled trial.[158] Patients with COPD in the postoperative and postextubation settings also benefit from NIV. In a group of patients after lung resection, one randomized controlled trial showed reduced intubation and mortality rates when NIV was compared to conventional therapy.[159] For patients in the post-extubation setting, several studies have shown improved outcomes including reduced rates of ventilatory failure, reintubation, and mortality when used

in hypercapnic patients at risk for failing extubation.[160,161] Another approach has been to facilitate extubation in COPD patients who required intubation upon presentation or who failed initial NIV.[162,163] The European Respiratory Society/American Thoracic Society guideline[156] gave a conditional recommendation for both postoperative and post-extubation applications of NIV.

Another application of NIV for patients with COPD is in those who have declined intubation.[164] This application has been controversial, with some arguing that there is little to lose because it may reverse the acute deterioration or, at least, provide relief of dyspnea and a few extra hours to finalize affairs.[165] Others have argued that this merely prolongs the dying process, consumes resources inappropriately, and may add to discomfort or counter patients' wishes about avoiding life-prolonging measures.[166] In prospective observational studies of 113[164] and 131[167] patients treated with NIV who had *do-not-intubate* (DNI) orders, survival to hospital discharge was greater than 50% for COPD and congestive heart failure patients, whereas it was lower (14–25%) for those with a diagnosis of hypoxemic respiratory failure (pneumonia) or advanced cancer. Thus, NIV can be used to treat respiratory failure for DNI patients with acutely reversible processes such as COPD exacerbations. The patient or family should be informed that NIV is being used as a form of life support that may be uncomfortable and can be removed at any time. More recent information suggests that high flow nasal cannula oxygen (see Chapter 137) may be a good choice for palliation in terminal patients with respiratory failure. In one study, 183 patients with respiratory symptoms tolerated the therapy well and 85% improved or at least remained stable.[168] Not all of these patients had COPD or ventilatory failure, though, and further study is needed to determine how well HFNC performs in the COPD subpopulation.

Table 132.2 Selection Criteria for Noninvasive Positive-Pressure Ventilation in Acute Exacerbations of COPD

ESTABLISH NEED FOR VENTILATORY ASSISTANCE

- Moderate to severe respiratory distress
- Tachypnea (e.g., RR > 24 breaths/min)
- Accessory muscle use or abdominal paradox
- pH < 7.35, arterial P_{CO_2} > 45 mm Hg *or*
- Arterial P_{O_2}/F_{IO_2} < 200

EXCLUDE PATIENTS WITH CONTRAINDICATIONS TO NONINVASIVE VENTILATION

- Cardiac or respiratory arrest
- Medically unstable (septic or cardiogenic shock, uncontrolled upper gastrointestinal bleeding, acute myocardial infarction with planned intervention, uncontrolled arrhythmias)
- Unable to protect airway
- Severe encephalopathy
- Excessive secretions
- Uncooperative or agitated
- Unable to fit mask
- Recent upper airway or upper gastrointestinal surgery

F_{IO_2}, fractional concentration of oxygen in inspired gas; NIV, noninvasive ventilation; P_{CO_2}; partial pressure of carbon dioxide; P_{O_2}, partial pressure of oxygen; RR, respiratory rate.

Modified from Liesching T, Kwok H, Hill NS. Acute applications of noninvasive positive pressure ventilation. *Chest*. 2003;124:699–713.

High Flow Nasal Cannula Oxygen

High flow nasal cannula (HFNC) consists of oxygenated gas heated and humidified to body conditions, delivered to the nares at flows up to 40 to 80 L/min depending on the manufacturer. Use of HFNC has been increasing rapidly worldwide because it is well tolerated by patients compared to standard oxygen or NIV, keeps mucous membranes moist and enhances secretion mobilization, augments ventilatory efficiency by virtue of its dead-space clearing effect, slows respiratory rate, and raises expiratory airway pressure slightly.[169] Although its greatest benefit appears to be in hypoxemic respiratory failure,[170] some studies have shown reduced work of breathing in patients with severe COPD related to reduction of dead space and respiratory rate.[171] In one controlled study based in emergency departments, patients with a variety of causes of respiratory failure were randomized to receive HFNC or NIV. There was no significant difference between groups in the major outcome variable, "treatment failure," that included both the need to cross over to the other arm of the study and intubation.[172] The lack of difference in treatment failure was seen not only in pooled patients, but also in the COPD subgroup. The authors concluded that HFNC was "noninferior" to NIV for "treatment of respiratory failure from various causes in adult patients presenting to the emergency department who do not require immediate intubation."[172] However, there was a sizable imbalance in crossovers in the study, with more HFNC patients crossing over to NIV and avoiding intubation. Thus, it is difficult to have a high level of confidence about the noninferiority of HFNC compared to NIV to treat acute ventilatory failure in COPD based on this study alone. Although HFNC offers some physiologic benefit to patients with severe COPD, pending further clinical study, NIV should still be considered the modality of first choice for patients with ventilatory failure due to COPD. In milder COPD exacerbations or in patients intolerant of NIV, HFNC may offer a noninvasive alternative, but this remains to be investigated. On the other hand, HFNC may be used as a complementary therapy in patients with acute ventilatory failure being treated with NIV. One recent study showed that HFNC is more comfortable and prevents dyspnea and increased respiratory rate when used as an alternative to standard oxygen therapy during breaks from NIV.[173]

Practical Application of Noninvasive Ventilation

A thorough discussion of the application of NIV is beyond the scope of this chapter, and the reader is referred to Chapter 136 and elsewhere for more complete descriptions.[174] The following sections focus on aspects relevant to applications in COPD patients with acute ventilatory failure.

Patient Selection. Selection of appropriate patients is key to the successful application of NIV. The selection process should take into account the patient's clinical characteristics and risk of failure on NIV (Table 132.2). Predictors of success of NIV have been identified[175–177] (Table 132.3) and include a good neurologic status (and hence more cooperativeness), ability to protect the airway, and only mild-moderate acid-base or gas-exchange derangement. Several studies have also found that improvements in pH, arterial P_{CO_2}, and level

Table 132.3 Predictors of Success for Noninvasive Positive-Pressure Ventilation in the Acute Setting

EFFECTIVE SYNCHRONY OF PATIENT WITH VENTILATOR
■ Able to cooperate and comply with NIV
■ Good neurologic status
■ Younger age
■ Minimal air leaks
■ Dentate
ABLE TO PROTECT AIRWAY
■ Low volume of secretions
■ Low aspiration risk
NOT TOO ACUTELY ILL
■ No pneumonia or ARDS
■ Lower APACHE or SAPS II score
■ Moderate arterial hypercapnia
■ Moderate acidosis
GOOD INITIAL RESPONSE (WITHIN FIRST 1 TO 2 HOURS)
■ Improvement in pH
■ Reduction in respiratory rate
■ Reduction in arterial P_{CO_2}
■ Improved level of consciousness

APACHE, Acute Physiology, Age, and Chronic Health Evaluation; ARDS, acute respiratory distress syndrome; NIV, noninvasive ventilation; P_{CO_2}, partial pressure of carbon dioxide; SAPS, Simplified Acute Physiology Score.

Data from Hess DR. The evidence for noninvasive positive-pressure ventilation in the care of patients in acute respiratory failure: a systematic review of the literature. *Respir Care*. 2004;49:810-829.

of consciousness within the first hour or two of NIV initiation are strong predictors of success.[175–177] These studies indicate that there is a "window of opportunity" when initiating NIV that opens when patients need ventilatory assistance but closes if they progress too far and become severely acidemic. Ultimately, it becomes a clinical judgment that takes into account the patient's diagnosis that led to the respiratory failure, the need for ventilator assistance, and the absence of contraindications (see Table 132.2).[178]

Mask Selection. Tolerance of the mask is key to the success of NIV. Thus, the mask must fit well and be strapped on sufficiently to control air leaks while avoiding excessive strap tension. For acute applications, the standard full-face (oronasal) mask is usually preferred because it is better tolerated and avoids the leaking of air through the mouth that can limit the efficacy of nasal masks.[179] Nasal masks may be better tolerated by some patients,[178] although air leakage through the mouth is a common problem. The helmet, available in certain European countries but not in the United States, consists of a plastic cylinder that seals over the neck and shoulders, and offers an alternative interface. It is effective for delivery of CPAP in particular. Although difficulty achieving patient-ventilator synchrony has been reported when using the helmet to deliver pressure support ventilation, increasing the PEEP level to render the helmet less compliant[180] and a newer helmet designed specifically for use with NIV[181] help with this problem. Within each mask category, many varieties of masks are available. Practitioners should have a current knowledge of available masks and their proper application in order to maximize the likelihood of NIV success.

Ventilator Selection. In the acute setting, both "critical care" and "bilevel" ventilators (pressure-limited devices designed especially for the administration of noninvasive positive-pressure ventilation) have been used with similar success rates. Earlier versions of bilevel ventilators were designed mainly for home use, lacked sophisticated alarms, and had limited oxygenation capabilities, but more recent versions offer oxygen blenders, a variety of ventilator modes, waveform display, and sophisticated alarms. In addition, many ventilators designed primarily for invasive mechanical ventilation now offer noninvasive modes programmed to improve leak compensation, silence nuisance alarms triggered by air leaks, and permit limitation of inspiratory time to enhance patient-ventilator synchrony.[182] The capabilities of these modes differ considerably between different ventilator manufacturers, however, and may require additional adjustment if there are mask leaks.[183]

NIV Initiation. Initial ventilator pressures are usually set low to enhance patient comfort and acceptance but must often be adjusted upward as tolerated to provide adequate ventilatory assistance. Typical initial settings on pressure-limited ventilators are 8 to 12 cm H_2O for inspiratory pressures and 4 to 5 cm H_2O for expiratory pressures (e.g., PEEP), with subsequent adjustments as needed to alleviate respiratory distress and hypercapnia, counterbalance intrinsic PEEP, or treat hypoxemia. Some modes offering volume-assured pressure support permit selection of a target tidal or minute volume based on the patient's ideal body weight and can facilitate the initial adjustment process.[184,185]

Some ventilators permit adjustments in airflow to enhance synchrony, such as the "rise time," which determines the time to reach the target inspiratory pressure and the adjustable inspiratory time. These may be helpful in optimizing comfort in COPD patients who tend to prefer relatively high inspiratory flows[186] (and hence short rise times, often 0.1 sec) and short inspiratory times (usually <1 second) to avoid prolongation of delivered inspiratory pressures during expiration.

Oxygenation and Humidification. Most patients with COPD exacerbations do not have severe oxygenation defects and can be managed successfully with pressure-limited bilevel ventilators designed for home care. With these ventilators, oxygen is administered at rates up to 15 L/min into ports in the mask or via a T-connector at the proximal end of the ventilator tubing, adjusted to maintain the desired level of oxygenation (usually to an arterial oxygen saturation greater than 90–92%). However, because fractional concentration of oxygen in inspired gas using this arrangement does not exceed 45–50%, ventilators with oxygen blenders designed for delivery of NIV in critical settings have replaced the earlier versions of bilevel for patients with COPD exacerbations complicated by more severe hypoxemia. Humidification should be used routinely because it may reduce the work of breathing, facilitate secretion removal, and enhance comfort and tolerance of NIV.[180,187,188]

Adaptation and Monitoring. Coaching and encouragement, especially during the first few hours, are critically

important in achieving adaptation. Judicious administration of low doses of sedatives may enhance patient acceptance. Close bedside monitoring is essential until the patient's respiratory status stabilizes. Although NIV can be administered on general medical wards, the acuteness of the patient's illness and need for close monitoring should dictate the site of administration. Acutely ill patients should be treated in an ICU or step-down unit until their condition stabilizes.[145,189] As shown in Table 132.4, patient comfort and tolerance are key initial goals, together with a reduction in work of breathing and respiratory distress and optimization of patient-ventilator synchrony. Arterial oxygen saturation is monitored continuously, and blood gases obtained as clinically indicated, at baseline and at least once during the first hour or two.

Commonly Encountered Problems and Possible Remedies. Noninvasive ventilation is safe and well tolerated in most properly selected patients. The most commonly encountered problems in COPD patients are similar to those in other patients and are related to the mask, air pressure, or airflow (see Table 132.4). Minimizing air leaks is also an important aim.

Increasing Use of NIV and HFNC for COPD

Probably lagging behind Europe by 5 to 10 years, studies in the United States using nationwide hospital databases have shown trends toward increasing use of NIV by approximately 2.5- to 4.5-fold from 2000 to 2010, especially in patients older than 85 years.[190] This increased use of NIV has been accompanied by a drop in the use of invasive mechanical ventilation and a gradual decline in mortality. The mortality rate for patients failing NIV and having to transition to invasive ventilation has crept up over the same time period, raising the concern that NIV may be used occasionally in excessively ill patients who should have been intubated initially.[191] At a single community hospital in Massachusetts, use of HFNC increased by 17.5% annually during the years 2008 through 2014 at a time when use of NIV increased 10.2% annually. The greatest increase in use was for the diagnoses of pneumonia and COPD, the latter despite the lack of evidence to substantiate benefit.[192]

Invasive Mechanical Ventilation

Indications and Patient Selection. Although invasive mechanical ventilation is being used less often for acute exacerbations, it still has an important role in supporting patients who are not eligible for or fail NIV and desire aggressive support. These and other indications for invasive mechanical ventilation are listed in Table 132.5.

Invasive mechanical ventilation in COPD must be administered with care to minimize the risk of complications. Excessive tidal volumes and rates must be avoided, and the urge to normalize arterial P_{CO_2} must be repressed in an effort to minimize intrinsic PEEP and excessive hyperinflation and alkalosis. Excessive respiratory rates reduce the respiratory cycle, shorten expiratory time, and prevent complete exhalation. This problem is aggravated by large tidal volumes. The potential adverse consequences are air trapping and intrinsic PEEP. With severe intrinsic PEEP, increased intrathoracic pressure reduces venous return and lowers cardiac output. Patients with severe intrinsic PEEP may be hypotensive with low cardiac output and elevated pulmonary artery wedge pressure (although pulmonary artery catheters are now rarely placed) due to transmission of the intrathoracic pressure. Their clinical presentation may therefore mimic that of cardiogenic shock. Temporary disconnection from the ventilator can differentiate hemodynamic compromise

Table 132.4 Monitoring Noninvasive Positive-Pressure Ventilation in COPD

ACUTE SETTING

- Patient comfort
- Mask fit and leak
- Patient-ventilator synchrony
- Sternocleidomastoid muscle activity
- Vital signs (heart and respiratory rate; systemic blood pressure)
- Continuous oximetry (until stabilized)
- Occasional blood gases (initial and after 30 to 120 minutes, then as clinically indicated)

CHRONIC SETTING

- Patient comfort
- Mask fit and leak
- Hours of use
- Problems with adaptation (e.g., nasal congestion, dryness, gastric insufflation, conjunctival irritation, inability to sleep)
- Symptoms (e.g., dyspnea, fatigue, morning headache, hypersomnolence)
- Gas exchange (daytime, nocturnal oximetry, blood gases periodically to assess arterial P_{CO_2})
- Polysomnography (if symptoms of sleep disturbance persist or nocturnal desaturation persists without clear explanation)

P_{CO_2}, Partial pressure of carbon dioxide.

Table 132.5 Indications for Invasive Mechanical Ventilation in COPD

- Severe dyspnea with the use of accessory muscles and paradoxical abdominal motion
- Severe tachypnea (e.g., respiratory rate >35 breaths/min)
- Life-threatening hypoxemia
- Severe or worsening acidosis and hypercapnia
- Respiratory arrest
- Somnolence; impaired mental status
- Cardiovascular complications (hypotension; shock; heart failure)
- Other complications (metabolic abnormalities; sepsis; pneumonia; pulmonary embolism; barotrauma; massive pleural effusion)
- Contraindication to attempt NIV
- Failure of noninvasive positive-pressure ventilation for any reason

F_{IO_2}, fractional concentration of oxygen in inspired gas; P_{CO_2}, partial pressure of carbon dioxide; P_{O_2}, partial pressure of oxygen.

From Pauwels RA, Buist AS, Calverley PM, et al. Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease: NHLBI/WHO Global Initiative for Chronic Obstructive Lung Disease (GOLD) workshop summary. *Am J Respir Crit Care Med.* 2001;163:1256-1276, and with data from Davidson AC, Banham S, Elliott M, et al., BTS Standards of Care Committee Member, British Thoracic Society/Intensive Care Society Acute Hypercapnic Respiratory Failure Guideline Development Group, On behalf of the British Thoracic Society Standards of Care Committee. BTS/ICS guideline for the ventilatory management of acute hypercapnic respiratory failure in adults. *Thorax.* 2016;71(Suppl 2):ii1–35.

due to intrinsic PEEP from true cardiogenic shock because the release of intrathoracic pressure permits rapid resolution of shock due to intrinsic PEEP but not cardiogenic shock. Intrinsic PEEP may also cause patient-ventilator asynchrony if ventilator triggering is missed when patients cannot reach the triggering threshold due to the inspiratory threshold load.

Recommended Ventilator Settings. Volume-limited or pressure-limited modes can be used, but volume-limited assist-control is the most frequent choice initially and provides control over the tidal volume, which is important in avoiding dynamic hyperinflation. A small tidal volume (e.g., 5 to 7 mL/kg predicted body weight) should be used to avoid hyperinflation, overventilation, and alkalemia. The backup respiratory rate for COPD patients receiving invasive mechanical ventilation should be set between 10 and 14/min. Given an inspiratory time of 1 second, if the respiratory rate is 20/min, the expiratory time is only 2 seconds; at a respiratory rate of 15/min, expiratory time increases to 3 seconds. Thus, relatively small changes in rate have large effects on expiratory time. Another way to increase expiratory time is to shorten the inspiratory time by increasing the inspiratory flow rate. However, this strategy is not as fruitful because substantial increases in flow rate result in only minor decreases in inspiratory time. For example, if the inspiratory time is 1 second and inspiratory flow is 60 L/min, an increase in the inspiratory flow rate to 100 L/min decreases the inspiratory time to 0.6 second (if tidal volume is held constant); thus, expiratory time increases only from 2.0 to 2.4 seconds. Furthermore, rapid flow rates may increase the spontaneous respiratory rate[193] and sensation of respiratory distress; COPD patients prefer flow rates in the 60 L/min range and tend to sense faster or slower rates as less comfortable.[186]

ASTHMA

Acute ventilatory failure due to acute asthma should be unusual if patients adhere to a medical regimen including inhaled corticosteroids, monitor their peak flows, and alter their medical regimen (with the addition of oral steroids) when peak flow declines. However, patients still experience severe asthma exacerbations and studies on near-fatal asthma have identified risk factors, including poor access to health care, substance abuse, nonadherence with therapy, underuse of corticosteroids, and underestimation of the severity of attacks.[194] In addition, heavy exposures to antigens, host factors that render patients particularly sensitive to specific antigens, or lack of adherence to environmental controls may also contribute. Episodes of severe asthma exacerbations can be reduced by the use of as-needed inhalers combining corticosteroids and long-acting β-agonists[195] and biologic asthma medications, including the anti–immunoglobulin E antibody, omalizumab, first available in 2003, as well as newer agents targeting interleukin-5, including mepolizumab, reslizumab, benralizumab, and dupilumab.[196] Even though episodes of acute ventilatory failure in asthmatics appear to be dropping, such attacks remain potentially lethal, with 3500 asthma-related deaths in the United States annually.[197]

Medical Management of Acute Asthma

Patients presenting with severe asthma should be promptly treated with systemic, as well as inhaled, corticosteroids and bronchodilators. Rapidly acting β_2-agonists are administered by inhalation, although no optimal method of administration or dose has been established. Metered-dose inhalers with spacers or nebulizers may be used, usually every 20 minutes for the first hour. Some centers use continuous nebulization for severe acute asthma. Magnesium, either intravenous or inhaled, has been administered, with some evidence to suggest that it aids aggressive β_2-agonist therapy, especially in the most severely ill asthmatics.[198]

Heliox has been used since the 1930s to lower resistance to flow related to turbulence in the airways of asthma patients, just as in COPD patients. However, a Cochrane analysis concluded that there is no defined role for heliox in treating severe acute asthma.[199]

Ventilatory Management

Assessment of Ventilatory Status. In patients with acute asthma exacerbations, ventilatory failure is unusual, but signs of severe respiratory distress, such as excessive use of accessory muscles, extreme tachypnea, or abdominal paradox, warrant prompt evaluation. Considering that asthmatic patients with respiratory distress are usually hyperventilating, arterial blood gases showing normocapnia in a patient with severe respiratory distress should cause alarm because, as they fail, patients reach a "crossover" point when they can no longer sustain hyperventilation but have not become sufficiently fatigued to retain CO_2. These patients should be monitored closely and considered for noninvasive ventilation to avert the need for invasive mechanical ventilation with its attendant potential complications.

Continuous Positive Airway Pressure. CPAP alone or NIV may ameliorate respiratory distress in asthmatics by reducing the work of breathing via a direct bronchodilator effect of positive pressure,[200] enhancing the effect of inhaled albuterol and offsetting intrinsic PEEP. However, the unequal distribution of airway resistance in asthma, in contrast to the more simultaneous closure of airways in COPD, creates areas with very different expiratory time constants. In this setting, CPAP can promote overdistention of some lung regions. Thus, caution should be exercised when applying CPAP to these patients, at least at levels exceeding 5 cm H_2O, and CPAP should be reduced to 5 cm H_2O if there is no further amelioration of respiratory distress at higher levels.

Noninvasive Ventilation. The role of NIV in the management of asthma exacerbations has not been clearly defined.[201] An early cohort study observed substantial improvements in blood gases (arterial P_{CO_2} dropping from 65 to 52 mm Hg in the first 2 hours) in 17 patients treated with NIV, only two of whom required intubation.[202] More recent studies have shown more rapid improvement in airflow[203] or equivalent improvement with less β-agonist medication.[204] In a study assessing the effects of bilevel ventilation on airflow in asthmatics, bronchodilators were withheld for the first hour of therapy and the higher bilevel setting was associated with greater improvement in FEV_1 than oxygen therapy alone.[205] These results suggest that

positive airway pressure might exert a bronchodilator effect; however, neither an RCT[206] nor meta-analysis[207] were able to demonstrate clinically meaningful benefits of NIV for acute asthma. Despite the absence of data supporting its use, a 2016 cohort study[208] using data collected over 4 years from a consortium of 97 U.S. hospitals found that 556 of 13,980 patients admitted with acute asthma (4%) were treated with initial NIV compared to 5% treated with initial invasive mechanical ventilation. The NIV failure rate was 4.7%, and hospital mortality among NIV failures, those placed on initial invasive mechanical ventilation, and NIV successes, was 15.4%, 14.5%, and 2.3%, respectively. In view of the uncertainty of the evidence, the European Respiratory Society/American Thoracic Society NIV Guideline Task Force made no recommendation on the use of NIV for acute asthma.[156] They did allow that an attempt at using NIV to avoid need for intubation might be warranted in patients behaving more like COPD patients (i.e., fixed airway obstruction).

Invasive Mechanical Ventilation. Invasive mechanical ventilation in patients with acute ventilatory failure due to asthma should be used as a last resort but is necessary when patients present with coma or delirium or with hemodynamic instability. Another clear indication is failure of standard medical therapy that may include NIV. Of patients admitted to the ICU with acute severe asthma, about one-third have been reported to require invasive mechanical ventilation.[194,209] Invasive mechanical ventilation is best avoided because of the frequency and severity of potential complications but, if needed, it should be initiated before a respiratory arrest. Complications of mechanical ventilation in asthmatics include barotrauma such as pneumothorax and pneumomediastinum, reported in 6.5% of patients in one series,[210] the need for sedation and paralysis with associated risk of postparalysis myopathy, ventilator-associated pneumonia, and mortality rates in the 5–10% range.[211]

If invasive mechanical ventilation is necessary, great care must be exercised to minimize the risk of complications, using an approach similar to that used for COPD patients. Excessive respiratory rates and tidal volumes should be avoided, with the ultimate goal of keeping plateau pressures under 30 to 35 cm H_2O. Permissive hypercapnia,[212] first described in invasively ventilated asthma patients,[213] remains a sensible approach in severely obstructed patients. With permissive hypercapnia, plateau pressures are maintained in a relatively safe range (<30 cm H_2O) as the first priority while allowing the CO_2 to rise, in some reports up to more than 100 mm Hg. Using this strategy, the major risks of positive-pressure ventilation can be minimized while providing time for the medical therapy to take effect. Bicarbonate can be administered if the pH drops too low, but this is probably not necessary and may not even be effective in raising the pH, a situation also described in patients with ARDS.[214] Because of the variability of resistance between airways, some of which may be obstructed, measurement of intrinsic PEEP using the expiratory hold technique may underestimate the severity of regional hyperinflation.[215] When ventilation remains difficult, even with lung-protective ventilation and permissive hypercapnia, heliox, general anesthesia with bronchodilator anesthetics (e.g., halothane),[216] or induced hypothermia have been used in the past, but in more recent years, centers with access to it have placed patients on extracorporeal membrane gas exchangers.

Extracorporeal Gas Exchangers (see Chapter 138). Extracorporeal membrane oxygenation has been used successfully to support patients with very severe asthma attacks when mechanical ventilation fails as evidenced by case reports.[217,218] Extracorporeal membrane oxygenation can be achieved using venovenous approaches where blood is removed, pumped through a gas-exchanging membrane, and then returned to the venous system via a dual-lumen catheter. Not only is the blood oxygenated, but CO_2 is removed, and this can be used to support patients through severe asthma attacks, allowing time for the asthma to subside. Extracorporeal membrane oxygenation can also be used in a venoarterial set-up, in which blood is removed from a vein and returned to an artery providing arterial pressure, in essence providing cardiopulmonary bypass for patients with not only respiratory but also circulatory failure.[219]

Another extracorporeal form of gas exchanger focuses on CO_2 removal rather than oxygenation and is referred to as extracorporeal CO_2 removal. This also removes venous blood, pumps it through a membrane gas exchanger, and returns it to venous blood using a dual-lumen catheter, but it operates at approximately 10% of the flow rate of extracorporeal membrane oxygenation,[219] which operates at nearly full cardiac output. Therefore, extracorporeal CO_2 removal cannot be used to restore hemodynamic stability but, by removing approximately one-third of the body's CO_2 production (80 mL/min), it may reduce ventilatory needs sufficiently to avoid intubation in patients failing NIV, allow mechanical ventilation at very low airway pressures, or facilitate extubation in patients with hypercapnic respiratory failure having difficulty weaning, particularly in COPD patients.[220,221] Although not currently approved or available in the United States, extracorporeal CO_2 removal is undergoing a clinical study in the United States (VENTAVOID study) in COPD patients with hypercapnic respiratory failure to determine whether it can reduce the number of invasive mechanical ventilation days compared to standard therapy plus NIV.

VASCULAR IMPAIRMENT

An increase in physiologic dead space by disorders affecting the pulmonary vasculature reduces alveolar ventilation in relation to overall minute ventilation. Although hypercapnia might be expected in such a circumstance, it is typically prevented by a modest increase in overall ventilation. Thus, acute ventilatory failure is seldom seen in primary pulmonary vascular disease. In pulmonary thromboembolism, for example, hypercapnia is unusual. Hypercapnia following pulmonary embolism can be seen, however, in patients with a comorbid condition such as severe COPD, with blunting of ventilatory drive, or with impaired function of the ventilatory pump. Indeed, acute respiratory acidosis, with or without concomitant worsening in oxygenation, may be the initial manifestation of pulmonary thromboembolism in a patient on controlled mechanical ventilation or with a high

cervical spinal cord injury or pharmacologic paralysis who cannot increase minute ventilation.

Another rare circumstance in which acute ventilatory failure may develop as a result of a disorder of the pulmonary circulation is venous air embolism, which leads to an abrupt increase in dead space, contributing to hypercapnia and a marked discrepancy between arterial and end-tidal exhaled CO_2 levels.[222] Hypercapnia may also complicate the acute chest syndrome in patients with sickle cell disease; one series documented respiratory acidosis in 42% of patients who developed this syndrome.[223]

Key Points

- Ventilatory failure is the consequence of inadequate alveolar ventilation, generally due to poor central drive, neuromuscular disease, profound mechanical derangement of lung parenchyma or chest wall, or a combination of these factors. Presently in the United States, acute ventilatory failure due to depression of central drive is mainly a consequence of opiate use.
- Respiratory muscle weakness, regardless of the origin of the impairment (e.g., immunologic, motor neuron disease, myopathic, associated with critical illness), may either precipitate intensive care unit admission or be acquired in the intensive care unit.
- Clinical assessment, including physical examination, measurement of maximal inspiratory and expiratory pressures, breathing pattern during spontaneous breathing trials, or bedside ultrasound to visualize the diaphragm, can be helpful in identifying respiratory muscle weakness.
- COPD exacerbation is the most common cause of acute ventilatory failure seen in acute care hospitals. COPD patients may develop acute or acute-on-chronic ventilatory failure due not only to bronchitis but also to complicating comorbidities including pneumonia, congestive heart failure, pulmonary embolism, or pneumothorax.
- Noninvasive positive-pressure ventilation reduces work of breathing by applying extrinsic *positive end-expiratory pressure* (PEEP) to counterbalance intrinsic PEEP and pressure support to assist inspiration. It is especially useful in exacerbations of COPD but may also play a role in other forms of acute ventilatory failure due to COPD, such as in facilitating extubation of those who fail a trial of spontaneous breathing or in avoiding reintubation in those who fail extubation.
- Noninvasive ventilation may also be tried in other forms of acute ventilatory failure, such as those caused by acute exacerbations of asthma or in acute-on-chronic respiratory failure in patients with obesity-hypoventilation syndrome, although evidence to support these applications is not as strong as in COPD.
- Invasive mechanical ventilation can generally be accomplished using small tidal volumes of roughly 6 mL/kg predicted body weight, which limits intrinsic PEEP in COPD, reduces the risk of ventilator-induced lung injury in those with parenchymal lung disease, and minimizes the circulatory compromise that can complicate restrictive chest wall conditions.
- When initiating noninvasive ventilation, there is a window of opportunity that opens when patients need ventilatory assistance but closes if they progress too far and become severely acidemic. Improvements in pH, arterial P_{CO_2}, and level of consciousness within the first hour or two of noninvasive ventilation are strong predictors of success.
- In patients with respiratory failure due to asthma or COPD, attempts to normalize arterial P_{CO_2} generally lead to dynamic hyperinflation, thereby risking hypotension and pneumothorax; instead, permissive hypercapnia is used to limit minute ventilation and maintain airway pressures in a safe range while allowing the arterial P_{CO_2} to rise.
- Newer extracorporeal membrane gas-exchange approaches, such as extracorporeal membrane oxygenation or extracorporeal CO_2 removal, can also be used to avert intubation and support patients with severe ventilatory failure; studies are ongoing to establish the efficacy of these approaches.

Increased Permeability Edema
OUTCOME
Resolution of Pulmonary Edema
KEY POINTS

INTRODUCTION

Pulmonary edema, defined as excessive extravascular water in the lungs, is a common and serious clinical problem. Pulmonary edema can be life-threatening, but effective therapy is available to rescue patients from the consequences of disturbed lung fluid balance. Because rational and effective therapy depends on understanding basic principles of normal and abnormal liquid, solute, and protein transport in the lungs, this chapter begins with a brief overview of the major factors that govern fluid and protein filtration in healthy lungs before focusing on the pathophysiology of pulmonary edema. Next, the chapter discusses diagnosis, treatment, and resolution of pulmonary edema. Because a thorough understanding of the lung's normal fluid clearance mechanisms is helpful to categorize the subtype of pulmonary edema and decide on treatment, the reader is encouraged to review Chapters 1, 3, and 6. Chapter 134 also contains excellent information specific to *acute respiratory distress syndrome* (ARDS).

PATHOPHYSIOLOGY

Pulmonary edema results when fluid is filtered from the pulmonary circulation into the extravascular compartments of the lungs faster than it can be removed. Accumulation of fluid has serious consequences on lung function because gas exchange is impaired in fluid-filled alveoli. Lung structure relevant to the forces governing fluid and protein movement in healthy lungs and lungs with pulmonary edema has been the subject of classic and more recent reviews.[1–6] In health, there is always a net outward flux of fluid and protein crossing from the pulmonary vascular circulation into the lung interstitium. This net outflux exists because the prevailing hydrostatic driving forces normally cause filtration from the bloodstream into the interstitium and, second, because the microvascular endothelium is a modestly permeable barrier under normal circumstances. Lung lymph flow, which reflects the flow of fluid crossing the microvascular barrier or bed (the term used in this chapter to refer to sites of fluid exchange in the lungs), normally is less than 0.01% of total lung blood flow. In addition to the vast interconnecting network of capillaries embedded in the alveolar walls, fluid is exchanged across capillaries in the interstitium at alveolar wall junctions (corner vessels) and across small interstitial arteries and veins. The essential factors that govern fluid exchange in the lungs are expressed in the Starling equation for the microvascular barrier, which is elaborated in Fig. 133.1 and mathematically describes the opposing forces of a hydrostatic pressure gradient and the protein osmotic pressure gradient between capillary and interstitium.

Microvascular hydrostatic pressure is the principal force causing fluid filtration in the lungs. If blood was not flowing through the lungs, the opposing hydrostatic and osmotic forces on either side of the microvascular barrier would be equal, their sum would be zero, and there would be no filtration. However, the pumping action of the heart causes blood to flow through the lungs, generating the microvascular hydrostatic pressure that establishes the steady-state values of the other driving pressures causing filtration of fluid.[5,7] According to the Starling equation, the difference between the prevailing transmural hydrostatic pressures ($P_C - P_i$) and the protein osmotic pressures ($\pi_C - \pi_i$) provides the driving force for fluid filtration (see Fig. 133.1). The actual amount of filtrate that forms at any given driving force is determined by the integrity of the barrier to filtration, which is reflected in the *conductivity* (L_p) and *reflection* (σ) coefficients. The equation predicts the development of two fundamentally different kinds of pulmonary edema: (1) increased pressure or hydrostatic pulmonary edema—when the net result of the driving forces increases, fluid filters across the barrier at a rate that exceeds removal by lymphatic drainage and other pathways,[8] and (2) increased permeability pulmonary edema—when the normal barriers to fluid filtration are damaged, typically by some form of injury, and conductance of liquid and protein in the lungs is allowed through paracellular pathways. A third type of pulmonary edema is caused by impaired lymphatic drainage of filtered fluid, but this is a very rare cause. The lymphatic drainage of the lungs provides a vital means for removing filtered fluid and proteins from the perimicrovascular interstitial space, as discussed later.[5,7,9] When fluid accumulates in the lung interstitium from increased filtration across the lung endothelium from either hydrostatic or

$$Jv = L_pS[(P_c - P_i) - \sigma(\pi_c - \pi_i)]$$

Figure 133.1 Fluid exchange as explained by the Starling equation. The Starling equation explains the movement of fluid across a semipermeable barrier. *Jv* is the net fluid-filtration rate (volume flow) across the microvascular barrier; L_p is the hydraulic conductivity ("permeability") of the microvascular barrier to fluid filtration (a measure of how easy it is for water to cross the barrier); *S* is the surface area of the barrier; P_c is the pulmonary capillary (microvascular) hydrostatic pressure; P_i is the interstitial ("perimicrovascular") hydrostatic pressure; π_c is the capillary (microvascular) plasma protein osmotic pressure; π_i is the interstitial (perimicrovascular) fluid protein osmotic pressure; and σ is the average osmotic reflection coefficient of the barrier (a measure of how effective the barrier is in hindering the passage of solutes from one side of the barrier to the other).

Table 133.1 Safety Factors That Protect the Lungs Against Interstitial and Alveolar Edema Formation in the Presence of Increased Pressure

Opposing osmotic pressure
Compliant interstitial space
Resorption into blood vessels
Lung lymphatic system
Drainage into the mediastinum
Drainage into the pleural space
Extremely low alveolar epithelial barrier permeability (in health)
Low alveolar surface tension from surfactant
Active transport by alveolar and distal airway epithelial cells

increased permeability, the alveolar epithelial barrier functions as the principal protection against the accumulation of alveolar edema. Fluid and protein do not normally move into alveoli because the alveolar epithelial barrier has a low permeability, even to small molecules (similar to cell membrane permeability); in addition, any fluid that is filtered is continuously being pumped back into the interstitium by vectorial ion transport across alveolar epithelial cells,[2,10] drained away from the alveolar walls through the interstitium, and removed by lymphatic vessels, bronchovascular pathways, and the lung microcirculation.

The several factors that normally protect the lungs against edema have been called *safety factors* (Table 133.1). Under normal conditions, the lymphatic system pumps filtered fluid and protein out of the lungs as rapidly as they are formed, even when filtration of fluid and protein from the bloodstream into the interstitium is increased. Increases in fluid and protein filtration across the microvascular barrier also can be drained away from the alveolar walls down the prevailing pressure gradient into the loose peribronchovascular connective tissue or can be resorbed directly into blood vessels.[4] The lung lymphatics can increase their pumping capacity significantly, particularly when the microvascular wall has been injured.[5]

The safety factors are resilient in the face of significant increases in hydrostatic pressure. With higher hydrostatic pressure, the increase in filtration of water across the microvascular barrier is much larger than that of protein because the microvascular barrier has a low protein conductance.

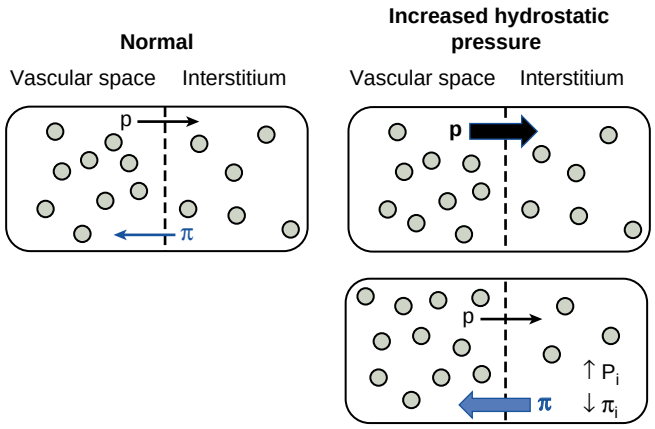

Figure 133.2 The safety factor of opposing hydrostatic and osmotic pressures across a normal microvascular barrier. In the normal state, the pressures are in relative balance, with the osmotic pressure of the proteins (π) constraining the fluid shifts from increases in hydrostatic pressure (p). With an increase in hydrostatic pressure (*large black arrow*), as more fluid moves into the interstitium, interstitial hydrostatic pressure rises and interstitial osmotic pressure falls. Both effects limit further flow from the vascular space to the interstitium (*large blue arrow*). P_i, interstitial hydrostatic pressure.

This results in dilution ("wash-down") of interstitial protein concentration and thereby an increase in the balance of the protein osmotic pressure opposing the higher hydrostatic pressure because plasma protein concentration remains high (Fig. 133.2). Furthermore, the interstitial gel also becomes hydrated, and the exclusion volume for protein decreases, either because of swelling or because its composition changes as hyaluronan is washed out from the interstitium, reducing the concentration of protein by expanding the available volume. This "sinking effect," whereby the hydrostatic gradient decreases and the protein osmotic gradient increases as microvascular hydrostatic pressure rises, is a safety factor only when the microvascular barrier is normal, as in increased pressure edema. In contrast, if the endothelial barrier is injured and its functional integrity is compromised—as in increased permeability edema—barrier conductance increases and the osmotic reflection coefficient decreases, rendering this safety factor ineffective.

The high compliance of the interstitial space also protects the lungs against edema. Increases in interstitial volume result in only small elevations of interstitial pressure until the interstitial volume is large. One study demonstrated that as much as 500 mL of edema fluid can collect in the lung interstitial space before there is alveolar flooding.[1] The accumulation of lung interstitial fluid maintains a suitably low hydrostatic driving pressure across the alveolar barrier. When interstitial pressure within the lungs rises to greater than pleural pressure, fluid flows across the highly permeable visceral pleura into the pleural space, where its effects on lung function are relatively minor. Pleural fluid is drained by lymphatics in the parietal pleura and, even when pleural liquid accumulates, does not flow back from the pleural space into the lungs[8] (see Chapter 14). Fluid that does accumulate in the alveoli is pumped out by active ion transport.[2] Several mechanisms can upregulate the rate of alveolar fluid clearance (see Chapter 3).

In summary, pulmonary edema results from increases in either driving pressures (increased pressure edema) or

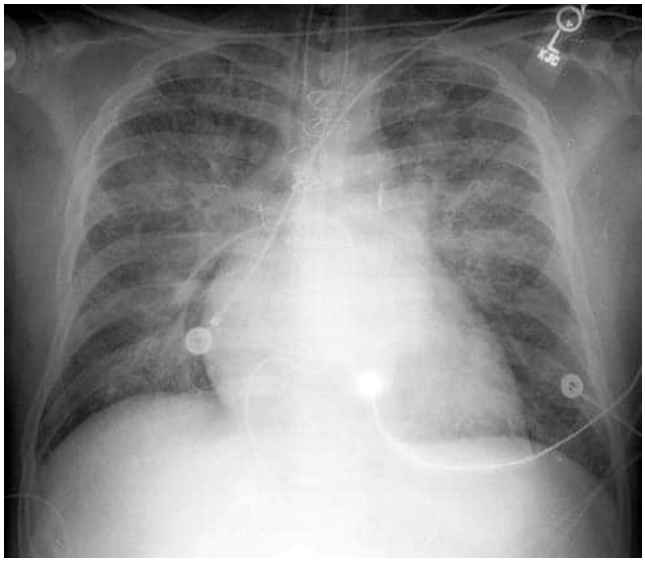

Figure 133.3 Frontal chest radiograph in a 55-year-old man with increased pressure edema due to heart failure. The heart is enlarged and bilateral perihilar linear and ground-glass opacities are present. This distribution is often referred to as a "butterfly" or "batwing" pattern and is commonly seen with chronic volume overload. (Courtesy Michael B. Gotway, MD.)

barrier conductance (increased permeability edema), or both. What distinguishes between the two types is barrier permeability, which is normal in increased pressure edema but high in increased permeability edema. Fluid flow into the lungs is driven across the barrier in both types of edema, according to the prevailing pressures and alveolar barrier permeabilities.

INCREASED PRESSURE EDEMA

Increased pressure pulmonary edema (Fig. 133.3) is caused by an increase in the net sum of driving forces for fluid filtration into the lungs. The essential feature of this edema is that the barriers to fluid and protein flow into the lungs are functionally intact. Increased pressure edema is often called cardiogenic, high-pressure, or hydrostatic pulmonary edema.

Pathophysiology

The flow of fluid and protein into the lungs increases when the sum of driving pressures is elevated. If the rate of fluid accumulation exceeds the rate at which it can be removed, increased pressure edema can result. Because the barriers limiting fluid and protein flow into the lungs are intact, the lungs are protected against edema by the prevailing (normal) safety factors. Especially important is the ability to protect against increases in the principal driving pressure, lung microvascular hydrostatic pressure. As previously explained, the reduction in plasma interstitial protein osmotic pressure in response to increased hydrostatic pressure mitigates alveolar flooding because both the hydrostatic and oncotic pressure gradients shift to favor less flow from the microvasculature to the lung interstitium. In experimental animals, slightly less than 50% of an increase in hydrostatic pressure is offset by the increase in osmotic pressure difference.[7,11] Increased pressure edema may be

Table 133.2 Effects of Vascular Congestion, Interstitial Edema, and Alveolar Flooding on Pulmonary Function and Lung Mechanics

VASCULAR CONGESTION
Increased diffusion capacity
Increased arterial P_{O_2}
Decreased compliance
Bronchoconstriction
INTERSTITIAL EDEMA
Increased closing volume
Decreased maximal expiratory flow
Increased ventilation-perfusion mismatching
Decreased arterial P_{O_2}
ALVEOLAR FLOODING
Right-to-left shunting of blood (compromising gas exchange)
Increased closing volume (air trapping)
Increased vascular resistance
Decreased lung volume (especially vital and inspiratory capacities)
Decreased compliance
Decreased diffusing capacity

P_{O_2}, partial pressure of oxygen.

gradual in onset and progression because any elevation in microvascular hydrostatic pressure is attenuated by a rise in protein osmotic pressure difference across the microvascular barrier, owing to a decline in interstitial protein osmotic pressure.

The consequences of increased pressure edema on lung mechanics and gas exchange (Table 133.2) depend on how much edema accumulates and typically proceed in a predictable manner.[12,13] At the vascular congestion stage preceding interstitial or pulmonary edema, increases in hydrostatic pressure result in enlargement of the intrapulmonary blood volume, as vessels, including capillaries, are both recruited and distended. The vascular changes cause the diffusing capacity to increase above normal, and the arterial *partial pressure of oxygen* (P_{O_2}) may rise because ventilated units are better perfused.[14] During this stage, small reversible changes in airflow resistance and dynamic compliance may also be observed, sometimes termed cardiac asthma.[15]

When interstitial edema is present, closing volume may be increased, leading to ventilation-perfusion mismatching, and maximum expiratory airflow may be decreased. These changes are likely due to a decrease in caliber of small airways caused by compression by rising volume and pressure in the peribronchovascular connective tissue spaces. This effect would have to be in airways larger than bronchioles because bronchioles and smaller airways do not have loose connective tissue sheaths,[16] and their diameter is influenced more by lung volume than transpulmonary pressure. Arterial P_{O_2} often declines due to areas of low ventilation-perfusion matching, but gas exchange is not seriously compromised until the alveoli are flooded.

With alveolar flooding, lung function declines significantly. Lung volumes are diminished.[13] Airways may close

at higher-than-normal distending pressures, resulting in trapping of larger volumes of gas in the lungs.[14] Lung compliance is reduced because lung volume decreases, and edematous lungs require more pressure to inflate. Because the flooded alveoli remain perfused, very low ventilation to perfusion lung units and right-to-left shunts are created, resulting in low arterial Po_2.[15] In addition, there is an increase in wasted ventilation (ventilation of units in which there is decreased or absent perfusion, or units with high ventilation-perfusion ratios).

Light and electron microscopic examination of human and animal lung tissue in increased pressure edema shows alveolar edema and variable red blood cell accumulation; thickened interstitial compartments, especially large peribronchovascular fluid cuffs or fluid surrounding the bronchi and vessels; and increased capillary surface area and volume.[17] Other than an increase in intercellular vesicles, there are no detectable changes in the ultrastructure of the vascular endothelium, with normal gap widths at intracellular junctions. However, when pulmonary edema is longstanding, for instance in chronic mitral stenosis, there may be remodeling that limits the development of further lung flooding. Dogs exposed to a pacing-induced chronic congestive heart failure model had thicker alveolocapillary barriers, spanning endothelium, interstitium, and epithelium.[18] Furthermore, they exhibited resistance to develop increased pressure edema—at high pulmonary vascular pressures, only half as much water and protein moved across the endothelial barrier—compared with that of control animals. Thus, remodeling may confer some protection against the development of high-pressure–induced alveolar edema and may shift up the pressure threshold at which edema forms. In addition, alveolar epithelial type 2 cells may be more numerous in chronic increased pressure edema than in normal lungs, which might signify an increased capacity to remove alveolar edema by vectorial ion transport.[2] Further, there is an increase in alveolar macrophages,[19] conceivably to clear red blood cells that accumulate in the alveoli due to chronic heart failure. However, sites of chronic severe increased pressure edema may also become organized and fibrotic and may even calcify.[20]

Mechanisms

By far the most common cause of increased pressure edema is elevated lung microvascular hydrostatic pressure. Less commonly, driving pressures into the alveolus can increase due to a reduction in perimicrovascular or alveolar hydrostatic pressure or a reduced protein osmotic pressure difference across the microvascular barrier. The possibilities are listed in Table 133.3 and reviewed individually later.

Table 133.3 Mechanisms of Increased Pressure Pulmonary Edema

INCREASED MICROVASCULAR HYDROSTATIC PRESSURE
Left ventricular dysfunction
Mechanical obstruction of left atrial outflow
Circulatory volume overload
Pulmonary venous hypertension
Overperfusion
Increased lymphatic outflow pressure
DECREASED PERIMICROVASCULAR HYDROSTATIC PRESSURE
Inspiratory airway obstruction with extremely negative intrathoracic pressure
Rapid aspiration of air or fluid from the pleural space
Increased alveolar surface tension

Increased Microvascular Hydrostatic Pressure. Congestive heart failure is the most common cause of increased pressure edema. That is why increased pressure edema is often called "cardiogenic," even though the heart is not always primarily involved. Elevated pressures in the pulmonary microvasculature are usually due to left-sided heart failure, with elevated left atrial pressures transmitted retrograde into the pulmonary circulation. Common causes are left ventricular dysfunction (e.g., caused by acute myocardial infarction, severe coronary insufficiency, tachyarrhythmias, bradyarrhythmias, cardiomyopathies, constrictive pericarditis, aortic stenosis or regurgitation, mitral regurgitation, coarctation of the aorta, rupture of chordae tendineae or intraventricular septa, systemic hypertension) or mechanical obstruction of the left atrial outflow tract (e.g., mitral stenosis, left atrial myxoma). Left atrial and pulmonary microvascular pressures can also be elevated by severe fluid volume overloading in a patient with a normal or diseased heart.

An unusual cause of increased microvascular hydrostatic pressure is pulmonary venous hypertension in the absence of left ventricular or atrial disease, which can arise if the pulmonary veins are contracted, compressed, or obstructed (e.g., because of veno-occlusive disease or fibrosing mediastinitis). Bronchial venous hypertension, in contrast, does not appear to increase fluid filtration in the lungs.[21]

Increases in fluid filtration also can be associated with increases in vascular pressure proximal to the filtration sites in the lungs. For example, pulmonary hypertension, combined with depressed left ventricular function, has been implicated in the pathogenesis of cocaine-induced pulmonary edema. Whether such increases lead to pulmonary edema depends on what happens to microvascular pressure. If high right-sided pressures are caused by increased resistance proximal to the main site of filtration in the lungs, as found in hypoxic pulmonary vasoconstriction of small arterial vessels,[22] pulmonary arterial hypertension, and pulmonary artery or valvular stenosis, pulmonary edema does not typically develop. Conversely, if the lung vascular bed is only partially constricted or obstructed, or if the vascular surface area is greatly decreased (e.g., by lung resection), higher flow in perfused vessels can lead to increased pressure edema[23] because microvascular pressures at the fluid exchange site are elevated in the overperfused lung. For example, in one study, pulmonary edema complicated approximately 15% of pneumonectomy cases and seemed to be exacerbated by administration of fresh frozen plasma,[24] likely because of increases in intravascular volume. Any increase in blood flow through the lungs increases the pulmonary microvascular pressure at the fluid exchange sites even when pulmonary venous pressure remains constant.

The mechanism of an uncommon cause of pulmonary edema, *high-altitude pulmonary edema*[25] (also discussed in

Chapter 105), may also be related, in part, to elevated pulmonary vascular pressures. As noted earlier, overperfusion of a restricted pulmonary vascular bed, even in the absence of hypoxia, causes increased pressure edema, not increased permeability edema.[23] This can explain why some cases of high-altitude pulmonary edema are correctly classified as increased pressure pulmonary edema. Evidence from climbers studied at high altitude suggests that high intravascular pressures can cause physical damage to vascular walls (so-called stress failure). In experimental animals, stress failure has been demonstrated after extreme, but sometimes transient, increases in pulmonary vascular pressures.[26] Such structural failures need not happen to many pulmonary vessels to explain an increase in permeability edema because edema would form readily and in a quantity driven by the prevailing elevated vascular pressure.[27] The suggestion has been made that high-altitude pulmonary edema results from the stress failure of overdistended, relatively thin-walled pulmonary arteries, rather than from microvascular rupture,[28] which might help explain why the prevailing vasoconstriction does not seem to offer much protection to downstream vessels, why there are no reports of gradual progression through an indolent prodrome of increased pressure edema before stress failure results, and why high-altitude pulmonary edema is first detected radiographically in the central lung fields surrounding large vessels, rather than in the lung bases and periphery. Alternative mechanisms for the increased permeability in high-altitude pulmonary edema have been proposed. However, inflammatory responses in high-altitude pulmonary edema may be a consequence rather than a cause of the edema.[29] The rapid reversibility of high-altitude pulmonary edema with descent to lower elevation, oxygen therapy, or pharmacologic reduction of pulmonary vascular pressure is more characteristic of an increased pressure pulmonary edema, not of an increased permeability pulmonary edema with coexisting inflammation.

Neurogenic pulmonary edema,[30] which can be radiographically indistinguishable from other forms of edema, also may result in part from elevated pulmonary vascular pressures. Measurements of edema fluid protein concentration relative to plasma protein concentration in 12 patients with neurogenic pulmonary edema have been reported.[31] Seven of the patients had ratios typical of increased pressure pulmonary edema. However, the other five had elevated ratios that could be consistent either with increased permeability pulmonary edema or with sampling during the later resolution phase of increased pressure pulmonary edema, at which time edema fluid protein concentration rises as fluid is reabsorbed from the alveoli at a faster rate than protein.

Decreased Perimicrovascular Hydrostatic Pressure. The sum of driving pressures favoring flow out of the vasculature would increase if perimicrovascular hydrostatic pressure was greatly diminished, thereby resulting in an increase in fluid and protein filtration at the microvascular barrier in the lungs. Pulmonary edema has been described in circumstances in which this might happen. The best clinical example may be postobstructive pulmonary edema as a consequence of upper airway obstruction or its release. Postobstructive pulmonary edema has been described after obstructions caused by laryngospasm, endotracheal tube obstruction, foreign body aspiration, epiglottitis, croup, severe acute asthma, airway compression by tumors, strangulation, or hanging. High negative intrathoracic pressures generated by inspiratory attempts against the occluded airway are transmitted to the interstitium, lowering interstitial hydrostatic pressure and promoting fluid movement into the interstitium. Mechanical effects on the cardiovascular system likely contribute to this kind of edema because high negative intrathoracic pressure increases cardiac preload, afterload, and pulmonary blood flow, all of which increase the microvascular hydrostatic pressure. In three patients with upper airway obstruction and pulmonary edema, all had low edema fluid protein concentration relative to plasma protein concentration (ratios of 0.44, 0.31, and 0.52, respectively), favoring increased pressure pulmonary edema instead of a permeability mechanism.[32,33]

Aspiration of air or fluid from the pleural space, as by thoracentesis, with consequent reexpansion of a collapsed lung, could result in a decrease in perimicrovascular hydrostatic pressure as the lung expands to fill the thorax. So-called reexpansion pulmonary edema has been reported both in experimental animals[34] and in humans[35] after lung reexpansion; however, there are conflicting reports as to the edema fluid protein concentration from human subjects[36,37] and animal models,[38] suggesting that either hydrostatic or permeability mechanisms may predominate. If high alveolar surface tension was transmitted to the interstitium, perimicrovascular hydrostatic pressure would also be lowered, thereby increasing filtration across the microvascular barrier. Such an effect has been suggested by experimental findings in dog lungs.[39] The effect of alveolar surface tension on lung fluid balance is discussed later.

Decreased Transmural Protein Osmotic Pressure Difference. Increased pressure pulmonary edema may also result from decreases in the protein osmotic pressure difference opposing the hydrostatic pressure difference across the microvascular barrier. The osmotic difference may decrease when plasma protein concentration is lowered due to cirrhosis, nephrotic syndrome, or malnutrition, or in the presence of high interstitial protein concentration. This theoretical mechanism of increased pressure edema has been the subject of study in experimental animals, with contradictory results.[40] When plasma protein osmotic pressure is low, the ability of the osmotic pressure gradient to widen in response to increased hydrostatic pressure is diminished, and edema accumulates at hydrostatic driving pressures lower than those needed to cause edema when plasma protein concentration is normal. Low protein osmotic pressure may also contribute to pulmonary edema in pregnancy and early postpartum settings.[41] Although it is uncommon to attribute pulmonary edema exclusively to the mechanism of diminished protein osmotic pressure gradient,[42] this physiologic state frequently complicates pulmonary edema due to either increased pressure or increased permeability so that patients with low plasma protein osmotic pressure develop severe edema more rapidly and may have a delayed recovery.

Alveolar Barrier Function. Although the preceding section has focused mainly on driving pressures from the microvascular (endothelial) space to the interstitium, the

same principles apply to driving pressures across the interstitial and alveolar (epithelial) barriers. Increased pressure edema can result from several conditions: if interstitial hydrostatic pressure is raised, if alveolar hydrostatic pressure falls, or if the osmotic pressure difference across the alveolar barrier is lowered. Interstitial hydrostatic pressure rises as interstitial edema accumulates in the lungs.[4,9] Increased interstitial hydrostatic pressure would raise the sum of driving pressures across the alveolar barrier and could drive edema formation across the alveolar or airway epithelium.

Experimentally, a relationship between higher alveolar surface tension and decreased interstitial hydrostatic pressure, which favors edema formation, has been observed,[43] leading to alveolar edema. Administration of a detergent aerosol in an animal model resulted in loss of surfactant activity, higher alveolar surface tension, lower static compliance, atelectasis, and pulmonary edema.[43] Supporting an increased pressure mechanism for this model of pulmonary edema, alveolar edema fluid protein concentration was low[43] and, because neither protein osmotic pressure nor pulmonary microvascular hydrostatic pressure was altered,[44] the interstitial hydrostatic pressure was likely affected. However, it is also possible that detergent administration may have directly injured the alveolar epithelium. Because increased pressure edema can impair surface activity of dog lung extracts and isolated rabbit lungs, it is possible that changes in alveolar surface tension may accelerate edema formation. However, the notion that changes in alveolar surface tension in edema lead to a self-perpetuating vicious circle of edema formation is not borne out clinically.

Near-drowning is the one clinically pertinent form of pulmonary edema caused by transmural osmotic pressure differences at the alveolar barrier.[45] Seawater is three times more osmotic (1000 mOsm) than plasma, so the volume of fluid in the air spaces after saltwater aspiration increases threefold to reach osmotic equilibrium, thus markedly increasing the alveolar edema volume beyond the aspirated seawater in the alveoli. Osmotic equilibrium is reached in minutes as water is drawn from neighboring blood vessels into the alveoli by osmotic pressure.[45] Alveolar barrier function is not significantly compromised, unless perhaps the patient aspirates gastric contents or the seawater is contaminated or rich in particulate matter, and the alveolar edema tends to be cleared rapidly if driving pressures are otherwise normal, with 50–60% of excess alveolar fluid being cleared in 4 hours. Freshwater near-drowning classically proceeds in the opposite fashion: Osmotic equilibrium is reached rapidly by flow of water out of the alveoli into the interstitium and bloodstream. Rapid water flux and hypotonicity can cause severe hemodilution, with hemolysis and fibrinolysis, and severe distortion of pulmonary ultrastructure, including damage to type 1 and type 2 cells, endothelial cell swelling, basement membrane detachment, and cell disruption. Both the alveolar epithelium and microvascular endothelium can thus be injured by the hypotonic fluid, leading to increased permeability pulmonary edema rather than an increased pressure type of pulmonary edema. In addition, aspiration of water, whether freshwater or seawater, can wash out surfactant and contribute to pulmonary edema.

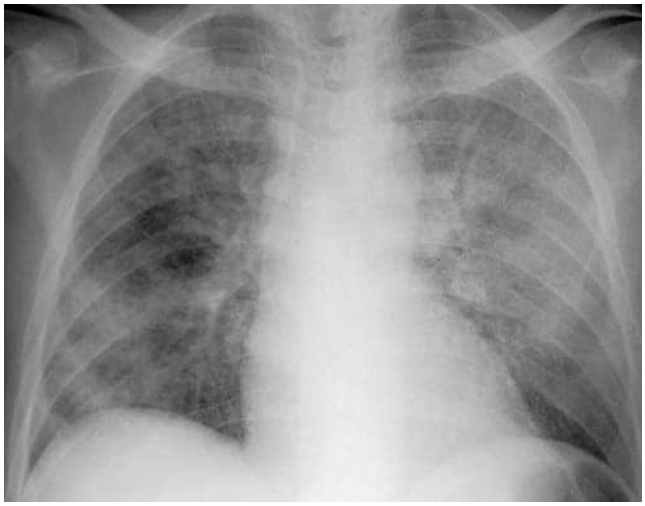

Figure 133.4 Frontal chest radiograph in a patient with increased permeability edema. Bilateral consolidation, more prominent on the left, is present. The heart is not enlarged, and no pleural effusions are present. No features typical of volume overload are evident. (Courtesy Michael B. Gotway, MD.)

INCREASED PERMEABILITY EDEMA

Increased permeability pulmonary edema (Fig. 133.4) is caused by an increase in liquid and protein conductance across the barriers in the lungs. The essential feature of this edema is impaired barrier integrity to fluid and protein flow into the lung interstitium and alveoli. Increased permeability edema is sometimes called *noncardiogenic pulmonary edema,* and the resulting clinical syndrome in humans, when clinical and radiographic criteria are met (Table 133.4), is referred to as ARDS, discussed in detail in Chapter 134.[46]

Pathophysiology

If the rate of fluid and protein accumulation from lung endothelial and epithelial barrier injury exceeds the rate at which it can be removed, increased permeability edema can result. Because the barriers limiting fluid and protein flow into the lungs do not function normally when the lungs are injured, the lungs are not protected against edema by all the safety factors listed in Table 133.1. Although the excess fluid and protein are removed by lymphatics and drained away from the alveolar walls as in increased pressure edema, much more fluid and protein are filtered at any given sum of driving pressures because the barriers to their flow are much less restrictive than normal. As a result, edema formation in injured lungs becomes extremely sensitive to driving pressures.[27] In addition to the changes in the barrier function, driving pressures are often increased when the lungs are injured because of the vasoactive effects of inflammatory mediators such as thromboxanes, which may shift the main site of resistance to postcapillary venules, thus increasing hydrostatic pressure at the microvascular fluid exchange sites,[47] or because of the effects on the heart and on the circulation. For example, elevated left atrial pressure, pulmonary venoconstriction, and an increase in cardiac output in sepsis can all increase hydrostatic pressure at microvascular fluid exchange sites.[48]

Table 133.4 Berlin Definition of ARDS[65]

Mild	Pao_2/Fio_2 > 200–300 mm Hg with PEEP ≥5 cm H_2O	Bilateral radiographic opacities consistent with pulmonary edema and not explained by effusions or atelectasis, and judged not to be explained by increased left atrial pressure	Acute onset (within 1 week of risk factor, or within 1 week of symptom onset)
Moderate	Pao_2/Fio_2 > 100–200 mm Hg with PEEP ≥5 cm H_2O		
Severe	Pao_2/Fio_2 ≤ 100 mm Hg with PEEP ≥5 cm H_2O		

ARDS, acute respiratory distress syndrome; Fio_2, fractional concentration of oxygen in inspired gas; Pao_2, partial pressure of arterial oxygen; PEEP, positive end-expiratory pressure.

Because the endothelial-epithelial barrier is more permeable than normal, protective protein osmotic pressure differences are lost so that driving pressure is unopposed by protein osmotic pressure. Thus, even at normal hydrostatic pressure, there is significant fluid and protein extravasation into interstitial and alveolar spaces. Maximal lung lymph flow increases more when the microvascular wall has been injured than when hydrostatic pressure alone is increased, but even this augmented lymphatic pumping capability is insufficient. If the epithelial barrier is injured, edema may accumulate readily in the alveoli because most of the resistance to fluid and protein flow into the alveoli resides in the epithelial barrier.[49] As mentioned earlier, because the injured barriers offer much less resistance to flow and the safety factor provided by the osmotic pressure difference is lost, increased permeability edema is often rapid in onset and progression. And, although it was historically believed that increased permeability edema was characterized by low intravascular hydrostatic pressure, and the prior ARDS consensus definition even specified that the *pulmonary artery wedge pressure* (PAWP) should be 18 mm Hg or less if measured,[50] ARDS and increased hydrostatic pressures frequently coexist. In that situation, edema may be expected to form rapidly due to elevated driving pressure unopposed by a normal barrier.

The consequences of increased permeability edema on lung mechanics and gas exchange depend on the quantity of edema and the severity of the causative lung injury.[51] As with increased pressure edema, alveolar flooding causes major effects on pulmonary mechanics. In experimental lung injury, functional residual capacity decreases as a consequence of alveolar flooding, and this loss of ventilated units accounted for virtually all the observed decrease in static lung compliance.[52] *Computed tomography* (CT) has provided new insights into structure-function relationships in ARDS[53] and demonstrated the significant heterogeneity in lung aeration even when the chest radiograph suggests diffuse edema. In classic early diffuse ARDS, edema accumulates in all lung regions with a nongravitational distribution. Increased lung weight due to edema causes collapse of more dependent lung regions through the transmission of hydrostatic forces (compression atelectasis, caused by the weight of edema).[53]

Measurements of pulmonary mechanics in mechanically ventilated patients with diffuse injury to the lung have shown a decreased static lung compliance as a consequence of loss of ventilated lung. In addition, airflow resistance is increased as a result of decreased lung volume.[51] Bronchospasm may add to the increase in airflow resistance and can be substantially reversed by bronchodilator inhalation.[54] Chest wall compliance is reduced, probably because of alterations of intrinsic mechanical properties of the chest wall by abdominal distention, chest wall edema, and pleural effusion.[51] Respiratory mechanical abnormalities and responses to *positive end-expiratory pressure* (PEEP) may differ between patients with severe ARDS originating from pulmonary disease (pneumonia with consolidation) compared to those with severe ARDS from extrapulmonary disease (associated with pulmonary edema and alveolar collapse).[55] Alternatively, it may be that the extent of radiographic consolidation—diffuse versus focal—is a major determinant of response to PEEP in ARDS,[56] regardless of the inciting injury.

Alterations to pulmonary surfactant volume and function may contribute to permeability edema pathophysiology. The injured lung may release substances that interfere with the normally low surface tension in the alveoli,[57] and activated polymorphonuclear leukocytes impair surfactant function in vitro and degrade the major surfactant apoproteins by proteolysis and oxidant-radical–mediated mechanisms.[58] Lung surfactant obtained by *bronchoalveolar lavage* (BAL) from patients at risk for diffuse injury to the lung and from those with established injury is abnormal in chemical composition and functional activity.[59] Abnormalities also may be caused by interactions between surfactant and edema proteins because plasma proteins, including fibrin, fibrinogen, and albumin, interfere with surfactant function. Intraalveolar coagulation may compound surfactant depletion. Proteinaceous edema fluid has been associated with surfactant inhibition in various experimental models.[60] The role of surfactant in the development and treatment of diffuse lung injury and the potential role for surfactant therapy are discussed in more detail later in this chapter.

Oxygenation is often severely compromised in increased permeability edema, owing both to intrapulmonary shunting of blood and to low ventilation-perfusion lung units.[61] Patients with early lung injury also have a marked increase in their pulmonary dead space fraction, indicating that many ventilated lung units are not well perfused[62]; this finding explains why minute ventilation rises to twice normal (12–16 L/min) at the onset of severely increased permeability edema. An elevated pulmonary dead space fraction also has been reported in pediatric patients with widespread lung injury,[63] the mechanism that may, in part, be explained by an increase in procoagulant and antifibrinolytic pathways in parenchymal damage.

The pathologic sequence of increased permeability edema has been well described using oxygen toxicity as one prototypical inciting cause.[64] ARDS was classically described as evolving from an exudative stage to one characterized as proliferative and then fibrotic in sequence. The earliest "exudative" changes are marked by widespread alveolar and interstitial edema and hemorrhage, along with capillary congestion and atelectasis. Hyaline membranes,

composed of precipitated plasma proteins, fibrin, and necrotic debris, are often observed, and pathologists use the term *diffuse alveolar damage* (DAD) to describe this combination of edema, hemorrhage, and/or hyaline membranes.[64] However, although DAD is often described as the morphologic hallmark of ARDS,[65] neither DAD nor hyaline membranes were universally found in the pathologic samples from patients with ARDS,[46,64] and DAD can be described in other lung diseases. More recently, a large Spanish autopsy study reported that only 45% of lungs from patients who died with ARDS exhibited DAD and, even among those with severe ARDS for at least 72 hours, the proportion with DAD was only 69%.[66] Although some have argued that ARDS in the absence of hyaline membranes may not be ARDS, a better explanation is that ARDS with hyaline membranes represents a specific subtype or level of severity.[67]

In some patients, the exudative phase is followed by a proliferative phase, which begins as early as 5 to 7 days after the onset of injury.[68] The relative contributions of the original insult, repair processes, and effects of therapies to this and subsequent phases are not well known. Furthermore, it is likely that historical mechanical ventilation strategies using larger tidal volumes (between 12 and 15 mL/kg predicted body weight)[69] were a major contributor to the pathologic progression of lung injury. In the proliferative phase, some of the edema fluid has been reabsorbed from the air spaces. Fibrin may be prominent in alveoli and interstitium, and there is infiltration with inflammatory cells and fibroblasts. The alveolar epithelium is often cuboidal, made up largely of proliferating type 2 cells. The air-blood barrier can be thickened by interstitial and epithelial enlargement. The pulmonary vascular bed may be partially or completely disrupted, and structural alterations may reduce its surface area. A final stage may follow, often about 10 to 14 days after the initial insult, in which fibrotic changes of the alveolar ducts, alveoli, and interstitium predominate; alveoli may be obliterated, alveolar walls coalesced, and functional lung units lost. Less common, the lungs show emphysema-like bullous changes.[68] Pulmonary function test results in 5-year survivors of severe increased permeability edema usually return to normal or near-normal values, but exercise limitation and physical, cognitive, and psychological impairments often persist.[70,71]

Mechanisms

The major types of clinical conditions associated with increased permeability edema are listed in Table 133.5. The most common causes are pneumonia, sepsis, gastric aspiration, and major trauma. Reperfusion injury is one of the causes of the pulmonary edema seen in transplanted lungs and appears to be predominantly an increased permeability edema.[72] In all cases, the lungs can be injured either via the airways as a *direct* injury or via the bloodstream as an *indirect* injury. The exact mechanisms by which diffuse lung injury leads to increased permeability edema have been the subject of intense investigation in humans, animal models, and cellular systems, summarized in several reviews.[73–75] Human studies have provided descriptive data about events in the air spaces before and after the onset of lung injury.

Studies using BAL in patients before and after the onset of diffuse lung injury have shown that there is a major acute inflammatory response that begins before lung injury is clinically recognized, peaks during the first 1 to 3 days of clinical involvement, and then resolves slowly over the next 7 to 14 days in patients who remain intubated.[73,76] These studies have shown the complexity of the evolving inflammatory responses, which are characterized by the accumulation of acute response cytokines and their inhibitors, oxidants, proteinases and antiproteinases, lipid mediators, growth factors, and collagen precursors involved in the repair process.[74,77–82] Extensive efforts have been made to identify single biologic markers that predict the onset or the outcome of diffuse injury to the lung, but these have met with only limited success.[47,83,84]

Table 133.5 Clinical Disorders Associated With Increased Permeability Edema

Infections, both pulmonary (pneumonia) and non-pulmonary
Sepsis
Aspiration
Trauma
Reperfusion (posttransplant)
Hemodynamic disturbances (shock)
Medications and toxins
Smoke inhalation
Drowning, especially in fresh water
Hematologic disorders
Neurologic disorders

CLINICAL ASSESSMENT

When pulmonary edema is severe, the patient is overtly hypoxemic and in respiratory distress, making the identification of edema fairly straightforward. More nuanced, however, may be the distinction between increased pressure and increased permeability edema. Although many aspects of treatment are shared between both major forms of pulmonary edema, the distinction is important as the clinician seeks to reverse the underlying cause.

SYMPTOMS AND SIGNS

The clinical manifestations of pulmonary edema vary with its severity and depend on the underlying pathophysiology and the extent to which excess edema fluid has accumulated in the lungs. Characteristic symptoms include dyspnea, cough, and tachypnea. Wheezing, when audible, may suggest a problem of airflow obstruction rather than edema.[85] Once alveoli have flooded, the diagnosis of pulmonary edema is not subtle. Patients with alveolar edema usually have severe respiratory distress with tachypnea and often productive cough of frothy and sometimes blood-tinged edema fluid. Crackles and rhonchi are heard over the lung fields, and wheezing may be present. The patient may be cyanotic if alveolar flooding has seriously compromised gas exchange.

Development of increased pressure pulmonary edema is often slow and progressive because the alveoli are protected by the normal safety factors (see Table 133.1). (However, there is a form of increased pressure edema that develops suddenly [or unexpectedly] and sometimes is called flash pulmonary edema, when protective safety factors have been surmounted.) In contrast to the typical subacute progression seen with increased pressure edema, alveolar flooding and symptoms of respiratory distress often progress rapidly from insult to respiratory failure with increased permeability edema.

Because pulmonary edema is always a sign of an underlying pathologic process, its cause must be identified so that effective therapy can be directed at the underlying problem producing abnormal transvascular fluid and protein flow into the lungs. Increased pressure edema is most often caused by cardiac failure—systolic dysfunction with impaired myocardial contractility or diastolic dysfunction with impaired relaxation—and thus is usually accompanied by a history of heart disease. Manifestations include signs and symptoms of any of the many causes of chronic and acute congestive heart failure, such as coronary insufficiency, hypertension, valvular heart disease, and severe volume expansion. Elevated jugular venous pressure, cardiac enlargement, gallop rhythms, heart murmurs, arrhythmias, an enlarged tender liver, and peripheral edema almost always suggest an underlying abnormality of cardiac function. However, pulmonary edema may be the only manifestation of silent myocardial infarction or diastolic dysfunction of the left ventricle.[86]

History and physical examination may also be helpful in differentiating between increased pressure and increased permeability pulmonary edema because most patients in the latter category usually do not have signs or symptoms of underlying cardiac disease. The cause of increased permeability edema may be suggested by a history of exposure (e.g., to toxic gases or chemicals or infectious agents, near-drowning, drug ingestion, trauma), the clinical setting (e.g., sepsis, pneumonia, emesis, seizures, pancreatitis), or the physical findings (e.g., chest trauma, long bone fractures, coma, shock). Because infections, including sepsis, are the leading causes of increased permeability edema in patients, a thorough search must be made for signs and symptoms of infection. Pulmonary and intra-abdominal sources are the most common sites of involvement, and all patients should be examined carefully, with special attention being paid to sites vulnerable to more subtle findings, including abdominal, rectal, skin, and pelvic examinations.

DIAGNOSTIC STUDIES

Laboratory and other diagnostic studies are often helpful but, by the time many of the results are confirmed to be abnormal, the diagnosis is usually obvious. Appropriate cultures for microorganisms and toxicology screens of blood and urine are useful in identifying underlying causes of increased permeability edema and to ensure appropriate antimicrobial therapy. Examination of sputum or tracheal aspirate, bronchoscopy with protected-specimen brushing or BAL, or mini-BAL are all useful in diagnosing pneumonia in ventilated patients, even those who are being treated with antimicrobial drugs.[87–90] Lung biopsy can sometimes provide a specific diagnosis in critically ill patients,[67,91] but the results may not be helpful because lung injuries caused by diverse underlying conditions have similar histologic appearances and because specific therapies may not be available. Serum and plasma testing focused by the patient's history, particularly when infection seems less likely, might include testing for pancreatitis, for carboxyhemoglobin if smoke inhalation was suspected, or for transfusion-related factors (e.g., cognate antibodies to human leukocyte antigen class I or II, or to human neutrophil antigen) if the patient recently received any blood products.[92]

CHEST IMAGING

The plain chest radiograph is the most practical test available for the detection of pulmonary edema.[93,94] Disadvantages are that chest radiographs are insensitive to small changes in lung water and are only semiquantitative.[1] An additional limitation is that chest radiographs are not consistently helpful in distinguishing increased pressure edema from increased permeability edema.[94,95] In the *Fluid and Catheter Treatment Trial* (FACTT), studying the use of central venous and pulmonary arterial catheters to target volume strategies in ARDS, the vascular pedicle width, measured as a horizontal distance from where the superior vena cava crosses the right mainstem bronchus to the left subclavian artery exiting the aortic arch,[96] had moderate correlation with PAWP but only fair sensitivity to predict whether a target PAWP had been achieved.[97] Despite these limitations, chest radiographs are noninvasive, inexpensive, easily repeatable, readily available, and free of serious side effects, apart from a small amount of radiation.

Before alveolar flooding, plain chest radiographs typically show distended vascular shadows (particularly in the upper lung fields), enlargement and loss of definition of hilar structures, development of septal lines (Kerley lines) (Fig. 133.5A and Fig. 108.3B), loss of peribronchial and perivascular definition or cuffing (see Fig. 133.5B and Video 133.1), and perihilar haze indicating the presence of interstitial pulmonary edema. Acinar shadows, often confluent and creating irregular, patchy increases in lung density that obscure vascular markings, indicate the presence of alveolar edema. Air bronchograms may be observed in severe edema. Because the radiographic signs of interstitial and alveolar edema are determined by gas and blood volumes and their distribution in the lungs in addition to the presence of edema, the recognition and quantitation of edema are not precise, and the radiographic appearance of edema is strongly influenced by the lung volume at the time the film is made. The appearance of the chest radiograph is an integral part of the Berlin definition of ARDS,[65] but the interpretation of chest radiographs is not well standardized, and significant interobserver variations have been reported.[98] One approach for scoring the chest radiograph and accounting for atelectasis correlated well with lung weight in lungs studied from brain-dead potential organ donors.[99] More recently, investigators have reported a *radiographic assessment of lung edema* (RALE) score assessing both the extent of alveolar opacity and the density of consolidation in each quadrant. This composite score exhibited strong interreviewer agreement, strong correlation with total lung weight of donor lungs, and association with arterial Pa_{O_2}/*fractional concentration*

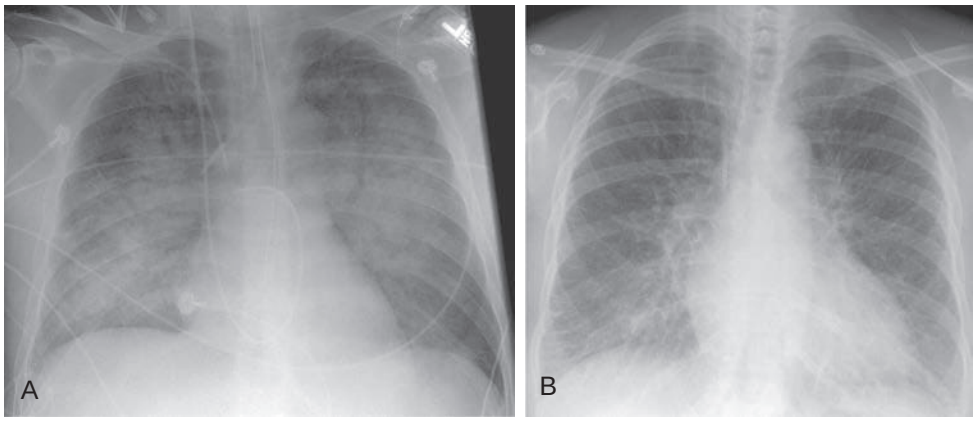

Figure 133.5 Two patients with increased pressure edema from heart failure. (A) Frontal chest radiograph in a patient with increased pressure pulmonary edema from heart failure showing alveolar edema and bilateral consolidation. Note presence of air bronchograms. (B) Frontal chest radiograph in a 56-year-old woman with increased pressure pulmonary edema from chronic heart failure showing interlobular septal thickening. Thin linear opacities are best seen in the inferolateral thorax, particularly on the right, representing thickened interlobular septae, or Kerley B lines. See the chest computed tomography scan for this patient in Video 133.1. (Courtesy Michael B. Gotway, MD.)

of oxygen in inspired gas (F_{IO_2}) ratios.[100] Although not yet widely adopted, the RALE score demonstrates the potential to apply more quantitative methods to ARDS clinical research and perhaps to clinical trials.

In addition to chest radiographs, CT of the chest may have a role in the diagnostic workup for ARDS and potentially for guiding therapy.[101] The higher resolution of CT compared to chest radiography offers more detail about the degree and density of consolidation or ground-glass opacification, which may suggest different etiologies of lung injury. CT can also display the degree of septal thickening and pleural effusion, potentially helping to discriminate increased pressure from permeability edema, and might display atelectasis, abscess, fibrosis, or pneumothorax, each of which might alter the therapeutic approach. Of importance, the use of chest CT in ARDS clinical research has fostered a better appreciation for the striking heterogeneity in aeration across different lung units[102] and has demonstrated that PEEP differentially, rather than uniformly, inflates various regions of the lung.[103] However, CT poses some challenges for critically ill patients, including the transportation of patients to the scanner and the higher radiation dose limiting frequent reassessment.[101]

Lung ultrasound, in contrast to CT, has the advantages of being portable, easy to repeat, and without radiation exposure. Thoracic ultrasonography has shown high sensitivity (97%) and specificity (95%) for pulmonary edema[104] and, when paired with cardiac ultrasound, may offer some clues to distinguish increased pressure from increased permeability edema, such as the presence of pleural effusion and impaired left ventricular function or enlarged inferior vena caval diameter.[105] Lung ultrasound has also been proposed as a mode to assess the aeration response to PEEP, although caution should be noted as there is no ultrasound corollary for lung overdistension, and thus ultrasound is not recommended as the sole method to select PEEP.[106] Lung ultrasound has been particularly useful in resource-limited areas of the world, where it can be used to identify bilateral opacities ("B" lines or consolidation without associated pleural effusion) when chest radiographs are unavailable[107,108] (see Chapters 23 and 24).

ARTERIAL BLOOD GAS STUDIES

The arterial P_{O_2}, arterial P_{CO_2}, and pH are the most informative laboratory indicators of gas exchange in patients with pulmonary edema. Arterial blood gas studies are not sensitive to early edema. Interstitial pulmonary edema does not usually affect oxygen uptake in the lungs beyond modest hypoxemia caused by ventilation-perfusion mismatching. In contrast, alveolar flooding seriously compromises gas exchange, resulting in right-to-left shunting of blood from ongoing perfusion of fluid-filled or collapsed alveoli. In two studies of groups of patients with increased permeability edema from lung injury, oxygenation appeared to depend more on the ability of the pulmonary circulation to mediate hypoxic pulmonary vasoconstriction—and thereby reduce perfusion to damaged and edematous areas of the lungs—than on the amount of edema present.[109,110]

In patients hospitalized for acute cardiogenic pulmonary edema, arterial P_{CO_2} may be low, especially in the early stages, when tachypnea results in alveolar hyperventilation. Arterial P_{CO_2} may also be within the normal range or elevated, the latter indicating alveolar hypoventilation, which can be caused by underlying lung disease, increased metabolic production of carbon dioxide (perhaps related to increased work of breathing), increased wasted ventilation (ventilation of poorly perfused alveoli), or mechanical impairment caused by weak respiratory muscles.[111] An elevated pulmonary dead space fraction in the first 24 hours after development of severe increased permeability edema identifies patients with a higher risk for death, particularly if the dead space fraction is greater than 0.60.[62]

When pulmonary edema is severe or the lungs have been injured, many patients develop metabolic acidosis as a result of tissue hypoxia, increased work of breathing, intrinsic lung lactate production, or all of these.[112] Attempts to correct acidosis with parenteral bicarbonate administration usually are not necessary; rather, the underlying cause must be identified and treated appropriately. Maintenance of a satisfactory systemic blood pressure is crucial. Respiratory acidosis caused by alveolar hypoventilation can be treated either by *noninvasive ventilation* (NIV) or by invasive mechanical ventilation with endotracheal intubation. Metabolic acidosis can be partially corrected by alleviating hypoxemia and improving cardiac function; the possibility of underlying disease amenable to surgery (e.g., intestinal ischemia or infarction, perforation of a viscus) or pancreatitis should be considered.

For further information on experimental methods to distinguish hydrostatic from permeability edema, to assess lung water and barrier function, and to consider potential biomarkers of hydrostatic pressure and permeability edema, see ExpertConsult.com.

Measurement of Pulmonary Edema Fluid Protein Concentration

When florid pulmonary edema is present, measurement of protein concentrations in both simultaneously collected edema fluid (suctioned through an endotracheal tube) and plasma provides a rapid, noninvasive method for distinguishing increased pressure edema from increased permeability edema.[113] Because the microvascular barrier is functionally intact in increased pressure edema, plasma proteins remain largely confined to the intravascular space, and edema fluid protein concentration is low relative to plasma protein concentration (the ratio of edema fluid to plasma protein concentration is generally <0.65). In contrast, in increased permeability edema, when the microvascular barrier is injured, plasma proteins cross the vascular barrier in high concentrations into the interstitial and alveolar compartments, which raises edema fluid protein concentration relative to plasma protein concentration (ratio of edema fluid to plasma protein concentration generally >0.75). Intermediate values (between 0.65 and 0.75) may indicate that both types of edema are present and suggest the relative contributions of each.

Measurement of the ratio of edema fluid to plasma protein concentrations has been shown to be a simple method for separating the two different pathophysiologic types in numerous reported series of patients with pulmonary edema.[114–117] Three studies indicated that an increasing protein concentration in serial measurements of edema fluid in increased permeability edema was a good sign, reflecting a functioning epithelial barrier and net removal of edema fluid from the alveoli.[116,117] There is new evidence that the edema fluid to plasma protein ratio has prognostic and diagnostic value.[118] Such measurements need to be correlated with the patient's clinical condition because an increasing protein concentration in edema fluid over time might also mean that increased permeability edema was complicating what had been increased pressure edema or that the lungs were injured more severely or more extensively as time passed.

Edema fluid can be collected by inserting a standard 14- to 18-gauge catheter through an endotracheal tube and advancing it into a wedged position in the distal air spaces, similar to the procedure for wedging a fiberoptic bronchoscope. Gentle suction is applied as the catheter is slowly withdrawn, and fluid is collected in a small trap. Several attempts may be needed; if no fluid can be suctioned, the clinician should try changing the patient's position. Samples grossly contaminated with airway secretions, which have a very low protein concentration (<1 g/dL), or which have a gross appearance of mucus, pus, or debris, should be discarded. The protein concentration in the edema fluid and the plasma can be measured by the clinical laboratory or estimated quickly at the bedside from the protein scale of a handheld refractometer. Standard BAL using fiberoptic bronchoscopy and mini-BAL (with a wedged suction catheter) have both been used as research and diagnostic tools that may also yield useful information about the cellular biochemical and microbial composition of the air space,[119] but lavage is not useful as a method to measure alveolar protein concentration because the instilled saline dilutes alveolar fluid by approximately 50- to 100-fold, depending on the method.[47]

MEASUREMENT OF LUNG WATER AND BARRIER FUNCTION

In theory, measurement of the quantity of water or edema fluid in the lungs could be useful in detecting early pulmonary edema and in assessing its clinical course and response to treatment; however, no optimal technique is available. Methods in use or under investigation focus on either measurement of lung density or equilibration of tracers with water in the lungs.[1,120] Interest in such measurements assumes that accurate knowledge about lung water content would be useful in diagnosis and would be beneficial in the treatment of patients with pulmonary edema. Use of a single thermal indicator for measuring extravascular lung water has shown promise based on some studies, although the actual clinical utility has not been convincingly proven.[121]

Barrier Function

The clinical distinction between increased pressure edema and increased permeability edema is difficult.[95,122] In theory the two types of edema can be separated on the basis of differences in barrier function. Detection of increased transvascular fluid flow into the lungs and measurement of barrier integrity might be more helpful than measurement of lung water content. A simple and practical method exists to evaluate barrier integrity (edema fluid protein concentration measurements, discussed earlier). By tracking the change in edema fluid protein concentration over time, it is possible to estimate alveolar fluid clearance in both animal models[117,123] and human pulmonary edema.[124,125] Furthermore, the baseline rate of alveolar fluid clearance exhibited moderate inverse correlation with baseline plasma concentrations of the *receptor for advanced glycation end products* (RAGE), a plasma marker with strong association with both development of and mortality from ARDS.[124] Although these observations lack a validated test and thresholds to use for either alveolar fluid clearance or RAGE concentrations clinically, it is nonetheless encouraging that potential quantitative measures of alveolar barrier function exist.

Acute Decompensated Heart Failure: History and Biologic Markers

Acute decompensated heart failure (ADHF) is diagnosed by history and physical examination aided by specific testing, including *amino-terminal pro–brain natriuretic peptide* (NT-proBNP). When clinical signs and symptoms strongly support a diagnosis of acute heart failure, including exertional dyspnea, fluid retention, orthopnea, and signs such as elevated jugular venous pressure, peripheral edema, and pulmonary edema, particularly in the absence of fever, the diagnosis of ADHF can be made with high probability even in the absence of additional testing.[126] For dyspneic patients with intermediate probability of ADHF, however, such as patients with abnormal electrocardiograms, patients with historical features of heart failure but without clinical signs of heart failure, or those with no prior history

of heart failure, the addition of serum natriuretic peptide testing is warranted.[126] In a prospective multicenter study of patients with acute dyspnea presenting to the emergency department, increased serum NT-proBNP (>450 pg/mL for patients younger than 50 years and >900 pg/mL for patients 50 years and older) was the strongest independent predictor for ADHF.[127] A serum NT-proBNP level less than 300 pg/mL had a negative predictive value of 99%.[127] Combining NT-proBNP testing with clinical judgment is recommended by guidelines,[128] and a clinical prediction score known as the PRIDE acute heart failure score has been validated, with a score 6 or more points demonstrating sensitivity of 96%, specificity of 84% and positive and negative predictive values of 77% and 98%, respectively, for a diagnosis of ADHF.[126]

However, although NT-proBNP performs well in an unselected population with dyspnea, the marker may have limited utility to distinguish increased pressure from increased permeability edema. In a prospective cohort study of patients with ARDS or ARDS risk factors, NT-proBNP was reported at a median value greater than 3000 pg/mL, well above the value to exclude heart failure; only one-third of ARDS subjects had normal NT-proBNP values.[129] Furthermore, although the NT-proBNP values observed in ARDS were numerically lower than those observed in the ADHF subjects from the PRIDE study, the difference between them was not statistically significant.[127,129] A few smaller studies have assessed the ability of BNP to distinguish ARDS from cardiogenic pulmonary edema, using clinician judgment as the gold standard to determine edema type, and reported limited discriminative utility.[130–132]

Biologic Markers of Lung Injury

Potential biologic markers of imminent increased permeability edema from various kinds of lung injury have been the subject of many studies and comprehensive reviews.[47,133] Naturally, considerable interest revolved around finding a simple blood, urine, or BAL test to identify patients destined to develop or who are already in the earliest stages of increased permeability edema. Such a marker could lead to an early intervention to prevent ARDS, or prognostication of outcome among patients with injured lungs. To be of clinical use, such a marker would have to be accurate, rapid, and inexpensive, as well as sensitive and specific for the detection of lung injury. An extensive search has been made for a reliable biologic marker for the detection of early or impending lung injury comparable to the decisive clinical role played by troponin measurements for diagnosing acute myocardial infarction. The long-sought silver bullet for diagnosis of increased permeability edema remains distant. Nonetheless, a growing panel of circulating and edema fluid markers have demonstrated consistent association with ARDS diagnosis, severity, or prognosis, and we will highlight a few (eTable 133.1). For more complete discussion, comprehensive reviews have been published.[74,134–136]

Most biomarkers of increased permeability edema can be characterized as playing a role in endothelial regulation, lung epithelial health, modulation of inflammation, or specific injury pathways, mirroring the current understanding of processes that contribute to lung injury.[73] Plasma angiopoietin-2, an endothelial-restricted protein that increases permeability when added to endothelial monolayers,[137] has predictive value for ARDS diagnosis in an emergency room population.[84] This marker also has prognostic significance, in that its plasma concentrations rise with ARDS severity and are higher in ARDS patients who die and, in selected populations, it seemed to be a therapeutic response indicator.[138–142] Using genetic data to perform causal inference analysis, in which observational data is used to infer biologic mechanisms, plasma angiopoietin-2 seems to be under partial genetic control and mediates a portion of ARDS risk.[143] Additional endothelial markers with consistent association with ARDS diagnosis or prognosis include soluble intercellular adhesion molecule, soluble thrombomodulin, plasminogen activator inhibitor-1, von Willebrand factor antigen, and protein C.[144–148] Plasma markers that are largely released from lung epithelium and strongly associate with ARDS diagnosis include RAGE and surfactant protein D.[149–151] Soluble RAGE in plasma is particularly interesting in that it also correlates with alveolar fluid clearance in experimental models and in humans with ARDS[124,152,153]; thus, RAGE might be a functional readout of ARDS resolution. Numerous plasma inflammatory markers also strongly associate with ARDS diagnosis among critically ill patients and associate with mortality. The best studied among these include *interleukins* (IL)-6, IL-8, and *soluble tumor necrosis factor receptor I and II* (sTNFR1, sTNFR2).

Because increased permeability edema follows a wide variety of insults that range in severity, and because many abnormalities detected in increased permeability edema are found in other severe illnesses of diverse etiology that do not involve the lungs, it seems unlikely that any single marker will be found that unequivocally identifies the risk or the presence of severe lung injury. Increased attention is being given to the sensitivity and

specificity of combinations of markers. In support of this approach, one study found that combinations of three plasma biomarkers had a significantly improved prognostic value for predicting death compared with standard clinical predictors alone.[83] More recently, a parsimonious model using plasma markers (IL-8, IL-6, protein C, and sTNFR1) along with clinical variables (serum bicarbonate, receipt of vasoactive medications) in various combinations proved capable of reliably identifying the ARDS hyperinflammatory phenotype in multiple populations,[154,155] which could facilitate clinical trial enrichment strategies in the future.

TREATMENT

Treatment of pulmonary edema often requires vigorous life-saving measures, followed by specific therapy directed at the factors that led to accumulation of water in the extravascular spaces of the lungs. Effective therapy also requires an accurate diagnosis and an understanding of the nature of the underlying disease state and of the strategies that might prove useful in limiting further edema accumulation and in accelerating fluid removal from the lungs.[156,157]

EMERGENCY THERAPY

Patients with alveolar edema are frequently severely ill and require immediate treatment for acute respiratory failure. The basic principles of treatment of hypoxemic respiratory failure are discussed in Chapters 134 and 135. Essential requirements for patients with pulmonary edema include preservation of the airway and provision of satisfactory alveolar ventilation and arterial blood oxygenation. Maintenance of arterial blood pressure is critical. Reliable means of monitoring and sustaining oxygen saturation and blood pressure in rescue operations and ambulance travel are now widely used. Ventilatory management in patients with alveolar flooding and severe gas exchange abnormalities, regardless of cause, has generally required emergent endotracheal intubation, high inhaled oxygen concentrations, and PEEP. After stabilization, obligatory lung-protective strategies are introduced in patients with increased permeability edema (see later discussion). An alternative approach to management is being directed at noninvasive ventilatory methods (discussed later) that hasten improvement in respiratory distress and metabolic disturbances in patients with increased pressure edema, nearly always from congestive heart failure.

INCREASED PRESSURE EDEMA

In increased pressure pulmonary edema, the common goal of therapy is to reduce the movement of fluid into the lungs. Because the rate of edema formation increases exponentially with increases in pulmonary vascular pressures,[7] hydrostatic pressure control is crucial for successful therapy. Therapy must be clearly goal oriented, responsive to the underlying pathophysiology, and frequently reassessed until the patient is stable.

General Principles

The acute recognition and management of increased pressure pulmonary edema, exemplified by congestive heart failure, has been the subject of comprehensive reviews.[5,6,11,123,158,159] With increased pressure edema, the goal of therapy is to reduce the hydrostatic pressure causing edema formation in the lungs. The major objective is to achieve a net negative fluid balance without adversely affecting myocardial performance. The work of the heart must be reduced as much as possible, including by preventing pain and anxiety, which act to increase cardiac work by increasing sympathetic tone. As the heart fails, cardiac performance is reflexively preserved by progressive increases in vascular volumes that act to increase cardiac stroke volume and work (the Frank-Starling mechanism). This compensatory increase in preload of the left ventricle results in pulmonary venous hypertension and raises the driving pressure for fluid filtration out of the pulmonary microcirculation. As heart failure worsens, cardiac output falls, pulmonary and systemic venous pressures rise, systemic vascular resistance increases, and edema in the lungs and in the periphery becomes the major manifestation of compromised cardiac function.

In patients with increased pressure edema, a reduction of vascular volume and an increase in cardiac output decrease the driving pressure for edema formation. Because the normal safety factors protecting the lungs from edema are intact, the pressure needs to be lowered only toward normal. At PAWP less than 20 mm Hg, fluid filtration in the lungs usually will not cause pulmonary edema. Patients with severe cardiac failure may tolerate higher pressures—because baseline barrier permeability is lowered in the lungs and lymphatic removal capability is increased—and may even require such pressures to maintain cardiac output. Therapy is directed at reducing the work the heart must perform and at increasing the heart's efficiency for the work it must do, including, in some patients with severe increased pressure pulmonary edema, the use of positive-pressure NIV and, in the most severe cases, invasive mechanical ventilation. The resolution of alveolar edema in these patients may not simply be a function of lowering lung vascular pressures; other mechanisms to augment alveolar fluid clearance may be important.[123]

Most patients with acute pulmonary edema caused by cardiac failure have systolic dysfunction from decreased contractility, but approximately 30% of patients have diastolic dysfunction. Cardiac contraction is normal, but relaxation is impaired. Because the ventricle does not relax normally, end-diastolic pressure is increased, thereby increasing hydrostatic pressure in the lung microcirculation. Acute diastolic dysfunction producing pulmonary edema is now recognized as a common manifestation of acute myocardial ischemia or uncontrolled hypertension. Other causes include diabetes mellitus, aortic stenosis, infiltrative cardiomyopathies, endocardial fibroelastosis, hypothermia, septic shock, elevated thoracic pressures from mechanical ventilation, and pericardial effusion. Causal or aggravating conditions should be corrected (e.g., revascularization for coronary artery disease, control of systemic hypertension). The goal of therapy in acute diastolic dysfunction is to lower elevated filling pressures, by the cautious use of diuretics and afterload reduction, without significantly reducing cardiac output. These patients are prone to develop hypotension in response to diuretics and nitrates because adequate cardiac output depends on elevated filling pressures in the heart. Because systolic function is normal, positive inotropic agents do not help and can actually aggravate ischemia.

In the setting of acute increased pressure pulmonary edema, it is especially important to identify and treat correctable causes of heart failure. Acute myocardial infarction, ongoing myocardial ischemia, arrhythmias, valvular lesions, systemic hypertension, ventricular septal rupture, rheumatic or other inflammatory myocarditis, digitalis intoxication, pulmonary embolism, infection, thyrotoxicosis, or severe anemia may have caused the heart to fail and must be addressed. Cardiac patients presenting with pulmonary edema may not complain of chest pain despite significant coronary artery disease, and pulmonary edema may be the only manifestation of silent myocardial ischemia.

Ventilatory Strategies

Most patients hospitalized with increased pressure edema suffer from acute or chronic heart failure and require oxygen treatment to ensure satisfactory arterial blood oxygenation. Depending on the prevailing severity of oxygen deficiency, patients with mild abnormalities may require only supplementary oxygen administered through a nasal catheter or simple mask; those with moderate oxygen deficiency may be helped with noninvasive methods of oxygen administration. High-flow nasal cannula may be a useful means of delivering oxygen and some PEEP (see Chapter 137 and below). Finally, profound gas exchange abnormalities require endotracheal intubation with high oxygen concentrations and elevated end expiratory pressures.

Noninvasive positive-pressure ventilation, by either *continuous positive airway pressure* (CPAP) or *bilevel positive airway pressure* (BPAP) ventilation, is strongly recommended for patients with acute respiratory failure due to cardiogenic pulmonary edema, as in 2017 guidelines, with moderate certainty of evidence.[160,161]

Both CPAP and BPAP cause more rapid improvement in respiratory distress and metabolic abnormalities than standard oxygen treatment.[162] NIV is discussed more fully in Chapter 136. Here we will discuss their role briefly. CPAP is the equivalent of noninvasively applied PEEP, whereas BPAP adds inspiratory pressure support above the PEEP setting. PEEP exerts effects both on the lung, including increased functional residual capacity, recruitment of collapsed or partially flooded alveoli, and a higher mean airway pressure, typically improving oxygenation, and on the circulation, causing decreased preload, decreased afterload, and lower myocardial oxygen demand.[163] As reviewed, the net effect of PEEP on cardiac output will depend on both right ventricular and left ventricular function and ventricular interdependence so that higher PEEP may be particularly helpful in states attributed to high afterload, whereas PEEP may exacerbate states of high pulmonary vascular resistance and right ventricular septal bowing.[163] Although an early randomized trial reported no effect on short-term mortality or intubation rates comparing NIV to standard oxygen therapy,[164] systematic review and meta-analysis of an additional 24 studies encompassing more than 2600 subjects reported moderate evidence for NIV in reducing hospital mortality and reducing endotracheal intubation, without increasing acute myocardial infarction or other adverse events.[161] Patients with cardiogenic shock and pulmonary edema were traditionally excluded from randomized trials studying NIV; however, observational data from the CardShock cohort described a lower mortality for subjects in shock treated initially with NIV compared to those immediately intubated and placed on invasive mechanical ventilation.[165] The mortality difference was not observed after propensity matching that accounted for initial organ failures and severity of illness,[165] suggesting that survival was not wholly attributable to the selection of NIV. Given the preponderance of evidence, NIV is a recommended initial therapy for patients presenting with acute respiratory failure due to increased pressure edema, with close observation and timely reassessment for improvement in work of breathing, oxygenation, ventilation, and overall perfusion. If these are not rapidly improving, or certainly if they worsen, prompt intubation is indicated.

High-low nasal cannula (HFNC), an alternative means to deliver highly concentrated oxygen at high flows, and with probable, although unquantified, PEEP, has not been well studied in the cardiogenic pulmonary edema population, which was excluded from many early trials[166] (see Chapter 137). In one small, likely underpowered study, randomized assignment to HFNC versus conventional therapy in the emergency department resulted in a small decrease in respiratory rate without a reduction in the number requiring admission, NIV, or intubation, nor in observed mortality.[167] Although there are theoretical advantages to HFNC compared to NIV, particularly with regard to patient comfort and facilitating communication due to the mask interface, as yet there are incomplete data to endorse HFNC in this setting.

Invasive mechanical ventilation is used for 60–80% of patients with cardiogenic shock,[165,168] and acute cardiac dysfunction complicates 18% of ventilated patients in the United States.[169] Nonetheless, few studies have investigated the effect of ventilator strategies specifically in patients with increased pressure edema. The *National Heart, Lung, and Blood Institute* (NHLBI)'s FACTT study highlighted the coexistence of increased cardiac filling pressures with ARDS,[170] confirming that almost a third of patients have elevated PAWP or central venous pressure on study enrollment.[171] However, whereas a volume- and pressure-limited ventilator strategy has strong evidence for reducing mortality in ARDS,[172,173] data are less definitive for applying this strategy to non-ARDS respiratory failure. Observational studies in populations without ARDS suggest that higher tidal volume (>8 mL/kg *predicted body weight* [PBW]) is an independent risk factor for the development of incident ARDS[174,175] and for pulmonary complications.[176] However, a randomized trial enrolling subjects with acute respiratory failure but without ARDS and randomizing to a low (<6 mL/kg PBW) or intermediate (<10 mL/kg PBW) tidal volume strategy did not observe a difference in duration of ventilation or mortality.[177] One-fourth of study participants were ventilated as a result of cardiac arrest and 5% with cardiac failure, so subjects with increased pressure pulmonary edema seem likely to have been included. In the absence of an adequately powered trial exclusively conducted in patients with increased pressure edema, it seems reasonable to recommend that consideration be given to a ventilator strategy of lower tidal volumes (<6 mL/kg PBW), adequate PEEP to improve saturation and reduce the fraction of inspired oxygen (F_{IO_2}), and a plateau airway pressure less than 30 cm H_2O,[172] with an appreciation that tidal volumes may be liberalized as needed for patient tachypnea, acidemia, or comfort.[177]

As discussed earlier, PEEP has significant hemodynamic effects in addition to its impact on oxygenation, and increased pressure pulmonary edema may be particularly responsive to application of moderate PEEP. In selecting an initial PEEP, clinicians could use a table pairing different PEEP levels with varied F_{IO_2} settings, as has been used in ARDS clinical trials,[178] or by selecting the PEEP that seems to optimize both saturation and perfusion as gauged by blood pressure and urine output. Of note, the association between mortality and airway driving pressure, calculated as the difference between an inspiratory plateau pressure and PEEP in volume-cycled ventilator settings,[179] was not observed in a cohort of mechanically ventilated patients without ARDS.[180]

For information on right heart catheterization, see ExpertConsult.com.

Right Heart Catheterization

In 1970 Drs. H.J.C. Swan and William Ganz introduced the balloon flotation catheter for measurements of right atrial pressure, right ventricular pressure, pulmonary artery pressure, and pulmonary capillary wedge pressure, and for assessment of cardiac output and oxygen saturation values in the right heart chambers.[181] The widespread use of the *pulmonary arterial catheter* (PAC) contributed to an explosion of cardiovascular and respiratory physiologic knowledge, along with new conceptual models for the management of acute myocardial infarction, heart failure, and cardiogenic shock based on readily obtained hemodynamic data.[182] Much was learned about the cardiopulmonary physiology of sepsis and how to use a PAC to differentiate increased pressure from increased permeability edema.[50] Unfortunately, the ability to measure cardiac filling pressures did not reliably translate to improved patient outcomes, and both complications and flawed PAC interpretations were observed.[183–185] There is now general agreement that invasive hemodynamic monitoring, such as by a PAC, is not recommended for normotensive patients with acute decompensated heart failure.[128,186,187] Similarly, a systematic review from the Cochrane group concluded "that the use of a [pulmonary artery catheter] did not alter the mortality, general [intensive care unit] or hospital [length of stay], or cost for adult patients in intensive care."[188] Current guidelines for the management of heart failure maintain a class I recommendation to monitor with a PAC "in patients with respiratory distress or impaired systemic perfusion when clinical assessment is inadequate," or, with a class IIa recommendation, when persistent symptoms remain "despite empiric adjustment of standard therapies."[128] Additional indications for the PAC are commonly used, particularly to diagnose and monitor pulmonary vascular disease.[182,186]

Specific Pharmacologic Therapy

After emergency treatment has been instituted and the patient's condition stabilized, three major therapeutic options—vasodilators, diuretics, and inotropic agents—need to be considered and administered when appropriate. The goal of therapy with these agents is to lower the hydrostatic pressure at the filtration sites in the pulmonary vascular bed while maintaining adequate systemic delivery of oxygen. The choice of therapy is dictated by the patient's condition and the cause of the pulmonary edema. *The American College of Cardiology Foundation and the American Heart Association* (ACCF/AHA), in collaboration with several additional international societies, has published an extensive guideline for the management of heart failure,[128] and readers are directed to that publication's discussion of treatment for ACCF/AHA stage C and D heart failure. As follows, we consider the acute management that may be concurrent with assisting ventilation for patients with decompensated heart failure and pulmonary edema.

Vasodilators. Depending on their specific therapeutic indications, vasodilators are used for hypertension, congestive heart failure, and angina. Several medications are available, usually in combination and as part of a long-term treatment regimen. Vasodilators are useful pharmacologic agents for the treatment of acute increased pressure pulmonary edema because their effects happen rapidly, usually in minutes. Through dilation of veins, vascular capacitance is increased and blood is redistributed peripherally, thereby lowering the driving pressure for fluid filtration in the lungs. Through dilation of arteries, systemic vascular resistance (cardiac afterload) falls, increasing cardiac output and stroke volume, and the heart works more efficiently. Three classes of vasodilators may be useful in pulmonary edema: venodilators (e.g., nitrates), arteriolar dilators (e.g., phentolamine, hydralazine), and mixed dilators (e.g., nitroprusside). The most common side effects of vasodilators, such as dizziness, especially when standing, are related to low blood pressure. Tolerance to vasodilators may require revision of long-standing therapy.

Diuretics. Patients with symptoms of pulmonary edema, especially from increased vascular pressure, usually benefit from administration of diuretic agents.[128,189] These drugs may exert a modest immediate effect by increasing venous capacitance and decreasing the relative perfusion of flooded alveoli (acting as vasodilators), but their principal mechanism of action is to increase sodium and water excretion by the kidneys,[190] and they are most effective when paired with a strategy of limiting sodium intake.[191] The resultant diuresis causes a decrease in left ventricular volume and pressure and thereby a reduction in left atrial pressure and in pressure at the filtration sites in the lungs. Among the potent loop diuretics administered by slow intravenous injection, furosemide is highly effective and generally regarded as the agent of choice. Dozens of different dosage regimens of furosemide have been and are still being used to treat symptomatic patients with pulmonary edema from acute congestive heart failure. Equivalent doses of other loop diuretics (bumetanide, torsemide, or ethacrynic acid) have essentially the same effects. Decades of clinical experience have documented that intravenous administration of loop diuretics nearly always results in prompt diuresis and symptomatic relief. Nevertheless, information about safety and efficacy is lacking and optimal use of diuretics in heart failure management needs much further study and improvement.[192]

If the patient is hypotensive or in frank shock, diuretics are seldom of benefit, because poor renal perfusion limits any effects they might have on kidney function. In this circumstance, continuous venovenous ultrafiltration can reduce intravascular volume even in patients who require vasopressors for blood pressure support.[193] Similarly, if the patient has severely diseased kidneys, continuous arteriovenous hemofiltration with or without countercurrent dialysis or venovenous ultrafiltration should be considered.[194] These techniques represent considerable advances over traditional hemodialysis, which was often impossible in hemodynamically unstable patients, especially those with low cardiac output or hypotension, and peritoneal dialysis, which was both slow and poorly tolerated. Hemofiltration can be instituted, maintained, and managed successfully by well-trained intensive care unit nurses and physicians, and it is not typically complicated by hypotension because the circuits have small volumes and pressures are low. Considerable fluid (<200–300 mL/hr) can be removed when needed, with the amount being titrated to the patient's cardiovascular status.

Inotropic Agents. Patients with cardiogenic shock and other cardiac catastrophes that lower systemic blood pressure often require inotropic agents as a temporary lifesaving measure. According to ACCF/AHA guidelines,[128] patients with cardiogenic shock awaiting either resolution of the heart failure precipitant or definitive mechanical, revascularization, or transplant therapy, should receive temporary intravenous inotropic support to maintain end-organ perfusion. Adrenergic agents, including dobutamine and dopamine, as well as phosphodiesterase inhibitors, such as milrinone, are recommended.[128] In addition, short-term continuous inotropic support may be an option for symptom control in selected patients who are not eligible for mechanical cardiac support or cardiac transplantation.[128] However, long-term use of inotropes, except when explicitly used for palliative care, is potentially harmful. In addition, the ACCF/AHA guidelines recommend against use of inotropes in hospitalized patients without documented severe systolic dysfunction, low blood pressure, or significantly impaired perfusion with significantly depressed cardiac output.[128] Thus it is *not* recommended to add inotropes for a patient with depressed ejection fraction and pulmonary edema but without hypotension or impaired perfusion because such a strategy may cause harm.[195]

When increased pressure pulmonary edema accompanies impaired myocardial contractility, it has proven difficult to treat and has a poor prognosis. Options include techniques of coronary reperfusion, cardiac resynchronization therapy, durable or temporary mechanical support with ventricular assist devices, expanded use of extracorporeal membrane oxygenators for severe respiratory failure, and improvements in heart and/or lung transplantation.[128] For this reason, early consultation with heart failure experts is strongly encouraged for critically ill patients with increased pressure edema and structural heart disease.

Morphine Sulfate. Narcotics, and particularly morphine sulfate 2 to 4 mg or its equivalent, given intravenously over several minutes, has long been an emergency therapy for acute cardiogenic pulmonary edema. The reasons for using morphine include its actions as a potent vasodilator, its effect as a sedative, and its lack of myocardial contractility depression. Its vasodilating effects can substantially reduce pulmonary capillary pressure and may improve depressed cardiac output, whereas the reduced dyspnea may result in a lower afterload for the failing heart. However, observational data from several large cohorts of patients with acute pulmonary edema have detected an association between morphine and increased mortality that is incompletely explained by baseline characteristics, at least as handled by propensity score matching.[196,197] Uncertainty regarding the safety of morphine in this setting has led the European Society of Cardiology to recommend against routine use of morphine and to suggest only cautious use in patients with severe dyspnea,[198] whereas the ACCF/AHA guidelines discuss morphine only in the context of palliative care.[128] Recognizing that morphine is effective at symptom improvement and that prior reports of increased mortality are limited by their retrospective nature, there is a clinical trial planned to test the randomized administration of morphine compared to midazolam when severe dyspnea remains despite receipt of diuretics, oxygen, and vasodilator therapy for acute pulmonary edema.[199] If complications are believed to result from morphine, prompt administration of naloxone (Narcan) is recommended.

INCREASED PERMEABILITY EDEMA

As already emphasized, increased permeability pulmonary edema caused by various types of severe lung injury differs from increased pressure pulmonary edema in two crucial respects: first, the endothelial and epithelial barriers are damaged in permeability edema, whereas they are usually normal in increased pressure edema, and second, when barriers are damaged, edema develops even at low driving pressures. The goals of therapy (Table 133.6) are to treat the underlying cause of acute lung damage, to provide support while the repair phase begins, to use a lung-protective ventilator strategy that will not worsen the lung injury, and to minimize the driving pressures for fluid movement across the injured barriers into the lungs.

General Principles

Finding and treating the underlying precipitant of permeability edema is crucial. The cause of lung injury may not always be apparent and, when the cause is not obvious, it should be assumed to be infection—the most common treatable underlying cause of increased permeability edema. Although the patient is often seriously ill, diagnostic studies must be performed to identify a possible source of infection so that appropriate source control and antimicrobial therapy can be instituted. If chest radiographs provide insufficient information, ultrasonography, CT, and bronchoscopy with BAL can all be helpful. There are important mimics of ARDS to consider. These mimics might have specific, or at least conventional treatment, including atypical infections, organizing pneumonia, hypersensitivity pneumonia, eosinophilic pneumonia, or diffuse alveolar hemorrhage.[200] Chest CT may be particularly helpful for diagnosing such conditions, along with bronchoscopy and potentially transthoracic or surgical lung biopsy.[67,91] Because specific therapy for increased permeability is not usually available, unless the cause is a treatable infection or a steroid-responsive inflammation, supportive therapy is extremely important. The initial concerns are to support ventilation and circulation.

Patients with increased permeability edema may be hemodynamically unstable, and ventilatory support can be complicated by hypotension or frank shock. PEEP, which is usually required for adequate oxygenation, may compound the problem by impeding venous return to the heart and decreasing cardiac function. Furthermore, when inadequate cardiac output, due to either hypovolemia or impaired cardiac function, complicates permeability edema and results in low mixed venous saturations, the oxygen tension of arterial blood may fall dramatically, as systemic venous blood traversing "shunt" units with poor ventilation mixes with postcapillary blood from aerated units in a process termed venous admixture.[201] Improving both oxygen saturation and perfusion are often the critical, and at times highly challenging, early goals of caring for patients with permeability edema, and care involves a careful assessment of circulating volume, cardiac function, oxygen consumption, and end-organ perfusion in addition to a focus specifically on the lungs.

Aggressive hemodynamic support of critically ill patients can be detrimental if the complications of therapies become more harmful than the underlying disease itself. Strategies to increase systemic oxygen delivery (e.g., with inotropes,

Table 133.6 ARDS Management Principles

SUPPORTIVE CARE
Supplemental oxygen to ensure adequate oxygenation
Lung-protective ventilation
▪ Volume and pressure limited
▪ Ensure ventilator synchrony
▪ Prone position if Pao_2/Fio_2 < 150 despite protective ventilation
Reduce oxygen consumption if hypoxia is critical
Support adequate perfusion for other organs; focus on both cardiac output and blood pressure
FIND AND TREAT UNDERLYING CAUSE
Consider infections, mimics
MINIMIZE FURTHER EDEMA ACCUMULATION
Seek lowest pulmonary microvascular pressure that maintains adequate perfusion
Diurese/reduce vascular volume while maintaining adequate perfusion
AVOID HARM
Volume- and pressure-limited ventilation strategy
Avoid both hypotension and volume overload
Goal-directed sedation with frequent reassessment
Avoid hyperoxia
Consider early physical rehabilitation
Seek and treat neuromuscular, cognitive, and psychological impairments during recovery

intravascular fluids, and blood transfusions) or to achieve supranormal values for the cardiac index or normal values for mixed venous oxygen saturation did not improve mortality when applied to critically ill patients.[202] After an initial single-center randomized trial conducted in the emergency department reported a striking mortality benefit from adding central venous saturation greater than 70% and hemoglobin greater than 10 g/dL as early perfusion goals among patients with septic shock,[203] several larger multicenter trials have failed to show benefit from this approach when applied to all septic patients.[204–206] One ARDS Network clinical trial showed that, in patients without shock, as defined by lack of need for vasopressor treatment, a strategy to restrict fluids to reduce intravascular pressures improved clinical outcomes by reducing the duration of mechanical ventilation in patients with ARDS.[207] Of note, there was no benefit observed for *pulmonary artery catheters* (PACs) over central venous catheters; PACs were associated with significantly increased complications, although not with excess mortality.[171]

A multicenter, *randomized, controlled clinical trial* (RCT) of transfusion requirements in critically ill patients with euvolemia after initial treatment compared a restrictive strategy of transfusing red blood cells if the hemoglobin concentration dropped to less than 7 g/dL to a more liberal strategy of maintaining hemoglobin concentration greater than 10 g/dL. Restricting transfusion requirements to maintain hemoglobin concentration at 7 to 9 g/dL was at least as effective and possibly superior to the strategy of giving transfusions to maintain hemoglobin concentration at 10 to 12 g/dL. Of note, few patients with acute coronary syndrome were included in this trial, making these conclusions less relevant to increased pressure pulmonary edema.[208] Transfusion thresholds for patients with acute coronary syndrome remain unclear, although a pilot trial suggested benefit of a more liberal transfusion strategy.[209]

Lung-Protective Ventilator Strategies

In experimental animals, ventilation with high tidal volumes increases vascular filtration pressures and produces stress fractures of microvascular endothelium, alveolar epithelium, and basement membrane.[210,211] The resulting injury appears to be due to the combination of large tidal excursions at high lung volumes, coupled with elevated airway pressures. This was called *volutrauma* because tidal volumes were roughly double for the same peak airway pressure when no PEEP was applied. Because the evidence from animal studies and small clinical trials provided compelling experimental rationale,[212,213] early investigations tested the potential benefit of lower tidal volumes and lower airway pressures versus standard (high) tidal volumes and elevated pressures.[214] A subsequent large National Heart, Lung, and Blood Institute ARDS Network multicenter trial was stopped prematurely after the enrollment of 861 patients with well-defined ARDS. The trial compared lower tidal volumes of 6 mL/kg and airway plateau pressures limited to 30 cm H_2O or less with a "traditional" ventilator management using initial tidal volumes of 12 mL/kg of ideal body weight and plateau pressures less than 50 cm H_2O. Mortality was lower in the group treated with lower tidal volumes than in the group treated with traditional tidal volumes—31% versus 39.8% (P = 0.007), respectively, and the number of days without ventilator use during the first 28 days after randomization was greater in this group (mean ± SD; 12 ± 11 vs. 10 ± 11, respectively; $P = 0.007$).[215]

The results of this seminal trial and several follow-up studies transformed the management and outcomes of patients with ARDS.[173] Low tidal volume ventilation strategies are also being successfully applied to critically ill patients without ARDS, albeit with varying effect on preventing lung injury or pulmonary complications.[176,177] The protocol for implementing the lung-protective ventilatory strategy is detailed in Table 134.3 and further discussed in Chapter 134.

Of interest, enacting a low tidal volume strategy in ARDS patients seems to attenuate inflammatory responses in both the lungs and bloodstream, as measured by a reduction in neutrophil and inflammatory cytokine concentrations in BAL fluid and a reduction in cytokines in circulating blood.[216] Other studies have confirmed that low tidal volume lung-protective ventilation is associated with reduction in inflammatory markers in the lung.[217] In addition, alveolar epithelial injury is probably reduced, considering the decline in surfactant protein D levels (a type II epithelial cell marker) and RAGE (a type I epithelial cell marker) in the plasma of patients treated with the lung-protective ventilator strategy.[218,219]

Although the use of PEEP has been advocated in treating ARDS since the syndrome's initial description,[46] the best method to select optimal PEEP for permeability edema remains uncertain. The pivotal ARDS Network trial comparing two tidal volume strategies used a table with a range of PEEP settings paired with different F_{IO_2} settings; as an example, a patient requiring an F_{IO_2} of 70% would be set to a PEEP of 10 to 14 cm H_2O.[172] A strong advantage of this approach includes its relative simplicity to use, so it could be enacted as a protocol for initial ventilator settings. Several randomized trials were conducted to compare a higher PEEP strategy, sometimes termed "open-lung ventilation," to this conventional PEEP strategy and, although higher PEEP groups had improved oxygenation, mortality was not different, even when the trials were combined in meta-analysis.[178,220–222] Subgroup analyses suggested that patients who were more hypoxemic might benefit from higher PEEP or that patients with improving oxygenation when randomized to higher PEEP might benefit.[222,223] Using a machine-learning algorithm known as latent class analysis and both clinical and experimental plasma markers as input variables, one group of investigators identified two subclasses of subjects with ARDS, with one being dominated by a plasma signature of high concentrations of inflammatory markers.[155] The authors detected a statistical interaction between randomized assignment to high PEEP and the subclass assignment on the observed mortality effect[155]; the effect of high PEEP was beneficial in the hyperinflammatory subphenotype group, whereas there was no benefit in the less inflamed group. Although warranting prospective validation, this work suggests that PEEP might be personalized to a patient's inflammatory state. There has been interest in the possibility that the optimal PEEP in ARDS might be selected by measuring esophageal pressure as a surrogate for pleural pressure and determining the PEEP that maintains a slightly positive transpulmonary

pressure.[224] Despite elegant rationale and a promising pilot study,[225] a randomized multicenter trial of 200 subjects comparing PEEP titrated to esophageal manometry to PEEP titrated by a PEEP-FIO_2 table did not observe any difference in mortality or days free from mechanical ventilation.[226]

Two further methods for PEEP titration bear mention. One method is to select the PEEP that minimizes the airway *driving pressure* (ΔP), which is the set inspiratory pressure on pressure-cycled ventilation or the difference between plateau pressure and PEEP on volume-cycled ventilation, while preserving oxygen saturation and blood pressure. A mediation analysis of multiple trials comparing different ventilator strategies in ARDS reported that ΔP was the variable that seemed to mediate mortality risk better than all others, including tidal volume and plateau pressure.[179] To select PEEP in this way, one practical approach would start with a conventional PEEP-FIO_2 combination and measure the plateau pressure and ΔP, then readjust the PEEP and remeasure plateau and ΔP. If ΔP is falling, PEEP continues to be titrated up and, if rising, PEEP is turned down. Another method used CT to learn if the radiographic pattern of lungs—diffuse consolidation versus focal—would predict the response to a high PEEP recruitment maneuver.[56] In patients with focal ARDS, high PEEP may overdistend the aerated lung before recruiting the consolidated regions. However, in a study of more than 400 subjects with ARDS, a strategy of personalizing the PEEP, tidal volume, and proning strategy to the diffuseness of chest radiograph did not decrease mortality.[227] Despite a lack of overall benefit from the personalization strategy, the data suggested possible harm when patients with radiographically focal ARDS received a high PEEP strategy or when diffuse ARDS received lower PEEP and larger tidal volumes.[227] In addition, this trial highlights the challenges of standardizing radiographic assessment in ARDS. In 2017, a trial was also published that demonstrates the potential danger of a high PEEP strategy, particularly when high PEEP (25–35 cm H_2O) is added while maintaining a driving pressure of 15 cm H_2O, for a maximum plateau pressure 40 to 50 cm H_2O.[228] This regimen of high PEEP recruitment had been described for refractory hypoxemia,[229] yet when patients with moderate or severe ARDS were randomized to this strategy, the mortality was 55% compared to 49% in the control group receiving conventional low tidal volume ventilation.[228] Thus, we advocate maintaining a goal plateau pressure less than 30 cm H_2O and not adopting these high PEEP recruitment strategies.[229]

Prone Position. In tandem with lung-protective ventilation, a strategy of placing the patient in the prone position for at least 16 hours a day was shown to reduce mortality and days on the ventilator for patients with moderate to severe ARDS.[230] Initial interest in prone position ventilation dates as far back as the late 1970s, when an early report described a mean PaO_2 increase of 69 mm Hg relative to supine position,[231] and an additional case series described similar efficacy[232] (see Chapter 134 and Fig. 134.7).

Physiologic studies in humans with ARDS suggested that there were two main contributors to the observed improvement in oxygenation: repositioning the heart off the posterior lungs, thereby reducing compression and airway closure, and redistributing ventilation more uniformly, thereby reducing the risk of overdistension of lung units with preserved ventilation.[233–235] Although initial RCTs of prone positioning for ARDS did not confirm a mortality benefit,[236,237] meta-analysis of six RCTs that paired prone position with a volume- and pressure-limited ventilation strategy reported a mortality benefit (relative risk of death, 0.74; 95% confidence interval, 0.59 to 0.95), whereas the benefit was attenuated in four trials that did not mandate a protective ventilation strategy.[238] In addition to this effect modification by ventilation strategy, the mortality effect of prone position seemed to differ by duration, whereby longer periods of proning (≥16 hours) demonstrated mortality benefit but shorter duration did not.[238] These data prompted a multicenter RCT of early, long-duration (≥16 hr/day) prone positioning paired with protective ventilation compared to protective ventilation alone for ARDS with PaO_2/FIO_2 ratio less than 150. More than 500 subjects were enrolled, and prone positioning resulted in a 16% reduction in unadjusted mortality and approximately 4 additional days alive and ventilator free.[230] Given this strong signal for benefit, it was surprising that, in recent trials of moderate to severe ARDS, the proportion of patients who received prone position was 3–16%[226,239] and not higher than the proportion reported in an observational survey.[240] Even in a trial enrolling subjects with very severe ARDS and PaO_2/FIO_2 ratio less than 80, prone position was instituted in only 60% before randomization.[241] Research identifying the barriers to implementing prone position and strategies to improve its use may be valuable.

Although prone position is strongly encouraged for ARDS with PaO_2/FIO_2 ratio less than 150 after application of adequate PEEP, questions remain about the application of prone position to increased pressure edema. No direct test of this therapy has been undertaken in patients with pulmonary edema from decompensated heart failure. Among adults undergoing elective surgery placed in the prone position, some anesthesia reports describe a decrease in cardiac index by up to 25%, particularly when the heart was elevated relative to limbs and head (jackknife position) and when the inferior vena cava was compressed by increased abdominal pressure.[242–244] Blood pressure was variable in these small studies, with some revealing a decrease and others no change. Patients with preexistent cardiac disease may have a more deranged hemodynamic response to prone position because one study using quantitative CT imaging showed that patients with a history of prior myocardial infarction exhibited decreased ejection fraction when prone, and patients with ischemic heart disease had more diastolic function.[244] Thus, careful attention to the patient's blood pressure, perfusion, and potentially central venous saturation (as a marker of oxygen delivery, which is proportional to cardiac output) upon assuming prone position is warranted.

Specific Pharmacologic Therapies

Several therapeutic agents, which are listed in eTable 133.2, have been studied in patients with various forms of lung injury and sepsis. None of these agents has shown a significant mortality benefit in large-scale, prospective RCTs.[245,246] In addition, some promising therapies based on pilot results in smaller ARDS populations[247] or healthy volunteers[248] have failed to show benefit in larger phase II trials, including keratinocyte growth factor[249] and mesenchymal stromal cells.[250]

Whether or not newer anti-inflammatory therapies or modified applications of some of the therapies listed in eTable 133.2 will be useful in patients with increased permeability edema from damaged lung barriers remains an important question. Although inflammatory reactions can damage tissue, it is important to remember that inflammation plays an important beneficial role in the elimination of invading microorganisms. Because inflammatory pathways are redundant, blocking any one inflammatory mediator, or even multiple mediators, may have little or no effect on the overall inflammatory response. If the mechanisms of lung injury differ after various clinical events, the application of therapy directed at one particular mechanism would not be appropriate until most or all of the underlying mechanisms have been recognized and treated successfully.

See ExpertConsult.com, as well as Chapters 134 and 138, for a discussion of evidence concerning corticosteroids, neuromuscular blocking agents, and extracorporeal membrane oxygenation.

OUTCOME

The outcome of patients with pulmonary edema depends on which of the two major pathophysiologic categories of edema formation is involved. Until recently, much less was known about the resolution of pulmonary edema than about its formation. Water, and any extravasated proteins and cellular debris, must be removed from the alveoli and the interstitial spaces to restore the lungs to their pristine, healthy condition. Edema fluid clears from the lungs via five routes: lymphatics, airways, blood vessels, pleural space, and mediastinum; in contrast, cellular debris and particulate matter must be removed from the alveoli by macrophage uptake or through the airways.

RESOLUTION OF PULMONARY EDEMA

The considerable advances in our understanding of the clearance of fluid and solute from alveoli have been the subject of several reviews.[2,10,273,274] Active sodium and chloride vectorial transport across the alveolar epithelial barrier into the interstitium drives reabsorption of edema from the air spaces (as discussed in Chapter 3). The uninjured alveolar epithelium has a remarkable ability to remove edema fluid from the air spaces rapidly. For example, serial edema fluid protein concentration measurements relative to simultaneous plasma protein concentrations in a saltwater near-drowning patient showed that 50–60% of the excess alveolar fluid in the lungs was removed over the course of just 4 hours.[45] In experimental studies in rabbits, instillation of 4 mL/kg of seawater into the lungs resulted in a 300% increase in alveolar fluid volume in less than 5 minutes, owing to the movement of mainly pure water driven by osmotic forces from the plasma into the hyperosmolar (881 ± 290 mOsm) instillate, 80% of which was cleared from the alveoli in 6 hours.[275] Equivalent volumes of iso-osmotic (292 ± 6 mOsm) saline instilled into rabbit lungs were cleared at a similar rate. In neither seawater nor saline instillation was there evidence of injury to the alveolar epithelial barrier, which is more resistant than the endothelial barrier to a wide range of injuries, including ischemia, alveolar and intravenous endotoxin and bacteria, intravenous oleic acid, acid aspiration, saltwater aspiration, hyperoxia, intratracheal bleomycin, septic and hypovolemic shock, and rewarming after severe hypothermia.

Even after mild to moderate alveolar injury, the capacity to transport salt and water is often preserved. In severe injury, however, when the barrier is disrupted, the capacity to clear edema is lost, and the vascular endothelium becomes the limiting barrier between the vascular system and the air spaces. Clinically, the capacity to remove some alveolar edema fluid, as indicated by increase in the edema fluid to plasma protein concentration ratio in the first 4 to 12 hours after the development of increased permeability edema, is a favorable prognostic finding associated with a mortality of only 20%, whereas the inability to resorb alveolar edema fluid early in the course of severe lung injuries was associated with a mortality of nearly 80%.[116,117] Thus, the functional capability of the alveolar epithelial barrier in acute increased permeability edema may be a useful prognostic index, perhaps because it serves as a marker of the severity and extent of lung injury.

Alveolar fluid clearance may also be manipulated in certain settings. Lung Na^+,K^+-ATPase activity was increased in rats recovering from experimental thiourea-induced increased permeability pulmonary edema.[276] Moreover, alveolar fluid clearance can be increased by salmeterol in uninjured ex vivo human lung,[277] and experimental studies have shown that alveolar fluid clearance can be increased pharmacologically (e.g., by catecholamines), even in the presence of increased permeability edema with alveolar flooding.[2] These observations raise the potential of therapy to hasten the resolution of alveolar edema, although an increase in alveolar clearance requires an intact alveolar epithelial barrier. In one RCT of 282 patients with ARDS, aerosolized albuterol failed to show benefit, although it is possible that an aerosolized agent did not reach the most edematous areas of lung or the alveolar barrier could not respond.[278]

Fluid cleared from alveolar spaces into the alveolar interstitium can leave the lungs by flowing into the lymphatic capillaries or by moving down the prevailing pressure gradient into the loose peribronchovascular connective tissue spaces. Large amounts of fluid in the air spaces may be partially cleared into peribronchovascular cuffs through the hypothesized "leaky" terminal-airway epithelium,[279,280] leaving alveolar fluid and solute behind to be cleared more slowly through the more impermeable alveolar epithelium.

Most of the interstitial water in pulmonary edema is in the peribronchovascular loose connective tissue spaces rather than in the alveolar walls. Because the lymphatic capillaries are arranged to drain only the alveolar wall interstitium, this route for edema removal is not available for most interstitial water. A study in goats showed that lung lymph originated mainly from alveolar wall interstitial fluid, and the contribution of the lung lymphatic system to the clearance of interstitial edema in bronchoalveolar cuffs and interlobular septa was small.[281] The maximum

Mesenchymal stromal cells
Mesenchymal stem cells (adipose derived)

Corticosteroids. Of all the possible pharmacologic agents used to treat critical lung injuries, corticosteroids have the longest history. Despite a seemingly compelling rationale for their use in the setting of increased permeability edema from sepsis, five separate prospective, randomized, double-blind, placebo-controlled trials of methylprednisolone therapy failed to show a reduction in ARDS mortality.[251—255] Trials differed substantially in the dose of steroids, from as low as 1 mg/kg/day to as high as 120 mg/kg/day of methylprednisolone or equivalent, and the durations ranged from 4 hours to 30 days. Two trials administered corticosteroids early in the course of ARDS, whereas three trials tested later administration, as discussed subsequently.[256] The mortality effect was deemed moderately heterogeneous between trials, although no clear factor (dose; duration; year of trial) was clearly identified to explain heterogeneity.[256] In addition, corticosteroid therapy did not prevent the development of ARDS in patients with the sepsis syndrome; neither did it hasten the reversal of ARDS, lower mortality, or improve respiratory function.[256–260] Moreover, use of corticosteroids was associated with both a greater 14-day mortality rate in patients who developed ARDS and an increased frequency of associated infections. High-dose corticosteroids also were ineffective in the sepsis syndrome and may have caused harm.[261]

Fat embolism syndrome may be one specific subtype of ARDS for which corticosteroids may have value. A prospective, randomized, double-blind, placebo-controlled trial of corticosteroid treatment in 64 patients with long bone fractures showed that high-dose methylprednisolone effectively prevented the development of the fat embolism syndrome.[262] Fat embolism is an uncommon clinical syndrome usually described in single-case reports from orthopedists; corticosteroid treatment has not been routinely used, and thus far a large-scale multicenter, randomized trial does not seem warranted.

The generally disappointing results of corticosteroid trials in patients with early or impending lung injury have not discouraged further investigations; rather, ongoing studies indicate that corticosteroids might be beneficial in subsets of patients or when given at a particular time (e.g., during the proliferative phase) or for a more sustained period.[263] Results of studies of corticosteroid therapy late in the course of ARDS (so-called rescue therapy) were encouraging, and a small (24-patient), randomized, double-blind, placebo-controlled clinical trial in patients with severe ARDS whose Lung Injury Score had failed to improve by the seventh day of respiratory failure showed improvement in lung injury and other organ dysfunction scores, as well as reduced mortality in treated patients.[253] However, an NHLBI-sponsored trial of corticosteroid therapy (methylprednisolone, 2 mg/kg) beginning on day 7 to 21 of ARDS showed no reduction in 60- or 180-day hospital mortality in patients treated with corticosteroids compared with placebo.[254] In addition, there were important neuromuscular complications in patients treated with methylprednisolone. One study suggested potential benefit with steroids in severe lung injury, although the design of the trial was suboptimal.[252] Despite the lack of consistent mortality benefit for corticosteroids, three "late steroid rescue" trials did report increased days alive and ventilator free,[256] suggesting the potential for more cost-effective care, although concerns remain about the impact of corticosteroids on neuromuscular function after ARDS. Finally, observational studies from the 2009 pandemic H1N1 influenza crisis suggested no benefit from corticosteroids, even when attempting to account for severity factors with propensity score adjustment.[264,265]

Neuromuscular Blocking Agents. When oxygen saturation is critically low, reducing oxygen consumption to the minimum is advised to reduce oxygen consumption, decrease work of breathing, and achieve ventilator synchrony. However, whether *neuromuscular blockade* (NMB) is a necessary component of a low oxygen consumption strategy has been a topic of debate. In 2010 a randomized-controlled trial showed improvement in adjusted 90-day survival and time off the ventilator in patients with ARDS and Pao_2/Fio_2 ratio less than or equal to 150 receiving early cisatracurium compared with placebo for 48 hours.[266] Because questions remained about the efficacy of NMB and its potential risks,[267,268] the NHLBI sponsored a new multicenter trial that enrolled more than 1000 subjects with moderate to severe ARDS and was completed in 2018. As in the earlier trial, randomized NMB versus placebo was administered for 48 hours along with a limited tidal volume and high PEEP ventilation strategy.[239] Patients were enrolled early after ARDS onset, and only 17% of control group subjects received NMB at any time, compared to 97% of the group randomized to NMB. At 90 days, the mortality did not differ between groups (43% in both study arms). Although subjects randomized to NMB were more deeply sedated, less physically active, and had

higher cardiovascular organ failure scores early during treatment, there were no differences in patient-reported health outcomes at 1 year.[239] Hence, although NMB can be a useful adjunct when oxygen is severely low or when ventilator synchrony is difficult to achieve, early protocolized use of NMB does not seem to improve outcomes for unselected patients with moderate to severe ARDS.

Extracorporeal Membrane Oxygenation

As further discussed in Chapter 138, *extracorporeal membrane oxygenation* (ECMO) technology has greatly evolved since the initial randomized trial described very high (90%) mortality for ARDS.[269] ECMO is now a safe and potentially efficacious alternative for severe ARDS.[241,270] The *ECMO to Rescue Lung Injury in Severe ARDS* (EOLIA) multicenter trial, published in 2018, enrolled subjects with very severe ARDS—eligibility required Pa_{O_2}/F_{IO_2} less than 50 mm Hg for 3 hours, Pa_{O_2}/F_{IO_2} less than 80 for 6 hours, or arterial blood pH less than 7.25 with Pa_{CO_2} of at least 60 mm Hg for 6 hours—and randomized them to immediate venovenous ECMO or to continued conventional lung-protective ventilation with recommended prone position and NMB. Mortality in the control group was 46% and 35% in the ECMO group, a difference that did not achieve statistical significance (relative risk, 0.76; 95% confidence interval, 0.55 to 1.04; $P = 0.09$).[241] Thus many have opined that this large and difficult trial has failed to shift opinions on whether ECMO is useful in ARDS.[271] One interpretation might be that mortality in the control group was better than predicted when using protective ventilation and prone positioning, and if a patient is improving with these interventions, perhaps the added invasiveness of ECMO is not warranted. By the same token, almost 30% of patients randomized to conventional ventilation were crossed over by their clinicians to ECMO after displaying severe persistent hypoxemia, and these patients had a very high mortality even with ECMO.[241] Would earlier ECMO have changed their outcome? That cannot be determined from the data presented. From observational and registry data, we know that when ECMO is used, outcomes tend to be better when patients are younger, immunocompetent, and on ventilators fewer than 8 days.[272] The EOLIA trial bolsters confidence in the safety of ECMO, yet selecting the patients most likely to benefit may remain a challenge.

possible contribution by lung lymphatics to the clearance of interstitial edema liquid was less than 10%.[281] In a study of in situ perfused sheep lungs with experimental low- and high-protein pulmonary edema during recovery from pulmonary edema, interstitial liquid was resorbed into the circulation in inverse proportion to its protein concentration, and only a very small fraction of interstitial edema was cleared by the lung lymphatics during recovery from either type of edema.[282,283]

So, where does the interstitial edema in the peribronchial cuffs go? Once in the peribronchial cuffs, edema may drain along pressure gradients toward the mediastinum and also toward the pleural space, where it may flow across a leaky mesothelial layer into the pleural space. Pleural effusions are fairly common, found in approximately 25–50% of patients with increased pressure pulmonary edema and in roughly 35% of patients with increased permeability edema as well.[284–286] Formation and removal of pleural effusions are discussed in detail in Chapters 14 and 108. As much as 25–30% of pulmonary edema fluid may leave the lungs through the pleural space.[8,286]

Protein is handled quite differently. Because clearance of protein from flooded alveoli is much slower (1–2% per hour) than clearance of protein-free fluid (10–20% per hour),[287,288] the protein left behind in the alveolus becomes concentrated. The increase in alveolar protein concentration does not slow fluid clearance because precipitated protein exerts no osmotic pressure, and the concentration of soluble macromolecules is too small to counteract the differences in ion concentration resulting from transepithelial transport. Removal of edema fluid from flooded alveoli may be slowed if the fluid clots, which can be seen especially when lung vascular permeability is increased. Edema fluid may clot because, after extravasation of plasma into the air spaces, the clotting system may be activated by surfactant or macrophage-derived procoagulants.

Alveolar protein clearance over the short term appears to proceed primarily by paracellular diffusion, not by transcytosis via vesicles, and is size dependent.[6] Most proteins are cleared intact rather than being degraded into smaller fragments. Over the long term, cellular mechanisms, principally phagocytosis and catabolism by macrophages, account for most protein clearance from the alveolar space.[73,289,290] Insoluble, precipitated proteins are removed in this way. Macrophages and regulatory T lymphocytes are also responsible for removing senescent and dead polymorphonuclear leukocytes and other debris. The lack of a ciliated surface area in the distal air spaces seems to indicate that the mucociliary route could account for only a minor fraction of alveolar protein clearance, although proteins might reach the mucociliary escalator along currents in the alveolar fluid layer. Even so, removal would be very slow: The half-time for mucociliary clearance of particles from the alveolar space is more than 4 weeks. Complete clearance of alveolar protein from pulmonary edema by any route is slow.[6]

Little is known about the mechanisms and signals that regulate endothelial barrier function or how increased endothelial permeability returns to normal[291]; on the other hand, the mechanisms for resolution of lung inflammation are beginning to be understood.[73]

Increased Pressure Edema

The outcome of increased pressure pulmonary edema is determined by the underlying cause and the treatment used to correct it. Because the great majority of cases of increased pressure edema are caused by heart disease, outcome is largely determined by the patient's underlying cardiac function. Although traditional reports were that patients with pulmonary edema uncomplicated by acute myocardial infarction fared reasonably well, with an annual mortality rate of less than 10%,[292] more recent data suggest hospital mortality rates exceed 26% regardless of whether *coronary artery disease* (CAD) is present,[293] perhaps signifying that hospitalization for heart failure is being reserved for patients with more severe symptoms in modern times. The presence of CAD is a risk factor for heart failure readmission after hospitalization with acute pulmonary edema, whereas revascularization and surgical procedures were associated with improved survival, perhaps indicating some degree of selection bias.[293] Typically, patients who recover from increased pressure pulmonary edema caused by chronic congestive cardiac failure require long-term outpatient management aimed at preventing recurrent episodes.

Some patients develop increased pressure pulmonary edema from noncardiac causes. Most cases are iatrogenic, being related to excessive, sometimes inadvertent, volume overload, or due to the use of drugs such as cocaine, which impair cardiac function.[294] Pulmonary edema associated with congenital or acquired heart disease is an uncommon but important problem in pregnancy, but pulmonary edema without heart disease is, perhaps, even more frequent. As discussed in Chapter 129, pregnancy complicated by pulmonary edema is occasionally caused by tocolytic treatment, fluid overload, or preeclampsia.[295]

Increased Permeability Edema

The outcome of increased permeability pulmonary edema from both ARDS and forms of milder lung injury is determined by its underlying cause and extent of lung injury, the presence of comorbidities, and the particular treatment strategy used. Trends in ARDS mortality in 2451 mechanically ventilated patients enrolled in the NHLBI ARDS Network showed "clear temporal improvement in survival," from 35% in the late 1990s to a low of 26% in 2005.[296] Although mortality in clinical trials has fallen to as low as 17%,[297] selection bias for trial populations may underestimate the true mortality burden, because observational data from global populations still report mortality of roughly 45% for severe ARDS, 32% for moderate, and 27% for mild ARDS.[65,240]

Patients with sepsis have significantly higher mortality rates than patients with other clinical disorders associated with the development of increased permeability edema.[298] Mortality is also much higher in patients with chronic liver disease or with histories of chronic alcohol abuse than in other predisposing conditions. Besides damaging the liver, chronic ethanol ingestion may reduce alveolar type 2 cell glutathione content and impair surfactant synthesis and secretion.[299] In general, mortality from ARDS increases with increasing age and ARDS severity.[65,300] Patients with self-limited causes of injury, including venous air and fat embolism, isolated lung contusion and other trauma,

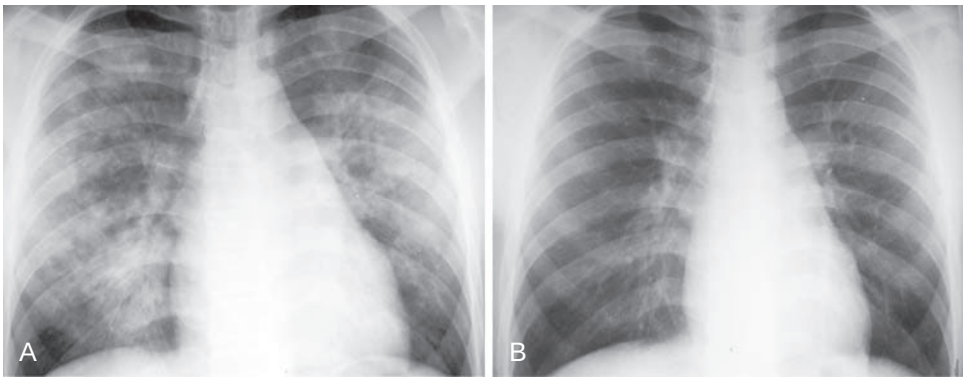

Figure 133.6 Frontal chest radiographs in a 22-year-old patient with heroin-induced increased permeability edema. The radiograph at presentation (A) shows patchy bilateral peribronchial thickening and consolidation, somewhat more prominent and nodular on the right. The vascular pedicle is narrow, with no features suggestive of volume overload. The radiograph 24 hours later (B) shows complete clearing of lung opacities. Increased permeability edema may resolve rapidly if the initiating agent of lung injury is transient and mild and the chronic phase of parenchymal lung injury (type 2 cell hyperplasia, fibrosis, connective tissue deposition, vascular remodeling) does not develop. (Courtesy Michael B. Gotway, MD.)

massive blood transfusions, postictal pulmonary edema, and heroin pulmonary edema (Fig. 133.6), have a greater chance of survival, and edema often clears rapidly. A more recently described entity, vaping-induced lung injury,[301] may also have a favorable prognosis relative to the severity of hypoxemia, although experience with this disease is in its infancy, and fatalities have been reported.

As survival from ARDS improves, the population of survivors grows, and long-term sequelae pose increasing problems. From a purely respiratory standpoint, survivors of ARDS do well on average; at 1 year post-ARDS, many have normal chest radiograph results, minimal or no complaints of dyspnea on exertion, normal lung volumes and airflow measurements, and normal resting and exercise arterial blood-gas findings, including shunt fraction.[302] Diffusing capacity seems to be the pulmonary function parameter most likely to be abnormal at 1 year[71,303] although, by 5 years, even this improves to a median of 80% of predicted (interquartile range, 70–86%).[70] At 5 years post-ARDS, while the chest radiograph is often normal, the chest CT may reveal "minor, nondependent fibrotic changes."[70]

Despite post-ARDS return of pulmonary function test results to normal or near-normal values, survivors and their partners report a significant deterioration of health-related quality of life. Disabling symptoms from muscle wasting, weakness, and fatigue were consistently noted, with reduced *6-minute walk distance* (6MWD) during the first 12 months in previously high-functioning, mostly young subjects.[71] Even 5 years after ARDS, survivors' functional ability remains impaired, with 6MWD approximately 76% of what is predicted for age.[70] The roles played by treatment of ARDS with corticosteroids and neuromuscular blocking are not clear-cut, but neither agent fully explains the deficits observed. Cognitive and emotional function was significantly impaired in those surviving ARDS at hospital discharge, 78% of whom remained symptomatic after 12 months.[71] Furthermore, psychological sequelae such as anxiety, depression, and posttraumatic stress disorder persisted in 20–40% of survivors over the ensuing 5 years.[70] The burden of ARDS on families is also substantial; caregivers commonly report symptoms consistent with depression, anxiety, and posttraumatic stress disorder themselves.[304–306]

Healing involves a fibroproliferative response in a subset of ARDS survivors, which seems to begin early in the course of increased permeability edema,[307–309] perhaps as a consequence of ventilator-induced lung injury before the era of lung-protective ventilation (Video 133.2).[310] How much of this problem is due to disease and how much to treatment is not known, but a fibroproliferative reaction portends a poor prognosis: either increased mortality or prolonged ventilation dependence. It might also be possible to accelerate reconstitution of alveolar structure in injured lungs; this hope underlies the optimism that interventions such as mesenchymal stromal cells or adult progenitor cells may improve ARDS outcome.[308,311]

Key Points

- The two main categories of pulmonary edema are (1) increased pressure edema from an increase in the hydrostatic or protein osmotic forces, or both, that act across normal endothelial and epithelial barriers restricting movement of fluid and protein in the lungs and (2) increased permeability edema from damage to those barriers.
- An evaluation of the cause of pulmonary edema should include a detailed history with a focus on risk factors for either increased pressure or increased permeability edema, a thorough physical evaluation, and laboratory and imaging data, including a chest radiograph, electrocardiogram, cardiac injury markers, microbiologic cultures, and consideration of ultrasound and echocardiography.
- Increased pressure pulmonary edema typically has one of two cardiac origins: from new-onset acute myocardial infarction or from inadequately treated and/or refractory heart failure.
- Treatment for cardiogenic (increased pressure) pulmonary edema should include support of oxygenation and ventilation, often with noninvasive ventilation, and pharmacologic measures to reduce preload and afterload. Revascularization for coronary artery disease and temporary support with ventricular assist devices may be therapeutic options.
- The diagnosis of increased permeability pulmonary edema or *acute respiratory distress syndrome* (ARDS) should include a thorough investigation for a treatable infection.

- Increased permeability pulmonary edema may be complicated by elevated pulmonary intravascular pressures; the two types of pulmonary edema can coexist in the same patient.
- Patients with increased permeability edema who require invasive ventilation should receive lung-protective ventilation with limited tidal volumes (6 mL/kg predicted body weight) and limited plateau pressures (<30 cm H_2O) with adequate positive end-expiratory pressure. When ARDS is moderate to severe (Pa_{O_2}/F_{IO_2} ratio < 150 mm Hg despite lung protective ventilation), prone positioning has been shown to reduce mortality. Extracorporeal membrane oxygenation is a safe alternative when hypoxemia is severe and persistent (Pa_{O_2}/F_{IO_2} ratio < 80 mm Hg).
- The identification of biologically distinct subgroups within ARDS populations that respond differently to different therapies offers the promise of precision therapy in the future.

DIAGNOSIS AND EPIDEMIOLOGY

DIAGNOSIS

Acute respiratory distress syndrome (ARDS) is described as noncardiogenic pulmonary edema accompanied by severe lung inflammation, hypoxemia, and decreased lung compliance leading to respiratory failure. As its name suggests, ARDS is a syndrome, reflecting a constellation of clinical and physiologic observations thought (but not confirmed) to represent a common pathology. No diagnostic gold standard exists for ARDS, and it remains unclear whether it represents a single pathophysiologic process or multiple processes with similar clinical presentations. The heterogeneity of clinical conditions associated with ARDS (discussed later), variance in outcomes by risk factor, and the existence of at least two different phenotypes suggest that ARDS is not simply a common pathologic pathway but may be a collection of pathways of injury that have not yet been separately identified. These uncertainties necessarily permeate any discussion or research into ARDS, and this chapter is no exception.

The first clinical description of ARDS appeared in a remarkable case series reported by Ashbaugh and colleagues in 1967.[1] They described 12 patients aged 11 to 48 years who presented with respiratory distress, hypoxemic respiratory failure, and patchy bilateral opacities on chest radiographs (Fig. 134.1). Most of the cases were preceded by severe trauma or viral infection and the onset of symptoms was rapid, usually within 48 to 72 hours of the insult. Many patients required positive-pressure ventilation and exhibited low respiratory system compliance, and some experienced improvement in oxygenation with the application of *positive end-expiratory pressure* (PEEP). This syndrome was initially termed the *adult* respiratory distress syndrome to distinguish it from the respiratory distress syndrome seen in infants. Subsequently, recognizing that it can also be seen in children, it was renamed the *acute* respiratory distress syndrome.

The cases described by Ashbaugh generated interest and research into ARDS. Unfortunately, the lack of diagnostic criteria and pathophysiologic understanding of the disorder made it difficult to conduct research and compare findings between studies. In 1988, a formalized and expanded definition of ARDS was proposed that consisted of three parts[2]: (1) the first part described whether the illness was acute or chronic, (2) the second part specified any associated risk factors or medical conditions (e.g., sepsis, pancreatitis, inhalational injury), and (3) the third part assigned points based on the severity of pulmonary dysfunction using the modified Lung Injury Score. This score incorporates the degree of hypoxemia, the level of PEEP, the respiratory system compliance (if available), and the degree of radiographic

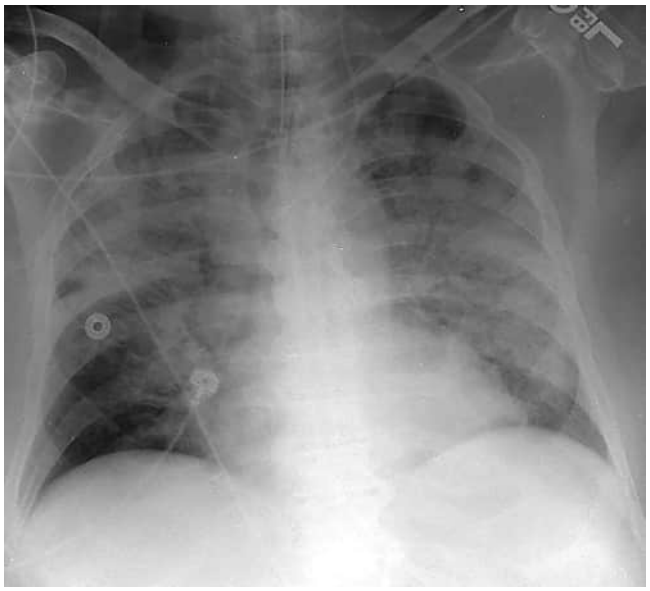

Figure 134.1 Chest radiograph of acute respiratory distress syndrome. Frontal chest radiograph in a mechanically ventilated patient shows extensive, multifocal, bilateral lung opacities, essentially involving all lobes and without features suggesting increased pressure edema, such as interlobular septal thickening or pleural effusion. (Courtesy Michael B. Gotway, MD.)

abnormality. A Lung Injury Score greater than 2.5 was considered diagnostic of ARDS. One advantage of this system was its identification of associated medical conditions, which might be pertinent to the etiology of ARDS. However, there was no attempt to exclude cardiogenic pulmonary edema because it was assumed that clinicians would do so automatically.

In 1994, investigators convened the *American and European Consensus Conference* (AECC) and published an updated definition of ARDS, which was widely adopted.[3] Aiming for simplicity, ARDS was defined as (1) a syndrome of acute onset respiratory failure with (2) bilateral opacities on chest radiography consistent with pulmonary edema, (3) pulmonary artery occlusion pressure of 18 mm Hg or less (or absence of clinical evidence of left atrial hypertension), and (4) hypoxemia as measured by the ratio of the *arterial partial pressure of oxygen* (arterial P_{O_2}) to the *fractional concentration of oxygen in inspired gas* (F_{IO_2}). Recognizing the spectrum of severity of the disease, the consensus panel recommended that arterial P_{O_2}/F_{IO_2} of 300 or less would define an entity termed *acute lung injury* (ALI) while an arterial P_{O_2}/F_{IO_2} of 200 or less would define ARDS. The simplicity of the definition led to its widespread acceptance by clinicians and its incorporation into clinical research.

One issue with the AECC definition was that the radiographic criteria (bilateral opacities consistent with pulmonary edema) were open to interpretation. This was demonstrated by one study that presented a random series of chest radiographs from intubated hypoxemic patients with arterial P_{O_2}/F_{IO_2} less than 300 to an international group of expert clinicians, many of whom conducted research in ARDS. This select group of physicians demonstrated only moderate agreement in their classification of the radiographs (kappa statistic 0.55).[4] The percentage of radiographs deemed to be consistent with ARDS by each physician ranged from a low of 36% to a high of 71%. However, in a separate study, two physicians (an intensivist and a radiologist) were able to achieve excellent agreement after consensus training.[5]

The AECC definition has also been criticized for not taking the level of PEEP into consideration. Clinicians have long appreciated that applying PEEP can improve oxygenation. This implies that the arterial P_{O_2}/F_{IO_2} will change as the level of applied PEEP changes; indeed, a patient who initially meets the AECC criteria for ARDS may no longer meet them after PEEP has been increased.[6] A study of 170 patients meeting the AECC definition for ARDS on varying ventilator settings showed that when PEEP was increased to 10 cm H_2O or greater only 70% of patients still met the ARDS criteria.[7] Moreover, by day 1 of study inclusion, only 50% of patients still met the AECC criteria for ARDS. Thus, the AECC definition, while simple to use, encompasses a heterogeneous group of patients.

In 2012, the Berlin definition of ARDS was developed to address some of these limitations (Table 134.1).[8,9] The degree of hypoxemia was stratified into mild, moderate, and severe based on the arterial P_{O_2}/F_{IO_2} ratio and a requirement for a PEEP level of 5 cm H_2O or greater was included (whether applied by endotracheal tube or, in the setting of mild disease, by noninvasive ventilation). The term ALI was eliminated. Given that the use of pulmonary artery catheters has fallen off dramatically due to lack of benefit,[10,11] the pulmonary arterial wedge pressure criteria was eliminated, and it was recommended that objective testing (e.g., echocardiography) be performed to exclude cardiogenic edema in cases for which no risk factor for ARDS could be identified. "Acute" was explicitly defined as ARDS developing within 1 week of a known risk factor.

Although considerable effort went into its design, when compared to the AECC criteria, the Berlin definition is only slightly better at predicting mortality from ARDS.[9] Moreover, interobserver variability remains high, with a recent study estimating a kappa of 0.5, corresponding to only moderate reliability; 67% of the variability was attributed to differences in interpreting chest imaging.[12]

Two additional points should be made about the diagnosis of ARDS. Whereas physicians properly think of ARDS as being distinct from cardiogenic pulmonary edema, it is important to acknowledge that many patients with ARDS will have left atrial hypertension during the course of their illness[13] and, in fact, its presence does not exclude a diagnosis of ARDS.[8] Secondly, despite the use of B-type natriuretic peptide as a diagnostic tool for acute congestive heart failure, its ability to distinguish ARDS from cardiogenic pulmonary edema is unclear.[14–16] Thus, until the discovery of a specific diagnostic marker for ARDS, cardiogenic edema is likely to remain a significant confounding factor in the diagnosis of ARDS.

Pediatric diagnostic criteria are discussed at ExpertConsult.com.

INCIDENCE

Given the multitude of definitions and the difficulty of making a confirmed diagnosis of ARDS, it is not surprising that determining the incidence of the syndrome has been

PEDIATRIC DIAGNOSTIC CRITERIA

In 2015, a set of pediatric ARDS criteria known as the *Pediatric Acute Lung Injury Consensus Conference* (PALICC) criteria were published (eTable 134.1).[17] These criteria are similar to the adult ARDS criteria with a few notable differences, such as the use of alternative indices of oxygenation (e.g., S/F ratio = pulse oximetric oxygen saturation/fraction of inspired oxygen) and the inclusion of criteria for patients on noninvasive mechanical ventilation. In keeping with the Berlin Definition, the PALICC criteria use the categories mild, moderate, and severe pediatric ARDS based on degree of hypoxemia.

When both the Berlin criteria and the PALICC criteria are applied in children, the PALICC criteria identify more pediatric patients as having pediatric ARDS; however, these patients have an overall lower mortality.[17,18]

eTable 134.1 PALICC Definition of Pediatric ARDS[17]

Criterion	Definition
Age	Exclude patients with perinatal lung disease
Timing	Within 7 days of known clinical insult
Origin of edema	Respiratory failure not fully explained by cardiac fluid or fluid overload
Chest imaging	Findings of new opacities consistent with acute pulmonary parenchymal disease
Oxygenation	1. Noninvasive mechanical ventilation with full face mask bilevel ventilation *or* CPAP ≥5 cm H_2O *and* P/F ratio ≤300 *or* S/F ratio ≤264 2. Invasive mechanical ventilation with: ■ Mild: OI 4–8 or OSI 5–7.5 ■ Moderate: OI 8–16 or OSI 7.5–12.3 ■ Severe: OI ≥16 or OSI ≥12.3

ARDS, acute respiratory distress syndrome; CPAP, continuous positive airway pressure; OI, oxygenation index = (FIO_2 × mean airway pressure (in mm Hg) × 100)/PaO_2; OSI, oxygen saturation index = (FIO_2 × mean airway pressure × 100)/O_2 saturation; PALICC, Pediatric Acute Lung Injury Consensus Conference; P/F ratio, ratio of partial pressure of oxygen (PaO_2) to fraction of inspired oxygen (FIO_2); S/F ratio, ratio of pulse oximetric oxygen saturation (SpO_2) to fraction of inspired oxygen (FIO_2).

Table 134.1 Berlin Definition of ARDS

Criterion	Definition
Timing	Within 1 week of a known precipitant or new/worsening respiratory symptoms
Chest imaging*	Bilateral opacities not fully explained by effusions, lobar/lung collapse or nodules
Origin of edema	Respiratory failure not fully explained by cardiac fluid or fluid overload If no risk factor for ARDS is present, need objective assessment (e.g., echocardiogram) to exclude hydrostatic edema
Oxygenation	
Mild	200 mm Hg < Pao_2/Fio_2 ≤300 mm Hg with PEEP or CPAP ≥5 cm H_2O
Moderate	100 mm Hg <Pao_2/Fio_2 ≤ 200 mm Hg with PEEP ≥ 5 cm H_2O
Severe	Pao_2/Fio_2 ≤100 mm Hg with PEEP ≥ 5 cm H_2O

*By chest radiography or computed tomography.

ARDS, acute respiratory distress syndrome; CPAP, continuous positive airway pressure; Fio_2, fraction of inspired oxygen; Pao_2, arterial Po_2; PEEP, positive end-expiratory pressure.

challenging. In Europe, the reported incidence of "ARDS" (AECC definition) or "moderate" to "severe" ARDS (Berlin definition) has ranged from 1.5 per 100,000[19] to 75 per 100,000 person/years[20]; however, most estimates have been in the range of 5 to 8 cases per 100,000 person/years.[21,22] In the United States, estimates have been much higher, ranging from 33.8/100,000 person/years[23] up to 75/100,000 person/years.[24] The discrepancy between United States and European figures is difficult to justify but, since most incidence studies assess only *intensive care unit* (ICU) patients, it may reflect the higher availability of ICU beds in the American context.[22]

The incidence of ALI (per the AECC definition) was estimated in a prospective study of ICU patients in Washington State to be 78.9 cases per 100,000 person/years.[25] A second study using 3 years of screening data from the original *National Heart Lung and Blood Institute ARDS Network* (ARDSNet) study calculated an incidence ranging from 22/100,000 person/years to 64/100,000 person/years depending on the assumptions used.[26] This heterogeneity may reflect differences in methodology of various studies leading to discrepancies in classification of cases and identification of the size of the population from which those cases arose. However, this variability in results may also reflect true regional variation because differences, including genetic or environmental factors and specific disease associations such as cardiopulmonary bypass or lung transplantation, may account for some of the variability.[27]

Very few comparative data exist to determine whether ARDS incidence differs between geographic regions. The *Large Observational Study to Understand the Global Impact of Severe Acute Respiratory Failure* (LUNG SAFE study) was a worldwide effort that included data from 459 ICUs in 50 countries.[28] Patients were prospectively screened over a 4-week period in the winter of 2014. The ICU incidence of ARDS (mild, moderate, and severe, per the Berlin definition) was estimated to be 10.4% of ICU admissions and 23.4% of patients receiving mechanical ventilation. There was some geographic variation, from 0.27 cases per ICU bed in Asia to 0.57 cases per ICU bed in Oceania; Europe and North America were similar at 0.46 and 0.48 cases per ICU bed, respectively.[28] The authors did not estimate population incidence because they were unable to calculate catchment areas for all of the screening hospitals. The results of the LUNG SAFE study have been criticized as overestimating the incidence of ARDS due to an unvalidated algorithm for diagnosing ARDS that was discordant with clinician assessment (only 60% of patients identified by the algorithm were diagnosed as having ARDS by the treating clinician) and the fact that 17% of patients met criteria for ARDS for less than 24 hours, which seems at odds with the natural history of the syndrome.[29] However, the mortality data revealed an average in-hospital mortality rate of 40%, which is consistent with other studies of ALI/ARDS and indicates that the acuity of the patient population was high.[28]

RISK FACTORS

Sepsis, trauma, aspiration of gastric contents, and multiple transfusions (more than 15 units in 24 hours, in one study) are associated with the highest risk of developing ARDS. The presence of more than one risk factor further increases the incidence of ARDS.[30] In early studies, up to 43% of patients with sepsis, 40% of patients receiving massive blood transfusions, and 25% of patients with multiple trauma developed ARDS.[31] A systematic review of risk factors for ARDS concluded that the strongest evidence of a causal relationship was for sepsis, trauma, multiple transfusions, aspiration of gastric contents, pulmonary contusion, pneumonia, and smoke inhalation.[32]

Premorbid conditions can also affect the likelihood of ARDS. One of the most significant predisposing factors is a history of chronic alcoholism (relative risk, 2.0; 95% confidence interval, 1.3 to 2.9). This relationship remained significant after adjustment for gender, at-risk diagnosis, and severity of illness. Patients with ARDS and a history of alcoholism also had a higher mortality rate than those without this history (odds ratio, 6.3; 95% confidence interval, 2.2 to 20.4).[33] The mechanisms of this association are unknown. More recently, active or passive exposure to cigarette smoke has been associated with the development of trauma-associated ARDS.[34]

The heterogeneity of risk factors for ARDS is remarkable. At the American-European consensus conference, investigators divided the known risk factors into those thought to cause *direct* lung injury (e.g., pneumonia), and those in which the mechanism of lung injury was thought to be *indirect* (e.g., sepsis) (Table 134.2). While conceptually attractive, this classification scheme may not reflect underlying differences in the mechanisms, severity, or outcome of lung injury.[35]

Table 134.2 Conditions Associated With Acute Respiratory Distress Syndrome by Possible Mechanisms of Injury

Direct Injury (Pulmonary)	Indirect Injury (Nonpulmonary)
Pneumonia (bacterial, viral [e.g., influenza, COVID-19])	Sepsis
Aspiration	Major trauma
Pulmonary contusion	Multiple blood transfusions
Toxic inhalation	Pancreatitis
Near-drowning	Cardiopulmonary bypass
Reperfusion injury (e.g., post–lung transplant)	Drug overdose
	Adverse effects of medication

COVID-19, coronavirus disease 2019.

ETIOLOGY AND PATHOGENESIS OF ARDS

OVERVIEW OF PATHOPHYSIOLOGY

In the past, ARDS was called *noncardiogenic pulmonary edema*, a descriptive term that reflected what was known of the pathogenesis of the disorder. Unlike congestive heart failure, in which elevated left-sided cardiac pressures cause hydrostatic pulmonary edema, in ARDS, the edema fluid that fills the alveoli is exudative. In other words, the alveolar-capillary barrier exhibits increased permeability, allowing for the leakage of protein-rich fluid into the airspaces. Alveolar filling leads to decreased respiratory system compliance as well as right-to-left shunting and profound hypoxemia. Although alveolar P_{CO_2} is generally within the normal range, dead space ventilation is significantly increased, as demonstrated by increased minute ventilation. Pulmonary hypertension is also common in ARDS, and a number of mechanisms have been proposed to account for this, including hypoxic vasoconstriction, intravascular fibrin deposition, and compression of blood vessels by positive-pressure ventilation. This section reviews the pathology of ARDS and discusses current theories of its pathogenesis.

PATHOLOGY

The pathologic features of ARDS have classically been described using three overlapping and sequential stages.[36] In the first *exudative phase* of lung injury, hyaline membranes (composed of cellular debris, proteins, and surfactant components) and protein-rich fluid fill the alveolar spaces. There is widespread epithelial disruption as well as infiltration of the interstitium and airspaces with neutrophils. These pathologic findings are termed *diffuse alveolar damage* (DAD). The exudative phase is thought to last for 5 to 7 days and is followed in some patients by the *proliferative phase*. At this point, hyaline membranes are reorganized and fibrosis appears. Obliteration of pulmonary capillaries and deposition of interstitial and alveolar collagen may also be observed, along with a decrease in the number of neutrophils and the extent of pulmonary edema. The final phase of ARDS is the *fibrotic phase*, so-called because of the appearance of pulmonary fibrosis in a subset of patients with persistent ARDS (i.e., greater than 2 weeks). Fibrosis may start sooner than previously appreciated; elevated levels of N-terminal procollagen peptide III, thought to represent collagen synthesis, can be detected in *bronchoalveolar lavage* (BAL) fluid of patients with ARDS as early as 24 hours after the onset of illness. In addition, the BAL fluid from ARDS patients has been shown to stimulate cultured fibroblasts to proliferate in vitro.[37] These and other observations have led some investigators to hypothesize that fibroproliferation may begin simultaneously with (rather than after) inflammatory lung injury.[38] (See radiologic correlates of the different ARDS phases in Fig. 134.2.)

Although DAD is considered the pathologic correlate of ARDS, multiple studies have confirmed that only about 50% of ARDS patients show evidence of DAD on autopsy or lung biopsy.[39] The patients with evidence of DAD tend to be younger, more severely ill, have poorer lung compliance, lower alveolar P_{O_2}/F_{IO_2} ratios, and require higher ventilator driving pressures. Patients with confirmed DAD also have a higher mortality and, in one study, were five times more likely to die of hypoxemic respiratory failure than patients without DAD. The pathologic findings of ARDS in patients without DAD include abnormalities such as infectious pneumonia, diffuse alveolar hemorrhage, acute eosinophilic pneumonia, and drug-associated pneumonitis.[39] Currently, there are no noninvasive techniques to identify which ARDS patients have DAD; the development of a biomarker of DAD would enable the early identification and prospective study of this high-risk subgroup of ARDS patients and would also enable the appropriate treatment of those non-DAD patients with treatable pathologies.

THE ALVEOLAR-CAPILLARY MEMBRANE

If ARDS is a disorder of increased alveolar-capillary permeability, it stands to reason that the pulmonary microvascular endothelium or the alveolar epithelium (or both) must be involved in its pathophysiology. Damage to the alveolar epithelium is thought to be a key event precipitating ARDS.[40,41] Multiple mechanisms contribute to epithelial cell death in ARDS, including cell necrosis, apoptosis, coagulation, and mechanical stretch.[41] Loss of epithelium disrupts barrier integrity, contributing to edema formation, and also prevents alveolar fluid clearance. In addition to the alveolar epithelium, the microvascular endothelium is involved; loss of pulmonary vascular endothelial barrier integrity is both necessary and sufficient for the development of ARDS.[42,43] The mechanism of alveolar-capillary membrane injury in ARDS is unknown, although epithelial and endothelial apoptosis,[44] as well as neutrophil-induced damage, are thought to play central roles (see below).

SURFACTANT

Surfactant is a complex mixture of phospholipids and proteins that reduces alveolar surface tension. Many researchers have described alterations to surfactant in patients with ARDS, including decreased amounts of surfactant-related protein and decreased amounts of the phospholipids

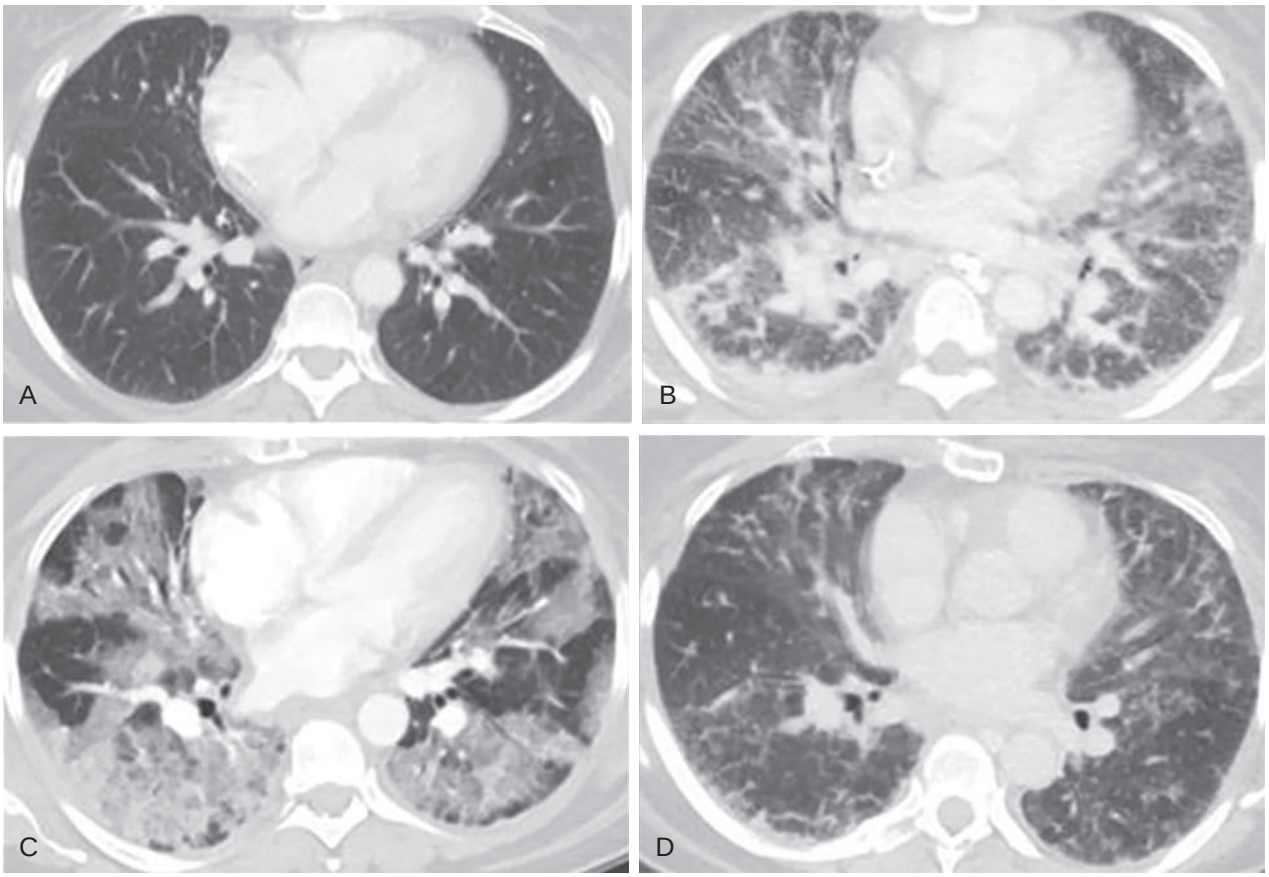

Figure 134.2 Computed tomography demonstration of the phases of the acute respiratory distress syndrome. (A) Axial enhanced chest *computed tomography* (CT) obtained approximately 1 year prior to the development of *acute respiratory distress syndrome* (ARDS) serves as a baseline. (B) Axial enhanced chest CT as the exudative phase of ARDS was developing as a complication of multifocal pneumonia shows multifocal bilateral ground-glass opacity associated with reticular opacities, but without features of increased pressure edema, such as pleural effusions. (C) Axial enhanced chest CT several weeks after the development of hypoxemic respiratory failure shows some mild architectural distortion, best seen anteriorly in the right middle lobe, with some dependent consolidation, suggesting developing organization and typical of the proliferative phase of ARDS. (D) Axial enhanced chest CT more than 1 month after the development of hypoxemic respiratory failure shows resolution of much of the ground-glass opacity, with linear and reticular abnormalities now more prominent, particularly anteriorly, consistent with the fibrotic phase of ARDS. (Courtesy Michael B. Gotway, MD.)

dipalmitoylphosphatidylcholine and phosphatidylglycerol. The proportion of large (active) to small (inactive) aggregates of surfactant is also diminished, due both to decreased production of surfactant and to increased conversion of large to small forms. Plasma proteins that leak into the alveolar space through the alveolar-capillary barrier may also interfere with surfactant function. Additionally, neutrophil elastase causes degradation of surfactant A protein in vitro,[45] consistent with degraded surfactant A being found in BAL washings from patients with ARDS.[46]

Impairment in surfactant function in ARDS theoretically predisposes alveolar units to collapse. In addition, surfactant proteins are known to have antimicrobial properties,[47,48] although whether the loss of these properties is relevant to the pathogenesis of ARDS is not known.[49] Indeed, the extent to which abnormalities of surfactant contribute to the pathogenesis of ARDS remains controversial, unlike in the *neonatal* respiratory distress syndrome in which a deficiency of surfactant underlies the pathophysiology of the disease. Four large, randomized controlled trials of exogenous surfactant supplementation in adult ARDS failed to demonstrate improvement in mortality or in the need for mechanical ventilation[45] (see "Treatment" section). Only one trial using calfactant, a natural surfactant, in pediatric patients with ARDS has shown any benefit[50]; whether this is due to the unique surfactant studied or the patient population enrolled in this trial is unknown.

NEUTROPHILS AND OTHER INFLAMMATORY MEDIATORS

Histologically, one of the hallmarks of ALI/ARDS is the accumulation of neutrophils in the microvasculature of the lung.[51] As key players in innate immunity, neutrophils can generate an impressive array of cytotoxic compounds. These include reactive oxygen species, cationic peptides (e.g., defensins), eicosanoids, and proteolytic enzymes such as leukocyte elastase. In addition, once activated, neutrophils release growth factors and cytokines, such as *tumor necrosis factor-α* (TNF-α) and *interleukin-1β* (IL-1β), that may enhance the inflammatory response. Given this destructive potential, it has long been theorized that neutrophils may be central to the pathogenesis of ARDS[52,53] (Fig. 134.3). There is an abundance of clinical and preclinical data to support this hypothesis. For example, in humans with sepsis-associated ARDS, the presence of neutrophils in

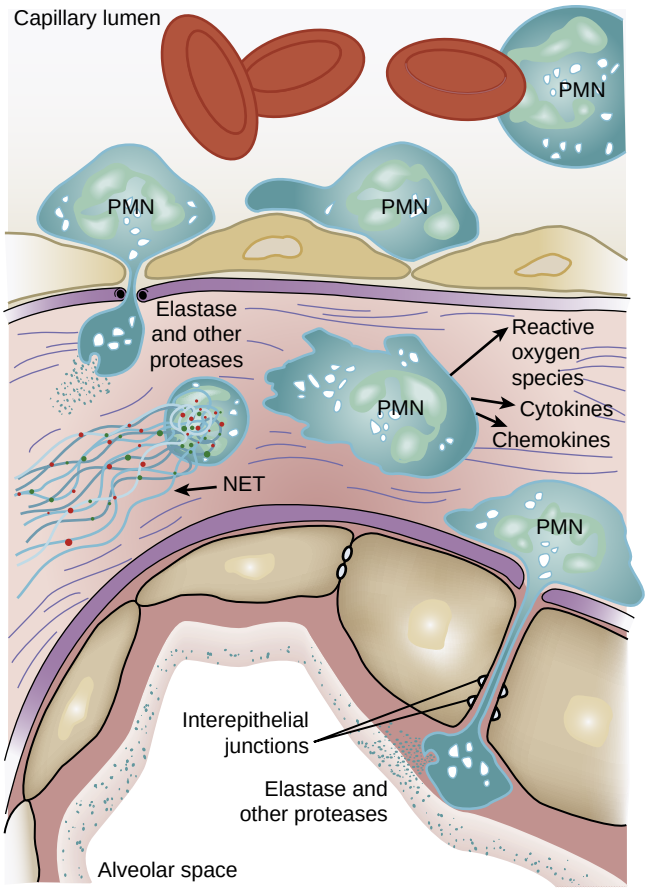

Figure 134.3 Role of neutrophils in the pathogenesis of acute lung injury. Activated *polymorphonuclear neutrophils* (PMNs) exit the bloodstream and transmigrate across the alveolar-capillary membrane, releasing cytokines, proteases, reactive oxygen species, and other compounds, as well as *neutrophil extracellular traps* (NETs). Although crucial for host defense against pathogens, compounds released by neutrophils have the capacity to damage host tissue.

BAL fluid is associated with a poor prognosis.[54] Conversely, neutrophil-depleted mice exposed to hyperoxia develop less lung injury than normal mice.[55]

One of the earliest manifestations of ARDS, even before hypoxemia, is a transient leukopenia due to sequestration of neutrophils in the lung microvasculature.[56] The diameter of the average pulmonary capillary is smaller than the diameter of the average neutrophil; therefore, they must deform to pass through the microvasculature. Activated neutrophils become "stiff" and cannot negotiate these narrow capillary segments,[57,58] leading to sequestration within the pulmonary capillaries. Inhibitors of actin polymerization can prevent this stiffening, implicating a change in the actin cytoskeleton as part of the mechanism.[59] Once sequestered in the lungs, neutrophils can migrate into the lung without the need for adhesion molecules such as L-selectin and β2-integrins.[60] Sequestered neutrophils may also induce changes in the endothelial cells that promote endothelial barrier breakdown,[61] leading to enhanced migration of neutrophils into the pulmonary interstitium.

Many studies have focused on the mechanisms of neutrophil activation. One area of interest is the interaction between neutrophils and platelets and how mutual activation may contribute to ARDS and sepsis.[62–65] Other studies have investigated components of intracellular signal transduction pathways, such as kinases (enzymes that phosphorylate substrates) and transcription factors. One such kinase is the p38 mitogen-activated protein kinase, which is activated when cells are stimulated with lipopolysaccharide.[66] Activation of mitogen-activated protein kinase stimulates TNF-α production as well as release of macrophage inflammatory protein-2, a chemotactic factor for macrophages.[67] Interestingly, inhibition of mitogen-activated protein kinase in mice, even hours after exposure to aerosolized lipopolysaccharide, attenuates neutrophil chemotaxis and migration from the lung microvasculature into alveoli.[68] Another kinase that is central to inflammation is phosphatidylinositol 3-kinase. This enzyme phosphorylates phosphatidylinositol, a lipid-derived second messenger whose phosphorylated forms have been implicated in a myriad of intracellular signaling events. Phosphatidylinositol 3-kinase-γ is preferentially activated in neutrophils exposed to the inflammatory mediators IL-8 or fMLP (a bacterial-derived peptide).[69] When compared to control mice, phosphatidylinositol 3-kinase-γ knockout mice displayed decreased neutrophil accumulation, cytokine production, and lung injury after exposure to intraperitoneal endotoxin.[70]

Neutrophils also produce proteolytic enzymes that may contribute to the pathogenesis of ARDS, particularly *neutrophil elastase* (NE) and metalloproteinases.[53] NE is a proteolytic enzyme that has the ability to degrade growth factors and cytokines and may be involved in regulating the inflammatory response. It has also been shown to degrade epithelial and endothelial cadherins, proteins that are major components of the adherens junctions holding cells together; cadherin destruction may predispose to alveolar flooding. Despite its potential to cause unwanted tissue damage, NE is likely crucial to host defense. In NE-deficient mice, administration of intraperitoneal *Klebsiella pneumoniae* causes 100% mortality within 48 hours compared to only 50% mortality in normal mice.[71] However, NE-deficient mice are paradoxically resistant to lethal doses of lipopolysaccharide. Furthermore, mice that lack both NE and another neutrophil protease (cathepsin G) are protected against alveolar damage induced by endotoxic shock.[72] These seemingly contradictory results suggest that NE, while important for a regulated inflammatory response, may nonetheless participate in inflammatory injury under certain circumstances. Unfortunately, a clinical trial of an NE inhibitor in ARDS was halted because preliminary analysis suggested lack of efficacy.[73]

Neutrophil extracellular traps (NETs) are web-like structures made of DNA, histones, and antimicrobial peptides (including myeloperoxidase, NE, cathepsin G, cathelicidin, gelatinase, and proteinase C) that are released by neutrophils and serve to trap and kill extracellular microbes.[74] One key benefit of NETs is their ability to eliminate large pathogens, such as fungal hyphae, that are too big to be phagocytosed. Some pathogens have evolved strategies to avoid NETs, including secretion of DNase enzymes that degrade the DNA structure of the NETs.[75] In sepsis, large numbers of NETs are released, which can lead to NET-associated endothelial damage as well as thrombus formation. Evidence from experimental animal models suggests NETs may play a role in the development of ARDS; in a mouse intratracheal

lipopolysaccharide model of ARDS, NET formation was identified in the lungs of experimental animals and was accompanied by severe destruction of lung structure.[76] When the animals were treated with DNase to degrade NETs, lung injury was attenuated. NET degradation also lowered IL-6 and TNF levels, suggesting that NETs promote inflammation. In a separate study, NETs were shown to be important in a mouse model of acid aspiration–induced ARDS.[77] Treatment with DNase resulted in improved lung function and survival, as did treatment with an NE inhibitor, alvestat. Finally, BAL fluid from patients with ARDS secondary to aspiration of gastric contents showed evidence of NETs, and the NET concentration correlated inversely with the degree of ARDS.[77] These studies suggest that NETs might be a target for future ARDS therapies.

Despite the evidence implicating neutrophils as a cause of lung injury, it is important to note that ARDS has been described in patients with profound neutropenia.[78,79] Indeed, it is possible that the neutrophil infiltration observed in non-neutropenic ARDS is adaptive (i.e., a physiologic response to a primary injury) rather than destructive. At present, little is known about the mechanism of neutrophil-independent ARDS, although some authors have postulated that alveolar macrophages, which are recovered in BAL fluid from these patients, might be a source of lung damage.[80,81] Understanding the mechanism of neutropenic ARDS must be a goal of future investigations.

INFLAMMATION AND COAGULATION

Inflammation and coagulation are interconnected processes, and both may play a role in the development of ARDS. The proinflammatory cytokine TNF-α, for example, causes an increase in thrombin and fibrin formation, stimulates tissue factor expression on endothelial cells, and inhibits fibrinolysis. Meanwhile, fibrin fragments are known to be chemotactic for neutrophils.[82] Activated protein C, an endogenous anticoagulant, has both direct and indirect anti-inflammatory effects. These include down-regulating IL-6 levels and attenuating neutrophil activation in sepsis.[83,84] Because abnormalities of coagulation are very common in sepsis, the most common cause of ARDS, investigators have wondered whether altered coagulation might be involved in the pathogenesis of ARDS. Animal studies have shown that anticoagulation can attenuate the severity of sepsis-induced lung injury.[85] However, human studies with activated protein C have been disappointing; a small randomized controlled trial of activated protein C in patients with ARDS was stopped prematurely due to lack of efficacy,[86] and activated protein C was subsequently pulled from the market after a large multicenter trial showed it provided no mortality benefit in patients with septic shock.[87]

Other molecular determinants of inflammation are still under investigation as therapeutic targets in ARDS. Some investigators have focused on improving the endogenous counterinflammatory response; in one study, the gene for heat shock protein 70 was ligated to an adenoviral promoter and the recombinant construct was administered into the lungs of rats with sepsis-induced ARDS. Increased heat shock protein 70 expression in the lung was associated with a significant reduction in pulmonary edema, inflammation, and even mortality.[88] Conversely, mice deficient in heat shock protein 70 showed increased mortality and lung injury.[89] The mechanisms underlying the beneficial effects of heat shock protein 70 are unclear, but may involve suppression of the proinflammatory transcription factor, nuclear factor-κB, and/or decreased lung parenchymal apoptosis.[90]

NA^+ AND WATER

Na^+ channels at the apical surface of alveolar epithelial cells mediate intracellular Na^+ uptake from the alveoli (see also Chapters 3 and 133). This creates an osmotic gradient and causes alveolar fluid to follow, thereby allowing for the clearance of pulmonary edema. Na^+/K^+ adenosine triphosphatases (ATPases) in the basolateral membrane of the epithelial cell exchange intracellular Na^+ for extracellular K^+, maintaining the intracellular sodium gradient. This process allows for the net removal of Na^+ and fluid from the alveolar space and can be accelerated (experimentally) by catecholamines.

Dysfunction of either the apical Na^+ channels or the basolateral Na^+/K^+ ATPases (or both) has been postulated to be involved in the pathogenesis of ARDS. For example, it is known that hypoxia decreases epithelial Na^+ reabsorption by impairing the expression of subunits of the epithelial Na^+ channel.[91] Hypoxia also decreases the activity of both the apical Na^+ channel[92] and the Na^+/K^+ ATPase.[93] In an animal model of hemorrhagic shock–induced lung injury, the normal up-regulation of alveolar fluid reabsorption in response to catecholamines was absent. This defect was attributed to an increase in nitric oxide in the lung, possibly due to an effect on β-adrenergic receptor signaling.[94] In a model of ventilator-induced lung injury in rats, overexpression of the Na^+/K^+ ATPase improved the clearance of lung liquid.[95] However, attempts to increase alveolar fluid clearance in a clinical setting (by using β2-adrenergic agonists) have so far been disappointing (see below).[96]

ANGIOPOIETINS

Angiopoietins are peptides involved in embryonic vascular development. Although four angiopoietins have been identified, *angiopoietin 1* (Ang1) and *angiopoietin 2* (Ang2) are the best described. Ang1 is expressed by numerous cell types, while Ang2 is expressed by endothelial cells. Both act on the Tie2 receptor tyrosine kinase that is found predominantly on endothelial cells and hematopoietic stem cells.[97] Ang1 is thought to enhance endothelial barrier integrity while Ang2 often acts as a competitive antagonist to Ang1. Several observations have generated interest in the role of these proteins in ARDS. First, elevated levels of Ang2 have been described in patients with sepsis and ARDS.[98,99] Moreover, administration of exogenous Ang2 to mice resulted in pulmonary vascular leak, an effect which could be reversed in vitro by Ang1.[100,101] Second, overexpression of Ang1 was protective against endotoxin-induced septic shock and lung injury in mice,[102] with a similar benefit observed using a synthetic agonist of the Tie2 receptor.[43,103] Third, genetic variants in Ang2 have been associated with higher plasma Ang2 levels and with increased risk of ARDS in patients of European ancestry.[99] While the mechanism of these effects remains uncertain, the data

emphasize the important role of the endothelium in the development of and recovery from ARDS and may suggest a role for Ang2 in the pathogenesis of ARDS. Agonists for Tie2 are likely to be tested in clinical trials within the next several years.

VENTILATOR-INDUCED LUNG INJURY

Although mechanical ventilation for ARDS may be lifesaving, there is abundant preclinical and clinical evidence that it can also be harmful.[104] While it was quickly recognized that excessive airway pressure could lead to barotrauma, including pneumothorax, pneumomediastinum, and subcutaneous emphysema, attention has since turned to more subtle but more common manifestations of lung injury. Mechanical ventilation can induce pulmonary edema by causing increases in both epithelial and endothelial permeability.[104] Indeed, 50 years ago, Webb and Tierney demonstrated that ventilation of rats with high peak airway pressures could lead to severe pulmonary edema[105] and, 30 years ago, investigators noted that mechanical ventilation could produce a form of increased-permeability pulmonary edema remarkably similar to ARDS.[106] Now, accumulated evidence suggests that mechanical ventilation may aggravate, if not induce, ARDS in some patients,[107] by a process called *ventilator-induced lung injury* (VILI) (see also Chapter 135).

An important mechanism of VILI is overdistension of lung units. Normal rats ventilated with high airway pressure and high tidal volumes developed increased permeability, whereas rats ventilated with the same end-inspiratory pressure but with smaller tidal volumes (achieved by strapping the chest wall to reduce the transpulmonary pressure) did not develop increased permeability.[104] Rats were also ventilated using low airway pressures with high tidal volumes (by applying negative inspiratory pressures at the chest wall). Among all these ventilatory strategies, the rats ventilated with high tidal volumes had the highest incidence of pulmonary edema, regardless of high or low airway pressures. In particular, the negative (low) pressure and high tidal volume group had the worst edema. These important observations, also confirmed in other species,[108] led to the appreciation that large tidal volumes are the most important determinant of ventilator-induced pulmonary edema. The term *volutrauma* was coined to recognize this fact.

The repetitive opening and closing of terminal lung units is also considered to be detrimental. The mechanism of this injury, termed *atelectrauma*,[109] is thought to be high shear stresses generated at the interface of collapsed and aerated tissue when a collapsed airway is reopened.[110] Theoretically, PEEP should minimize this injury by keeping the lung recruited and promoting greater lung homogeneity; however, any such advantage of PEEP would have to be balanced by the potential for greater overdistension of lung units (Fig. 134.4).

It is important to note that patients with ARDS may be especially vulnerable to VILI because of the heterogeneous nature of the parenchymal injury. Computed tomography scans of lungs from patients with ARDS show areas of normal-appearing lung interspersed with densely consolidated injured lung; as a consequence, there are marked regional differences in lung compliance.[111] A tidal volume designed to inflate an entire lung will preferentially inflate the "normal" lung, potentially leading to overdistention and volutrauma. Similarly, patients with ARDS may be more vulnerable to atelectrauma; although normal lungs can likely tolerate short periods of cyclic opening and closing of airways,[112] injured lungs, such as in ARDS, are exposed to higher shear stresses and would not be expected to fare as well.[113]

There has been a growing appreciation that VILI is not only a mechanical injury, but also reflects an underlying cellular and molecular response. The term *biotrauma* has been coined to describe the phenomenon by which mechanical ventilation causes local and systemic inflammation.[114,115] In animal studies, it has been shown that ventilation with either high tidal volumes or zero PEEP causes elevations in inflammatory cytokines in BAL fluid. Lungs ventilated with both high tidal volumes and zero PEEP showed a synergistic elevation in cytokine levels.[116] This inflammatory response to an injurious ventilation strategy has also been shown to extend beyond the lung. In an acid aspiration rat model of lung injury, a strategy of high tidal volumes and zero PEEP was associated with an increase in blood levels of various cytokines; this was not observed in animals ventilated with small tidal volumes or in those ventilated with large tidal volumes but higher PEEP levels (Video 134.1).[117]

Similar observations have been made in human patients with ARDS. In one study, patients were randomized to 36 hours of either *lung-protective* ventilation, in which the tidal volume was set to avoid over-distention and PEEP was set above the lower inflection point of the pressure-volume curve, or to a *control strategy* targeted to achieve normal arterial carbon dioxide levels and with PEEP set to achieve the greatest improvement in arterial oxygen saturation without worsening hemodynamics.[118] The first strategy aimed to avoid volutrauma and atelectrauma, whereas the second strategy aimed to optimize gas exchange. In the lung-protective group, BAL and plasma cytokine levels declined, but they rose significantly in the control group. Post hoc analyses revealed a higher number of ventilator-free days in the lung-protective group. The impact of ventilator strategy on the development of biotrauma can be remarkably quick. Within 1 hour after switching patients from a protective ventilatory strategy, Stuber and colleagues found an increase in proinflammatory cytokines in the lungs and plasma of patients with ARDS.[119]

As is discussed in the section on outcomes, patients with ARDS often die of systemic inflammatory response syndrome and multiorgan dysfunction. Thus, the observation that injurious mechanical ventilation can increase pulmonary and systemic cytokine levels is intriguing. These findings suggest that mechanical ventilation has the potential to injure the lungs and lead to a loss of compartmentalization of the pulmonary inflammatory response. Systemic dissemination of this response could be associated with the development of systemic inflammatory response syndrome and, potentially, with multisystem organ failure[120] (Fig. 134.5). One study has shown that injurious mechanical ventilation in rats not only causes elevated plasma and lung cytokine levels but also causes increased renal epithelial cell apoptosis and renal dysfunction.[121]

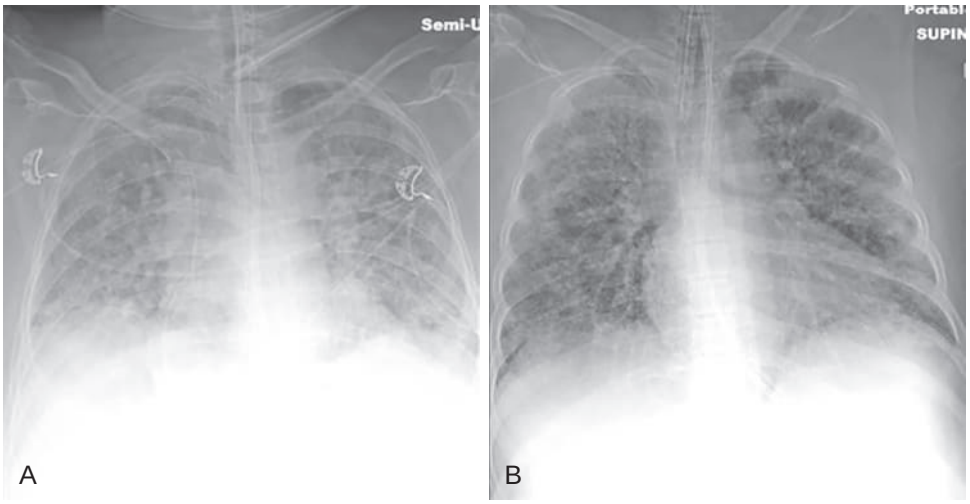

Figure 134.4 Chest radiograph showing the effects of *positive end-expiratory pressure* (PEEP). (A) Frontal chest radiograph in a patient with acute respiratory distress syndrome and a PEEP of 6 cm H_2O. (B) Frontal chest radiograph shortly after A with PEEP adjusted to 12 cm H_2O shows improved lung aeration.

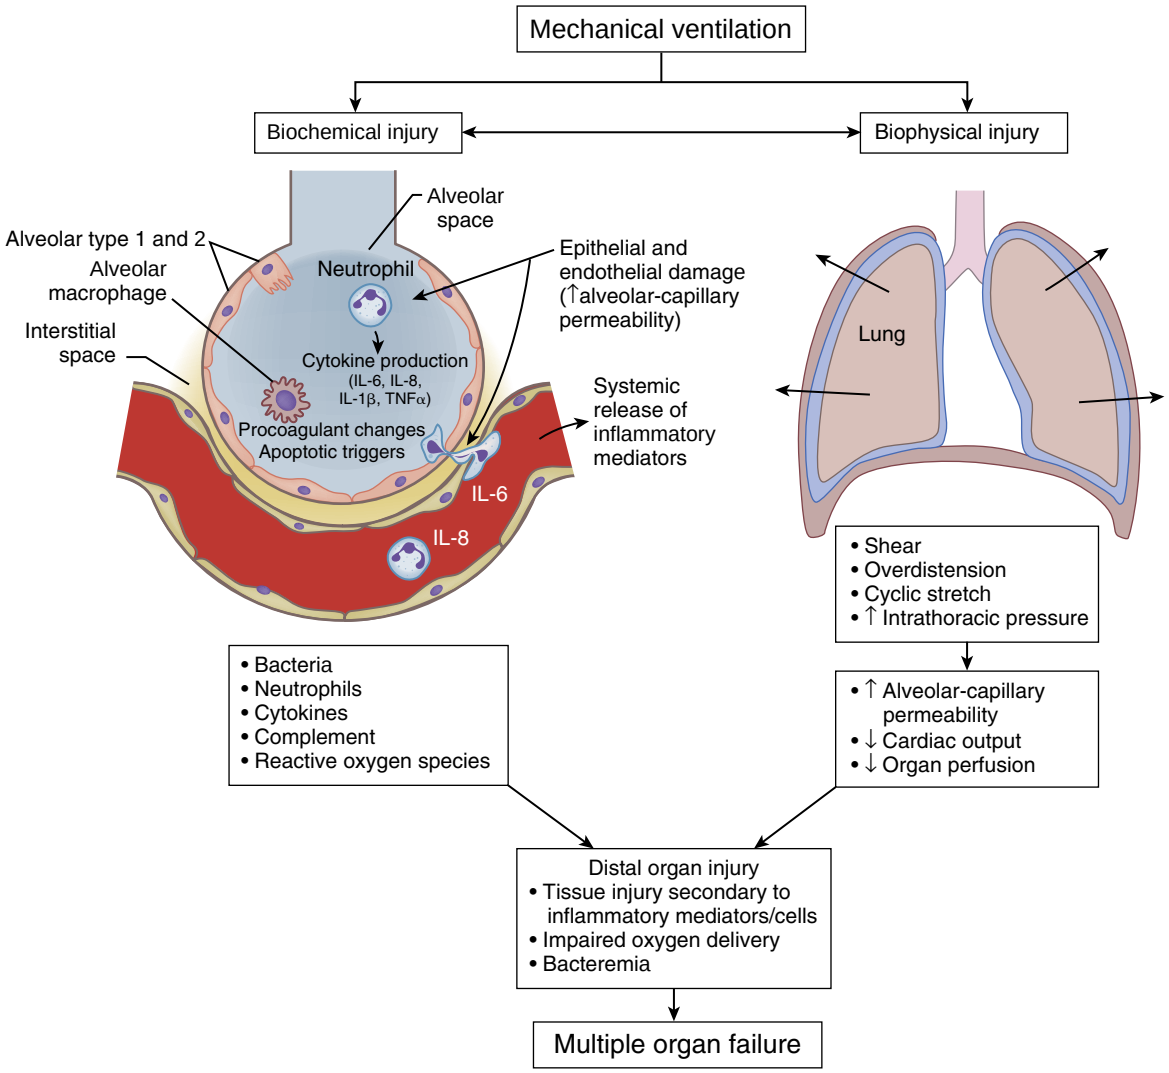

Figure 134.5 Potential mechanisms by which mechanical ventilation might cause or contribute to multiple organ failure. Both biochemical and biophysical effects of mechanical ventilation can lead to systemic inflammatory and toxic effects and, ultimately, to multiple organ failure. IL, Interleukin; TNF, tumor necrosis factor.

Finally, patients with ARDS often require a high inspired fraction of oxygen. The toxic effects of hyperoxia on the lung have been well described,[122] and the histologic appearance mirrors that of ARDS. Oxygen toxicity is thought to be mediated by both reactive oxygen and nitrogen species, which can damage tissues by a multitude of mechanisms.[123] Moreover, hyperoxia appears to worsen VILI.[124] Antioxidants have been considered as a potential therapeutic strategy for preventing and treating ARDS, although clinical trials have so far been disappointing.

GENETIC DETERMINANTS OF ACUTE LUNG INJURY

Although the heterogeneity of patients with ARDS may impede the identification of important genetic associations, genome-wide association studies in humans have suggested several candidate genes that increase the risk of ARDS. These include the *DARC* gene (Duffy antigen/receptor for chemokines) in African American patients,[125] the nuclear factor-κB gene in white patients,[126] and the *PPFIA1* (liprin alpha) gene in trauma patients.[127] Finally, genetic variants in *ANG2* were shown to be associated with plasma Ang2 levels as well as with the risk of developing ARDS in patients of European ancestry but not in patients of African ancestry.[99,128]

Another gene that has been implicated in ARDS susceptibility via genome-wide association studies is the *angiotensin converting enzyme (ACE)*. Both ACE and its homolog, *angiotensin converting enzyme-2* (ACE2), are metalloproteinases that play essential roles in the renin-angiotensin system. ACE promotes vasoconstriction by converting angiotensin I to angiotensin II, a powerful vasoconstrictor, while ACE2 counteracts the effects of ACE by degrading both angiotensin I and angiotensin II, thereby promoting vasodilation.[129] ACE and ACE2 are both expressed in the lung on alveolar epithelial type 2 cells. Although results have been somewhat mixed, a 2015 meta-analysis concluded that the absence of a 289 base pair *Alu* repeat in intron 16 of the *ACE* gene is a genetic risk factor for ARDS, particularly in white populations.[130–132] The presence of the deletion correlates with higher levels of circulating ACE in healthy human subjects.[133]

Animal studies support the hypothesis that the renin-angiotensin system plays a role in ARDS pathogenesis. Knockout of the *Ace* gene in mice improves outcomes from multiple types of experimental lung injury, while knockout of the *Ace2* gene worsens outcomes.[134] Moreover, injection of the ACE2 protein can protect mice against ARDS.[134]

Intriguingly, the *severe ARDS coronavirus* (SARS-CoV-1) was shown to bind to the ACE2 receptor.[135] In experimental models, both SARS-CoV-1 infection and overexpression of the SARS-CoV-1 spike protein, led to reduced ACE2 expression.[135] These findings suggest a mechanism whereby SARS-CoV-1 infection via the ACE2 receptor causes a reduction in ACE2 levels, thereby promoting ALI.

The novel *severe acute respiratory distress syndrome coronavirus 2* (SARS-CoV-2) also binds to the ACE2 receptor. Evidence for this interaction includes a high degree of structural homology between the SARS-CoV-1 and SARS-CoV-2 spike proteins, as well as high theoretical binding affinity of the SARS-CoV-2 spike protein for the ACE2 receptor.[136] In vitro, expression of ACE2 in human cells enabled SARS-CoV-2 infection, confirming that the virus can enter via this receptor.[137] Like SARS-CoV-1, SARS-CoV-2 causes severe lung injury in a subset of patients, which is often fatal.[138] As a result of these observations, infusion of ACE2 has been suggested as a potential therapeutic strategy in SARS-CoV-2–associated respiratory failure.[139] Whether a similar strategy would be efficacious in other forms of ARDS is an open question.

SUBPHENOTYPES OF ARDS

Latent class analysis is a statistical technique to identify unobserved groups within a dataset. In an effort to identify ARDS subsets that might be biologically different and respond differently to therapeutic interventions, latent class analysis was applied to data taken from two large clinical trials: the ARDSNet trial of high versus low tidal volume ventilation (ARMA) and the ARDSNet trial of high versus low positive-end expiratory pressures (ALVEOLI).[140] Baseline clinical data and biomarker levels for eight plasma proteins were used to define classes for the analysis. In both cohorts, a two-class model provided the optimal fit. Subphenotype 1 showed lower levels of the inflammatory markers IL-6, IL-8, soluble TNF receptor-1, and plasminogen activator inhibitor-1 along with lower heart rate, lower minute ventilation, higher blood pressure, and higher protein C levels. This was referred to as the *hypoinflammatory* phenotype.[140] Patients with phenotype 1 were less likely to be receiving vasopressors, were more likely to have trauma-associated ARDS, and were less likely to have sepsis-associated ARDS. Conversely, subphenotype 2 was described as a *hyperinflammatory* phenotype and was characterized by higher levels of inflammatory markers along with tachycardia, hypotension, higher minute ventilation, and lower levels of protein C. Subphenotype 2 was also characterized by greater vasopressor use, longer duration of mechanical ventilation, and higher mortality. The authors noted that plasma biomarker levels contributed more strongly to phenotype definitions than did clinical variables, suggesting that the phenotypes may be difficult to distinguish clinically.

When the results of the ALVEOLI trial were reanalyzed according to ARDS subphenotypes, the investigators noted differences in how the patients responded to PEEP. Patients belonging to subphenotype 1 responded favorably to low PEEP, with a 90-day mortality of 16% versus 24% for low PEEP versus high PEEP strategies.[140] Conversely, patients belonging to subphenotype 2 responded more favorably to high PEEP with a 90-day mortality of 51% versus 42%. A similar analysis was carried out using data from the Fluid and Catheter Treatment Trial of liberal versus conservative fluid management in ARDS.[141] Once again the presence of hypoinflammatory and hyperinflammatory ARDS subphenotypes was confirmed. When outcomes were reanalyzed according to subphenotypes, the investigators found a significant difference in their response to fluid strategy. Patients belonging to the hypoinflammatory subphenotype 1 responded favorably to a liberal fluid strategy (90-day mortality of 18% vs. 26%). Conversely, patients in the hyperinflammatory subphenotype 2 responded better to the conservative fluid strategy (90-day mortality rate of 50% vs. 40%).

Recently, latent class analysis was used to reanalyze the data from the HARP-2 trial, which compared simvastatin versus placebo in early ARDS.[142] The HARP-2 trial enrolled 540 adults at 40 hospitals in the United Kingdom and Ireland and did not find a difference in terms of ventilator-free days, organ-failure-free days, or 28-day mortality.[143] Latent class analysis confirmed the existence of two subphenotypes among the patients enrolled in HARP-2, a hypoinflammatory and a hyperinflammatory subphenotype. Patients belonging to the hyperinflammatory subphenotype 2 showed a positive response to simvastatin treatment, with significantly higher 28-day survival in patients receiving simvastatin compared to those receiving placebo.[142] Conversely, patients belonging to the hypoinflammatory subphenotype 1 did not show any significant response to simvastatin treatment.

Although they have yet to be prospectively tested, the concept of ARDS subphenotypes makes intuitive sense. In reanalyzing the ALVEOLI, Fluid and Catheter Treatment, and HARP-2 trials, we are left with the impression that ARDS subphenotypes are interacting differently with treatment options, resulting in confounding of study results and falsely negative clinical trials. The development of point-of-care testing strategies and prospective validation of subphenotypes and their response to therapy will be required to develop this concept into a workable clinical paradigm.

MORTALITY AND COMPLICATIONS OF ARDS

MORTALITY

The mortality rate for ARDS has fallen over the last 30 years, with a number of studies describing a decline from more than 60% to less than 40%.[144–146] The reasons for the improvement are unknown, although some have attributed it to the use of lung-protective ventilatory strategies and better supportive care in the ICU. Fewer data are available for pediatric populations; however, there does not appear to be a significant reduction in pediatric mortality rates over time. A recent meta-analysis reported a pooled hospital mortality rate of 35%,[147] similar to the mortality rate for adults, although significant disparities have been observed based on geographic location.

PREDICTORS OF POOR PROGNOSIS

Despite the importance of hypoxemia among the clinical manifestations of ARDS, the severity of hypoxemia early in ARDS does not appear to be a good predictor of death.[148] Pulmonary injury scoring systems such as the Lung Injury Score and the ARDS score have been shown to predict a prolonged (>2 weeks) requirement for intubation and ventilation,[149] while scoring systems that measure the overall severity of illness, such as the Simplified Acute Physiology Score, correlate better with survival.[150] The categories of mild, moderate, and severe ARDS, as defined by the Berlin definition, also show some correlation with duration of mechanical ventilation (5 days, 7 days, and 9 days, respectively) and mortality (27%, 32%, and 45%, respectively). However, both the Berlin and AECC definitions are poor predictors of mortality in ARDS, with *areas under the receiver operator curve* (AUROC) of only 0.58 and 0.54, respectively, representing a predictive capacity that is only slightly better than chance alone.[9]

The classic teaching is that patients with ARDS do not usually die of refractory hypoxemia, which may seem paradoxical given that hypoxemia is frequently the focus of resuscitative efforts. In fact, most patients with fatal ARDS die of sepsis and multiorgan failure.[151,152] The explanation for this apparent paradox is unknown, although it has been hypothesized that injurious mechanical ventilation may be involved (see earlier information on *biotrauma*).[120] As discussed earlier, ventilation using excessive tidal volumes has been shown to increase pulmonary and systemic cytokine levels and has been linked to renal dysfunction in an animal model.[153]

Cumulative data from multiple studies have suggested that the mortality rate from ARDS varies depending on the precipitant. The highest risk of death has consistently been reported in sepsis, whereas ARDS in the setting of major trauma has a much better prognosis.[154] In addition, it is known that chronic liver disease,[148] older age,[155] chronic alcoholism,[33] and nonpulmonary organ dysfunction[148] are all associated with higher mortality from ARDS. Other predictors of death have included a history of organ transplantation and HIV infection.[156] One study also described a higher mortality rate in African American patients relative to European-American patients and in men compared to women.[157]

As mentioned earlier, risk factors for ARDS have been classified as being direct or indirect (pulmonary or nonpulmonary) in origin. It remains unclear whether this distinction has prognostic importance. The ARDSNet investigators retrospectively analyzed data from their randomized study of low tidal volume ventilation versus traditional tidal volume ventilation. While confirming that the mortality rate for ARDS was highest in patients with sepsis and lowest in patients with trauma, there was no difference in mortality, days off mechanical ventilation, or the development of organ failure between patients with pulmonary versus nonpulmonary risk factors. In addition, there was no statistical evidence that the low tidal volume strategy was less efficacious in any particular subgroup.[154] A meta-analysis came to a similar conclusion,[35] and the recent Berlin definition of ARDS no longer includes pulmonary and nonpulmonary ARDS as distinct categories.

The development of pulmonary fibrosis is also thought to connote a worse prognosis in ARDS. In one study, 22 of 25 consecutive patients with ARDS underwent transbronchial biopsies of the most abnormal-appearing areas on the chest radiographs. The mortality rate in patients whose biopsies showed fibrosis, regardless of severity, was significantly higher than in patients whose biopsies showed no fibrosis.[158]

Lastly, there is extensive interest in the identification of biomarkers to predict mortality from ARDS.[140] Associations have been reported between elevated serum levels of the cytokines IL-6 and IL-8 and poor prognosis.[159] In patients with noninfectious ARDS, high baseline serum Ang2 levels were also shown to predict mortality whereas, in patients with infectious ARDS, mortality was

associated with increasing serum Ang2 from baseline to day 3, but not with baseline levels alone.[98] Biomarkers have also been combined with clinical predictors in an attempt to improve mortality prediction; one model combined the *Acute Physiology and Chronic Health Evaluation III* score,[160] a clinical prediction score applied at ICU admission, with five plasma biomarkers (intercellular adhesion molecule-1, von Willebrand factor, IL-8, soluble TNF receptor-1, and surfactant protein D). This model achieved moderate predictive accuracy, with an AUROC of 0.79. (An AUROC of 0.5 is no better than chance while an AUROC of 1.0 indicates perfect predictive accuracy.[161]) However, this strategy was only marginally better than Acute Physiology and Chronic Health Evaluation III score alone.

COMPLICATIONS OF ARDS

ARDS is complicated by *ventilator-associated pneumonia* (VAP) in 30–65% of cases. VAP usually presents more than 5 to 7 days after the onset of mechanical ventilation and is often preceded by colonization of the lower respiratory tract by potential pathogens.[162] The most frequent organisms include nonfermenting gram-negative rods, methicillin-resistant *Staphylococcus aureus*, and Enterobacteriaceae.[163] Although the development of VAP prolongs the duration of mechanical ventilation in ARDS, it does not appear to result in increased mortality.[162,164,165] Making a definitive diagnosis of VAP in patients with ARDS can be challenging because these patients already have radiographic opacities and not uncommonly have leukocytosis and fever. If diagnostic techniques such as BAL or protected specimen brushes are used, the yield is higher when lungs are sampled bilaterally and the patient is off antibiotics.[165,166] (See also Chapter 49.)

Another feared complication of ARDS is barotrauma (e.g., pneumothorax, pneumomediastinum, or subcutaneous emphysema; eFig. 134.1) due to the effect of positive-pressure ventilation in heterogeneous lungs with diminished compliance. Most patients with ARDS will be supine (rather than erect), so diagnosing a pneumothorax requires vigilance. The radiographic appearance of a pneumothorax can be subtle in the supine patient (e.g., air in the costophrenic angle, the deep sulcus sign), and lung ultrasound is increasingly being used to detect pneumothoraces.[167] Fortunately, data from prospective studies suggest that the incidence of barotrauma in ARDS is reasonably low (12–13%), likely due to the widespread adoption of lung-protective ventilation strategies.[168,169]

TREATMENT

SUPPORTIVE CARE

One of the first goals of therapy in ARDS is to treat the underlying cause. In particular, patients with sepsis may respond to aggressive source control, including antibiotics and, when appropriate, surgical débridement and drainage. In patients with ARDS and sepsis of unknown origin, both the lung and the abdomen should be considered and excluded as foci of infection.[151,152] Additional goals are the prevention of complications and the provision of supportive care (e.g., nutrition, ventilation) to allow the body time to heal.

HEMODYNAMIC MANAGEMENT

The optimal approach to hemodynamic management in ARDS has become less controversial since the ARDSNet study of liberal versus conservative fluid strategies.[170] Previously, it had been unclear whether clinicians should attempt to decrease pulmonary edema by diuresis at the expense of possible hypovolemia and inducing or aggravating shock, or to liberalize fluids to improve hemodynamics at the expense of increased pulmonary edema. The trial randomized 1000 patients with ARDS to one of two highly protocolized fluid strategies. Through the administration of fluids, diuretics, or vasoactive agents, the two protocols targeted either a lower intravascular pressure (conservative fluid strategy) or a higher intravascular pressure (liberal fluid strategy), as measured by a pulmonary artery or central venous catheter for 7 days. Patients randomized to the lower pressure/conservative fluid strategy had significant improvements in oxygenation and more ventilator-free and ICU-free days than the patients in the higher pressure/liberal strategy group. Importantly, patients in the conservative arm did not have a higher incidence of dialysis or shock than those in the liberal arm; in addition, mortality rates in the two arms were similar. Thus the results of this study suggest that conservative administration of fluids is safe and beneficial to patients with ARDS.

One caveat is that the ARDSNet study used a very complex algorithm for fluid administration. A simplified protocol has since been proposed but has not been validated.[171] In the meantime, we recommend that clinicians manage fluids conservatively in patients who are not in shock, taking care to avoid overdiuresis and hypovolemia. Numerous clinical trials have demonstrated that, for most patients, the information from a pulmonary artery catheter does not improve outcome.[11] For this reason, we do not recommend the routine use of these catheters in patients with ARDS.

Which fluid to use in patients with ARDS remains an open question, with only a few studies focusing on the ARDS population. On a theoretical basis, the use of albumin is appealing because it would increase intravascular oncotic pressure and predispose to less pulmonary edema. A small placebo-controlled study in ARDS demonstrated that a regimen of albumin and furosemide infusions over 5 days caused a substantial and statistically significant improvement in oxygenation accompanied by a decrease in heart rate.[172] However, most of the enrolled patients had ARDS secondary to trauma, and less than 5% had ARDS secondary to sepsis. There were no differences in important clinical outcomes (e.g., mortality), although the study was underpowered to detect these outcomes.[172] A follow-up study established that the beneficial effect on oxygenation was due to the albumin, not the furosemide,[173] and a meta-analysis concluded that there was evidence for a beneficial effect on oxygenation in ARDS but not for mortality.[174] Although a large clinical trial of ICU patients concluded that albumin was as safe as crystalloid,[175] the study did not specifically enroll patients with ARDS and only looked

at short-term outcomes. It is also important to remember that, as a blood product, the administration of albumin is associated with a very small but finite risk of transmissible diseases. Thus, pending further trials, the role of albumin in the management of patients with ARDS remains unclear. Meanwhile, the use of starch-based colloids (i.e., pentastarch) has fallen out of favor because a trial demonstrated that they increased the incidence of renal failure in patients with severe sepsis.[176] Whether pentastarch has the same detrimental effect in patients with ARDS without severe sepsis is unknown.

With respect to crystalloid fluids, data from ARDS patients is lacking and optimal treatment strategies must therefore be inferred from studies of critically ill and septic patients. Studies have shown that the use of balanced crystalloids (i.e., lactated Ringer's solution or Plasma-Lyte-A), rather than normal saline, resulted in a decreased incidence of renal failure along with a slight improvement in mortality in critically ill patients[177] and septic patients.[178] Given these data, a strategy using balanced crystalloids in place of normal saline would seem most appropriate in the treatment of ARDS, particularly when associated with sepsis.

NUTRITION

It has been hypothesized that manipulating the patient's diet can favorably affect the immune system and improve the outcome of inflammatory diseases such as sepsis and ARDS. Such dietary strategies have involved supplementing enteral feedings with one or more of arginine, glutamine, omega-3 fatty acids, and antioxidants.

Two small randomized studies examined the effect of a commercial enteral formula containing eicosapentaenoic acid (an omega-3 fatty acid found in fish oil), gamma-linolenic acid, and antioxidants, compared to a control enteral formula, in patients with ARDS and suggested potential benefit with improved oxygenation, reduced inflammatory biomarkers in BAL fluid, decreased length of ICU stay, and reduced requirement for mechanical ventilation.[179,180] The control formula in these studies, however, contained a high amount of omega-6 fatty acids, which may be proinflammatory. Subsequent randomized trials comparing enteral fish oil to saline placebo, or twice daily supplementation with eicosapentaenoic acid, gamma-linolenic acid, and antioxidants compared with an equivalent volume of a standard feeding formula, found no differences in clinical or biologic outcomes between the intervention and control arms.[181,182] Supplementation with omega-3 fatty acids is thus not recommended as a therapy for ARDS.

Many other studies of modified enteral formulas (often called *immunonutrition*) have been conducted in less well-defined populations of critically ill patients, with conflicting results. Meta-analyses on the topic have highlighted the poor quality of the evidence and have suggested that the effect of immunonutrition varies depending on the group of patients being studied.[183,184] At this point, the role of immunonutrition in the management of ARDS remains unclear.

A related issue in this area has been how much enteral nutrition should be given. A randomized controlled trial found that the rate of enteral feeding (e.g., regular feeding rate versus a low "trophic rate" delivering one-third as many calories) does not affect short- or long-term outcomes of ARDS.[185–187]

PHARMACOTHERAPY

Attempts to develop pharmacologic therapies for ARDS have been frustrating and largely unsuccessful, with no pharmacotherapies that unequivocally reduce mortality from ARDS despite a multitude of randomized controlled trials of potential agents.[188] Despite showing effectiveness in vitro or in animal studies, most potential therapies have failed to reduce mortality or other important clinical outcomes in human clinical trials. Several agents improve oxygenation but do not affect mortality from ARDS. Post hoc analyses of subgroups from many of these studies suggest benefit, but prospective data are lacking.

Corticosteroids

Because of the presumed inflammatory pathophysiology underlying ARDS, multiple trials of high- and low-dose corticosteroids have been performed in ARDS. In some, the goal was prevention of ARDS in at-risk patients (e.g., patients with septic shock), while in others, the goal was to treat established ARDS. The typical high-dose regimen was methylprednisolone 30 mg/kg every 6 hours for 1 to 2 days. None of the trials using this high-dose treatment regimen showed any benefit,[189,190] and one showed a higher incidence of infection among patients who received steroids.[191] However, all of these studies were conducted prior to the widespread adoption of lung-protective ventilation, which clearly improved outcomes from ARDS.

In the absence of data from large clinical trials, a 2016 meta-analysis used individual patient data (n = 322) from four randomized controlled trials of ARDS patients to determine the effect of low-dose glucocorticoid treatment on time to liberation from mechanical ventilation.[192] The results suggested that low-dose methylprednisolone treatment shortened the time to liberation from mechanical ventilation and increased the likelihood of liberation from mechanical ventilation by day 28. They also showed a significant decrease in hospital mortality for patients randomized before day 14 of ARDS onset (20% vs. 39%). There was no association between steroid use and nosocomial infections. A follow-up meta-analysis incorporating the results of nine randomized controlled trials came to similar conclusions.[193] Based on these findings, the investigators recommended that low-dose methylprednisolone treatment be considered in the early stages of ARDS, followed by a prolonged taper over a total of 28 days to prevent rebound inflammation.[192,193] These recommendations were incorporated into 2017 guidelines from the Society of Critical Care Medicine and the European Society of Intensive Care Medicine.[194]

A 2020 multicenter randomized clinical trial from Spain also supports the use of steroids in ARDS. In this study, 277 patients with early ARDS were randomized to receive 10 days of intravenous dexamethasone (20 mg daily for five days followed by 10 mg daily for 5 days) or placebo. Both groups received lung-protective ventilation.[195] Results showed that patients receiving dexamethasone had significantly more ventilator-free days at day 28 (12.3 days vs. 7.5 days) and significantly lower mortality at day 60 (21% vs. 36%). Nosocomial infections were not significantly

different between the groups. This study is the strongest evidence to date in favor of steroid treatment for early ARDS. Further studies will be required to determine the exact dose and duration.

The use of steroids has also been contemplated later in the course of ARDS, during the fibroproliferative phase. A randomized placebo-controlled trial of 180 patients with ARDS of at least 7 days' duration was performed by ARDSNet.[196] Patients were randomized to placebo versus a single dose of 2 mg/kg methylprednisolone followed by 0.5 mg/kg every 6 hours for 14 days, then every 12 hours for 7 days, followed by a taper. Although the patients receiving steroids showed improvements in oxygenation as well as in the number of ventilator-free and shock-free days (during the first 28 days), there was no difference in 60-day mortality. A subgroup analysis revealed that patients who began receiving steroids more than 14 days after the onset of ARDS had significantly increased 60- and 180-day mortality rate. The utility of corticosteroids late in ARDS remains controversial, pending the results of further clinical trials.

Vasodilators

Prostaglandin E1 is a vasodilator that has been studied as a potential therapy for ARDS, based largely on its putative anti-inflammatory properties. In vitro and preclinical studies in animals have suggested that prostaglandin E1 given parenterally, especially when administered in a liposomal formulation, decreased neutrophil activation. Despite promising early data,[197] a large randomized, double-blind, multicenter trial of liposomal prostaglandin E1 found that there was no improvement in survival or in ventilator dependence although there was evidence of improved oxygenation.[198]

Prostacyclin is another vasodilator that, when administered by nebulization, acts selectively on the pulmonary vasculature. Because the aerosolized solution will tend to go to the most ventilated areas of lung, this should theoretically lead to selective vasodilation of the branches of the pulmonary artery supplying these areas, resulting in improved ventilation-perfusion matching and improved oxygenation.[199] Although prostacyclin has been used as rescue therapy for refractory hypoxemia and is well tolerated,[200] there are no large randomized studies or placebo-controlled studies of its use in ARDS.[201,202]

Nitric oxide (NO) is a highly reactive gas formed endogenously from the amino acid arginine by NO synthase. It stimulates cellular guanylate cyclase, leading to increased cyclic guanosine monophosphate levels. It acts as a potent vasodilator and, when given by inhalation, causes vasodilation of the pulmonary circulation. NO is inactivated in the bloodstream by combining with hemoglobin to form methemoglobin, which is rapidly metabolized and does not accumulate to levels that are thought to be toxic (i.e., serum methemoglobin levels < 5%). As a result, NO causes the most vasodilation in the areas of the lung that are best ventilated, thereby improving ventilation-perfusion matching.[203] In addition, NO has both anti- and proinflammatory properties, although their effects in the clinical setting are unclear.[204] NO can also react with oxygen and water to form toxic metabolites, such as nitrogen dioxide and nitrous and nitric acid. At concentrations of NO below 40 ppm, this problem is not usually clinically significant.

In the largest randomized double-blind, placebo-controlled study of NO in ARDS to date, more than 170 patients were randomized to different doses of NO (from 1.25 up to 80 ppm) or placebo.[205] Although 60% of patients had an improvement in oxygenation within 4 hours of NO administration, there was no difference in survival or in liberation from mechanical ventilation.[205] In addition, the initial improvement in oxygenation was not sustained over the course of study. There were few adverse effects of NO and, for patients who were administered less than 40 ppm, methemoglobin and NO_2 levels were the same as in the placebo group. The negative results of this study confirmed the findings from other smaller unblinded trials of NO in ARDS[206,207] and were supported by the results of a systematic review.[208] In another large randomized but unblinded study of NO in ARDS, a higher proportion of patients in the NO group required renal replacement therapy than in the control group.[209] A meta-analysis of trials using NO for ARDS concluded that, while NO caused initial improvement in oxygenation, it had no impact on survival and was associated with an increased risk of renal dysfunction.[210] We suggest that NO should not be used routinely in the treatment of patients with ARDS, other than perhaps as a rescue therapy for extreme life-threatening hypoxemia. In fact, a recent individual patient meta-analysis showed no mortality benefit to inhaled NO in patients with ARDS, regardless of the degree of hypoxemia.[211]

Surfactant

As discussed in the section on pathogenesis, abnormalities of surfactant have been described in ARDS. These include an increase in inactive forms, inactivation of surfactant by proteins that have leaked into the alveolar space, damage to alveolar epithelial type 2 cells (which produce surfactant), and destruction of surfactant constituents by the inflammatory process.[49] These changes, along with the efficacy of surfactant supplementation in the neonatal respiratory distress syndrome, led to the hypothesis that surfactant supplementation might be beneficial in ARDS. Data from animal studies and small case series were promising.[212]

Enthusiasm for surfactant was greatly dampened by the results of a large multicenter, randomized, blinded, placebo-controlled trial. In this study, investigators administered an aerosolized synthetic (protein-free) surfactant or saline placebo continuously for up to 5 days to patients with new-onset (<48 hours) sepsis-induced ARDS.[213] There was no physiologic or clinical benefit from the surfactant. Despite its methodological rigor, the study has been criticized because less than 5% of the administered dose of surfactant was thought to have reached the distal lung. In addition, the lack of surfactant proteins in the synthetic surfactant may have diminished its ability to reduce surface tension.[213]

Disappointing results were also reported from a phase I–II trial of 40 patients with new-onset ARDS who were randomized to a surfactant protein C–based preparation (given up to 4 times over 24 hours) or to no drug. The surfactant was administered through a catheter placed in the endotracheal tube. The drug had no effect on oxygenation or on ventilator-free days, which were the primary outcomes of the study. The authors reported a significant decrease in IL-6 levels in BAL fluid from patients who received the surfactant preparation, although it is unclear whether this was

a prespecified end point.[214] Finally, a phase III trial of the recombinant surfactant protein C–based preparation failed to show any improvement in oxygenation, ventilator-free days, or mortality.[215]

Only one trial, using calfactant (a natural surfactant) in pediatric patients with ARDS, has shown any mortality benefit[50]; whether this is due to the unique surfactant used in this study or to differences between the patients enrolled in this trial and in the negative trials (e.g., pediatric vs. adult) is unknown. Whether surfactant will prove to be useful in well-defined subgroups of patients with ARDS remains an open question.[45]

Antioxidants and Anti-Inflammatory Agents Other Than Steroids

Oxidative stress has long been postulated to be involved in the pathogenesis of ARDS.[123] In fact, lung injury due to hyperoxia is a commonly used model to study ARDS in animals. Reactive oxygen species form as a by-product of activation of neutrophils and macrophages; in addition, the requirement of many patients with ARDS for a high inspired fraction of oxygen may predispose to oxidative stress. Decreased levels of glutathione, a major endogenous scavenger of reactive oxygen species, have been observed in the alveolar fluid of patients with ARDS. Small clinical trials with *N*-acetyl cysteine and procysteine were promising.[216] Unfortunately, despite this promising start, larger clinical trials of antioxidants in ARDS have been disappointing. A multicenter trial of the antioxidant procysteine in ARDS showed no beneficial effect of the drug and was stopped early for lack of benefit.[51]

Other agents with putative anti-inflammatory effects have been tested in ARDS. These include ketoconazole, lisofylline, and (in patients with sepsis at risk for ARDS) the nonsteroidal anti-inflammatory drug ibuprofen. In separate, well-conducted, randomized, blinded controlled trials, none of these agents demonstrated benefit in ARDS.[217–219] A randomized controlled trial evaluated the effect of recombinant platelet-activating factor acetylhydrolase in preventing ARDS in patients with severe sepsis.[220] This trial of over 100 patients showed no reduction in the development of ARDS in patients who received the drug; however, the mortality rate was lower in patients receiving an intermediate dose of the study drug.[220] Other trials of anti-inflammatory therapies have been disappointing.[188,221] A recent study of the HMG-CoA reductase simvastatin also failed to show benefit in ARDS despite positive results in preclinical models.[143] However, a post hoc analysis subdividing patients according to ARDS subphenotypes showed that patients with the hyperinflammatory subphenotype 2 may have benefited.[142] Prospective studies will be required to confirm this finding.

Catecholamines

As discussed earlier in the section on ARDS pathogenesis, alveolar fluid clearance can be augmented by catecholamines. A small trial randomized 40 patients with ARDS to intravenous salbutamol or placebo for 7 days.[222] Patients receiving salbutamol had a decrease in extravascular lung water but a higher incidence of arrhythmia. A follow-up study was performed in almost 50 ICUs in the United Kingdom and enrolled over 300 patients with ARDS. However, the trial was halted early because of an increase in mortality in the group receiving intravenous salbutamol.[96] A similar-sized trial of aerosolized albuterol (given every 4 hours for up to 10 days) for ARDS found no benefit.[223] Thus routine use of β_2-agonists cannot be recommended in ARDS.

Mesenchymal Stem Cell Therapy

Mesenchymal stem cells (MSCs) are multipotent stromal cells usually from bone marrow but which can also be isolated from adipose tissue, cord blood, placenta, and pancreas.[224] Among their many advantages, MSCs have the capacity to self-renew in vitro while maintaining their multipotency, have minimal immunogenicity secondary to low expression of major histocompatibility antigens, and have an excellent safety profile. MSCs have multiple effects in vivo that may be beneficial in ARDS: they reduce inflammation, they restore endothelial integrity, they increase alveolar fluid clearance, they recruit regulatory T cells, and they stimulate alveolar macrophages to increase bacterial clearance. Many of these effects are mediated in a paracrine fashion through secretion of soluble factors, including lipoxin A4 and keratinocyte growth factor, as well as antimicrobial peptides such as cathelicidin. MSCs also release microvesicles that transfer cellular contents, including proteins, lipids, organelles, mRNAs, and micro-RNAs, to other cells. Studies have shown that microvesicles alone (without MSCs) can improve lung injury and survival in animal models of ARDS, a phenomenon dependent on the uptake of microvesicles by monocytes and alveolar epithelial cells.[225]

MSCs have shown beneficial effects in animal models of lung injury mediated by endotoxin, pneumonia, bleomycin, injurious ventilation, and hyperoxia.[226,227] Moreover, they can be administered either intravenously or intratracheally, with equal effect. In a sheep model of pneumonia-associated ARDS, treatment with intravenous human MSCs significantly improved oxygenation and reduced extravascular lung water at 24 hours.[228] Similarly, in an ex vivo human lung model of ARDS secondary to *Escherichia coli* pneumonia, treatment with MSCs improved alveolar fluid clearance, decreased inflammation (as measured by IL-1β and IL-8 levels), and reduced bacterial load.[229]

Phase II clinical trials of MSCs in ARDS are underway. A phase I trial enrolling nine patients with moderate to severe ARDS demonstrated that MSCs could be well tolerated.[230] Recently, the first phase IIa trial of MSCs in patients with moderate to severe ARDS was reported. The patients in the treatment group (n = 40) received a single dose of intravenous MSCs while the control group (n = 20) received placebo.[231] No adverse infusion-related events were reported. There was a trend towards higher mortality in the treatment group (30% vs. 15%; $P = 0.34$), but this may have been driven by higher baseline severity of illness. The treatment group did show a significant decrease in serum levels of Ang2, while levels of IL-6, IL-8, and protein C did not change. In addition, oxygenation index ([F_{IO_2} × mean airway pressure]/alveolar P_{O_2}) improved in the treatment group during the 48 hours following MSC infusion, suggesting beneficial effects on lung function. Planning is underway for a phase IIb trial to follow up on these results.

Discrepancies Between Studies in Animals and Humans

As discussed earlier, virtually all large-scale clinical trials of pharmacotherapy for ARDS have been negative despite promising and often exciting animal studies. There are a number of reasons why results from animal studies may not have been replicated in human clinical trials. First, in animal studies, the agent being investigated is often administered at the same time or shortly after the lung is injured (e.g., cecal ligation and perforation followed by administration of the test drug within a few hours). In contrast, the onset of lung injury in humans is much more difficult to define, and potential therapies are given many hours after the initial insult. Second, most proof of principle animal studies are of short duration and do not mimic the complicated clinical course of human ARDS. Third, experimental animals represent an essentially homogeneous group; in contrast, human patients have multiple comorbidities, multiple co-interventions, and are extraordinarily heterogeneous. Fourth, animal studies involve introduction of a uniform injury whereas, even in carefully selected subgroups, the injury in patients will differ in severity and duration. This heterogeneity makes it challenging to identify agents that may be of modest clinical benefit. Finally, as discussed earlier, the current definition of ARDS is problematic, and human studies may include many patients with markedly different pathophysiology/biology.

In spite of these challenges, multiple novel therapeutic strategies for ARDS have been proposed and may reach clinical testing in the coming years (Fig. 134.6). These include intravenous and intratracheal administration of MSCs and/or their products as well as therapies that target neutrophils, enhance alveolar fluid clearance by modulating sodium channels, and protect endothelial and epithelial integrity. The success of these strategies will depend, at least in part, on the ability to identify which patients are most likely to benefit.

MECHANICAL VENTILATION IN ARDS

Mechanical ventilation is life-saving and is the standard therapy for ARDS (see also Chapter 135). Ventilatory management of ARDS has undergone dramatic changes over the last 20 years, in large part due to increased usage of computed tomography to image the lungs as well as to advances in our understanding of VILI.

PRESSURE AND VOLUME LIMITATION

Mechanical ventilation of patients under anesthesia for surgery traditionally involved large tidal volumes of 10 to 15 mL/kg, with the goal of achieving normal arterial oxygenation and arterial pH. A similar approach to ventilating patients with ARDS was followed until the beginning of the 21st century. This emphasis on achieving normal physiologic parameters in patients with ARDS was understandable at the time, because ARDS was thought to involve the lungs diffusely and homogeneously based on plain radiography.[1] Chest computed tomography, however, demonstrated that the lungs of many patients with ARDS appear heterogeneous,[232] showing patchy opacities interspersed with more normal-appearing areas of lung. The heterogeneous distribution of injury in ARDS implies that positive pressure will preferentially inflate the more compliant (or normal) areas of

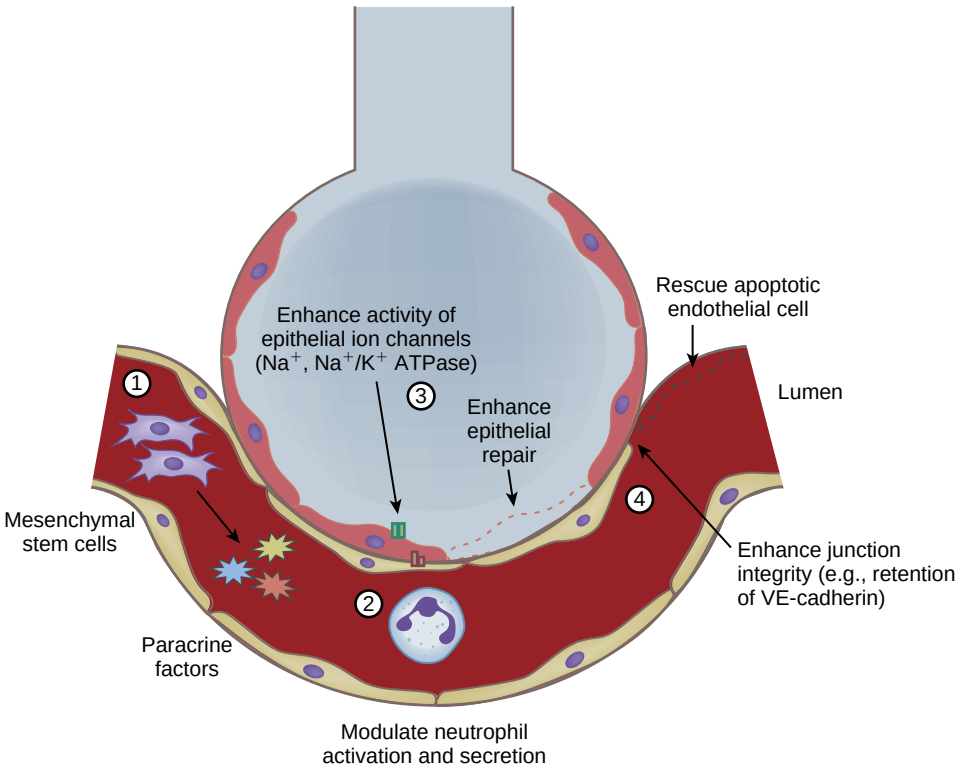

Figure 134.6 Schematic of potential novel therapeutic strategies for acute respiratory distress syndrome. *(1)* Mesenchymal stem cells can alleviate lung injury in animal models, perhaps by their paracrine effects. *(2)* Modulation of neutrophil recruitment, activation (e.g., degranulation), and apoptosis may prevent or lessen lung injury. *(3)* Alveolar fluid clearance may be enhanced by up-regulation of epithelial apical sodium channels. *(4)* The integrity of the lung endothelial barrier may be enhanced by preventing the internalization (and loss of function) of junctional proteins like vascular endothelial (VE)-cadherin and claudin-5 or by attenuating endothelial apoptosis.

lung. These regions are therefore at risk of overdistention and ventilator-associated lung injury. Mechanical ventilation with excessive tidal volumes, as discussed earlier, can cause pulmonary edema by provoking increased alveolar-capillary permeability, with remarkably similar histology to ARDS.

Despite the clear physiologic rationale and abundant experimental data to support pressure and volume limitation when ventilating patients with ARDS, it was not until the late 1990s that data from randomized clinical trials in humans began to accrue. Between 1998 and 2000, five randomized controlled trials of ventilation strategies in ARDS were published.[107,233–236] In all of these trials, patients were randomized to a strategy involving tightly regulated tidal volume or pressure limits versus a conventional ventilation strategy with higher tidal volume and pressure limits. Of the five studies, the largest was conducted by ARDSNet.[107] This landmark study randomized 861 patients to low tidal volumes (maximum 6 mL/kg of predicted body weight and plateau pressure up to 25 to 30 cm H_2O) versus traditional tidal volumes (with a plateau pressure below 50 cm H_2O). In both groups, respiratory acidosis was treated aggressively to achieve a pH of 7.3 to 7.45, and bicarbonate infusions were allowed for persistent acidosis. Preset combinations of PEEP and FIO_2 were used to target oxygen saturation of 88–95%, and sedation was used, as necessary, to reduce patient-ventilator dys-synchrony (Table 134.3).

The trial was stopped early because an interim analysis showed benefit to the small tidal volume strategy. The mortality rate was 39.8% in the traditional group compared to 31.0% in the small tidal volume group ($P = 0.007$). Patients in the small volume group were significantly more likely to be breathing without assistance on day 28; the patients in this group also had a higher number of ventilator-free days and organ failure–free days.

A key difference between the ARDSNet study and earlier studies was the use of predicted body weight to set the tidal volume instead of measured body weight. The rationale was that predicted body weight correlates better with lung size than measured body weight. The distinction is important because data from the ARDSNet study demonstrate that measured body weight was approximately 20% higher than predicted body weight. In other words, the tidal volumes used in other studies may have been higher than needed. Predicted body weight is calculated differently for men and women; the calculations for predicted body weight in kilograms are shown in the legend of Table 134.3.[107]

The ARDSNet study also adopted an aggressive approach to hypercarbia and acidemia, including the use of high respiratory rates, bicarbonate infusions, and loosening of ventilatory restrictions. As a result, hypercarbia and low pH were less marked in the treatment arm than in some other studies. This too may have contributed to lower mortality.

More recently, it has been proposed that limiting the driving pressure (plateau pressure – PEEP) may be more important than restricting tidal volume[237] in improving survival from ARDS, although this will require further study.

NEUROMUSCULAR BLOCKADE

Mechanical ventilation of patients with ARDS is often complicated by patient-ventilator dys-synchrony, which can worsen oxygenation and ventilation and exacerbate VILI.[238]

Table 134.3 Ventilation Protocol Used in the ARDSNet Study*

Parameter	Protocol
Mode of ventilation	Volume assist-control
Tidal volume	≤6 mL/kg predicted body weight†
Plateau pressure	≤30 cm H_2O
Frequency	6–35 breaths/min, titrated for pH 7.30–7.45
I:E ratio	1:1 to 1:3
Oxygenation goal	PaO_2 55–80 mm Hg, or SpO_2 88–95%
FIO_2/PEEP (cm H_2O) combinations allowed	0.3/5, 0.4/5, 0.4/8, 0.5/8, 0.5/10, 0.6/10, 0.7/10, 0.7/12, 0.7/14, 0.8/14, 0.9/14, 0.9/16, 0.9/18, 1.0/18, 1.0/20, 1.0/22, 1.0/24
Weaning	By pressure support, required when FIO_2/PEEP ≤0.4/8

*Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome.

†When height is measured in inches, predicted body weight for men (in kg) = 50 + 2.3 (height [in] – 60), and predicted body weight for women (in kg) = 45.5 + 2.3 (height [in] – 60). When height is measured in centimeters, the equation for men is 50 + 0.91 (height – 152.4), and for women is 45.5 + 0.91 (height – 152.4).

FIO_2, fractional concentration of oxygen in inspired gas; I:E ratio, ratio of the duration of inspiration relative to expiration; PEEP, positive end-expiratory pressure; SpO_2, peripheral oxygen saturation.

From The Acute Respiratory Distress Syndrome Network. *N Engl J Med.* 2000;342(18):1301–1308.

Additionally, increased work of breathing may increase total body oxygen consumption.[239,240] To overcome these issues, clinicians often use sedative medications and, occasionally, neuromuscular blocking agents. However, neuromuscular blocking agents have unwanted side effects, including the need for heavy sedation and severe and prolonged muscle weakness.[241,242] Several recent studies have attempted to clarify the utility of neuromuscular blockade in ARDS.

In the ACURASYS trial, 300 patients with early (<48 hours), severe ARDS were randomized to a 48-hour infusion of cisatracurium with heavy sedation versus placebo with heavy sedation.[243] Both groups received lung-protective ventilation. The authors reported that, compared with placebo, cisatracurium resulted in a significant reduction in 90-day mortality (31.6% vs. 40.7%) as well as an improvement in secondary end points, including barotrauma and organ failure. There was no increase in ICU-acquired weakness. Recently, the ROSE trial enrolled 1006 patients with moderate to severe ARDS.[244] Once again, patients were randomized within 48 hours of ARDS onset. Patients in the treatment arm received 48 hours of intravenous cisatracurium with heavy sedation versus lighter sedation without routine neuromuscular blockade. A high PEEP strategy was used in both groups. The ROSE trial found no difference in the primary end point of 90-day mortality (42.5% vs. 42.8%). Moreover, there was no difference in barotrauma between the groups. A number of important differences may explain the divergent results of the ACURASYS and ROSE trials. The most important is the use of "light sedation" in the control arm of the ROSE study. Heavy sedation is associated with

poor outcomes in critically ill patients, including delayed extubation and increased mortality.[245,246] Another hypothesis is that heavy sedation without neuromuscular blockade, as used in the control group of the ACURASYS trial, may increase mortality by increasing "reverse triggering" (triggering of a diaphragmatic contraction by a ventilator-initiated breath).[247] This type of dys-synchrony is paradoxically increased in patients receiving deep sedation without paralysis and can increase VILI through breath stacking. Finally, prone positioning was more common in the treatment arm of the ACURASYS trial than in the placebo arm. Because prone positioning is associated with better outcomes in ARDS,[248] this may have helped reduce mortality in the treatment arm. In our view, neuromuscular blockade cannot be routinely recommended in patients with moderate to severe ARDS but may still benefit some patients, particularly those with ventilator dys-synchrony and/or high respiratory drive that could contribute to increased VILI.[247] Thus neuromuscular blocking agents are not currently recommended for routine use in severe ARDS.

THE ROLE OF PEEP AND RECRUITMENT MANEUVERS

As mentioned earlier, the first description of ARDS commented on the apparent utility of PEEP in improving oxygenation. From a theoretical standpoint, PEEP may be beneficial in avoiding damage from cyclic opening and closing of terminal lung units (atelectrauma; see "Etiology and Pathogenesis of ARDS" section), and allow for a reduction in tidal volume (and hence volutrauma). In addition, an improvement in oxygenation with PEEP may allow for lowering of the F_{IO_2}, thereby decreasing the risk of oxygen toxicity (see Fig. 134.4). On the other hand, if too high, PEEP can cause excessive end-inspiratory lung volume and volutrauma. PEEP can also have negative effects on cardiac output and blood pressure. The optimal level of PEEP in patients with ARDS has therefore been a source of controversy.[249–251]

In lung-protective ventilation, low tidal volumes and pressures can lead to progressive derecruitment of the lung, which can worsen hypoxemia and potentially aggravate atelectrauma. To counteract derecruitment, so-called recruitment maneuvers have been proposed. These maneuvers involve an increase in airway pressure, although the pressure to be applied and the duration have not been standardized. One example of a recruitment maneuver would be the application of 40 cm of H_2O of continuous positive airway pressure for 40 seconds. Similar to the problems with setting the PEEP, however, it is difficult to predict which patients will benefit from recruitment maneuvers and which will be harmed. Overdistention of well-perfused lung units could result in diversion of blood to poorly perfused alveoli, with consequent worsening of right-to-left shunt and hypoxemia.[252] Moreover, it might also contribute to lung injury.

A number of randomized controlled trials have addressed the issues of PEEP and recruitment maneuvers in the management of ARDS. The ARDSNet investigators randomized 549 patients with ARDS to lower or higher PEEP levels, according to preset combinations of PEEP and F_{IO_2}. The patients in the lower PEEP arm received the PEEP/F_{IO_2} levels used in the original ARDSNet trial of lung-protective ventilation (see earlier). The level of PEEP used in the higher arm varied with F_{IO_2} but was on average 5 cm H_2O higher than in the control arm. Recruitment maneuvers were initially used in the higher PEEP group but were discontinued after the first 80 patients because they were not effective.[253] After enrolling 549 of the planned 750 patients, the study was stopped because it reached a prespecified stopping rule for futility. Of note, the mortality rate in both arms was about 25%, significantly lower than had been reported in other ARDS trials.[254]

A second large trial randomized almost 1000 patients with ALI/ARDS to an *open lung* strategy versus the original ARDSNet trial ventilation protocol.[255] The open lung strategy consisted of pressure-control ventilation, recruitment maneuvers, and high PEEP (while keeping the $P_{plat} < 40$). Low tidal volumes were used in both groups. On average, on day 1 of the study, PEEP in the open lung arm was 16 cm H_2O compared to 10 cm H_2O in the control group. This trial also found no difference in mortality rates between the two groups (i.e., each at about 40%), although the open lung group had improvements in secondary end points related to hypoxemia.

A large French trial randomized 767 patients with ALI to PEEP of 5 to 9 cm H_2O versus PEEP maximized with P_{plat} less than 28 to 30.[256] On day 1 of the study, the mean PEEP in the control arm was 7 cm H_2O while the higher PEEP arm had an average of 15 cm H_2O. The study demonstrated no difference in mortality, but the higher PEEP arm had improved compliance, oxygenation, and a decreased duration of mechanical ventilation and organ failure.[256] A more recent study randomized patients with moderate to severe ARDS to a strategy of lung recruitment and PEEP adjusted to maximize respiratory system static compliance versus set PEEP levels according to the ARDSNet protocol from 2000[257]; the group that received recruitment maneuvers and titrated PEEP displayed increased 28-day all-cause mortality.

Finally, esophageal balloon monitoring (i.e., measuring the pressure in the esophagus) has been used to approximate pleural pressure, with the goal of determining the transpulmonary pressure (i.e., airway pressure minus the pleural pressure). The rationale is that the pleural pressure may be abnormally high due to comorbidities such as chest wall edema, obesity, or ascites, resulting in a low transpulmonary pressure. Under these conditions, it is possible that a higher level of PEEP could be safely applied without over-distension of the lung. However, a trial comparing this approach to preset levels of PEEP for a given F_{IO_2} showed no difference in clinically important outcomes, including death.[258]

Taken together, the data from these trials suggest that higher PEEP levels than those used in the original ARDSNet trial are safe and may improve oxygenation, but there is no evidence that they change mortality. Given the very strong animal data demonstrating the benefits of higher PEEP levels, it is somewhat of a puzzle why this is not true in the clinical context. One possibility is the yin-yang of PEEP: to the extent that PEEP recruits lung units, it may be beneficial; to the extent that it causes over-distension of lung units, it may be harmful.

The data also suggest that recruitment maneuvers in ARDS are purely supportive, with no improvement in clinically important outcomes. Many studies report a variable

and transient improvement in oxygenation after some form of recruitment,[253] which can be better maintained with a higher level of PEEP post-recruitment. It is also possible that the same degree of recruitment could be achieved by simply raising the level of PEEP.[259,260] If a recruitment maneuver is performed, the patient must be closely monitored for adverse effects on hemodynamics or oxygenation.

PERMISSIVE HYPERCAPNIA

The use of lower tidal volumes to avoid VILI often results in respiratory acidemia, an effect that has been termed *permissive hypercapnia*. The theoretical detrimental effects of hypercapnia include myocardial depression, increased pulmonary vascular resistance, and decreased renal blood flow. Perhaps the most clinically important adverse effect of hypercapnia is elevated intracranial pressure from increased cerebral blood flow. However, there are data suggesting that hypercapnia has protective effects, including attenuation of free radical–mediated lung injury and pulmonary inflammation[261,262]; other studies have reported an injurious effect on alveolar epithelial cells.[263]

Given the uncertainty about permissive hypercapnia, it is worth remembering that the original ARDSNet trial, which was the only large randomized controlled trial to show a reduction in mortality in ARDS, treated respiratory acidosis aggressively.[107] In the absence of other data, avoidance of hypercapnia where possible seems prudent.

MECHANICAL VENTILATION OF PATIENTS IN THE PRONE POSITION (PRONING)

Placing patients with ARDS in the prone position was described almost 30 years ago as a means of improving oxygenation. The mechanisms may be multiple, but the most important factor is probably the effect of proning on chest wall and lung compliance.[264] In the supine position, the anterior portions of the lungs are preferentially ventilated. Some of this is due to gravity, but the weight of the heart and the abdominal organs also contributes, as does the relatively low compliance of the posterior part of the rib cage. When a patient is placed in the prone position, the anterior chest wall is fixed (by the bed) and becomes less compliant, thus equalizing chest wall compliance anteriorly and posteriorly.[265] In addition, the volume of lung that is being compressed by the heart due to gravity is substantially decreased. The net result is more homogenous ventilation of the lung with improved V/Q matching (Fig. 134.7). Data from studies in dogs also suggest that ventilation in the prone position can attenuate the severity of VILI.[266]

A number of multicenter randomized controlled trials have examined the efficacy of proning in patients with ARDS. One study enrolled over 300 patients with ALI or ARDS and randomized them to conventional treatment using the supine position versus prone position for at least 6 hours daily for 10 days. The study found that oxygenation improved in approximately 70% of proning procedures, and that most of the improvement was evident within 1 hour. However, there was no difference in mortality between the groups. Retrospective analyses of the quartile of patients with the poorest oxygenation or highest acuity of illness showed a lower mortality at 10 days, but this difference did not persist beyond ICU discharge.[267] The study has been criticized for the short duration of the intervention and the fact that most patients spent the majority of the day supine.[268]

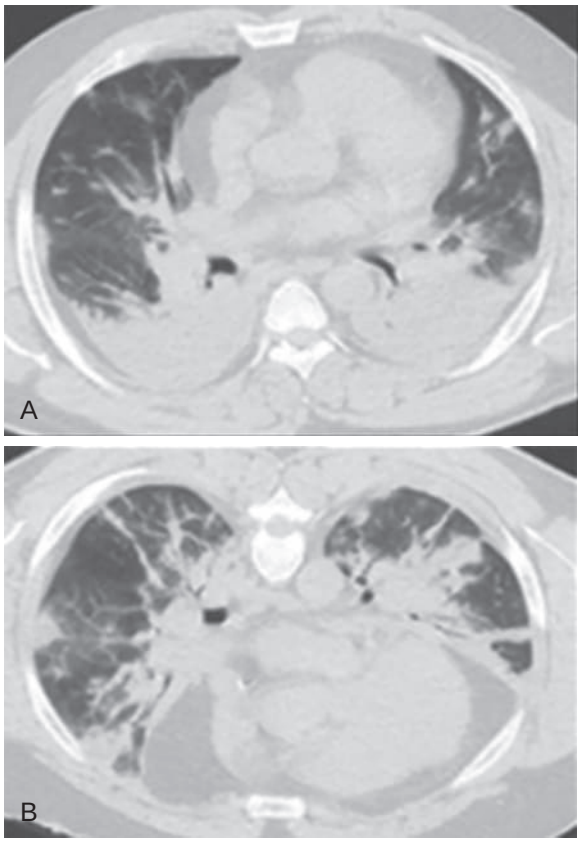

Figure 134.7 Computed tomography images of a patient with acute respiratory distress syndrome in supine and prone positions. Proning likely improves oxygenation principally by improving ventilation to the posterior portions of the lung, thereby improving ventilation/perfusion matching. Axial supine (A) and prone (B) chest computed tomography at the same positive end-expiratory pressure (5 cm H_2O) shows improved recruitment of nonaerated lung parenchyma in the prone compared to the supine position. (From Cornejo RA, Di-az JC, Tobar EA, et al. Effects of prone positioning on lung protection in patients with acute respiratory distress syndrome. *Am J Respir Crit Care Med*. 2013;188[4]:440-448.)

In 2013, the *Prone Positioning In Severe Acute ARDS* (PROSEVA) trial randomized over 400 patients with early (<36 hours) and severe ARDS (according to AECC criteria) to prolonged (>16 hours/day) proning or to standard supine positioning.[248] Patients in the proning group were placed in the prone position within the first hour after randomization and kept prone for at least 16 consecutive hours every day up to day 28. Most patients (≥80%) in both arms received neuromuscular blocking agents. Remarkably, the 28-day survival rate was 16% in the prone group and 33% in the supine group.

These results are very impressive and have led to widespread adoption of proning by intensivists. While proning was not associated with any complications in the PROSEVA trial, it is important to note that the study was conducted in centers with significant expertise in prone position ventilation, which requires much attention to detail. Lines and tubes are vulnerable to dislodgement during the process of rotating the patient, and sufficient staff must be on hand to assist with the move. Personnel should be ready for

immediate reintubation should the endotracheal tube be displaced during the maneuver. Patients who are placed in the prone position also have increased susceptibility to pressure sores on areas such as knees, anterior iliac spines, chin, and anterior shoulders, and exquisite care must be taken to ensure that no stray objects (e.g., syringes, electrocardiogram leads) are left under the patient because these will leave impressions and even scars on the body. An unstable spinal injury is an absolute contraindication to proning. In addition, in the event that CPR is required, the patient will have to be returned to the supine position emergently. Finally, the PROSEVA trial, had a number of important exclusion criteria, including elevated intracranial pressure, massive hemoptysis, recent tracheal or facial surgery, and a low (<65 mm Hg) mean arterial pressure.

VOLUME-CONTROL VERSUS PRESSURE-CONTROL VENTILATION

The volume and pressure-limited protocol used in the ARDSNet study used volume-assist control as the mode of ventilation. The Lung Open Ventilation study (described earlier) demonstrated that pressure-control ventilation could be used with equivalent outcomes.[255] Other studies that have examined this issue have also found little difference in physiologic parameters or outcome between the two modes of ventilation.[269,270]

HIGH-FREQUENCY JET VENTILATION AND HIGH-FREQUENCY OSCILLATION

In high-frequency jet ventilation, a small-gauge catheter is used to introduce gas under high pressure into the endotracheal tube. The high velocity of the gas entrains additional oxygen and humidified air from side ports in the system. This form of mechanical ventilation achieves a tidal volume of 2 to 5 ml/kg and involves frequencies of 100 to 200 breaths/min.[271] Exhalation is passive, secondary to lung and chest wall recoil. There is little evidence that high-frequency jet ventilation is superior to conventional mechanical ventilation for ARDS. A 1983 randomized trial of over 300 patients with respiratory failure compared conventional ventilation (using volume-cycled ventilation) to high-frequency jet ventilation. Although high-frequency jet ventilation was able to maintain oxygenation and ventilation with lower peak inspiratory pressures than with conventional ventilation, it did not offer any clinical benefit over conventional ventilation.[272]

In *high-frequency oscillatory* (HFO) ventilation, lung recruitment is maintained using a constant mean airway pressure, generated by an inspiratory bias flow and limitation of gas outflow from the circuit. Ventilation is achieved through rapid (e.g., 5 Hz) oscillations of a piston or diaphragm creating peak and trough pressures around the set mean airway pressure. The tidal volumes achieved through HFO are small, on the order of 1 to 5 mL/kg. In theory, HFO seems ideally suited for avoiding VILI; atelectrauma is minimized because of the relatively high mean airway pressure, which, along with small tidal volumes, limits derecruitment of the lung. Volutrauma is also minimized because the small tidal volumes limit end-inspiratory stretch.[273] Recruitment maneuvers (e.g., application of continuous positive airway pressure for approximately 30 to 40 seconds) should be applied after each time the patient is disconnected from the ventilator (e.g., open suctioning), because loss of pressure from the circuit upon disconnection will lead to portions of the lung becoming derecruited.

In an early randomized trial of HFO in adults, 148 patients with ARDS were randomized to conventional ventilation using pressure-control mode versus HFO.[274] Ventilatory parameters for both the conventional group and the HFO group were adjusted to achieve adequate oxygenation at a minimum F_{IO_2} (i.e., 88% at F_{IO_2} ≤0.60), as well as an arterial pH greater than 7.15. Because the study was begun before the publication of the ARDSNet trial on tidal volume limitation, the conventional ventilation arm targeted tidal volumes of 6 to 10 mL/kg. The trial was not powered to detect a mortality difference, and there was no significant difference in 30- or 90-day mortality or in any other outcome. In a retrospective analysis of predictors of mortality, being on conventional ventilation for more than 5 days correlated with a poor outcome.[274]

More recently, two large randomized trials of HFO compared to conventional lung-protective ventilation were published and showed no benefit in terms of survival or the duration of mechanical ventilation.[275,276] Indeed, one of the studies suggested that HFO might be harmful due to the amount of sedation required or due to its effects on hemodynamics. Because of these findings, the routine use of HFO for ARDS cannot be recommended.

LIQUID VENTILATION

Liquid ventilation relies on the oxygen and carbon dioxide–carrying capacity of organic liquids such as perfluorocarbons. These are modified hydrocarbons in which hydrogen atoms are replaced with fluorine, generating inert liquids that are nontoxic and minimally absorbed through the respiratory epithelium. The most widely studied perfluorocarbon, perflubron (perfluorooctyl bromide), can dissolve about 17 times more O_2 than saline solution and almost 4 times more carbon dioxide.[277] Total liquid ventilation is a technique in which the lungs are completely filled with liquid and an extracorporeal exchanger is used to add O_2 and remove carbon dioxide from the liquid. Partial liquid ventilation, which is much easier to use clinically, involves partially filling the lung with liquid and then using a traditional ventilator to deliver gas tidal volumes.[278]

The theoretical benefits of liquid ventilation stem from improved lung recruitment due to the lower surface tension of the perfluorocarbons and because the liquid tends to distribute to the dependent regions of the lung. Clearance of secretions (due to their displacement by the liquid) is also improved. Anti-inflammatory effects of perflubron have been described, although the clinical relevance of these effects is not well understood. To date, two randomized controlled trials of partial liquid ventilation in adults with ARDS have been published.[279,280] The first, published in 2002, randomized 90 patients with ARDS to partial liquid ventilation with perflubron or to conventional mechanical ventilation. Neither of the two ventilation strategies was protocolized, and the inclusion and exclusion criteria were modified slightly during the course of the study. No significant differences were identified in the number of

ventilator-free days (the primary outcome) or in any other prespecified outcome.[279] In 2006, a multicenter randomized trial of partial liquid ventilation with perfluorocarbon compared with conventional mechanical ventilation (tidal volume 10 mL/kg) enrolled over 300 patients with ARDS. The study found a trend towards higher mortality in the group receiving perfluorocarbon as well as a higher incidence of barotrauma, hypoxia, and hypotension.[280] Based on these data, partial liquid ventilation cannot be recommended for patients with ARDS.

SUMMARY

The modern approach to mechanical ventilation of patients with ARDS is premised on two principles: first, that the lung injury of ARDS affects the lung heterogeneously, and second, that mechanical ventilation itself can cause ALI. Until new data emerge, the lung-protective ventilation strategy adopted by the ARDSNet study[107] is the standard of care due to its beneficial effects on short-term and long-term outcomes.[281] Plateau pressure should be maintained less than 30 cm H_2O, and tidal volume should be limited to 6 mL/kg predicted body weight, when possible. The prone position should be considered in patients with a ratio of partial pressure of oxygen to fraction of inspired oxygen less than approximately 150 mm Hg in those centers that have expertise in proning patients. Given the dangers inherent to proning, it should be performed with caution and in accordance with published protocols.

The optimal level of PEEP in ARDS remains unclear, although randomized trial data indicate that using higher PEEP levels than the original ARDSNet study is safe and may improve oxygenation in patients with severe ARDS. We favor high levels of PEEP in order to prevent atelectrauma, reduce F_{IO_2}, and prevent hyperoxic lung injury in patients with severe hypoxemia (i.e., ratio of partial pressure of oxygen to fraction of inspired oxygen less than approximately 150 mm Hg), so long as the high PEEP does not depress the patient's hemodynamic status. We do not recommend the routine use of recruitment maneuvers. We use the lowest possible F_{IO_2} that maintains oxygen saturation above 90%, and empirically adopt a target F_{IO_2} of less than 0.6.

EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal membrane oxygenation (ECMO), also referred to as extracorporeal life support or extracorporeal lung assist, refers to the process by which the patient's blood is circulated to an external machine providing oxygenation and/or carbon dioxide removal (see also Chapter 138).[282] In theory, ECMO can be used to oxygenate patients with ARDS while minimizing mechanical ventilation, thereby avoiding VILI and oxygen toxicity and allowing the lungs time to heal. There are multiple case reports of ECMO being used in adults with ARDS, and it is routinely used in neonates with severe respiratory failure. An early randomized controlled trial of ECMO in ARDS was completed in 1979 and did not show any benefit; however, the mortality rate was approximately 90% in both the ECMO and the control arm.[283] Subsequently, a variant of ECMO dedicated to carbon dioxide removal (extracorporeal carbon dioxide removal) was developed and showed promise in a case series when compared to a historical control group.[284] This was followed by a randomized controlled trial in the 1990s comparing pressure-controlled ventilation with extracorporeal carbon dioxide removal in ARDS that failed to show any improvement in survival.[285] This study illustrates the importance of using concurrent controls when assessing a novel therapy.

One of the principal complications of ECMO is bleeding; in an early randomized trial, patients on ECMO were transfused an average of 1.7 L of blood *per day*. More recent data, however, indicate that ECMO can be safely performed in specialized centers without this high rate of transfusion. In 2009, the CESAR trial randomized patients with severe respiratory failure to be transferred to an ECMO center versus to remain at their original center for conventional mechanical ventilation.[286] The majority of patients in each arm had "pneumonia" (≈60%) or "other ARDS" (≈30%). Out of the 90 patients transferred to an ECMO center, only 68 (76%) received ECMO, while 22 (24%) were managed with ongoing conventional mechanical ventilation. In this study, referral to an ECMO center conferred a statistically significant survival benefit (relative risk of death at 6 months, 0.69; confidence interval, 0.05 to 0.97) and also significantly improved survival without disability (63% vs. 47%). However, patients in the conventional ventilation arm were cared for in multiple hospitals, did not follow a standardized ventilation protocol, and had a mortality rate of 45%. By contrast, among patients referred to the ECMO center, 76% received ECMO and a significantly higher percentage of patients received lung-protective ventilation. Thus, it is unclear whether the improvement in survival was attributable to ECMO or to better care in a specialized center. Complications associated with ECMO were relatively rare; one patient died during transfer due to a technical failure while another patient had a complication during cannulation. Major bleeding was not a significant issue. A cohort study by the same authors investigating outcomes of ECMO in patients with ARDS secondary to H1N1 influenza also suggested lower mortality with ECMO compared with matched controls.[287]

In 2018, the EOLIA trial assigned 249 patients with severe ARDS to ECMO versus conventional mechanical ventilation (with the possibility of ECMO as a rescue therapy) and showed a nonsignificant difference in mortality (35% vs. 46%, $P = 0.09$); however, there was significant crossover from the control group to ECMO (28% of patients), and the study was stopped early due to reaching a prespecified futility boundary.[288] Although the investigators believed it was unethical to prohibit rescue therapy with ECMO, the high rate of crossover may have confounded the results.[288]

There is growing interest in using extracorporeal life support as an adjunctive therapy to maximize the benefits of lung-protective ventilation. The premise is that, even at the recommended tidal volume of 6 mL/kg, there may be over-distension and VILI. In this approach, tidal volumes of less than 6 mL/kg predicted body weight are used and the resultant respiratory acidosis is managed by extracorporeal removal of carbon dioxide.[289] Because of ongoing technological improvements reducing the requirement for anticoagulation and the invasiveness of the devices, this is likely to be a fertile area of research in coming years.[290,291]

LONG-TERM OUTCOMES

Early work on ARDS outcomes has evolved from an emphasis on pulmonary physiology to generic health-related quality of life to functional and neuropsychological outcomes and their contribution to medical complexity and cost. In the context of an aging population with its multiple attendant comorbidities, ARDS may no longer be evaluated in isolation but rather assessed in the context of increasing case complexity. This is the challenge for ARDS outcomes research going forward.

PHYSICAL OUTCOMES

Despite the profound derangement in oxygenation and respiratory system compliance characteristic of ARDS, it is striking that patients who survive often have normal to near-normal pulmonary function 6 to 12 months later. Lung volumes and flows are generally normal or slightly reduced at 6 to 12 months, while diffusion capacity may remain slightly reduced.[292,293] Follow-up chest radiographs are usually normal, with a minority showing subtle abnormalities, including pleural thickening or small cysts.[293] When damage is evident, one observes linear fibrotic changes in the nondependent lung zones consistent with VILI (see Fig. 134.2D).[294] These data may reflect a fundamental survivorship bias whereby those who do survive are able to do so because their lungs do not develop extensive fibrosis as part of the reparative process.

Regardless of this impressive physiologic and radiologic recovery, patients who survive ARDS continue to have important functional limitations and a decreased health-related quality of life for at least 5 years after their illness.[295,296] This physical disability may be attributable to both ARDS and its ICU management. In one parallel cohort study, patients with ARDS reported significantly greater decrements in health-related quality of life than patients with an equivalent severity of illness due to sepsis or trauma, particularly as related to physical function and pulmonary symptoms,[297] in spite of having normal or near-normal lung function at 1 year and 5 years post ICU stay.[293,298] In other patients, a persistent reduction in physical functional capacity, as measured by a 6-minute walk test with a parallel decrement in the physical role domain of the Short-Form-36 generic quality-of-life measure, has been observed and has been attributed to persistent muscle wasting and weakness. Risk is augmented by exposure to corticosteroids, ICU-acquired comorbidities, and poor resolution of lung injury and multiple organ dysfunction.[293,299–301] This combined wasting and weakness has been termed intensive care–acquired weakness, which is a consequence of a myosin depletion myopathy and/or axonopathy arising in isolation or together.[302] Injury is partially attributed to upregulation of the ubiquitin-proteasome pathway and proteolysis that begins within hours of critical illness[303] and persists for the first week.[304] Muscle repair is heterogeneous among patients, and the recovery of contractile force and muscle mass may also be discordant at long-term follow-up.[305] Even with disability, however, patients who survive an episode of ARDS do not appear to have an increased mortality compared to other ICU survivors with similar severity of illness.[297]

PSYCHOLOGICAL OUTCOMES

Hopkins and colleagues first described neurocognitive and mood disorder outcomes in survivors of ARDS. They noted significant decrements in attention, concentration, processing speed, memory, and executive function up to 2 years after ICU discharge.[306] Schelling first described posttraumatic stress disorder in ARDS patients and its association with decrements in mental health.[307] These seminal observations have informed other investigators' evaluations of neurocognitive dysfunction. Risk factors include hypoglycemia during the ICU stay,[308] hypoxemia and fluid resuscitation,[309] duration of delirium,[310] and premorbid functional status.[311] Mood disorders including major depressive episodes and debilitating anxiety disorders are prevalent.[312]

Key Points

- *Acute respiratory distress syndrome* (ARDS) is defined by acute hypoxemia, bilateral opacities on chest imaging, and the absence of left atrial hypertension.
- The pathogenesis of ARDS is not yet known, but increased permeability of the alveolar-capillary membrane due to neutrophilic infiltration of the lungs is thought to be an important factor in many patients.
- ARDS is a syndrome, not a specific diagnosis, and clinicians must search for an underlying cause in order to institute specific therapy.
- The mortality rate for ARDS has fallen since the 1980s and is now less than 40%.
- Most deaths in patients with ARDS are from multiorgan failure rather than hypoxia.
- Mechanical ventilation is life-saving but can also induce or aggravate lung injury when inappropriately applied.
- ARDS management consists of treating the underlying cause, lung-protective ventilation with target volumes of 6 mL/kg of predicted body weight and plateau pressures below 30 cm H_2O, prone positioning in more severe patients, conservative management of fluids, and excellent supportive care.
- No pharmacologic therapies have been shown to improve survival in ARDS.
- Extracorporeal life support may improve survival in appropriately selected patients with severe ARDS.
- Survivors of ARDS often suffer from a reduced quality of life and physical, cognitive, and mental health impairments.

INTRODUCTION

Mechanical ventilation is the process of using a device such as a ventilator to support, partially or totally, the delivery of gas to the lungs. In this sense, the mechanical ventilator replaces or augments the function of the respiratory muscles. The desired effect of mechanical ventilation is to maintain adequate levels of P_{O_2} and P_{CO_2} in arterial blood while also unloading the inspiratory muscles. Although negative-pressure chambers or wraps might fulfill this definition, this chapter focuses on the use of devices that use positive airway pressures. Positive-pressure mechanical ventilation is used widely. In the United States, about 1 to 3 million patients annually are estimated to receive mechanical ventilatory support outside the operating room.[1]

POSITIVE-PRESSURE MECHANICAL VENTILATOR FUNCTION

BASIC FEATURES OF A POSITIVE-PRESSURE BREATH

Most modern ventilators utilize piston/bellows systems, turbines, or controllers of high-pressure sources to drive gas flow.[2,3] Tidal breaths are generated by this gas flow and can either be controlled entirely by the ventilator or be interactive with patient efforts. Pneumatic, electronic, or microprocessor systems provide for various breath types. In general, these can be classified by three variables: (1) the variable chosen to initiate the breath (breath trigger), (2) the variable chosen to regulate gas delivery during the breath (target variable), and (3) the variable selected to terminate the breath (cycle variable).[4,5] The *breath trigger* is generated by either a change in pressure or flow initiated by patient effort (assisted/supported breath) or by a set time (controlled breath). The *target variable* is chosen to regulate the breath delivery, generally either a set flow or a set inspiratory pressure. The *cycle variable* determines when the breath is terminated, which can either be a set volume, a set inspiratory time, or a set flow. A high-pressure cycle variable is usually also present to limit lung overdistention. Figure 135.1 uses this classification scheme to describe the five most common breath types available on the current generation of ventilators: *volume assist* (VA), *volume control* (VC), *pressure assist* (PA), *pressure control* (PC), and *pressure support* (PS).

DELIVERING VENTILATION: FLOW-TARGETED VERSUS PRESSURE-TARGETED BREATHS

There are two basic approaches to delivering positive-pressure breaths: flow targeting and pressure targeting (see Fig. 135.1).[2,4] With flow targeting (breaths 1 and 2 in Fig. 135.1), the clinician sets the inspiratory flow; *circuit pressure* (Pcir) is then the dependent variable. With pressure targeting (breaths 3 through 5 in Fig. 135.1), the clinician sets an inspiratory pressure target (with either time or flow as the cycling criterion); flow and volume are then the dependent variables (i.e., varying with the lung mechanics and patient effort). With a flow-targeted breath, changes in compliance, resistance, or patient effort will change Pcir but not flow; in contrast, with a pressure-targeted breath, similar changes in compliance, resistance, or effort will cause a change of *tidal volume* (V_T) but not Pcir (dashed lines in Fig. 135.1).

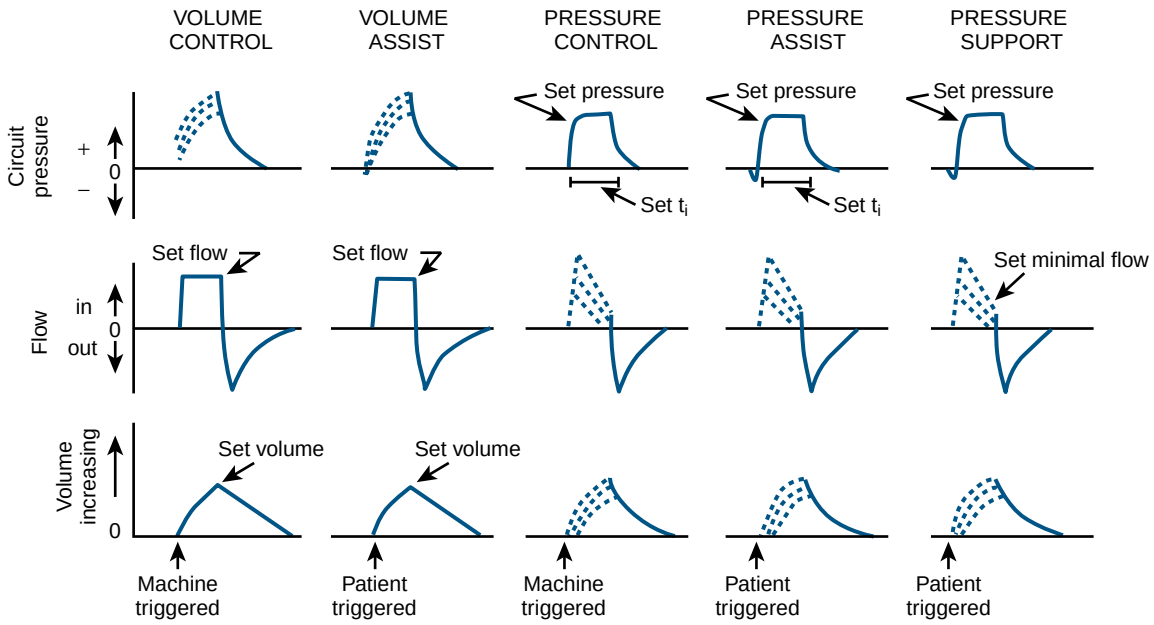

Figure 135.1 Circuit pressure, flow, and volume tracings over time depicting the five basic breaths available on most modern mechanical ventilators. Breaths are classified by the variables that determine the trigger (machine time or patient effort), target (t_i, set flow or set pressure), and cycle (set volume, set time, or set flow). The *solid lines* represent set or independent responses, and the *dashed lines* represent dependent responses. In all of these breaths, pressure is usually a "backup" cycle variable designed to terminate gas delivery if circuit pressure rises above an alarm limit.

Each strategy has advantages.[6] For flow-targeted breaths, a minimal VT is guaranteed. For pressure-targeted breaths, the rapid initial flow and subsequent adjustable flow of pressure targeting may enhance gas mixing and patient synchrony (see discussion on "Patient-Ventilator Interactions" later).

MODES OF VENTILATION

The simplest mode of mechanical ventilation is assist-control ventilation, which can provide either flow-targeted volume-cycled breaths (*volume assist-control ventilation* [VACV]) or pressure-targeted time-cycled breaths (*pressure assist-control ventilation* [PACV]). The ventilator is triggered to deliver a positive pressure breath at regular time intervals based on the set ventilation rate. If the patient's underlying respiratory rate exceeds this set rate, all breaths are patient-triggered breaths. If the patient's respiratory rate is below this guarantee, many, if not all, breaths will be time-triggered breaths (since ventilator respiratory cycle time is shorter than the respiratory cycle time of the patient's brainstem respiratory controller—the neural respiratory time).

Pressure support ventilation (PSV) is the most widely used mode of mechanical ventilation.[7] In PSV, all breaths are triggered by the patient. Once triggered, the ventilator delivers flow to meet a set inspiratory pressure. The ventilator cycles off once inspiratory flow declines to a threshold value set by the operator (usually 10–35% of peak inspiratory flow). By employing a flow threshold for cycling, PS allows patients greater control of the duration of inspiratory assistance (because inspiratory flow declines as patient effort declines) and can achieve greater synchrony with the patient's neural inspiratory time. Adjustments of the flow criteria of the PS cycle can be made to ensure appropriate synchrony of the cycle with the end of patient effort.[8] Waveforms should be carefully examined to confirm that the ventilator is not cycling prematurely (before patient effort is complete, leading to under-assistance) or late (after patient effort is complete, leading to over-assistance) (Fig. 135.2).[9] Proper breath synchrony is characterized by a comfortable patient, without evidence on the Pcir graph of continued inspiratory effort after cycling (premature cycling) or of expiratory efforts beginning during the inspiratory phase (delayed cycling).

A variety of other modes are available in clinical practice. *Synchronized intermittent mandatory ventilation* (SIMV) guarantees a set minimal number of positive-pressure breaths (delivered as VACV or PACV breaths) but, if the patient's respiratory rate exceeds this guarantee, the ventilator will allow unassisted breaths or flow-cycled PS breaths (SIMV + PS mode). SIMV has fallen out of favor based on evidence that it delays liberation from mechanical ventilation.[10]

Pressure-regulated volume control is a type of PACV mode that uses VT as a feedback control for continuously adjusting the pressure target.[11] Similarly, *volume support* (VS) uses patient-triggered, pressure-targeted, flow-cycled PS breaths where the pressure target is automatically adjusted to achieve a certain volume. Importantly, with both pressure-regulated volume control and VS breaths, an improvement in respiratory mechanics will result in a lower applied inspiratory pressure, whereas a worsening in respiratory mechanics will result in a higher applied inspiratory pressure. Similarly, increasing respiratory effort by the patient will result in a lower applied inspiratory pressure, whereas decreasing respiratory effort by the patient will result in a higher applied inspiratory pressure.

Adaptive support ventilation (ASV) is an assist-control, pressure-targeted, time-cycled mode of PACV that utilizes respiratory system mechanics to set the VT-frequency pattern.[12] The clinician sets only a desired minute ventilation and the patient's height (for estimating anatomic dead space).

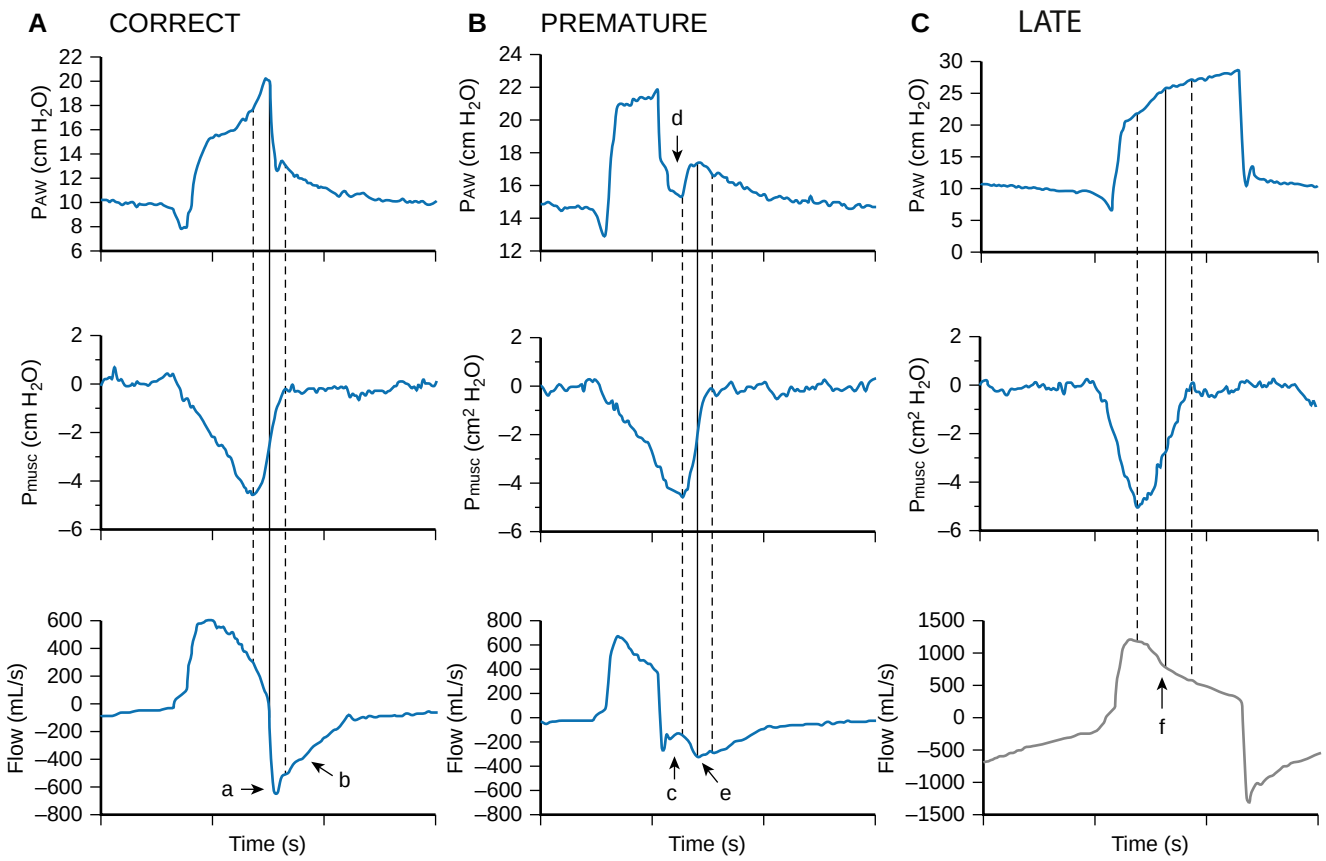

Figure 135.2 Evaluation of cycling off on pressure support ventilation by bedside waveform analysis. *Airway pressure* (PAW), *inspiratory muscle pressure* (P_{musc}), and flow are displayed where expiratory trigger sensitivity was set at 10% (A), 50% (B), and 25% (C) of cycling off. *Dashed lines* mark the beginning and end of inspiratory muscle relaxation; vertical continuous lines mark the optimal cycling off following the nadir in esophageal pressure, representing the completion of inspiratory effort. (A) During *correct* cycling off: fast decay of inspiratory flow switches directly into expiratory flow with immediate peak (*a*) followed by exponential decay (*b*). (B) During *premature* cycling off: patient inspiratory effort extended after cycling off breaks the expiratory flow, cutting off the expiratory peak (*c*) and causing a simultaneous dip in PAW (leading to under-assistance) (*d*); at the end of spontaneous inspiration, normal exponential decay of expiratory flow finally starts (*e*). (C) During *late* cycling off: sudden change from fast to slow exponential decay of inspiratory flow (*f*) marks the end of patient inspiratory effort and the beginning of a secondary phase of passive inflation (leading to over-assistance). (From Mojoli F, Iotti GA, Arnal JM, Braschi A. Is the ventilator switching from inspiration to expiration at the right time? Look at waveforms! *Intensive Care Med.* 2016;42:914–915.)

Using controlled breaths, ASV initially calculates resistance and compliance as well as the expiratory time constant (resistance × compliance). The ASV algorithm then adjusts the frequency-VT pattern to minimize ventilator work (integral of pressure over volume) and thus conceptually minimize applied forces to the lungs. The breathing pattern is also modulated by incorporating the expiratory time constant to avoid air trapping. As respiratory mechanics change, the frequency-VT pattern is automatically adjusted to maintain minimal ventilatory work. If patient efforts are triggering breaths with ASV, it behaves much like VS.

As noted above, mechanical ventilation is intended to unload the respiratory muscles; this means that greater ventilator support should be delivered when respiratory muscle effort is increased. However, none of the modes listed above delivers inspiratory pressure in proportion to patient effort. In pressure-targeted modes, the delivered ventilation is essentially independent of patient respiratory effort, while in flow-targeted modes, the delivered ventilation actually decreases when respiratory effort increases (since increased respiratory effort increases inspiratory flow). Two modes of ventilation have been introduced to address this deficiency (see discussions of "Patient-Ventilator Interactions" and "Innovations in Mechanical Ventilatory Support" later). *Proportional assist ventilation with load-adjustable gain factors* (PAV+) uses transient end-inspiratory occlusions to measure respiratory system elastance (the inverse of compliance) and resistance and estimates the pressure required to inflate the respiratory system from the equation of motion (below). The ventilator can then deliver a fixed proportion of this total inflation pressure. Accordingly, as higher patient efforts increase respiratory system inflation, delivered pressure from the ventilator also increases, reducing patient effort. *Neurally adjusted ventilatory assist* (NAVA) delivers pressure in proportion to patient effort, where patient effort is quantified from the diaphragm electrical activity signal, which is acquired from *electromyography* (EMG) electrodes affixed to an esophageal catheter; the electrodes detect electrical activation of the diaphragmatic crura, and the signal is transformed to deliver ventilator pressure in proportion to the magnitude of electrical activation. Similar to PAV+, as respiratory effort increases, ventilator pressures increase, unloading respiratory muscle effort.

OTHER ASPECTS OF VENTILATOR FUNCTION

Gas blenders mix air and O_2 to produce a *fractional concentration of oxygen in inspired gas* (FIO_2) ranging from 0.21 to

1.0. On newer systems, blenders are also available for other gases such as heliox (a mixture of helium and oxygen), nitric oxide, and anesthetic agents.

Positive end-expiratory pressure (PEEP), or positive airway pressure throughout expiration, can be generated to help maintain alveolar patency and improve *ventilation-perfusion* $\dot{V}/\dot{Q}$ matching (see "Physiologic Effects of Positive-Pressure Mechanical Ventilation" later).

With the upper airway bypassed by tracheal intubation, sufficient heat and moisture must be added to the inspired gas mixtures to avoid mucosal desiccation. *Active* humidifiers utilize external water sources and electrical power to adjust blended gas mixtures to near body conditions (tracheal temperature of >35°C, water content of >40 mg/L).[13] Heated wire circuits help facilitate this by preventing condensation and "rainout" in the ventilator tubing. *Passive* humidifiers use simple heat/moisture exchange devices in the ventilator circuit that reutilize heat and moisture trapped from expired gas. These disposable units can usually supply adequate heat and moisture (i.e., >30–33°C and water content of >28–32 mg/L) for many patients, particularly those receiving mechanical ventilation for only short periods of time.[13]

Therapeutic aerosols (e.g., bronchodilators, steroids, vasodilators, antibiotics) can be delivered through the ventilator circuitry[14] either by in-line nebulizers or by special adapters designed for metered-dose inhalers. The optimal site for aerosol delivery to maximize lung deposition appears to be in the inspiratory limb several centimeters proximal to the patient's Y-connector.[14] This location allows either nebulized medications or a metered-dose actuation to "charge" the inspiratory limb of the circuit during exhalation.

The circuit linking the ventilator to the patient usually consists of flexible tubing that often contains pressure or flow sensors, closed suctioning systems, and an exhalation valve. It is important to remember that, because this tubing has measurable compliance (2–4 mL/cm H_2O are representative values), applied inspiratory pressures may simply distend the circuitry rather than enter the patient's lungs when respiratory mechanics are severely impaired or airway opening pressure is high.[15]

PHYSIOLOGIC EFFECTS OF POSITIVE-PRESSURE MECHANICAL VENTILATION

VENTILATION AND RESPIRATORY SYSTEM MECHANICS

A firm grasp of respiratory physiology is essential to understand how mechanical ventilation is designed and how it achieves its intended goals. The pressure, flow, and volume required for ventilation depend on the mechanical characteristics of the patient's respiratory system and the efficiency of gas exchange. Knowledge of the physiology of ventilation (Chapter 10) and respiratory mechanics (Chapter 11) is essential to understand how the ventilator is applied to accomplish mechanical ventilation.

CO_2 Clearance: Alveolar Ventilation and the Equation of Motion

The primary mechanism of CO_2 clearance by conventional mechanical ventilation (similar to normal pulmonary function) is convection by bulk flow. The relationship between bulk flow obtained by the combination of patient respiratory effort and mechanical ventilation and the resulting pulmonary CO_2 clearance is given by the alveolar ventilation equation:

$$P_{aCO_2} = \frac{k}{\dot{V}_E\left(1-\frac{V_D}{V_T}\right)}\dot{V}_{CO_2}$$

where $\dot{V}_E$ is minute ventilation, $\dot{V}_{CO_2}$ is rate of CO_2 production, P_{aCO_2} is partial pressure of CO_2 in arterial blood, and V_D/V_T is dead space fraction. $\dot{V}_E$ needs to be adequate to eliminate $\dot{V}_{CO_2}$ in order to maintain a reasonable arterial P_{CO_2} (and pH).

Bulk flow (ventilation) is achieved by mechanical ventilation when pressure and flow are applied at the airway opening. These applied forces overcome respiratory system elastance (both lung and chest wall components), airway resistance, and respiratory system inertance (the resistance to a change in rate of flow) and lung tissue resistance to effect gas flow.[16,17] For simplicity, because inertance and tissue resistance are relatively small, they can be ignored yielding the simplified equation of motion:

$$P_{tot} = P_{mus} + P_{vent} = (E \times V_T) + (R \times \dot{V}) + PEEPi$$

where P_{tot} is the instantaneous total pressure required to inflate the respiratory system at any given point during the breath, given the V_T and inspiratory flow at that point; P_{vent} is the inspiratory pressure from the ventilator (peak pressure minus set end-expiratory pressure: $P_{peak} - PEEP$); P_{mus} is patient inspiratory muscle pressure generation (if present); $\dot{V}$ is the flow into the patient's lungs; R is the resistance of the circuit, artificial airway, and natural airways combined; E is the respiratory system elastance; and *PEEPi* is intrinsic PEEP. If there is PEEPi, it must be overcome by muscle and Pcir before flow and volume can be delivered; thus PEEPi will add to the inflationary pressure requirement (see later discussion).

In summary, the ventilator achieves adequate CO_2 removal by delivering sufficient pressure and flow to achieve adequate total bulk flow in and out of the lung. Increases in CO_2 production, dead space ventilation, or respiratory system resistance or elastance will increase the total pressure and flow required to achieve adequate ventilation. This pressure and flow must be applied bearing in mind not only CO_2 clearance but also the risks to the lung and their effects on respiratory muscle effort.

ALVEOLAR RECRUITMENT AND GAS EXCHANGE

Because of alveolar flooding, inflammatory exudates, and collapse, parenchymal lung injury leads to $\dot{V}/\dot{Q}$ mismatching and shunt.[18] Shunting and dead space volumes may be further exacerbated when high ventilatory pressures distend lung units that participate in ventilation, reducing blood flow to the ventilated lung. To mitigate the degree of end-expiratory lung collapse—with attendant increases in shunt and mechanical stress—the ventilator is set to maintain PEEP.

PEEP helps to recruit and maintain alveolar units open, providing several potential benefits. First, recruited alveoli improve $\dot{V}/\dot{Q}$ matching and gas exchange throughout the ventilatory cycle.[19] Second, as discussed in more detail later, alveoli that are patent throughout the ventilatory

cycle are not exposed to the risk of injury from the shear stress of repeated opening and closing.[20,21] Third, open alveoli with intact surfactant monolayers improve lung compliance.[22]

PEEP, however, can also be detrimental. Because the tidal breath is delivered on top of the baseline PEEP, end-inspiratory pressures are usually raised by the application of PEEP (although this increase may be less than the actual added PEEP because of improved compliance). This increase must be considered if the lung is at risk for regional overdistention (see "Ventilator-Induced Lung Injury" later). Moreover, since parenchymal lung injury is often quite heterogeneous, appropriate PEEP in one region may be suboptimal in another and excessive in yet another.[23–25] Optimizing PEEP is thus a balance between recruiting the recruitable alveoli in diseased regions without overdistending already recruited alveoli in healthier regions.

Another potential detrimental effect of PEEP is that it raises mean intrathoracic pressure, thereby compromising cardiac filling in susceptible patients (see "Positive-Pressure Ventilation and Cardiac Function" section later).

As described, the application of PEEP is designed to prevent derecruitment during exhalation.[19,23,26,27] Additional recruitment can sometimes be provided with the use of formal recruitment maneuvers or prolongation of inspiratory time.[28,29] Recruitment maneuvers can be performed using various methods, including sustained inflations (e.g., 30–40 cm H_2O) for up to 30 to 120 seconds, by transient elevations of the PEEP-V_T settings, and by single or multiple "sighs" that take the lung briefly to near total lung capacity.[28] Importantly, because recruitment maneuvers can have adverse hemodynamic consequences, close monitoring of the patient is mandatory during the maneuvers. Recruitment maneuvers provide initial alveolar recruitment only; maintenance of recruitment requires setting PEEP appropriately to prevent subsequent derecruitment.[28]

PEEPi and the Ventilatory Pattern

Intrinsic PEEP (PEEPi) is the positive end-expiratory alveolar pressure that arises because of inadequate expiration, caused by either inadequate expiratory time or airway collapse during expiration (or both). PEEPi increases with increased minute ventilation and decreased time for expiration (from either a decreased expiratory time fraction, or an increased respiratory system expiratory time constant).[30]

The development of PEEPi will have different effects on flow-targeted compared with pressure-targeted ventilation. In flow-targeted ventilation, the constant delivered flow and volume (and thus ΔPcir) in the setting of a rising PEEPi will increase both the peak pressure and the *plateau pressure* (Pplat). In contrast, in pressure-targeted ventilation, the set Pcir limit coupled with a rising PEEPi level will decrease ΔPcir and thus the delivered V_T (and minute ventilation). Importantly, this may help limit the buildup of PEEPi.

In the patient without respiratory effort, PEEPi can be recognized in two ways. First, when PEEPi is produced by an inadequate expiratory time, analysis of the flow graphic will show that expiratory flow has not returned to zero before the next breath is given. Second, PEEPi in alveoli with patent airways can be quantified during an expiratory hold maneuver that permits equilibration of the PEEPi with Pcir.[30]

In the patient with active respiratory effort, PEEPi can be assumed to be present if the expiratory flow has not reached zero before the next breath begins. However, the expiratory hold maneuver cannot be used to measure PEEPi in an actively breathing patient.

PATIENT-VENTILATOR INTERACTIONS

Given that the mechanical ventilator is intended to augment or replace the respiratory muscle pump, effective mechanical ventilation must interact properly with the patient's own respiratory efforts. Proper interaction entails that the ventilator delivers gas flow upon patient demand and ceases to do so when the patient's neural inspiratory cycle ends. Moreover, flow and pressure must be sufficient to unload the patient's work of breathing and relieve dyspnea. Excessive flow and pressure may impair the interaction and put the patient at risk of injury.

While some modes of ventilation are specifically designed to interact more effectively with the patient (e.g., partial-assist modes such as PSV, PAV+, and NAVA), patient respiratory effort may be present in any mode of ventilation, including assist-control modes.[31] Clinicians may incorrectly infer that changing from an assist-controlled mode to an assisted mode of ventilation will necessarily increase patient respiratory effort; in fact, patient respiratory effort may vary widely across all types of modes, whether controlled or partially assisted, and patient and ventilator may become dys-synchronous in any mode of ventilation. Consequently, both the patient's respiratory efforts as well as the ventilator's action require careful clinical assessment. Interactions take place during all three phases of breath delivery—breath triggering, flow delivery, and breath cycling—and are described in detail later in "Patient-Ventilator Dys-synchrony."

POSITIVE-PRESSURE VENTILATION AND CARDIAC FUNCTION

In addition to affecting ventilation and ventilation distribution, positive-pressure ventilation can also affect cardiovascular function.[32–34] In general, as mean intrathoracic pressure increases, right ventricular filling decreases and cardiac output/pulmonary perfusion consequently decreases. This is the rationale for using volume repletion to maintain cardiac output in the setting of high intrathoracic pressure. Of note, the effect of reduced cardiac filling on cardiac output may be partially counteracted by improvement in left ventricular function due to elevated intrathoracic pressure, which can reduce left ventricular afterload.[35] Importantly, in patients with left heart failure, the reduced cardiac filling and reduced left ventricular afterload effects of elevated intrathoracic pressure may improve cardiac function to the point that the removal of intrathoracic pressure may worsen cardiac function and thereby produce weaning failure.[36]

Intrathoracic pressures can also influence distribution of perfusion. The relationship of alveolar pressures to perfusion pressures in the three-zone West lung model helps explain this[37] (see Fig. 10.11). Specifically, the dependent lung is generally in a zone 3 (capillary distention) state. As intra-alveolar pressures rise, however, zone 2 and

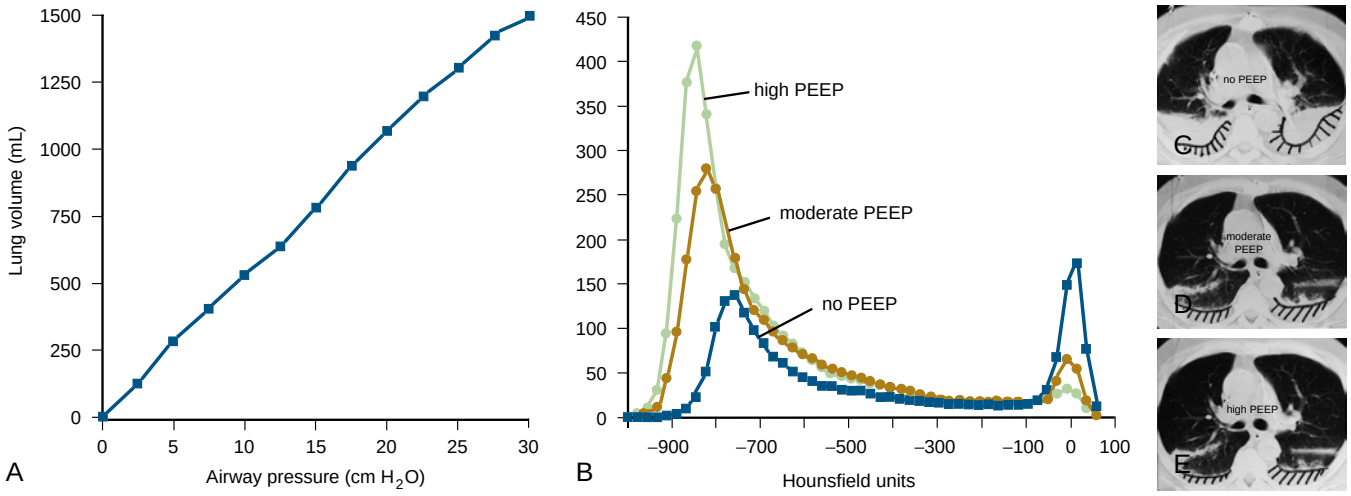

Figure 135.3 Effects of positive airway pressure in a lung with heterogeneous injury. (A) The almost linear pressure-volume relationship appears homogeneous as positive airway pressure is applied to the lungs does not reveal the underlying heterogeneity. (B) Distribution of Hounsfield units in three CT slices, at low pressure, at moderate airway pressure, and at the highest airway pressure demonstrates the underlying heterogeneity. Note that, although increasing pressure progressively reduces the number of atelectatic units (those with CT numbers near zero), these same pressures simultaneously increase the number of overdistended lung units elsewhere in the lungs (those with CT numbers less than –900 HU). (C–E) The three representative computed tomography (CT) lung slices are shown at low, moderate and maximal airway pressure. In the lung at low airway pressure (no *positive end-expiratory pressure* [PEEP]; C), note the substantial atelectasis in the dependent lung regions, which is progressively reduced as airway pressure is increased (moderate PEEP [D] and high PEEP [E]). (From Vieira SR, Puybasset L, Lu Q, et al. A scanographic assessment of pulmonary morphology in acute lung injury. *Am J Resp Crit Care Med.* 1999;159:1612–1623.)

zone 1 (capillary collapse/dead space) regions can appear, creating high $\dot{V}/\dot{Q}$ units. Indeed, increases in dead space can be a consequence of ventilatory strategies employing high ventilatory pressures, as well as with those producing PEEPi.

Positive-pressure mechanical ventilation can affect other aspects of cardiovascular function. Specifically, dyspnea, anxiety, and discomfort from inadequate ventilatory support can lead to stress-related catecholamine release with subsequent increases in myocardial oxygen demands and risk of dysrhythmias.[36] In addition, coronary blood vessel oxygen delivery can be compromised by inadequate gas exchange from the lung injury coupled with low mixed venous P_{O_2} due to high oxygen consumption demands by the inspiratory muscles.

COMPLICATIONS OF POSITIVE-PRESSURE MECHANICAL VENTILATION

VENTILATOR-INDUCED LUNG INJURY

When the mechanical stress applied to the lung is excessive, injury may result. The most obvious injury is barotrauma: alveolar rupture presenting as extra-alveolar air in the mediastinum (pneumomediastinum), pericardium (pneumopericardium), subcutaneous tissue (subcutaneous emphysema), pleural space (pneumothorax), or vasculature (air emboli).[38] The risk for extra-alveolar air increases as a function of the magnitude and duration of alveolar overdistention.

Even without producing extra-alveolar air and rupture, mechanical ventilation can induce *ventilator-induced lung injury* (VILI).[39,40] Excessive mechanical stress is translated into an inflammatory reaction within the lung (volutrauma) that can propagate via the circulation to other organs, leading to multiorgan dysfunction syndrome (biotrauma). In experimental models, acute lung injury can be produced by mechanical ventilation strategies that stretch the lungs beyond the normal maximum volume (at transpulmonary pressures of 30 to 35 cm H_2O).[41–43] A number of clinical trials clearly indicate that ventilator strategies exposing the injured human lung to transpulmonary pressures in excess of 30 to 35 cm H_2O are associated with VILI.[44–47]

Importantly, VILI is more than simply a consequence of excessive end-inspiratory stretch. Even in the setting of transpulmonary pressures less than 30 cm H_2O, excessive tidal stress and strain in the lung may contribute to VILI.[44,45] This VILI risk may be better quantified by referencing the V_T to the resting lung volume and can be termed mechanical strain.[48] In clinical practice, this stress/strain is best reflected by the *driving pressure* (Pplat – PEEP), a quantity that strongly predicts mortality in patients with *acute respiratory distress syndrome* (ARDS).[49] The frequency and velocity at which the stress is applied[50,51] may also be involved in the development of VILI. VILI may also result from shear stresses incurred when injured alveoli repetitively open and collapse during the ventilatory cycle (i.e., cyclical atelectasis or atelectrauma).[20,52,53] Additionally, vascular pressure elevations may contribute to VILI.[54,55]

The region of the lung most vulnerable to VILI is the relatively uninjured region participating in ventilation. Low-resistance/high-compliance units receive a disproportionately high regional V_T in the setting of high alveolar distending pressures. This can be appreciated using computed tomography under circumstances when pressures required for recruitment of diseased atelectatic regions simultaneously produce overdistention in already open, less-diseased regions (Fig. 135.3).[56] Regional protection of these healthier lung units is the rationale for using "lung-protective"

ventilation strategies that accept values for pH and arterial P_{CO_2} outside the usual physiologic range in exchange for lower (and safer) distending pressures (see "Applying Mechanical Ventilatory Support" later).[57]

VILI is manifest pathologically as diffuse alveolar damage.[20,41,42,58] Moreover, VILI is associated with cytokine release[58,59] and bacterial translocation,[60] which are implicated in the systemic inflammatory response with multiorgan dysfunction that results in VILI-associated mortality.

VENTILATOR-INDUCED DIAPHRAGM DYSFUNCTION

In the mid-1980s, autopsy studies in mechanically ventilated neonates found that prolonged mechanical ventilation was associated with marked diaphragm atrophy. An impressive body of experimental and clinical evidence has emerged supporting the concept that mechanical ventilation can cause diaphragm atrophy, injury, and dysfunction (*ventilator-induced diaphragm dysfunction* [VIDD]) through a variety of mechanisms (ventilator "myotrauma"). Because diaphragm dysfunction increases the risk of prolonged mechanical ventilation, VIDD raises the specter of a vicious cycle of ventilator dependence: acute respiratory failure renders patients ventilator dependent, and injurious mechanical ventilation weakens the respiratory muscles and perpetuates ventilator dependence. As with VILI, the risk of VIDD appears to depend on how mechanical ventilation is applied, suggesting that a detailed mechanistic understanding of the phenomenon may guide the development of safer, diaphragm-protective ventilation strategies that might prevent diaphragm myotrauma and accelerate liberation from mechanical ventilation.

Disuse Atrophy (Over-assistance Myotrauma)

Carefully controlled experiments in different animal models of VIDD have consistently demonstrated that (1) controlled mechanical ventilation leads to the rapid onset of diaphragm atrophy and loss of force-generating capacity in vitro, commencing within 12 hours of initiating controlled mechanical ventilation; (2) the muscle atrophy is specific to the diaphragm, and peripheral skeletal muscle is unaffected; (3) anaesthetized but spontaneously breathing control animals with only continuous positive airway pressure applied do not show any evidence of deteriorating muscle structure or function.[61–63] Taken together, these findings suggest that mechanical ventilation can be causally responsible for diaphragm atrophy.

Reduced diaphragm activity during mechanical ventilation is linked to diaphragm atrophy because of the production of reactive oxygen species,[64] possibly as a consequence of mitochondrial dysfunction.[65] This oxidative stress activates several proteolytic pathways (calcium-dependent proteolytic enzymes, ubiquitin-proteasome pathway, and autophagy).[66] The resulting imbalance between proteolysis and protein synthesis leads to progressive myofibrillar atrophy and may be responsible for myofibrillar disarray.

The development of muscular proteolysis and diaphragm weakness is attenuated when respiratory drive is intact,[67–69] and the severity of VIDD is significantly less when there are intermittent periods of spontaneous breathing during controlled ventilation.[70] Importantly, the magnitude of respiratory effort must exceed some minimum level to prevent diaphragm atrophy, because high levels of PS lead to diaphragm atrophy and muscle weakness nearly identical to the effects of controlled ventilation, whereas lower levels of PS did not result in VIDD. Thus, suppressing respiratory muscle effort injures the diaphragm irrespective of the mode of mechanical ventilation.

Clinical studies suggest that approximately 50% of patients develop at least 10% diaphragm atrophy during the first several days of mechanical ventilation.[71] These patients are at much higher risk of prolonged mechanical ventilation, reintubation, and tracheostomy.[72] Avoiding VIDD by maintaining adequate respiratory effort (the exact target is as yet uncertain) may therefore accelerate liberation from mechanical ventilation.

Load-Induced Diaphragm Injury (Under-assistance and Eccentric Myotrauma)

Excess respiratory muscle loads can cause diaphragm injury and respiratory failure. Acute inspiratory resistive loading can cause diaphragm inflammation, injury, and dysfunction when sufficiently high, although the contractile weakness is often delayed by up to 48 hours.[73] Diaphragm specimens obtained from both healthy subjects and COPD patients (who are subjected to chronically elevated resistive loads) following an inspiratory resistive loading protocol reveal sarcomere disruption, which is worse in patients with COPD.[74] The respiratory muscle load required for injury is uncertain but is surprisingly low in some studies (<20% of maximum inspiratory pressure). Loads exceeding the fatigue threshold have been documented during weaning trials in at least one study.[75]

Eccentric muscle contractions (contractile activation during muscle lengthening) are more injurious than concentric contractions (contractile activation during muscle shortening). Large eccentric contractile loads can cause significant acute diaphragm injury as demonstrated in experimental models.[76,77] The diaphragm can be eccentrically loaded during certain forms of patient-ventilatory dys-synchrony. Reverse triggering dys-synchrony, where mechanical insufflation induces neural inspiration, can result in diaphragm contractile activation while the ventilator cycles from inspiration to expiration (and lung volume precipitously falls).[78] If the ventilator cycles off into expiration prematurely (before the patient's inspiratory effort is complete), lung volume falls and the diaphragm may lengthen as it is contracting. Diaphragm contractions may also be eccentric in the context of expiratory braking, where the diaphragm is activated to prevent excessive loss of lung volume and development of atelectasis.[79] The prevalence and impact of eccentric loading on diaphragm function in the clinical setting remains to be determined.

Mechanical ventilation can prevent experimental load-induced diaphragm injury[80] and accelerates the recovery of diaphragm fatigue under high loading conditions.[81] Consequently, ventilatory support can protect the diaphragm, provided it does not excessively suppress respiratory effort or lead to patient-ventilator dys-synchrony.

OXYGEN TOXICITY

Very high inspired oxygen concentrations can cause oxidant injury in airways and lung parenchyma.[82] The data supporting this concept, however, have mostly come from

animals that often have quite different tolerances to oxygen than humans. It is thus not clear what the "safe" oxygen concentration or duration of exposure is in critically ill humans. Several observational trials suggest that even with a "safe" F_{IO_2} less than 0.4, maintaining an arterial P_{O_2} greater than 120 to 130 mm Hg may produce systemic oxygen toxicity over time.[83,84] Indeed, a single-center randomized trial of critically ill patients demonstrated that conservative oxygen therapy (targeting arterial P_{O_2} 70–100 mm Hg or oxygen saturation 94–98%) compared to a conventional strategy (targeting arterial P_{O_2} up to 150 mm Hg or oxygen saturation 97–100%) was associated with lower intensive care unit mortality rate.[85] A trial comparing even more restrictive targets (oxygen saturation 88–92% vs. ≥96%) in mechanically ventilated patients is currently underway.[86]

PATIENT-VENTILATOR INTERFACE COMPLICATIONS

The patient must be connected to the ventilator via ventilator circuitry and an artificial airway. Problems with this interface can lead to complications. The most obvious issue is disconnection from the ventilator (including artificial airway dislodgment). Other complications of the patient-ventilator interface include obstructions from secretions, circuit leaks, airway injury from inadequate heat/humidity, tracheal injury from the artificial airway, and loss of delivered V_T in a compliant circuit.

PATIENT-VENTILATOR DYS-SYNCHRONY

Patient-ventilator dys-synchrony describes the delivery of a breath from a mechanical ventilator that is not matched to patient effort. As noted earlier, this can take place during the triggering process, flow delivery, or breath cycling.

Breath Triggering Dys-synchrony

Ventilators may sense a spontaneous effort by either an airway pressure drop or an airway flow change.[87–89] Excessive or inadequate sensitivity in these triggering mechanisms gives rise to a mismatch between the patient's neural respiratory cycle times and the ventilator's respiratory cycle times, often (but not always) leading to significant patient discomfort. If ventilator triggering sensitivity is too sensitive, the ventilator may be triggered by artifactual swings in airway pressure ("auto-triggering") due to cardiogenic oscillations or water buildup in the ventilator circuit. On the other hand, insufficient sensitivity can result in significant isometric-like pressure loads on the inspiratory muscles during the triggering process. This may be worsened by excessive PEEPi from elevated airway resistance. If respiratory drive and effort are low, ventilator triggering may be ineffective, and no pressure or flow are delivered. Under these conditions, judicious use of applied PEEP can equilibrate expiratory pressure throughout the lungs and the ventilator circuit to reduce this triggering load.[90,91]

If the patient's inspiratory effort is prolonged, a second breath may be triggered as soon as the first mechanical breath is complete ("double triggering"). This results in "breath stacking," effectively doubling V_T, and putting the patient at risk of VILI. A recently described phenomenon, "reverse triggering," is produced when the machine-triggered breath elicits an inspiratory effort from the patient.[92] If the resulting effort persists beyond machine breath termination, a second breath can be triggered, and breath stacking results.

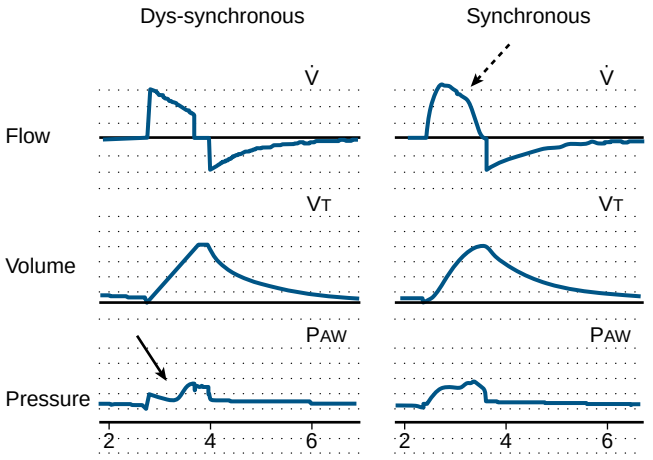

Figure 135.4 Flow and pressure pattern differences during dys-synchronous and synchronous breaths in a patient with a vigorous inspiratory effort. Depicted are flow (*upper panel*), volume (*middle panel*), and pressure (*lower panel*) for a dys-synchronous flow-targeted breath (*left*) and a more synchronous pressure-targeted breath (*right*) with matched mean flow, inspiratory time, and tidal volume (V_T). Note that, during the flow-targeted breaths (*left*), the fixed flow does not respond to the vigorous inspiratory effort, resulting in the circuit pressure being "sucked" downward (*solid arrow*). In contrast, with the pressure-targeted breath, flow adjusts and increases to meet the inspiratory effort better (*dashed arrow*). P_{AW}, airway pressure. (Modified from Yang LY, Huang YC, MacIntyre NR. Patient-ventilator synchrony during pressure-targeted versus flow-targeted small tidal volume assisted ventilation. *J Crit Care*. 2007;22:252–257.)

Flow Pattern Dys-synchrony

During an interactive breath, inspiratory muscles are contracting[93,94] and the ventilator flow delivery should be adequate to provide proper muscle unloading. This does not mean that muscle loads are eliminated. Instead, it means that a delivered flow pattern is associated with a muscle loading pattern that resembles normal, comfortable breathing[95] (synchronous flow delivery).

In general, flow synchrony is best assessed by clinical assessment and analyzing the graphic representation of Pcir over time in VACV.[95,96] Flow synchrony is manifested clinically as a relaxed patient who does not appear dyspneic. In contrast, flow dys-synchrony often manifests as tachypnea, air hunger (dyspnea), and the appearance of "flow starvation."[95] With synchronous flow delivery, the Pcir graph in ACVC should maintain either a steady baseline profile (a continuous positive airway pressure breath) or a convex upward shape (assisted/supported breath), indicating that flow is proportional to demand. Dys-synchrony (and imposed loading) is said to exist when the Pcir graph is literally "sucked downward" by effort in excess of flow delivery, often below the baseline[95,97] (Fig. 135.4). In pressure-targeted modes, flow is not controlled and therefore flow starvation is less obvious on the waveforms. However, insufficient pressure delivery can also manifest as dyspnea and distress.

Breath Cycling Dys-synchrony

Cycling dys-synchrony can arise in one of two ways. First, if the mechanical breath lasts beyond the duration of patient effort, an inadequate expiratory time may develop (along with air trapping) and/or patient expiratory efforts may be required to terminate the breath.[95] This can be a particular concern when using PS breaths in obstructive airway disease—the relatively steady inspiratory flow with PS coupled with the PS flow-cycling algorithm may significantly delay breath termination.[98] Second, if the mechanical breath terminates before the patient effort is finished, the patient may be left demanding additional flow without any being delivered. Significant imposed loading and, as noted earlier, double breath triggering may result.[95]

Clinical Implications

Determining the prevalence of patient-ventilator dys-synchrony is difficult because studies examining this question have used heterogeneous patient populations and different definitions of dys-synchrony, methods of detection, duration and timing of observation, and ventilatory modes.[95,99] Triggering dys-synchronies have been the most well studied. Depending on patient population, ventilator settings, and measurement techniques, triggering dys-synchronies have been reported in 26–82% of mechanically ventilated patients. Not surprisingly, trigger dys-synchronies were more common in patients with COPD and in those at risk for development of PEEPi.[95,99] Double triggering is the other commonly reported triggering dys-synchrony but is generally described in less than 10% of patients in these various studies.[95,99]

The incidence of other forms of dys-synchrony (flow dys-synchrony and cycle dys-synchrony) has not been as well characterized. However, a retrospective evaluation of the *National Institutes of Health ARDS Network* (ARDSNet) low V_T study reported cycling dys-synchronies associated with double triggering in 9.7% of all breaths analyzed.[100] Indeed, it is likely that patient-ventilatory dys-synchrony is ubiquitous if any patient is observed long enough during assisted/supported mechanical ventilation, especially if more sophisticated monitors (e.g., esophageal pressure or diaphragmatic EMG) are used to detect patient effort.

Although there is no doubt that many dys-synchronies are subtle and of little clinical relevance, significant dys-synchronies may be missed, thus overloading respiratory muscles and producing patient discomfort, which is a frequently cited indication for the administration of sedatives.[95,99] This may impact ventilator duration because high sedation usage is linked to longer ventilator use. Indeed, several observational studies have noted more days of mechanical ventilation and even trends toward higher mortality in patients with trigger dys-synchronies taking place more than 10% of the time.[99]

Managing Dys-synchronies

Synchronous ventilator settings first require setting the trigger to the most sensitive setting possible (without auto-triggering). If PEEPi is creating a triggering load, attempts should be made to minimize PEEPi and then judicious use of applied PEEP added to counterbalance the imposed triggering load as described later. If reverse triggering is present, reducing sedation and the need for a mandatory (controlled) breath rate should be reassessed.

Flow synchrony is often easier to achieve with variable flow pressure-targeted breaths, as noted earlier. Pressure-targeted breaths can also allow for adjustments in the rate of pressure rise (i.e., a rapid rate of rise is often desired in a patient with vigorous flow demands, whereas a much slower rate of rise is often preferable in patients with less vigorous demands[101]) and can compensate for endotracheal tube resistance (i.e., the ventilator provides the appropriate Pcir profile during both inspiration and expiration to create the desired square wave pattern in the trachea[102,103]) as a means of further enhancing synchrony. If flow-targeted breaths are desired, synchrony can be addressed with adjustments in flow magnitude and profile (sine wave, square wave, decelerating pattern). Importantly, because the patient's respiratory drive is modulated by mechanical feedback from the lungs and thorax, modes that avoid multiple different breath types (i.e., avoiding SIMV) tend to facilitate flow synchrony.[95] Finally, breath duration should be optimized for comfort and for elimination of double breaths by using adjustments in the cycle variable (volume, time, or flow).

APPLYING MECHANICAL VENTILATORY SUPPORT

MECHANICAL VENTILATORY SUPPORT INVOLVES TRADEOFFS

The goals of providing adequate support while minimizing the risk of VILI and other complications involve tradeoffs. Specifically, the need for potentially injurious levels of mechanical ventilation must be weighed against the benefits of supporting gas exchange. To this end, a rethinking of gas exchange goals has taken place over the past 2 decades so that pH levels as low as 7.15 to 7.25 and arterial P_{O_2} values as low as 55 mm Hg are now considered acceptable in order to protect the lung.[47,104,105] Ventilator settings are thus selected to provide at least this level of gas-exchange support while meeting three mechanical goals: (1) provision of enough PEEP to open the "recruitable" alveoli, (2) avoidance of a PEEP-V_T combination that unnecessarily overdistends lung regions at end-inspiration, and (3) limiting V_T to the physiologic range. These goals embody the concept of a lung-protective mechanical ventilatory strategy. Currently, these principles guide recommendations for the specific management of various forms of respiratory failure discussed below.[106–111]

CONSIDERATIONS IN CHOOSING VENTILATOR SETTINGS FOR DIFFERENT FORMS OF RESPIRATORY FAILURE

Parenchymal Lung Injury

Parenchymal lung injury means injury that involves the air spaces and the interstitium of the lung.[16,19,23,26,27] In general, parenchymal injury stiffens lungs and decreases lung volumes. It is important to realize that there are often significant regional differences in the degree of mechanical abnormalities, which should guide the ventilatory strategy. This is because delivered gas will preferentially go to the more normal regions, those with higher compliance and lower resistance, rather than to abnormal regions (Fig. 135.5). A "normal-sized" V_T may thus be distributed preferentially

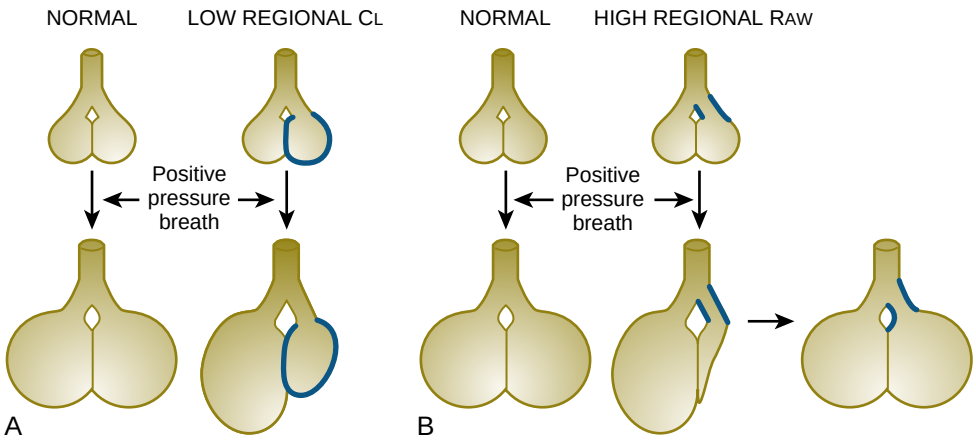

Figure 135.5 The distribution of ventilation in lung models with heterogeneous mechanical properties. Models of the lung are shown as two units with homogeneous mechanical properties (normal): (A) with abnormal compliance distribution (low regional *lung compliance* [CL]) and (B) abnormal resistance distribution (high *regional airway resistance* [RAW]). Note that in situations with heterogeneous lung mechanics, positive-pressure breaths are preferentially distributed to "healthier" regions of the lung and can produce regional overdistention—even when a normal-sized tidal volume is delivered. Note that in the obstructed example (high regional RAW), the overdistention may be transitory as gas moves from the low-resistance to the high-resistance unit over time (pendelluft). (Modified from MacIntyre NR. Mechanical ventilatory support. In Dantzker D, MacIntyre NR, Bakow E, editors. *Comprehensive Respiratory Care*. Philadelphia: WB Saunders; 1995:453.)

to the healthier regions, resulting in a regional overdistention injury. Parenchymal injury can also affect the airways, especially the bronchioles and alveolar ducts. These narrowed and collapsible small airways can also reduce regional ventilation to injured lung units, leading to regions of air trapping and possibly cyst formation during the healing phase.

Gas-exchange abnormalities in parenchymal lung injury are a consequence of alveolar consolidation, flooding, and/or collapse, producing a maldistribution of ventilation and resulting in mismatching and shunts.[18,19,23,26,27] Because $\dot{V}/\dot{Q}$ mismatching and shunt are more of an issue than dead space in parenchymal lung disease, hypoxemia tends to be more of a clinical problem than carbon dioxide elevation. (See Chapter 44.)

Frequency-VT settings for patients with parenchymal lung injury must focus on limiting end-inspiratory stretch. The benefit of reducing stretch in improving outcome has been suggested by several clinical trials[44–47,112] but has been most convincingly demonstrated by the ARDSNet Trial in which a ventilator strategy using a VT of 6 mL/kg *predicted body weight* (PBW) compared with 12 mL/kg PBW led to a 9% absolute reduction in mortality.[47] Thus initial VT settings should start at 6 mL/kg PBW.[45,113] Moreover, strong consideration should be given to reducing this setting further if end-inspiratory Pplat exceeds 30 cm H_2O.[44–47] Increases in the VT settings might be considered if there is marked patient discomfort or suboptimal gas exchange *provided that* the subsequent Pplat values do not exceed 30 cm H_2O.[44–47] Respiratory rate settings are then adjusted to control pH. Unlike the case in obstructive diseases, the potential for air trapping in parenchymal lung injury is low if the breathing frequency is less than 35 breaths/min; air trapping may not develop even at frequencies exceeding 50 breaths/min.

There is controversy as to whether *neuromuscular blockade* (NMB) and controlled mechanical ventilation should be used in the initial 24 to 48 hours of parenchymal lung injury. NMB use producing flaccid ventilatory muscles reduces total body oxygen demands and eliminates potential dys-synchronous interactions. However, ventilatory muscles inactive for as little as 24 hours are at risk for VIDD and long-term disability.[114–116] Moreover, the use of NMB usually requires substantial sedative use. A randomized trial in patients with ARDS (arterial P_{O_2}/F_{IO_2} ratios <120) showed improved mortality with NMB use for 48 hours.[117] However, a subsequent randomized trial from the Prevention and Early Treatment of Acute Lung Injury (PETAL) Network comparing 48 hours of continuous infusion of cisatracurium with deep sedation to usual care without routine NMB and lighter sedation targets demonstrated no difference in hospital mortality.[118] Importantly, patients in the intervention group were less physically active and had more adverse cardiovascular events while in the hospital than the control group. Thus, the routine use of NMB in patients with moderate/severe ARDS cannot be advocated. NMB use can be considered in selected patients to improve ventilator synchrony, particularly those at the highest risk of VILI.[119]

The inspiratory time and the *inspiratory/expiratory ratio* (I:E) in parenchymal injury is set with consideration of several issues. The usual initial I:E setting is 1:2 to 1:4, the normal and the most comfortable setting. The flow graphic should also be assessed to ensure that cycle synchrony is present and the expiratory time is adequate to avoid air trapping.

The PEEP and F_{IO_2} settings are optimized using both mechanical and gas exchange considerations. Conceptually, in setting the PEEP level in parenchymal lung injury, the goal is to provide ventilator settings between the upper and lower inflection points on the deflation limb of the pressure-volume curve (Fig. 135.6).[120] The most direct mechanical approaches use the static pressure-volume plot to set the PEEP and VT. This traditionally involves multiple VT/Pplat measurements and requires considerable clinician time along with patient sedation or even NMB. Although not widely used at present, performing a pressure-volume curve is now available as an automated feature on some newer ventilators. Another mechanical approach uses step changes

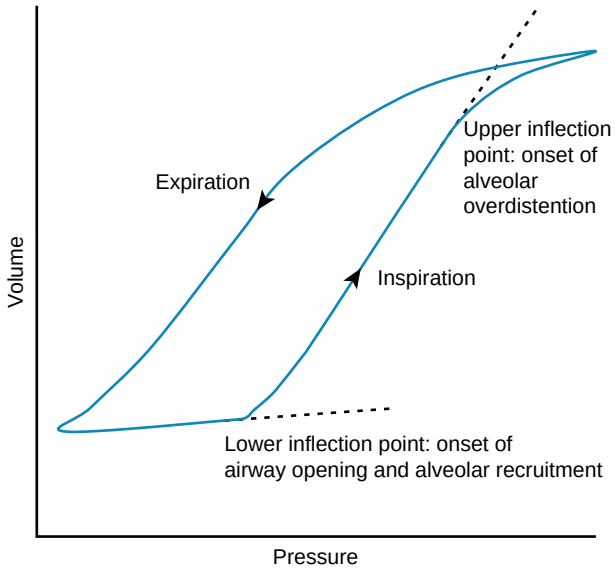

Figure 135.6 Setting ventilator pressures using the pressure-volume curve of a patient with acute lung injury. The relationship between pressure and volume (compliance) varies according to lung volume and lung volume history (i.e., incremental limb vs. decremental limb). Regions of lower compliance represent lung derecruitment (lower volume) or overdistention (upper volume). Pulmonary end-expiratory pressure is set above the lower inflection point to avoid derecruitment; maximal airway pressure is set below the upper inflection point to avoid overdistention. (Modified from Pinhu L, Whitehead T, Evans T, Griffiths M. Ventilator-associated lung injury. *Lancet*. 2003;361:332–340.)

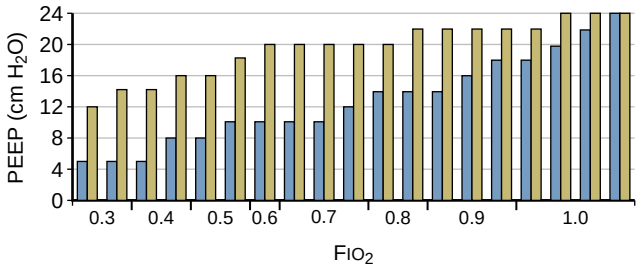

Figure 135.7 Two *positive end-expiratory pressure* (PEEP)/F_{IO_2} algorithms used in National Institutes of Health Acute Respiratory Distress Syndrome Network clinical trials. Plotted are F_{IO_2} on the horizontal axis and PEEP on the vertical axis. With both approaches, the oxygenation target (P_{aO_2} 55–80 mm Hg, S_{PO_2} 88–95%) and the maximal allowable plateau pressure (Pplat, 35 cm H_2O) are the same. Patients are moved in steps up and down the algorithm according to these targets. The two algorithms depicted either focus on higher PEEP levels ("high PEEP," *brown bars*) or lower PEEP levels ("low PEEP," *blue bars*). (Courtesy Art Wheeler, MD, and ARDS Network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med*. 2000;342:1301–1308.)

in PEEP to determine the PEEP level that gives the best compliance.[121] A simpler mechanical approach analyzes the Pcir profile during a constant-flow breath (stress index) to detect overdistention (late rising profile) or collapse/reopening injury (early rising profile).[122] With all of these approaches, a recruitment maneuver can be used to recruit the maximal number of recruitable alveoli before setting the PEEP. F_{IO_2} adjustments are then set as low as clinically acceptable.

PEEP can also be guided by gas exchange criteria, usually involving algorithms that adjust PEEP and F_{IO_2} according to certain targets. Note that constructing a PEEP/F_{IO_2} algorithm is usually an empirical exercise in balancing distending pressure, arterial O_2 saturation, and F_{IO_2} and depends on the clinician's perception of the relative "toxicities" of high thoracic pressures, high F_{IO_2}, and low arterial O_2 saturation. Although most of the reported PEEP/F_{IO_2} algorithms generally target modest levels of oxygenation (e.g., arterial P_{O_2} 55–80 mm Hg or S_{O_2} 88–95%), they tend to segregate into approaches that focus either on higher PEEP levels ("high PEEP" algorithms) or lower PEEP levels ("low PEEP" algorithms) (Fig. 135.7). Several trials have compared high versus low PEEP algorithms in conjunction with low V_T/limited Pplat strategies in patients with ARDS.[123–125] A meta-analysis of trials with mild ARDS (arterial $P_{O_2}/F_{IO_2} > 200$) compared with more severe ARDS (arterial $P_{O_2}/F_{IO_2} < 200$) demonstrated that higher PEEP strategies had a significant mortality benefit in more severe ARDS, whereas lower PEEP strategies showed a trend toward a potential benefit in mild ARDS.[126]

In patients with a rightward shift in the chest wall pressure-volume relationship and/or an increase in chest wall elastance (i.e., obesity, anasarca, abdominal compartment syndrome), the reliance on circuit airway pressures to guide ventilator settings will ignore the effect of elevated pleural pressures; for a given airway pressure, a higher pleural pressure means a lower transpulmonary pressure, which is the ultimate determinant of VILI and alveolar recruitment. Under these circumstances, it may be reasonable to allow modest increases in applied PEEP and target Pplat if usual PEEP levels are insufficient to achieve adequate arterial P_{O_2}. Alternatively, an esophageal catheter to measure esophageal pressure could be inserted to assess transpulmonary pressure directly and adjust settings accordingly.[127,128] Although a small clinical trial using esophageal pressure to guide PEEP settings suggested improved outcomes,[128] a subsequent randomized trial comparing esophageal pressure–guided PEEP titration versus a higher PEEP- F_{IO_2} table revealed no significant differences in the set PEEP nor clinical outcomes.[129] At the very least, these data suggest that esophageal manometry can be used to determine when it is safe to violate usual limits on Pplat to achieve adequate gas exchange.

Obstructive Airway Disease

Increases in airway resistance lead to respiratory failure from airflow obstruction and create two important pathophysiologic changes. First, the increased pressures required for airflow may overload inspiratory muscles, producing a "ventilatory pump failure" in which spontaneous minute ventilation becomes inadequate for gas exchange. Second, the narrowed airways create regions of lung that cannot properly empty and return to their normal "resting volume," thereby producing PEEPi.[30] These regions of overinflation create dead space and put inspiratory muscles at a substantial mechanical disadvantage that further worsens muscle function. Overinflated regions may also compress more healthy regions of the lung, impairing $\dot{V}/\dot{Q}$ matching. Regions of air trapping and PEEPi also function to increase the threshold load the patient must overcome to trigger mechanical breaths.

Frequency-V_T settings in obstructive diseases are chosen on the basis of many considerations similar to those in parenchymal lung injury. Specifically, V_T should be in the 6 to 8 mL/kg (PBW) range with Pplat targets of less than 30

cm H_2O.[44–47] In obstructive diseases, however, clinicians should also be aware that high *peak* airway pressures, even in the presence of acceptable values for Pplat, may transiently subject regions of the lung to periods of overdistention injury (see Fig. 135.5). Finally, setting the VT should also take into consideration the potential to develop PEEPi with its consequent impact on Pplat elevations and the risk of overdistention injury.

The ventilatory rate is used to control pH. Unlike the situation in parenchymal disease, however, the elevated airway resistance (and often the low recoil pressures of emphysema) greatly increases the potential for PEEPi and thus limits the range of breath rates available. Indeed, reductions in both VT and ventilatory rate to levels resulting in hypoventilation and "permissive" (or even "therapeutic"[104]) hypercapnia may be an appropriate tradeoff to limit PEEPi development and overdistention. I:E in obstructive lung disease is generally set as low as possible to minimize the development of air trapping.

The PEEP/FIO_2 settings assume a different role in obstructive lung disease than in parenchymal lung disease. Because alveolar recruitment is less of an issue and overdistention is more of an issue in obstructive lung injury than in parenchymal lung injury, the strategy in using the PEEP/FIO_2 steps in Figure 135.7 should probably be shifted more toward the use of FIO_2 for oxygenation support instead of PEEP. A specific role for PEEP in the obstructed patient arises when PEEPi serves as an added inspiratory threshold load for the patient attempting to trigger a breath. Under these conditions, judicious application of extrinsic PEEP (at levels up to 75–85% of PEEPi) can "counterbalance" PEEPi throughout the ventilator circuitry to reduce this triggering load and facilitate the triggering process.[90,91]

Finally, it is important to note that noninvasive ventilation has been demonstrated most convincingly to improve outcomes in patients with obstructive diseases.[130] In setting up noninvasive ventilation, the same principles described previously for invasive mechanical ventilation also apply (see Chapter 136).

Neuromuscular Respiratory Failure

The risk of VILI is generally less in a patient with neuromuscular failure (e.g., central nervous system injury, drug overdoses, anesthesia) because lung mechanics are often near normal and regional overdistention less likely. More "generous" VT (e.g., up to 10 mL/kg PBW) has thus been proposed as being useful to improve comfort, maintain recruitment, prevent atelectasis, and avoid hypercarbia that may adversely affect central nervous system function. However, this notion has been challenged recently by clinical trials of patients with normal lungs in the perioperative period showing reduced postoperative complications when VT is used in the 6 to 8 mL/kg (ideal body weight) range. Regardless of VT settings, maximal distending pressures should be kept as low as possible while still being compatible with the other goals noted previously.[44–47]

Mode selection in these patients is often determined by patient comfort and reliability of the respiratory drive. PEEP, even at low levels, is often beneficial at preventing derecruitment (atelectasis) when patients are supine and unable to clear secretions or sigh.

Resolving Respiratory Failure: Liberation from Mechanical Ventilation

As respiratory failure stabilizes and begins to reverse, clinical attention shifts to the process of ventilator withdrawal. Unfortunately, a number of large clinical trials have clearly demonstrated that current assessment/management strategies are not optimal, resulting in considerable delay in ventilator liberation.[130,131] Such delay leads to increased length of ICU stay, increased costs, prolonged exposure to Pcir, and increased risk of infection. Attempts to speed liberation, however, must be balanced against the risk of premature withdrawal with consequent loss of airway patency, aspiration, and inspiratory muscle fatigue. The use of a ventilator liberation protocol to identify a patient's readiness for liberation may reduce the duration of mechanical ventilation.[132] Patients should be considered candidates for liberation if (1) the lung injury is stable/resolving, (2) the gas exchange is adequate with low PEEP/FIO_2 requirements, (3) the hemodynamics are stable without pressors, and (4) the patient has the capability to initiate spontaneous breaths.[130] In these patients, a *spontaneous breathing trial* (SBT) for 30 to 120 minutes can be conducted to assess readiness for extubation. The optimal method for conducting an SBT is controversial; some guidelines recommend the use of inspiratory pressure augmentation of 5 to 8 cm H_2O[133] to counteract the imposed resistive load of the endotracheal tube, while others argue that the respiratory loading conditions postextubation are best matched by an SBT with no support (i.e., T-piece or zero airway pressure).[134] Assessments should include the ventilatory pattern, gas exchange, hemodynamics, and comfort. Patients passing this trial should be considered for ventilator liberation (i.e., extubation).

Among those patients who pass the SBT, separate assessments are required to determine if the artificial airway can be removed. These involve cough strength, suctioning frequency and, to a certain extent, the ability to follow commands.[130] Cuff leak, a bedside test that may demonstrate whether there is airway edema or compression around the endotracheal tube that could lead to postextubation airway obstruction, does not appear to be an important predictor of success, except perhaps in certain high-risk populations.[132] Extubation failures can be expected in 10–20% of all extubations. Many of these involve airway protection issues and thus indicate the need for prompt reintubation. However, in some patients, especially those with COPD, an extubation failure caused by increasing inspiratory muscle overload might be managed by noninvasive ventilation.[133,135,136]

In patients failing the SBT, a stable and comfortable level of support should be provided until the next SBT.[130] Frequent (e.g., every 2 to 12 hours) support reductions are usually not necessary because they have not been shown to speed the liberation process and only serve to consume resources and expose the patient to the risks of muscle overload. SBTs, however, should be repeated daily.[130,131] Importantly, aggressive strategies to reduce sedation can accelerate this process.[137] Indeed, some have advocated "spontaneous awakening trials" coupled to SBTs, but it is not clear if this approach is superior to carefully targeted sedation protocols.[138]

A common problem seen in patients recovering from respiratory failure but still deemed in need of an artificial airway is the presence of large VT despite low levels of ventilatory support (e.g., inspiratory pressure levels of 5 cm H_2O). Under these circumstances, a search should be made for causes of an excessive respiratory drive such as pain, metabolic acidosis, or anxiety, and these issues should be addressed. Most would argue that, in the absence of reversible causes, sedation should not be used simply to lower the VT. Regardless of the clinical scenario, whenever assisted-supported breaths are used, attention must be paid to ensuring synchronous interactions.

INNOVATIONS IN MECHANICAL VENTILATORY SUPPORT

ALTERNATIVE STRATEGIES FOR "LUNG PROTECTION"

A number of alternative strategies have been evaluated for their ability to reduce VILI.

Positive-Pressure Ventilation in the Prone Position

Mechanical ventilation of patients in the prone position offers several physiologic advantages.[139] Chief among these are two mechanisms that can improve ventilation distribution. First, the heart no longer rests on the left lower lobe, which allows better ventilation distribution to that region. Second, the sternum is restricted in its ability to move outward. This functionally stiffens the chest wall and forces a more even distribution of positive pressure.

Putting a patient in the prone position requires careful teamwork. Management of vascular lines, feeding tubes, artificial airways, ostomies, and so on need careful attention to avoid dislodging them. Avoiding pressure sores also requires careful nursing care.

There have been a number of randomized controlled trials of placing patients with ARDS in the prone position and, until recently, despite consistently better oxygenation, no consistent outcome benefit could be demonstrated.[139,140] However, the largest study to date focusing on ARDS patients with P_{O_2}/F_{IO_2} ratios less than 150 showed a significant mortality benefit to lung protective mechanical ventilation provided in the prone position for more than 16 hours/day,[142] and prone positioning has been incorporated into evidence-based guidelines.[109,111]

Airway Pressure Release Ventilation and High-Frequency Oscillatory Ventilation

Airway pressure release ventilation (APRV) (also known as biphasic ventilation, bilevel ventilation, and bilevel positive airway pressure) is a time-cycled, pressure-targeted form of ventilatory support.[141,143–146] It is actually a modification of pressure-targeted SIMV that allows spontaneous breathing (with or without PS) during any phase of the respiratory cycle.

The putative advantages of this approach are similar to others that utilize long inspiratory times. Specifically, the long inflation phase recruits more slowly filling alveoli and raises mean airway pressure without increasing applied PEEP (although PEEPi can develop with short deflation periods). The additional spontaneous efforts during inflation may enhance both recruitment and cardiac filling compared with other controlled forms of support. However, the end-inspiratory lung distention in APRV may not be less than that provided during other forms of support (and, indeed, could be substantially higher) because spontaneous VT can expand the lung beyond the volume at the APRV set pressure. In the few randomized studies that compare APRV to a true lung-protective strategy, most have not demonstrated differences in important outcomes.[144–147] A recent single-center controlled trial of 138 patients with ARDS randomized to APRV or VACV found significantly more ventilator-free days (19 vs. 2, $P < 0.001$) and shorter ICU stay (15 vs. 20, $P = 0.015$) in the APRV group.[147] However, the relatively small sample size, patients with more comorbidities randomized to the VACV group, and differences in sedation strategy between groups limit firm conclusions from this study.[148]

High-frequency oscillatory ventilation (HFOV) uses high breathing frequencies (120 to 900 breaths/min in the adult) coupled with very small VT (usually less than the anatomic dead space) to provide gas exchange in the lungs.[149] Gas transport under these seemingly unphysiologic conditions may involve such mechanisms as Taylor dispersion, coaxial flows, and augmented diffusion.[150] The putative advantages of HFOV are twofold. First, the small alveolar tidal pressure swings minimize cyclical overdistention and derecruitment. Second, a high mean airway pressure can also prevent derecruitment. Interestingly, tolerance of a higher mean pressure with HFOV may be explained by a better maintained alveolar structure with a slowly applied constant pressure as opposed to brief cyclical tidal pressures.[151]

A number of trials in the neonatal and pediatric patient population have demonstrated improved long-term lung function when HFOV is used in acute respiratory failure.[152,153] In adults, a meta-analysis of randomized trials using HFOV in adult respiratory failure suggested a benefit in patient outcomes with the use of HFOV.[154] Subsequently, however, two large randomized trials of HFOV in ARDS have called this conclusion into question. In one, mortality was identical in both the HFOV and conventional lung-protective strategy[155]; in the other, the trial was stopped early because of increased mortality in the HFOV group.[156] Both of these newer trials make it clear that HFOV should not be used routinely in adults with ARDS and, if used in patients who do not respond to any conventional lung protective strategies, should be used by clinicians experienced in the use of HFOV.[157]

AUTOMATED WEANING STRATEGIES

Over the years, a number of attempts have been made to automate the weaning process.[11] The concept behind automated weaning was that significant clinician time could be saved and ventilatory support could be automatically reduced in a timely fashion on the basis of simple ventilator measurements.

Volume support ventilation (VSV) is a strategy with the potential for automatic support reduction.[11,158] Proponents claim that this approach could "automatically" wean a patient by reducing PS as patient effort increases and respiratory system mechanics improve. Conversely, PS would

increase if patient effort diminished or respiratory system mechanics worsened. Similarly, it has also been suggested that VSV may be a useful way to maintain a more constant level of partial support in patients with fluctuating levels of effort related to drugs or neurologic conditions. All of these effects have been demonstrated in small studies focused on patients with rapidly recovering respiratory failure.[11]

Unfortunately, the simplicity of VSV may introduce problems.[11,158] For instance, if the volume set by the clinician is excessive for patient demand, a recovering patient may not attempt to take over the work of breathing for that volume and thus weaning may not progress. In addition, if the pressure level increases in an attempt to maintain an inappropriately high-set V_T in the patient with airflow obstruction, PEEPi may result. Conversely, if the volume set by the clinician is not adequate for patient demand, a patient may not receive adequate support. Under these conditions, a patient will perform excessive work to maintain a certain V_T even as the inspiratory pressure is being reduced. A transient increase in patient demand from pain or anxiety could also result in inappropriate support reduction with VSV.[158]

Adaptive support ventilation (ASV) has a sophisticated algorithm to adjust the ventilatory pattern during machine-triggered breaths, as described earlier. However, ASV performs similarly to VSV during patient-triggered breaths. Small clinical studies have demonstrated that ASV can automatically wean ventilatory support safely.[159] However, large trials have not yet compared ASV weaning to regular daily SBT strategies.

Inherent in all of these automated weaning systems is the notion that gradual support reductions (weaning) in between SBTs facilitates ventilator liberation—a notion that has little, if any, evidence supporting it in patients recovering from acute respiratory failure.[160] Two clinical scenarios, however, may be amenable to these automated approaches. The first is the patient rapidly recovering from sedatives/anesthesia where these systems can alert clinicians to the return of adequate spontaneous efforts. The second is the patient requiring prolonged mechanical ventilation who has not responded to multiple SBTs. Under these circumstances, an automated support reduction system could serve as a diagnostic tool alerting the clinician to recovery of respiratory function and the possibility of reinstating SBTs.

OPTIMIZING SYNCHRONY DURING ASSISTED MECHANICAL VENTILATION

Assisted mechanical ventilation is commonly used to improve comfort (and reduce sedation), especially during the recovery phase of respiratory failure. Alternative modes of ventilation that have conceptual appeal have been shown to perform as designed in both bench testing and small clinical studies. To date, however, large clinical trials demonstrating improvements in patient outcomes have not yet been performed.

Proportional Assist Ventilation

PAV is an approach to assisted ventilation in which the clinician sets the "gain" on patient-generated flow and volume.[161,162] PAV therefore has no set pressure, flow, or volume. Instead, the sensed patient effort is boosted according to a proportion of the measured work of breathing set by the clinician. PAV breaths are patient-initiated breaths triggered in a conventional way using Pcir or flow sensors. The PAV breath cycles when sensed flow demand has ceased. PAV+ uses transient end-inspiratory occlusions to measure respiratory system elastance and resistance, calculates work of breathing, and delivers support to a preset level of assistance.

Like pressure-targeted breaths, PAV+ flow delivery varies with patient effort; unlike pressure-targeted breaths, pressure also varies with patient effort. The conceptual benefit to PAV+ is that flow and cycle synchrony should be enhanced compared to conventional flow- or pressure-targeted breaths. Another conceptual benefit is that patient-driven V_T variability with its theoretical lung protective benefits may be enhanced.[163] Because there is no minimum pressure or flow provided, the patient is forced to breathe to receive ventilatory support. This theoretically avoids the risk of VIDD but also means that PAV+ must be used with caution in patients with low respiratory drive or respiratory muscle weakness (i.e., unable to generate inspiratory flow).

Most clinical studies with PAV have shown enhanced synchrony compared with conventional modes.[161–168] However, it is not clear how PAV+ support should be titrated in various clinical settings. One relatively new approach is to adjust the PAV support level to a target effort level; this is particularly feasible in PAV+ relative to other modes because patient effort can be directly estimated from airway pressures at a given assist level.[169] Moreover, clinical trials have not demonstrated any beneficial effects of PAV or PAV+ on important clinical outcomes (e.g., ventilator duration, sedation needs, mortality) when compared with conventional assisted/supported ventilation.[170]

Neurally Adjusted Ventilatory Assist

NAVA utilizes the diaphragmatic EMG signal to trigger, adjust flow, and cycle-assist breaths.[165,171] The conceptual benefit to NAVA is that synchrony with all three phases of breath delivery (trigger, gas delivery, and cycle) should be enhanced over conventional flow- or pressure-targeted breaths. Like PAV, another conceptual benefit is that patient-driven V_T variability with its theoretical lung protective benefits may be enhanced. Similar to PAV, there is no minimum pressure or flow provided with NAVA. Thus, NAVA must also be used with caution in patients with low respiratory drive. Moreover, there is concern about the stability of the EMG signal coming from a catheter that can move within the esophagus. Thus all patients on NAVA require careful monitoring and backup support modes.

Most clinical studies with NAVA have shown enhanced synchrony compared with conventional modes.[172–176] However, like PAV, it is unclear what the optimal EMG setting(s) should be in various clinical settings. The single randomized trial published to date found no benefit from NAVA in comparison to PSV.[177]

BEDSIDE IMAGING DURING MECHANICAL VENTILATION

Lung ultrasound is a point-of-care imaging tool that may be used to guide and monitor mechanical ventilation[178,179] (see also Chapters 23 and 24). Lung ultrasound findings

can help to identify areas of consolidation and their potential response to recruitment maneuvers, changes in PEEP, or position (e.g., proning).[180] Changes in lung aeration during a weaning trial may also help identify patients at high risk for postextubation distress.[181] Finally, lung ultrasound can help to diagnose common complications in mechanically ventilated patients, such as atelectasis, pleural effusions, and pneumothoraces.[180]

Electrical impedance tomography (EIT) is a noninvasive and radiation-free bedside imaging tool that can be used to monitor changes in lung volume, ventilation distribution, and regional respiratory mechanics during mechanical ventilation.[182] Although other imaging modalities, such as computed tomography, may have greater spatial resolution, EIT offers better temporal resolution and eliminates the need to transport the patient, making it more practical for bedside monitoring.[183] Although promising, studies using EIT have mainly focused on evaluating regional changes during PEEP titration and changes in ventilatory modes and physiologic end points. Future prospective studies are needed to investigate the utility of EIT-guided ventilatory strategies and its effects on patient important outcomes.

Key Points

- Positive-pressure breaths are characterized by three variables: the breath trigger, the flow delivery target (pressure or flow), and the cycle criteria.
- The interactions of positive-pressure breaths and respiratory system mechanics are described by the equation of motion: Pressure = (flow × resistance) + (volume/system compliance).
- In lungs with collapsed alveoli, alveolar recruitment is accomplished by transient increases in positive-pressure inflation and is maintained by positive end-expiratory pressure.
- Ventilator-induced lung injury can be caused by several mechanisms, including alveolar overdistention and repetitive alveolar collapse/reopening.
- Mechanical ventilation can also cause ventilator-induced diaphragm dysfunction through a variety of mechanisms (ventilator "myotrauma").
- Support with mechanical ventilation involves trade-offs—balancing the need for providing adequate support while minimizing the risk of ventilator-induced lung injury, ventilator-induced diaphragm dysfunction, and other complications.
- Expeditious liberation from mechanical ventilatory support requires regular sedation adjustments and assessments of spontaneous breathing capabilities.

ACKNOWLEDGMENT

KEY POINTS

INTRODUCTION

Mechanical ventilation (MV), a life-saving procedure with applications in acute and chronic respiratory failure, was initially delivered through an endotracheal tube or via a tracheotomy cannula. In the early 1990s, clinicians started to demonstrate a major interest in noninvasive techniques as a way of avoiding endotracheal intubation in the acute care setting.[1–3] The indications have progressively been extended from hypercapnic *acute respiratory failure* (ARF) to a large variety of clinical situations. Currently, there are a number of specific indications for noninvasive ventilation as the standard of care for ARF, but also several situations in which there is uncertainty about the usefulness or the limits of noninvasive ventilation (Table 136.1).

For this chapter, *noninvasive ventilation* (NIV) is considered to consist of two main modes: *continuous positive airway pressure* (CPAP) and, the most frequently used mode, *bilevel positive airway pressure* (BPAP). BPAP can be delivered via several specific ventilatory modes explained below. The purposes and applications of each are discussed.

Soon after the introduction of endotracheal MV, complications of MV began to be identified,[4,5] some directly related to the intubation procedure (e.g., cardiac arrest, laryngeal or tracheal injury, hemodynamic compromise, and ventilator-induced lung injury from excessive distension), as well as others related to the bypass of the normal upper airway barrier, thus setting the stage for ventilator-associated pneumonia. Invasive MV often requires sedation, which itself is often a cause of prolonged weaning. These major safety considerations prompted efforts to develop noninvasive methods for delivering positive-pressure ventilation. Thus, in patients with ARF, the main goal of NIV is to provide ventilatory assistance without endotracheal intubation, thereby lowering the risk of adverse events associated with invasive MV. There is convincing evidence that NIV has diminished the rates of nosocomial infections[6–8] because it reduces the overall invasiveness of patient management: sedation is either avoided or administered at low levels, and the use of central venous lines, urinary catheters, and other invasive devices is reduced (Fig. 136.1).[9]

Another important factor favoring the use of NIV is the growing number of patients who are unwilling to accept endotracheal intubation or considered poor candidates for invasive MV because of a fragile underlying health status.[10,11] In these patients, NIV can offer a chance of recovery with a lower risk of complications and can be considered as a ceiling of therapy with acceptable risks. Potential benefits and risks of the technique are discussed later and summarized in Table 136.2.

PATHOPHYSIOLOGY, RATIONALE, AND EXPECTED BENEFITS

COPD EXACERBATION

Exacerbation of COPD is a common cause of admission to the hospital and ICU. The main pathophysiologic pathway is inability to maintain adequate alveolar ventilation in the presence of major abnormalities of respiratory mechanics that, along with respiratory acidosis and hypoxemia, augment the respiratory drive. Patients are unable to take sufficient tidal volumes because of high intrinsic *positive end expiratory pressure* (PEEP), high airway resistance, and a flattened diaphragm. They breathe at the limit of exhaustion, allowing the arterial *partial pressure of carbon dioxide* (P_{CO_2}) to rise. The resulting transdiaphragmatic pressure can be considerably higher than normal, increasing the risk of respiratory muscle fatigue.[3] This vicious circle can

Table 136.1 Recommendations for the Use of Noninvasive Ventilation During Acute Respiratory Failure According to Disease and Clinical Status

DISEASE				CLINICAL STATUS	
Strong Recommendation	**Intermediate Recommendation**	**Weak Recommendation**	**No Recommendation or Contraindication**	**Yes**	**No**
Exacerbations of COPD Acute cardiogenic pulmonary edema Facilitation of weaning/extubation patients with COPD Postoperative hypoxemia after major abdominal or lung surgery Acute respiratory failure in patients with obesity-hypoventilation Do-not-intubate patients	Asthma Hypoxemic respiratory failure in non-immunocompromised patients Preventive use during procedures (upper endoscopies, endotracheal intubation) Community-acquired pneumonia in patients with COPD Neuromuscular disease	Mild ARDS Community-acquired pneumonia (non-COPD) Acute respiratory failure in immunocompromised patients Trauma Extubation failure (non-COPD) Postoperative preventive esophageal or lung surgery (using low pressures)	Severe ARDS ARDS with multiple organ dysfunction End-stage interstitial pulmonary fibrosis Facial trauma Facilitation of weaning (non-COPD) Non-drained pneumothorax	Conscious and cooperative (except encephalopathy from COPD) Hypercapnic failure Hemodynamically stable No other organ failures Improvement in gas exchange, respiratory and heart rate within first 2 hr	Hemodynamic instability Loss of consciousness Abdominal distention, nausea or vomiting Non-cooperative

ARDS, acute respiratory distress syndrome; ARF, acute respiratory failure; CPE, cardiogenic pulmonary edema; ICU, intensive care unit.

Figure 136.1 Noninvasive ventilation in the intensive care unit. Photograph shows a patient treated by noninvasive ventilation using an oronasal face mask covering the nose and the mouth. A ventilator with a double circuit is used.

be modified by NIV, which allows the patient to augment tidal volumes with less effort.[3,12] As alveolar ventilation increases, arterial P_{CO_2} and pH values improve, which reduce the respiratory drive and dyspnea.

CARDIOGENIC PULMONARY EDEMA

In *cardiogenic pulmonary edema* (CPE), pulmonary congestion reduces lung compliance causing hypoxemia and increased work of breathing. In turn, intense inspiratory efforts cause large negative swings in intrathoracic pressure that not only augment venous return but also increase left ventricular afterload, impeding left ventricular ejection. Many patients with CPE improve rapidly under therapy with medications alone. A few, however, develop severe respiratory distress and/or refractory hypoxemia/hypercapnia and require ventilatory support while medication treatment continues.[13,14] PEEP applied by CPAP and other types of NIV improves lung compliance and decreases shunt and ventilation-perfusion abnormalities, resulting in improved oxygenation and reduced work of breathing and sense of dyspnea. Moreover, positive intrathoracic pressures decrease left ventricular afterload in non–preload-dependent patients[15] and reduce right and left ventricular preload.[16] The net effect on cardiac function is usually beneficial. NIV has therefore become a useful complementary approach to drug therapy in patients with CPE.[17,18]

HYPOXEMIC ACUTE RESPIRATORY FAILURE

Unlike exacerbations of COPD or CPE, hypoxemic ARF represents a heterogeneous group of diseases with different prognoses and treatments. Robust large randomized controlled trials are relatively scarce in this setting, and guidelines and recommendations are often not straightforward.[19] Specific downsides of NIV in this setting have been described over the past several years.

The hallmark of hypoxemic ARF is acute hypoxemia (arterial P_{O_2}/fractional concentration of oxygen in inspired gas [F_{IO_2}] ratio ≤300) with clinical signs of respiratory distress, hyperventilation, and hypocapnia. Hypercapnia is a serious late complication, indicating impending respiratory muscle failure. The rationale for using NIV in hypoxemic ARF is to improve hypoxemia and to alleviate the high load imposed on the respiratory muscles (prevention of latent pump failure). Notwithstanding, NIV is not a cure for the disease and, when interrupted or poorly delivered, the patient immediately returns to the pre-NIV state. In fact, a beneficial effect of NIV on gas exchange and dyspnea may even mask an underlying disease deterioration. This could lead to life-threatening respiratory failure in case of interruption. During the initial phase, patients are often able to cope with the increased respiratory workload but, by the time they become unable to

Table 136.2 Potential Benefits and Risks of Noninvasive Ventilation for Acute Respiratory Failure

Benefits	Risks
■ Respiratory muscle unloading	■ Interface intolerance
■ Improved dyspnea and gas exchange	■ Skin lesions
■ Left ventricular afterload decrease	■ Abdominal distention and regurgitation
■ Left and right ventricular preload decrease	■ Impaired cough
■ Less invasive management	■ Masking deterioration of underlying disease
■ Decreased risk of nosocomial infections	■ Patient ventilator asynchrony
■ Decreased use of sedation and vasoactive drugs associated with intubation	■ Limited ability for lung protective ventilation/risk of lung injury

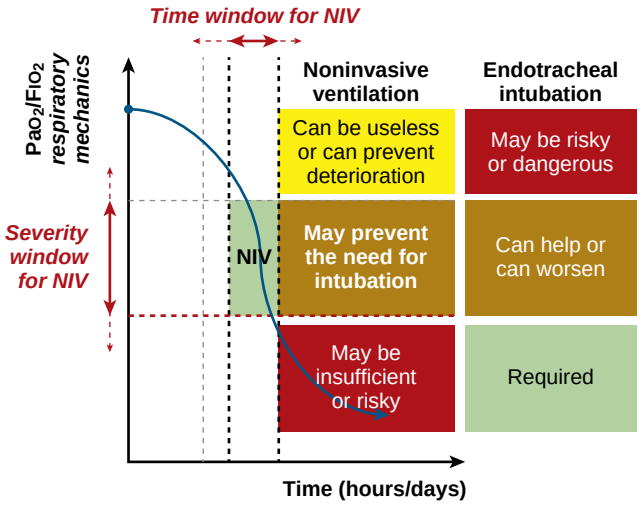

Figure 136.2 The decision windows for *noninvasive ventilation* (NIV) or endotracheal intubation. There is an optimal window of time and severity of injury in which to consider NIV. As a patient worsens over time (see curve of patient course), one must consider whether the severity is appropriate for NIV or intubation and invasive mechanical ventilation. For the right level of severity, NIV can be valuable in offering needed support and perhaps preventing the need for intubation. If the severity worsens further, NIV may be insufficient or risky, and intubation may then be required. If the condition is mild, neither NIV nor invasive mechanical ventilation would be warranted. Unfortunately, there are no strictly objective criteria that delineate the windows of severity or of time for determining exactly when NIV should be used.

meet the respiratory requirements, NIV use may be ineffective or even harmful. Therefore, there is probably a limited time and/or a severity window for delivering NIV as a preventive support beyond which its use may become risky (Fig. 136.2).[20]

Many patients with acute hypoxemia and *acute respiratory distress syndrome* (ARDS) may not be favorable candidates for NIV due to the need for delivering lung-protective ventilation. During NIV, high transpulmonary pressure swings and large tidal volumes may be generated, which could lead to the development of (unintentional) patient self-inflicted lung injury and contribute to the poor outcome observed in intubated patients who do not respond to NIV. NIV should provide a sufficient level of PEEP to improve oxygenation while ensuring an optimal pressure support to unload the respiratory muscles. These two additive pressures generate the peak airway pressure, one of the major determinants of leaks and asynchrony. Therefore, finding the right balance between the two may be challenging. Patients with poor lung compliance requiring high airway pressures may thus prove difficult to manage with NIV.

PRACTICAL AND TECHNICAL ASPECTS

MODES OF VENTILATION AND SETTINGS

Continuous Positive Airway Pressure and Bilevel Positive Airway Pressure

CPAP represents the application of a constant level of positive pressure at the airway opening during spontaneous breathing. CPAP is not always considered as a mode of ventilation support because it does not assist breathing. However, CPAP can increase functional residual capacity by opening atelectatic lung regions, which decreases intrapulmonary shunt, improves oxygenation and lung compliance, and potentially reduces the work of breathing, thus resulting in improvement in ventilation.[21] With CPAP, the presence of intrinsic PEEP can be counterbalanced with external PEEP, allowing a partial reduction of inspiratory effort. In addition, CPAP may reduce the left ventricular afterload by lowering the left ventricular transmural pressure in patients with left heart failure. In this chapter, CPAP is considered as a type of NIV.

BPAP assists the respiratory muscles by providing a pressure during inspiration, in addition to PEEP during expiration. It is most commonly delivered with *pressure support ventilation* (PSV) plus PEEP (which are often thought of as an invasive MV mode but are also feasibly and frequently delivered noninvasively). Often referred to by its proprietary name, BiPAP, BPAP is strongly recommended in cases of respiratory acidosis such as COPD exacerbations.[19] In addition to PSV plus PEEP, BPAP can also be delivered through various other ventilator modes discussed below. To avoid inducing leaks that would complicate NIV administration and impair patient-ventilator synchrony, the pressure delivered is often less than would be delivered during invasive MV; however, insufficient pressure may translate into insufficient inspiratory muscle unloading.

Asynchrony under BPAP

Success of NIV is associated with good clinical tolerance.[25,26] Intolerance can be related to patient-ventilator

asynchrony, defined as a mismatch between the patient's neural inspiratory time and the ventilator insufflation time.[25] Frequent asynchronies accounting for more than 10% of the respiratory efforts were present in 43% of patients undergoing NIV in an observational study.[27] The leading causes of asynchronies with NIV are leaks around the mask, which can be minimized by a properly selected interface and an optimal adjustment of ventilatory settings.[27] Inspiratory leaks cause prolonged inspiration (the most common asynchrony during NIV) and expiratory leaks promote auto-triggering.[28] When leaks develop during inspiration, the ventilator continues to insufflate because the delivered flow remains above the cycling criterion, resulting in a prolonged inspiration.[27] This problem was highly prevalent when using old versions of ICU ventilators. "NIV" modes are now available on ICU ventilators and on portable dedicated NIV devices. These modes include algorithms that measure and compensate for leaks.[28,29] When leaks develop during expiration, a pressure drop below the external PEEP level or a drop in expired bias flow can simulate the patient's effort and auto-trigger a breath. Auto-triggering may promote a short cycle or a flow distortion because the patient does not generate any effort and closes the glottis at the time the inspiration is auto-triggered. NIV-dedicated ventilators have specially designed algorithms that markedly limit auto-triggering.[30]

Other Modalities

In addition to PSV plus PEEP, BPAP can be delivered with various additional modes of ventilation: volume-targeted ventilation, negative pressure ventilation, and neurally adjusted ventilation, although these alternative modes are seldom used in clinical practice.

Volume-targeted ventilation delivers set flow, inspiratory time, and tidal volume with each breath; inflation pressure varies with the intensity of the patient's effort. Volume-targeted ventilation is rarely used in ARF because it may induce high peak pressures, causing discomfort and leaks, gastric distension, and skin necrosis.

Negative-pressure ventilation (i.e., iron lung) may be noninferior to invasive MV; however, it is available in only a few centers throughout the world.[3–33]

Neurally adjusted ventilation is based on the detection and quantification of the electrical activity of the diaphragm by means of an esophageal array of bipolar electrodes. The ventilator is triggered, limited, and cycled off directly by electrical activity of the diaphragm to synchronize mechanical ventilation with neural inspiration. One advantage is that neurally adjusted ventilation should not be affected by leaks. Several studies in heterogeneous groups of ICU patients demonstrated that NIV with neurally adjusted ventilation considerably reduces patient-ventilator asynchronies (mostly wasted efforts) relative to BPAP with traditional PSV plus PEEP.[34–39] Further studies will determine whether neurally adjusted ventilation improves NIV outcome.

In addition to studies of various ventilator modes for NIV delivery, there were also some early promising results on the use of helium-oxygen mixture for patients with COPD exacerbations treated with NIV. However, subsequent large trials were unable to demonstrate a significant benefit.[40–43]

VENTILATORS

Dual- or single-limb circuits can be used to deliver NIV. Mechanical ICU ventilators use a dual-limb circuit with one line for inspiration and one for expiration. Portable ventilators often use single-limb circuits and a mask with intentional leaks for CO_2 removal. Open single-tube circuits require either a vented mask with a built-in passive exhalation port or a nonvented mask with an active exhalation valve to allow for CO_2 removal. The Boussignac CPAP device is a small cylindrical plastic adaptor that fits on a modified face mask. The system uses the incoming flow of oxygen to generate a turbulent virtual pressure valve in the open expiratory side of the mask. The gas is accelerated and circumferentially enters into the open-ended cylinder, generating air entrainment and positive pressure.[44,45]

NIV can be delivered using ICU ventilators with NIV modes or ventilators specifically dedicated for NIV. ICU ventilators offer better monitoring capabilities and the ability to continue invasive MV and full ventilatory support in the event of intubation. They usually limit prolonged inspirations.[30,46] Irrespective of the type of ventilator used to deliver NIV, careful observation and frequent adjustment of the airway pressure and flow-time curves can improve patient-ventilator interaction and normalize arterial P_{CO_2} levels.[47,48]

Airway gas conditioning (i.e., the warming and humidification of inspired gas) is performed by the human airway during normal breathing. During NIV, the normal airway gas conditioning mechanisms can be insufficient when there are high-flow, high-airway pressure settings, and high inspired oxygen fractions. Inadequate humidification can cause damage to the nasal mucosa, inducing high nasal airway resistance.[49,50] ICU ventilators provide low levels of humidity compared with turbine or piston NIV ventilators due to the exclusive use of dry gas, and gas humidification is therefore needed. The humidification ability of moisture exchanger filters is reduced in the presence of leaks,[50] and their internal volume may impose an additional workload by generating CO_2 rebreathing.[51,52] Some experts have therefore suggested that heated humidifiers might be preferable to heated moisture exchangers. However, a randomized trial did not find any difference in the rate of NIV failure comparing heated moisture exchanger filters to heated humidifiers on ICU ventilators.[53]

INTERFACES

The interface is an essential component of NIV. An important distinction concerns leaky masks for single-circuit ventilators versus masks without intentional leaks for double-circuit ventilators or for a single circuit equipped with an expiratory valve. New masks are often made of two or more parts: a frame made of stiff transparent material and a cushion of soft material to seal the frame against the patient's face.[54,55] Improvements have been realized by using different cushions with new materials, by improving the fixation system, and by increasing the number of the attachment points, permitting a more uniform distribution of pressure.

Oral and nasal interfaces are mostly used for chronic NIV.[54,56] The use of nasal interfaces in ICU patients results in major leakage through the mouth that diminishes the effectiveness of NIV and promotes asynchrony and discomfort.[57–59] Oral interfaces are associated with significant leaks and asynchrony and require good patient cooperation.[60–67]

Face masks can be either oronasal or total face; both appear to have similar efficacy and patient tolerance.[68] Large masks enclosing the entire face or head (i.e., helmet) have been developed.[69,70] Large masks are comparable to standard full face masks in terms of respiratory muscle unloading, patient comfort, and arterial blood gas improvement, suggesting that the theoretical risk of rebreathing associated with the large internal volume may be small or nonexistent in clinical practice.[60,62–65,67,71]

Helmets cover the entire head and have several advantages: they allow patients to communicate, drink, and interact, are applicable regardless of the face contour, lower the risk of skin lesions, and may enhance patient tolerance. Compared with other interfaces, NIV with a helmet has been shown to reduce hospital mortality, intubation rate, and complications, mainly in patients with hypoxemic ARF.[72,73] In 2016, Patel et al. compared the traditional face mask approach with the helmet interface in patients with ARDS undergoing NIV. The single-center trial was prematurely stopped when the interim analysis found a 43% absolute reduction in intubation in favor of the helmet ($P < 0.001$).[74] Additionally, the helmet significantly reduced ventilator-free days and improved both in-hospital and 3-month mortality (56% and 34%, respectively). A concern with the helmet interface is that it may induce more rebreathing than conventional masks and may be less suitable for patients with hypercapnic respiratory failure.[75] However, changes in arterial blood gases and respiratory rate have been shown to be similar between the helmet and oronasal mask in patients with COPD and hypercapnic ARF.[76] The helmet is generally characterized by more asynchronies compared to face masks,[77,78] but a new helmet with less internal volume and better pressurization and triggering performance may improve synchrony and patient comfort.[79] However, helmets for NIV are not yet widely available.

In conclusion, although the helmet may ultimately prove to be the most beneficial NIV interface, oronasal and full face masks are often the first choice in the acute care setting. The helmet can be used as a first-line interface, when available, especially in patients who need high positive airway pressures and are intolerant to face masks. There is no ideal NIV interface for all patients in all circumstances, and several interfaces should be available at the bedside.

INDICATIONS

EXACERBATION OF COPD

In patients with COPD exacerbation, BPAP delivered via traditional PSV plus PEEP has repeatedly been shown to reduce the need for endotracheal intubation, reduce the rate of complications, shorten length of stay, and improve survival.[80–85] Early NIV can and should be used outside the ICU as an important component of first-line therapy for COPD exacerbations to prevent further deterioration.[80,85,86] In 2017, a Cochrane review of 17 randomized controlled trials involving 1264 patients with hypercapnic ARF due to COPD exacerbation confirmed that NIV decreased the mortality risk by 46%, with the number needed to treat to save an additional life of 12. It also decreased the risk of intubation by 65% and significantly decreased length of hospital stay and incidence of complications.[87] With these proven benefits, NIV is increasingly applied in COPD exacerbations with a concomitant decline in intubation, in-hospital mortality, hospital-acquired pneumonia, length of hospital stay, and cost.[88–90] Even in patients with hypercapnic encephalopathy due to COPD exacerbations, it may be worth trying to "wake them up" with NIV.[91,92]

Despite the benefits of NIV, even in experienced centers, patients who do not respond to NIV experience higher mortality than patients initially intubated and treated with invasive MV.[6,88–90,93–95] The most important determinants of NIV outcome are the process of care and careful patient selection. The most severely affected patients, such as those with a pH less than 7.30 on admission,[85] marked mental status alterations at NIV initiation, comorbidities, and a high severity score are at high risk of early NIV failure.[26,96–99] In these patients, NIV might be better applied in the ICU; indeed, many hospital centers require initiation of NIV and continued therapy for acute respiratory failure in an ICU setting. In addition, patients with respiratory arrest, apneic episodes, agitation requiring sedation, hypotension, or heart rate below 60 beats/min require urgent intubation.[19] Some patients experience late or secondary NIV failure after an initial improvement.[100] A longer time from onset of the exacerbation to NIV initiation may also reduce the likelihood of success. Every effort should be made to deliver NIV early; if NIV is begun late, when its use is known to be less effective, close monitoring is necessary.[101]

In conclusion, NIV offers many advantages over standard medical therapy and invasive MV to treat exacerbations of COPD. There is strong evidence that NIV is cost-effective, being both more efficient and cheaper compared with standard therapy alone.[102,103] The European Respiratory Society/American Thoracic Society guidelines strongly recommend a trial of BPAP for patients with ARF associated with COPD exacerbation who develop acute-on-chronic respiratory acidosis ($pH \leq 7.35$).[19]

ASTHMA

There has been a substantial increase in the use of MV (either invasive or NIV) for acute asthma over the past years, accompanied by a shift from invasive MV to NIV.[104,105] In a large retrospective series in the United States,[106] NIV was used in more than 40% of patients with acute asthma exacerbations with a failure rate (i.e., need for intubation) of 4.7%. In-hospital mortality in patients who were ventilated with NIV, ventilated with invasive MV, and experienced NIV failure was 2.3%, 14.5%, and 15.4%, respectively.[19,106] Despite its common use in asthma, the utility of NIV in asthma exacerbations has been rigorously evaluated in only a few small randomized trials with considerable heterogeneity in the protocol used, outcomes

analyzed, and results.[105,107–110] There is no evidence that NIV for the treatment of acute severe asthma reduces mortality. Therefore, no recommendation for the use of NIV in asthma exacerbation can be made, and further studies are required to shed light on this field.[19]

EXACERBATION OF OTHER CHRONIC LUNG DISEASES

All forms of acute-on-chronic ventilatory failure share several common pathophysiologic pathways. NIV seems to be an interesting option in patients with more restrictive lung disease and in cases of associated obesity, especially when respiratory system compliance is still preserved.[9,83,111–121] A large cohort study compared the efficacy of NIV in patients with COPD (n = 543) and in patients with acute respiratory failure due to obesity hypoventilation syndrome (n = 173).[122] Overall survival adjusted for confounders, length of stay, and hospital readmission were similar in both groups. In patients with COPD, obesity was associated with less late NIV failure and lower risk of hospital readmission. These results indicate that patients with obesity hypoventilation syndrome can be treated with NIV during an episode of acute exacerbation with similar efficacy as for patients with COPD.

CARDIOGENIC PULMONARY EDEMA

The first evidence of therapeutic efficacy of positive pressure use during acute CPE was shown in 1985.[123] Subsequent trials demonstrated that NIV improved arterial blood gases and respiratory rate and reduced the rate of intubation compared to standard therapy in CPE.[14,17,124,125] In 1069 patients with acute CPE randomized to receive standard medical treatment plus NIV (CPAP or BPAP) or oxygen therapy, dyspnea, heart rate, and metabolic abnormalities improved more rapidly with NIV, but the intubation and 7- and 30-day mortality rates were similar in both groups (9.8% vs. 9.5% and 16.4% vs. 15.2%, respectively).[126] However, a high crossover rate (15% of patients in the oxygen group crossed over to NIV) could have markedly diminished the ability to demonstrate benefits from NIV. A meta-analysis addressing NIV in patients with ARF due to CPE concluded that, compared with standard medical care, NIV reduced hospital mortality and decreased intubation rates with a number needed to treat for an additional beneficial outcome of 17 and 13, respectively.[127] Additionally, outcomes with CPAP were comparable to BPAP. Therefore, CPAP or BPAP should be applied early in patients with CPE and ARF, even in the pre-hospital setting.[19,128] CPAP can be recommended as a first-line treatment, but BPAP might be preferred in patients with hypercapnia associated with COPD or obesity. Notably, patients with cardiogenic shock, acute myocardial infarction, or altered level of consciousness were not included in most trials, and intubation might be the best option for them. Left ventricular ejection fraction less than 30%, B-type natriuretic peptide level of 3350 pg/mL or greater at baseline, and positive fluid balance of 400 mL or greater within 24 hours after CPE onset have been identified as risk factors for NIV failure.[129]

HYPOXEMIC RESPIRATORY FAILURE

NIV to Prevent Intubation in de Novo Respiratory Failure

De novo respiratory failure is defined as significant hypoxemia (arterial Po_2/Fio_2 < 300 mm Hg) with respiratory distress that does not develop postoperatively or post-extubation and is not associated with chronic lung diseases such as COPD or with CPE. It is the group of patients where the benefit of NIV is more questionable. Contrasting results exist between the benefits observed in short-term physiologic studies and some randomized controlled trials,[9,83,111–115,118–121,130] and the high rates of failure and risk of delaying intubation are concerning.[116,131] Meta-analyses demonstrated significant reduction in intubation rates but a less clear effect on mortality.[73,132] A large observational study in France[133] compared NIV outcomes in patients with acute exacerbation of chronic cardiac or respiratory failure to those with hypoxemic de novo respiratory failure. NIV considerably improved the outcome in the acute-on-chronic group, but not in the de novo group. In summary, identifying which subgroups of hypoxemic patients will truly benefit from NIV use with minimal risk remains unclear and is still a field for investigation. The following specific categories of patients have been studied.

NIV for Pneumonia

In patients with pneumonia, results of small randomized controlled trials are often difficult to interpret because of the concomitant presence of COPD or CPE.[83,130,134] Also, extrapolating these results to individual patients requires the same careful selection process, with exclusion of patients with contraindications. Contrary to randomized trials, observational studies of NIV in pneumonia have often shown higher rates of failure.[2,115,121,133] These results suggest that NIV should not be used when the risk of failure is high, and intubation should not be delayed when clinical signs and symptoms indicate impending NIV failure.[135] The presence of shock, loss of consciousness, respiratory arrest or respiratory pauses, NIV intolerance, or major secretions should be considered contraindications.

NIV for ARDS

ARDS is a strong predictor of NIV failure.[112,136,137] In a multicenter survey, early applications of NIV in patients with ARDS prevented intubation in no more than 50% of patients, with a 54% mortality rate among those with NIV failure.[138] On the other hand, fewer patients with mild ARDS who were treated with NIV required intubation and experienced organ failure than those receiving conventional treatment, according to a prospective, randomized controlled trial.[139] During the H1N1 pandemic, NIV was used widely with favorable results in many patients but also had a high rate of failure.[140–142] Viral transmission did not seem to be an issue, although more data are needed to address this question.[143,144] A 2016 trial that tested the performance of NIV via helmet in patients with ARDS was more encouraging. In the study by Patel et al., the rate of intubation in ARDS patients treated with helmet NIV was 18%, significantly lower than that of patients treated with NIV via face mask (62%).[74] Helmet NIV reduced 90-day

mortality by 22%, improved patient tolerance, and was related to better neuromuscular performance and functional outcomes after 1 year.[145] Notably, patients treated with helmets had higher PEEP and lower inspiratory pressure (PSV) levels than those treated with face masks, settings that may have reduced lung injury.

In general, NIV use in patients with ARDS remains debated due to several reasons. It is very difficult to target lung-protective ventilation during NIV. High respiratory drive and strong inspiratory efforts generate high transpulmonary pressures, resulting in lung stress and strain through high tidal volumes and pendelluft phenomenon (by redistribution of gas to the more abnormal and susceptible areas of lung), capillary leak, and lung edema.[146,147] An arterial Po_2/Fio_2 of 200 mm Hg or less and a tidal volume greater than 9 mL/kg of predicted body weight 1 hour following NIV have been strongly associated with need for intubation and mortality.[148,149] In the Lung Safe Study, NIV failure increased from 22.2% in mild ARDS to 42.3% and 47.1% in moderate and severe ARDS, respectively.[150] Data from Lung SAFE showed that NIV use was independently associated with increased ICU mortality (hazard ratio, 1.4; 95% confidence interval, 1.2 to 1.8) but not hospital mortality. In a propensity-matched analysis, ICU mortality was higher in NIV than in invasively ventilated patients with an arterial Po_2/Fio_2 lower than 150 mm Hg. Therefore, a recommendation against the use of NIV in ARDS patients with severe hypoxemia is reasonable. Beyond the severity of hypoxemia, factors such as high APACHE II and SOFA score, shock, increased heart rate, acidosis, altered level of consciousness, and tachypnea have been linked to NIV failure in ARDS.[149,151–154] Recently, the HACOR score, which evaluates the heart rate, acidosis, consciousness, oxygenation, and respiratory rate in hypoxemic patients, has been introduced.[154] A HACOR score of greater than 5 at 1 hour of NIV predicted NIV failure in hypoxemic patients with high accuracy (>80%) (Table 136.3).

Overall, no firm recommendations concerning the use of NIV in ARDS can be made.[19] If a trial of NIV is chosen, it should be offered at the earliest stages of ARDS, by an experienced clinical team, and in carefully selected patients (arterial Po_2/Fio_2 >200 mm Hg, no abnormal mental status, no organ failure). Patients should be closely monitored and intubation applied without hesitation in the absence of significant improvement.

NIV in Immunocompromised Patients

The prognosis of immunocompromised patients with ARF has clearly improved in the past 20 years. Invasive MV was repeatedly identified as an independent mortality predictor in this population, and the potential to reduce infectious complications and ventilator-induced lung injury was a strong rationale for NIV use in immunocompromised pat ients.[9,113,114,119,155] NIV has been shown to be beneficial in cancer patients with respiratory failure[9,113,119] and represented the first-line treatment in 49% of patients with cancer admitted to the ICU with respiratory failure, and demonstrated a 62% success rate in a large cohort.[156] Nonetheless, when ARDS was the cause of ARF in cancer patients, NIV failure was as high as 71%.[152] The application of NIV in hematologic malignancies is particularly challenging, and its failure is associated with a mortality of more than 70%. When applied in patients with hematologic malignancies, failure rates have been reported at around 50%, without significant benefit in mortality, infections, intubation rate, duration of mechanical ventilation, or ICU length of stay compared to oxygen therapy alone.[137,157–159]

NIV in ARF associated with immunosuppression has a dual effect: when it succeeds, NIV increases survival by avoiding invasive ventilation but, when it fails, mortality is higher than that compared to immediate intubation. It is therefore crucial to distinguish which patients will most likely benefit from NIV. Presence of hematologic malignancy, high SOFA score, need for vasopressors, renal replacement therapy, ARDS, severe hypoxemia, tachypnea during NIV, and delayed NIV application are predictors of NIV failure.[156,160] Therefore, NIV cannot be recommended in these patients.

Table 136.3 Calculation of HACOR Score to Predict NIV Failure

Variables	Category	Assigned Points
Heart rate (beats/min)	≤120	0
	≥121	1
Acidosis (pH)	≥7.35	0
	7.30–7.34	2
	7.25–7.29	3
	<7.25	4
Consciousness (Glasgow Coma Scale)	15	0
	13–14	2
	11–12	5
	≤10	10
Oxygenation (arterial Po_2/Fio_2)	≥201	0
	176–200	2
	151–175	3
	126–150	4
	≤100	6
Respiratory rate (breaths/min)	≤30	0
	31–35	1
	36–40	2
	41–45	3
	≥46	4

Points are assigned based on five physiologic variables according to specific categories and points above. Points are then added together for a total score ranging from 0 to 25. A score greater than 5 at 1 hour of NIV predicts failure in hypoxemic patients.

From Duan J, Han X, Bai L, Zhou L, Huang S. Assessment of heart rate, acidosis, consciousness, oxygenation, and respiratory rate to predict noninvasive ventilation failure in hypoxemic patients. *Intensive Care Med.* 2017;43(2):192–199.

PREVENTION OF POSTOPERATIVE COMPLICATIONS

Respiratory compromise complicates the course of approximately 10% of all surgical patients and almost 40% of patients undergoing an abdominal or thoracic surgery. NIV is becoming increasingly popular for the prevention or treatment of postoperative respiratory complications.[161–163]

Pathophysiology of Postoperative Respiratory Complications

After thoracic or upper abdominal surgery, the patient's pulmonary condition can worsen due to complications directly related to surgery, residual anesthesia, or pain. Major abdominal and thoracic surgeries and anesthesia may cause large reductions in functional residual capacity and transient diaphragmatic dysfunction leading to hypoxemia and/or hypercapnia. Perioperative fluid overload, high tidal volumes used during surgery, transfusion-related acute lung injury, inflammation, sepsis, and aspiration may further worsen respiratory function. Respiratory deficits are maximal in the first hours after surgery and generally recede over 1 or 2 weeks. Restoring lung volume, preventing atelectasis, improving gas exchange, and decreasing the work of breathing may be achieved through different forms of NIV, including CPAP.[161–163] The use of postoperative NIV has been advocated for both prophylactic and treatment purposes.[162,164,165]

Prophylactic NIV in the Postoperative Period

Institution of NIV early after extubation in postoperative obese patients improved oxygenation and lung function by preventing the development of atelectasis.[166–168] Early CPAP for at least 6 hours following thoracic or major abdominal surgery significantly reduced pulmonary complications and reintubation rate compared to standard care in several trials.[169–171] A 2014 multicenter trial, however, failed to demonstrate any benefit of postoperative NIV in COPD patients undergoing major lung resection.[172]

Therapeutic NIV in the Postoperative Period

NIV has been shown to improve outcomes when used as a treatment for respiratory failure after major surgery.[9,161,162,165,172–176] In a large multicenter randomized trial of 293 patients with postoperative ARF following abdominal surgery, when compared with standard oxygen therapy, NIV was associated with a decrease in the intubation rate (33% vs. 46%) and health care–associated infections (31% vs. 49%).[176] However, the ICU and hospital lengths of stay and mortality rate did not significantly differ in these studies.[165,176]

Overall, NIV (including CPAP) can be used after major surgery, either as a semi-preventive tool in hypoxemic patients or as a therapeutic tool to reduce the rate of pulmonary complications and reintubation.[19] More data are needed to assess whether this is associated with a decrease in mortality. Because the risk of surgical complications induced by positive-pressure ventilation is unclear, it is probably wise to keep airway pressures at the lowest effective level.[175]

Chest Trauma

Respiratory failure following trauma is not a classical indication for NIV, and its efficacy in systematic review analysis is, for the most part, unclear.[177,178] To date there are only three randomized trials in severe chest trauma: two compared CPAP with intubation and one compared BPAP with high-flow oxygen mask.[179–181] The results indicated no significant effect on mortality but suggested a potential benefit with regard to ICU and hospital length of stay, intubation rate, and incidence of pneumonia.

DO-NOT-INTUBATE PATIENTS

NIV is now used frequently in patients in whom intubation is not desirable.[182–188] This approach is feasible and often well tolerated, with an overall survival rate of 50–70%, depending on the patient population.[182,183] An important distinction should be made between NIV administered as the upper limit of care versus NIV as part of palliative care to relieve dyspnea at the end of life.[183,186] Regarding the first indication, NIV offers an interesting possibility to improve a substantial number of patients, and its application in do-not-intubate patients is not associated with a decline in health-related quality of life, mental health, anxiety, depression, or posttraumatic stress disorder of patients and their relatives.[189] We have only limited information on the real benefit of NIV in purely palliative care.[184,186] NIV in end-of-life patients aims to alleviate dyspnea and anxiety and to allow communication. Therefore, its use should be discouraged in patients who do not tolerate it and in those with decreased level of consciousness.

DURING THE WEANING PROCESS AND POST-EXTUBATION

Weaning

Approximately one-third of invasively ventilated patients experience difficulties in weaning, and extubation to NIV may accelerate the weaning process.[190,191] This approach was examined in several trials with contradictory results.[117,190-193] Times to extubation were usually reduced, but this was not consistently translated into a reduction in hospital and ICU stay and mortality because the total duration of ventilation was not reduced.[117,190,192,194,195] Nosocomial pneumonia and sepsis were either reduced or remained unaffected.[117,190] In the most recent multicenter trial, 364 patients who failed a spontaneous breathing trial were randomized to either early extubation to NIV or continued invasive ventilation until a successful spontaneous breathing trial.[192] The two strategies were identical in terms of liberation from MV, reintubation, tracheostomy, adverse effects, and survival. In a meta-analysis, weaning with NIV reduced mortality at hospital discharge, the incidence of VAP, the duration of invasive ventilation, and the ICU length of stay compared with standard weaning.[196] Greater benefits were seen in COPD patients, with some uncertainty about the effects of NIV weaning in the non-COPD population.

Post-extubation

In the post-extubation period, NIV can be used either to prevent the development of ARF or as a strategy to avoid reintubation when ARF develops. As a preventive measure, routine application of NIV in unselected non-high-risk patients does not reduce reintubation or mortality rates and is not supported by available data.[197] By contrast, in patients at high risk of extubation failure (i.e., >65 years, respiratory or cardiovascular comorbidities), NIV prevents post-extubation respiratory failure, reduces reintubation and, possibly, mortality.[198–203] The protective effect of NIV after extubation is greater in patients intubated due to respiratory acidosis or heart failure.[204]

NIV has been proposed as a way to minimize reintubations in the approximately 10–20% of critically ill patients who fail extubation.[205,206] However, available studies suggest that when post-extubation respiratory failure has developed, delivering NIV is often futile and, indeed, may delay reintubation and increase mortality.[199,207] In a landmark trial by Esteban et al., NIV use in patients who failed extubation significantly increased mortality, whereas a potential benefit was suggested only in patients with known COPD.[207]

In conclusion, in the post-extubation period, NIV use is justifiable only as a way to prevent ARF in selected patient populations such as patients with advanced age, underlying cardiac or respiratory disease, prolonged duration of MV, and/or hypercapnia during the weaning test. If these patients were invasively ventilated for more than 24 hours, NIV should be applied immediately after extubation, before the development of ARF.[19,208]

PREVENTIVE USE DURING PROCEDURES

Endoscopic Procedures

Endoscopic procedures of the airway, cardiac, and gastrointestinal tract are relatively invasive, often necessitate sedation, and may adversely affect gas exchange, lung mechanics, and hemodynamics. Respiratory failure is often severe, especially in patients with poor respiratory reserve.[209,210] The periprocedural NIV use can be beneficial in many ways: (1) before the procedure to preoxygenate the patient and increase the respiratory reserve, (2) during the procedure to prevent or treat alveolar derecruitment and compensate for the extra work of breathing imposed by the procedure, and (3) after the procedure to enhance patient recovery.[211] NIV is mostly studied during bronchoscopy in at-risk patients where it has been shown to improve oxygenation and lower the incidence of respiratory failure necessitating ventilator support.[61,212–216] This may translate into a reduction of procedure-related intubations, although more studies are necessary to answer this question.

Endotracheal Intubation

Severe hypoxemia during intubation of hypoxemic patients is common. Compared with bag-valve-mask, NIV preoxygenation could improve arterial P_{O_2} levels with a lower incidence of desaturations during the intubation procedure.[217] In patients already receiving NIV, discontinuation of NIV and preoxygenation with bag-mask has been associated with significantly increased adverse events.[218]

EPIDEMIOLOGY OF NONINVASIVE VENTILATION IN ACUTE CARE

Three multicenter international observational studies with up to 8000 patients, performed in 1998, 2004, and 2010,[219–221] showed that the use of NIV progressively increased from less than 5% to around 15% of all admitted ICU patients, with a consistent success rate and therefore a higher number of patients avoiding the need for intubation. A greater number of patients with COPD or heart failure were also successfully treated with NIV outside the ICU. Similar observational studies in France[26,182,222–224] showed a major increase in NIV use as first-line ventilation support for all ICU patients requiring MV. BPAP was the most used ventilatory mode (83%), followed by CPAP (8%) and assist-control ventilation (7%).[133] In the most recent French observational study,[182] NIV use continued to increase, but interestingly, with a slight but significant decrease in patients with hypoxemic ARF. Acute hypercapnic respiratory failure and acute CPE remain the most frequent indications for NIV. The type of hospital may affect the frequency of NIV use, with one study demonstrating that non-university hospitals use NIV to treat acute-on-chronic lung disease more frequently than university hospitals.[225]

HOME NONINVASIVE VENTILATION

Epidemiology

Home NIV refers to the long-term (>3 months) daily application of mechanical ventilation in the home setting through a nasal, oral, or oronasal interface.[226] Prescription of home NIV has massively increased over the past decades as a result of the increasing prevalence of obesity-hypoventilation and COPD. Major technologic improvements in ventilators and interfaces, with a progressive shift from volume-cycled to less expensive, lighter, and often more comfortable pressure-cycled ventilators, have also contributed to accelerating this approach.[226,227] The EuroVent Survey[226] studied patterns of home ventilator use in 16 European countries. The prevalence of patients receiving long-term ventilation varied widely between countries, with an overall average of 6.6 per 100,000. Although identical surveys are not available for the North American population, the prevalence is expected to be similar in the United States and Canada.[228,229] Herein we review the pathophysiology of respiratory failure in lung disease and main indications for home NIV, with special attention to the three major indications (neuromuscular diseases [NMD], obesity hypoventilation syndrome [OHS], and COPD). Monitoring of home NIV is also discussed.

Pathophysiology

Hypoventilation becomes chronic when the respiratory system becomes unable to cope with the metabolic production of CO_2 and maintain arterial P_{CO_2} within normal limits as a result of respiratory system load capacity imbalance.[230] In chest wall dysfunction and NMD, a typical vicious circle of decline begins with rapid eye movement sleep hypoventilation and bicarbonate retention. As diaphragm dysfunction progresses, non–rapid eye movement sleep hypoventilation appears and progresses to daytime hypercapnia.[231] The clinical course in COPD is most often punctuated with episodes of acute-on-chronic respiratory failure related to chest infections. Therefore, aims and targets of home NIV may not necessarily be the same for all disease categories.

Indications for Home NIV

Subjects with a condition known to cause alveolar hypoventilation should undergo regular workups to determine whether they are eligible for home NIV. Early symptoms suggestive of sleep hypoventilation should be specifically sought, such as excessive daytime sleepiness, fatigue,

morning headaches, cognitive dysfunction, depression, and dyspnea.[232] The American Academy of Sleep Medicine[233] defines hypoventilation during sleep as (1) arterial carbon dioxide (or a surrogate such as transcutaneous or end-tidal CO_2) greater than 55 mm Hg for 10 minutes or more or (2) an increase in arterial P_{CO_2} greater than 10 mm Hg from awake supine value to a value exceeding 50 mm Hg for 10 minutes or more. In addition to monitoring of early symptoms and detection of sleep hypoventilation, regular assessment of respiratory function and inspiratory muscle strength is essential for the decision to implement NIV electively for the prevention of acute respiratory failure, especially in NMD. Measuring vital capacity is highly reproducible, and decreases in vital capacity should lead to further investigations when it falls below 50% of the predicted value. Measurement of supine vital capacity is a sensitive marker of diaphragmatic dysfunction, and a fall greater than 15% when supine compared to sitting correlates well with orthopnea[234]; a decrease of greater than 20% is highly suggestive of diaphragmatic dysfunction. Inspiratory muscle strength (e.g., sniff nasal inspiratory pressure and maximal inspiratory mouth pressure) can easily be assessed with inexpensive portable devices. The former may be easier to perform in NMD, but both measurements are complementary. A negative pressure lower than −70 cm H_2O for men and −60 cm H_2O for women reasonably excludes significant inspiratory muscle weakness.[235]

Special Features in NMD

The clinical course of respiratory failure in NMD is dictated by the natural history of the underlying condition. Some conditions remain stable for decades with reported survival rates greater than 90% at 5 years, whereas others are slowly progressive or rapidly fatal. Therefore, the timing and frequency of clinical evaluation should take into account the underlying neurologic diagnosis. In NMD, an indication for home NIV is based on the reversal of early symptoms of hypoventilation and improvement of *quality of life* (QoL) in patients treated by NIV.[236] Treating subjects with an isolated nocturnal hypoventilation may be warranted. In a randomized controlled trial of NIV in NMD patients with nocturnal hypoventilation and daytime normocapnia, most patients in the control group required initiation of NIV within a few months after documentation of sleep hypoventilation.[237] Those treated by NIV had improved health-related QoL, whereas others were more likely to be admitted with acute-on-chronic ventilator failure.

Amyotrophic lateral sclerosis shares many similarities with other NMDs, but its rapid evolution requires a closer follow-up and more frequent respiratory assessment, usually every 3 months. In a randomized trial, Bourke et al. demonstrated that initiation of NIV resulted in a significant survival advantage of approximately 7 months in amyotrophic lateral sclerosis patients with mild to moderate bulbar involvement and either daytime hypercapnia or orthopnea but did not improve survival in those with severe bulbar involvement.[238]

Special Features of OHS

OHS is defined by the combination of obesity (body mass index > 30 kg/m^2), daytime hypercapnia (arterial P_{CO_2} > 45 mm Hg) during wakefulness, and sleep-disordered breathing in the absence of other causes of hypoventilation.[239] Prevalence of OHS is low in the general population, but reaches 10–20% in patients attending sleep clinics and 50% in patients hospitalized with a body mass index greater than 50 kg/m^2.[240] Pathophysiologic mechanisms include impaired respiratory mechanics with increased work of breathing, upper airway obstruction responsible for sleep-disordered breathing, and decreased respiratory drive.[241]

The choice of CPAP or BPAP for the initial management of OHS remains a complex issue. Several studies have evaluated the impact of CPAP versus BPAP therapy on short- and medium-term physiologic outcomes in patients with stable clinical condition with none showing superiority on resolution of respiratory failure.[242–244] In a 2015 large, multicenter trial, long-term patient-oriented outcomes and physiologic outcomes (hospital resource utilization, cardiovascular events, mortality, arterial blood gases, spirometry, quality of life, and side-effects) were also similar between CPAP and BPAP.[244] Taking into consideration the data from available literature as a whole, the majority of stable OHS patients with *obstructive sleep apnea* (OSA) can efficiently be treated with first-line treatment of CPAP. It is plausible that BPAP might have superior effectiveness in selected subgroups of patients. BPAP can therefore be recommended for (1) episodes of acute-on-chronic respiratory failure, (2) ineffective CPAP therapy (persistence of hypercapnia or respiratory events under CPAP, intolerance to high-pressure CPAP), and (3) when the patient has clinical characteristics strongly associated with the persistence of hypercapnia despite effective CPAP treatment (e.g., coexistence of another cause of chronic respiratory failure, very severe hypercapnia at initial presentation, low apnea-hypopnea index). Therapy with BPAP should also be assessed when the patient is in stable condition (Fig. 136.3), such as after a few months of treatment after acute hypercapnic respiratory failure,[245] or in patients with OHS who have experienced a significant weight loss.

During BPAP, expiratory positive airway pressure and inspiratory airway positive pressure can be titrated individually. Expiratory positive airway pressure is progressively increased to correct apnea and hypopnea due to obstructive physiology, and IPAP to correct hypoventilation. Use of "spontaneous" versus "spontaneous/timed" mode is under debate. In spontaneous mode, there is no backup rate, and the patient determines both the respiratory rate and the time spent in inspiratory airway positive pressure (within the set inspiratory airway positive-pressure time limits). In the spontaneous/timed mode, a backup rate is set and, if the patient does not initiate a breath within a specified time window, the NIV device will deliver a breath. The 2012 American Academy of Sleep Medicine recommendations suggest that the default setting should be "spontaneous" unless central sleep apnea is documented. However, recent clinical data have highlighted the importance of setting a backup respiratory rate when using NIV in OHS with OSA but no previously documented central sleep apnea. One study in OHS subjects on long-term NIV showed that spontaneous mode was associated with additional respiratory events, mainly central sleep apnea and mixed respiratory events, compared with spontaneous/timed mode.[246] Data from a randomized crossover trial comparing standard NIV titration to average volume-assured pressure support (AVAPS, Philips

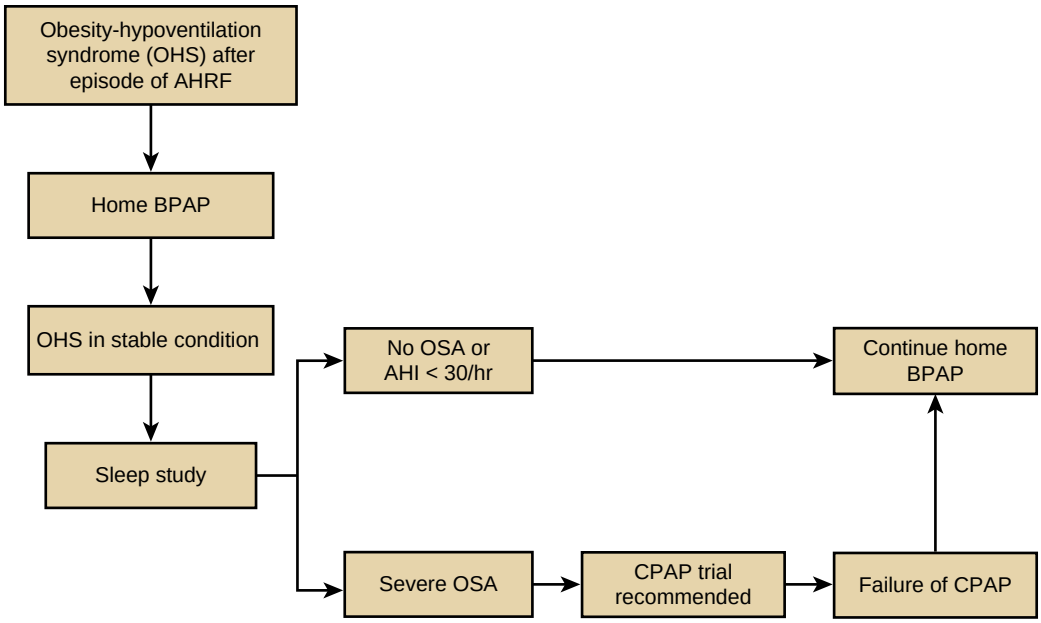

Figure 136.3 Home noninvasive ventilation in *obesity-hypoventilation syndrome* (OHS). Although *continuous positive airway pressure* (CPAP) is usually adequate for treatment of OHS, home *bilevel positive airway pressure* (BPAP) is recommended in patients with OHS after an episode of *acute hypercapnic respiratory failure* (AHRF). Ongoing need for BPAP therapy should be assessed a few months after hospital discharge and, if OSA is identified, changing to CPAP therapy may be an option. NIV, noninvasive ventilation; OSA, obstructive sleep apnea; AHI, apnea-hypopnea index.

Respironics) confirmed that controlled ventilation, defined as less than 50% of patient-triggered cycles, is associated with improved daytime arterial P_{CO_2}, better control of nocturnal hypoventilation, and improved health-related quality of life at 3 months in a post hoc subgroup analysis.[247]

Because cardio-metabolic comorbidities are important drivers of outcome in this population, cardio-metabolic and inflammatory markers should be sought for and treated. In a randomized trial with unselected OHS patients, inflammatory markers, endothelial function, and arterial stiffness were not improved after 1 month of NIV, although blood gas measures and sleep quality had improved.[248] We conclude that there is a need for a multimodal approach combining NIV therapy, lifestyle interventions, and rehabilitation programs to reduce the cardio-metabolic burden of OHS.[249,250]

Home NIV for Chronic Hypercapnic COPD

NIV is recommended for patients with ARF leading to acute or acute-on-chronic respiratory acidosis (pH ≤7.35) due to COPD exacerbation.[19] On the other hand, use of home NIV for chronic hypercapnic COPD has long been controversial. Results of early studies using a *lower level of pressure support* have been conflicting: some have yielded clear negative findings,[251] whereas others have demonstrated some improvements in dyspnea and reduced mortality after adjustment for confounders, but at the cost of a worsened QoL.[252] Most experts claim that effective delivery of pressure support to reduce arterial P_{CO_2} to a normal range or to achieve a 20% reduction in arterial P_{CO_2} is mandatory to improve QoL, readmission rates, and mortality.[253] Consequently, trials using high-intensity NIV (with higher pressure support) have been designed to address this knowledge gap. In a trial of high-intensity NIV in stable chronic hypercapnic patients, Köhnlein et al. reported a significant reduction in 12-month mortality (12% vs. 33% in the control group), as well as improvements in daytime arterial P_{CO_2}, exercise capacity, and health-related QoL.[254] Conversely, Struik et al. enrolled 201 patients surviving hypercapnic ARF after at least 48 hours without NIV. There were no significant differences between the 2 groups at 1 year in readmission rates, deaths, exacerbations, lung function, and health-related QoL.[255] In a United Kingdom trial, the authors enrolled 116 patients based on resolution of acidosis and persistent hypercapnia for at least 2 weeks but no more than 4 weeks after hospital admission for hypercapnic ARF. Time to readmission or death was significantly longer in the home NIV group compared with the oxygen alone group (4.3 months vs. 1.4 months, respectively).[256] Overall, newer studies using higher levels of NIV suggest that home NIV to treat chronic hypercapnic respiratory failure in patients with COPD may be beneficial, but a substantial degree of equipoise on this topic remains.

Evaluation and treatment of major comorbidities in COPD patients surviving the ICU may also be important to improve outcome. OSA and COPD are among the most prevalent chronic diseases and represent a major economic burden for health care systems worldwide.[257,258] Undiagnosed comorbidities, including OSA or heart failure in COPD patients surviving the ICU, are frequent[259,260] and may be associated with worse outcomes. The overlap syndrome (coexistence) of OSA and COPD is characterized by profound nocturnal hypoxemia and a higher risk of pulmonary hypertension and right heart failure. OSA and COPD share an increased burden of systemic inflammation via the activation of transcriptional factors (nuclear factor-κB and hypoxia-inducible factor-1), oxidative stress, sympathetic overactivity, and endothelial dysfunction.[261] Thus, it can be expected that cardiovascular diseases are more prevalent in patients with the overlap syndrome compared to either

OSA or COPD alone. While new OSA has been found to be highly prevalent in survivors of critical illness due to acute hypercapnic respiratory failure (the majority of whom have COPD), traditional screening questionnaires seem to perform poorly to diagnose OSA in this population compared with lung function assessment.[259] In a large prospective cohort with a median follow-up of 9.4 years, Marin et al. demonstrated that the coexistence of COPD and OSA is associated with an increased risk of death from any cause and more hospitalizations for COPD exacerbations.[262] Although there are no data from a randomized controlled study, most experts strongly encourage treatment of concomitant OSA and COPD with nocturnal NIV therapy. When OSA predominates, CPAP therapy is the most appropriate therapy. Recommendations for home NIV in COPD are summarized in Table 136.4.

Importance of Monitoring Home NIV

Patients using home NIV may develop unintentional leaks; residual respiratory events of obstructive, central, or mixed origin; patient-ventilator asynchrony; unrewarded inspiratory efforts; and periodic breathing.[263] These problems may have detrimental effects on quality of sleep and control of hypoventilation. A stepwise approach with specific goals is therefore recommended in order to adapt ventilator settings and interface accordingly (Fig. 136.4).[264]

The medical history is important, although often nonspecific and sometimes surprisingly unremarkable, despite

Table 136.4 Recommendations for Home NIV in COPD

- Use of home NIV is suggested in chronic stable hypercapnic patients (arterial P_{CO_2} > 52 mm Hg) with severe COPD.
- Use of home NIV is suggested after an acute episode of hypercapnic respiratory failure only if hypercapnia (arterial P_{CO_2} > 48 mm Hg) persists 2 to 4 weeks after the acute episode.
- When implementing NIV in COPD patients with CHRF, settings should be adjusted to decrease arterial P_{CO_2} below 48 mm Hg or reduce arterial P_{CO_2} levels by more than 20% of baseline level.
- When implementing home NIV in COPD, fixed pressure mode should be preferred to auto-titrating modes as first choice mode.

CHRF, chronic hypercapnic respiratory failure; NIV, noninvasive ventilation.

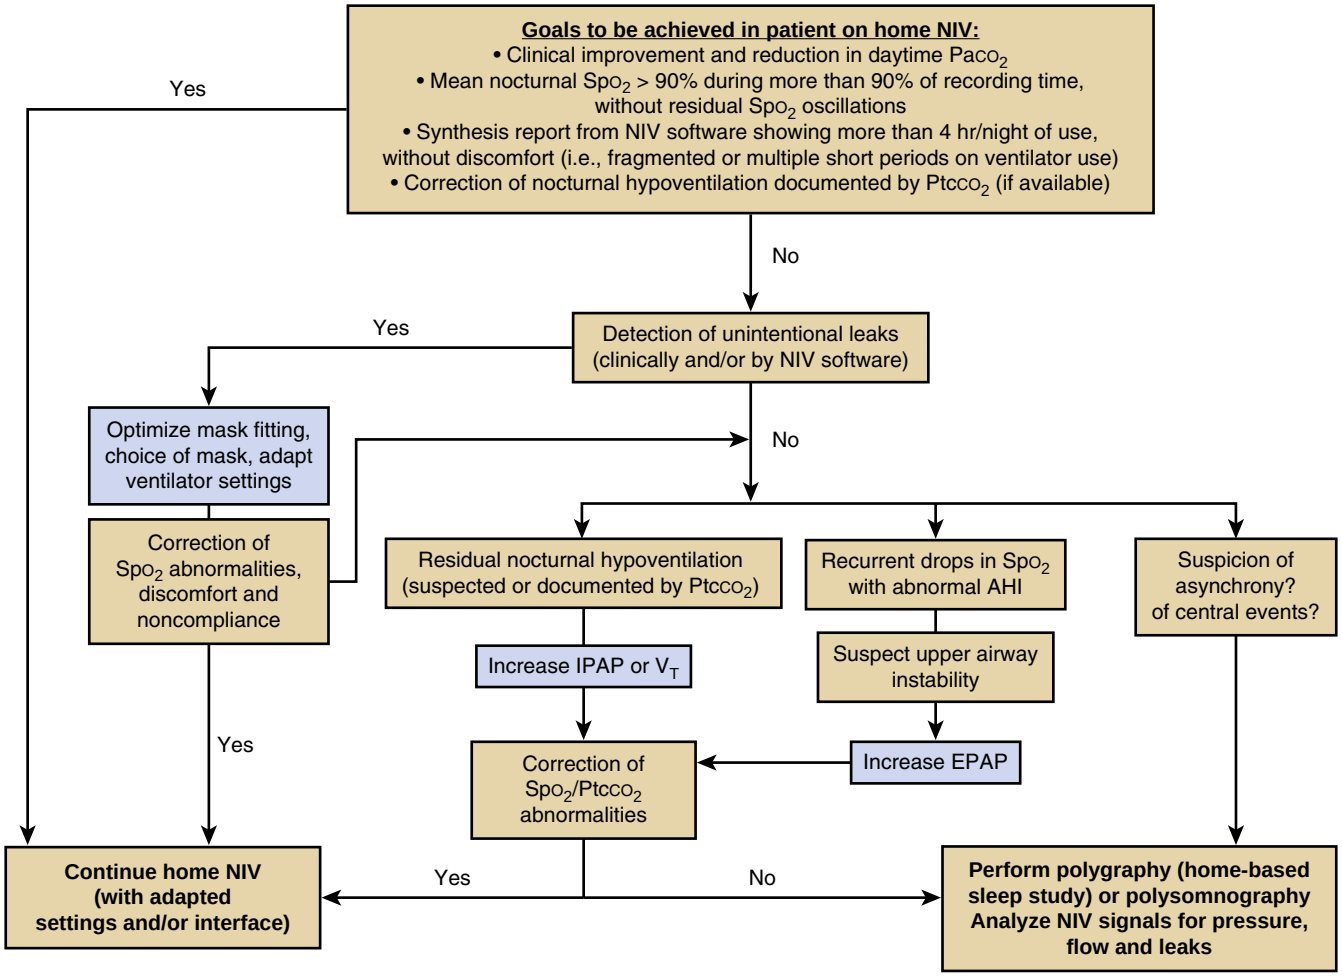

Figure 136.4 Stepwise approach to *noninvasive ventilation* (NIV) home monitoring to adapt ventilator settings and interface accordingly. At each monitoring visit for NIV, all of the goals in the box at the top of the algorithm should be reviewed. If they are met, home NIV should be continued. If any are not met, the presence of unintentional leaks should be evaluated. When leaks are present, steps on the left side of the algorithm should be taken to reduce them. If unintentional leaks are not found, lack of optimal treatment or improvement could be due to residual nocturnal hypoventilation, recurrent decreases in oxygenation with abnormal *apnea-hypopnea index* (AHI), NIV asynchrony, or central apneic events. Steps to evaluate each of those options are shown in the lower right of the algorithm. $Ptcco_2$: partial pressure of transcutaneous carbon dioxide; Spo_2, oxygen saturation detected by oximetry; IPAP, inspiratory positive airway pressure; V_T, tidal volume; EPAP, expiratory positive airway pressure. (Modified from Elliott MW, Nava S, Schönhofer B, eds. *Non-Invasive Ventilation and Weaning: Principles and Practice*. Boca Raton, FL: CRC Press, 2019.)

significant nocturnal respiratory events. Disease-specific health-related QoL questionnaires may be helpful to assess patient-oriented outcomes as a complement to physiologic monitoring of NIV. Indeed, most important domains of life affected by respiratory failure remain unexplored by physiologic monitoring. The Severe Respiratory Insufficiency Questionnaire[265] and the Maugeri Respiratory Foundation Questionnaire-28[266] are often used to assess patient-reported outcomes. However, their length and complex scoring algorithms limit their use in everyday clinical practice. Moreover, treatment-related side effects of NIV are not covered by these questionnaires. The S[3]-NIV questionnaire, an 11-item, short, self-administered tool, was designed to provide clinicians and patients with a simple and reliable tool to assess respiratory symptoms, sleep quality, and NIV-related side effects as a complement to physiologic monitoring.[267]

Pulse oximetry remains a simple tool to ensure that adequate oxygen saturation is provided and to detect short recurrent or prolonged desaturations. However, oximetry alone cannot distinguish between hypoxemia caused by ventilation-perfusion mismatch and that caused by alveolar hypoventilation. The addition of transcutaneous capnography will allow this discrimination.[268] Built-in software of home ventilators can provide informative data about compliance, pattern of NIV use, mask leaks, tidal volume, and residual apnea-hypopnea index.[268] Multichannel ventilator modules combining oxygen saturation measurement with estimation of leaks and minute ventilation have been shown to be reliable.[269] Unfortunately, the accuracy of estimated minute ventilation and leaks by the ventilator varies from one device to another,[270] and independent validation studies are still warranted for all commercially available ventilators. Finally, in OHS patients treated with NIV, a substantial agreement between automated apnea-hypopnea indexes derived from the ventilator software and manually scored apnea-hypopnea indexes using respiratory (home-based) polygraphy has been observed.[271,272]

As a rule, a stepwise approach to monitoring home NIV with simple tools is recommended as a first step. Resorting to polygraphy or polysomnography to optimize NIV settings is recommended only if targeted arterial P_{CO_2} reduction is not reached, if recurrent or prolonged alveolar oxygen saturation drops are still observed despite correction of unintentional leaks, or if NIV is poorly tolerated.[273]

Key Points

- The use of *noninvasive ventilation* (NIV) in the acute setting has increased markedly over the past decades. National and international multicenter studies have demonstrated that NIV is used in 30–52% of patients who are not intubated at the time of ICU admission.
- NIV can improve physiologic parameters, relieve dyspnea, reduce the invasiveness of patient management, and improve important clinical outcomes such as intensive care unit and hospital stay, complications, and mortality. There is convincing evidence that NIV diminishes the risk of nosocomial infections.
- The beneficial effects of NIV are best demonstrated in patients with acute exacerbation of COPD, obesity-hypoventilation syndrome, and cardiogenic pulmonary edema. In these settings, NIV is recommended as an important component of first-line therapy to prevent further deterioration. Outside of these settings, use of NIV in hypoxemic acute respiratory failure is controversial, and patients must be assessed carefully to ascertain which ones may benefit and which ones may be harmed by use of NIV because of a delay in intubation.
- NIV may be useful during the post-extubation process, as a preventive tool during the weaning process, or during various procedures such as fiberoptic bronchoscopy.
- NIV success is strongly associated with good clinical tolerance. Problems with tolerance can be related to the patient, the interface, the ventilator, and/or the ventilator settings. Mask leaks lead to discomfort and patient-ventilator asynchrony, prolonged inspiration due to inspiratory leaks, and auto-triggering due to expiratory leaks. An optimal adjustment of ventilatory settings may improve patient-ventilator synchrony, work of breathing, comfort and, potentially, the success of noninvasive ventilation.
- The interface is an essential component for NIV. In the acute care setting, the oronasal mask or full face mask is the usual first choice. On the basis of recent evidence, the helmet can be used as a first-line interface, especially in patients who need high positive airway pressures and are intolerant of face masks. There is no ideal interface for all patients, and several interfaces should be available at the bedside.
- NIV is the standard of care for home ventilation. Subjects with a condition known to cause alveolar hypoventilation should be evaluated regularly to determine whether they are eligible for home NIV.

137 NONINVASIVE SUPPORT OF OXYGENATION

SHIJING JIA, MD • ROBERT C. HYZY, MD

INTRODUCTION
INDICATIONS FOR OXYGEN THERAPY
DEVICES AND INTERFACES
Low-Flow Systems
Reservoir Systems
High-Flow Systems
INDICATIONS FOR HIGH-FLOW NASAL CANNULAS
Acute Hypoxemic Respiratory Failure
Cardiogenic Pulmonary Edema
Other Hypoxemic Lung Diseases
Hypercarbic Hypoxemic Respiratory Failure
Post-extubation Support
Preoxygenation for Intubation
Perioperative Period and During Procedures
Patients Near the End of Life or Not Wishing to be Intubated
KEY POINTS

INTRODUCTION

Oxygen gas was first discovered in the 1700s and was subsequently produced for inhalation at the turn of the 19th century.[1,2] By the early 20th century, oxygen was widely prescribed to patients with a variety of respiratory ailments; this oxygen therapy used nasal cannulas and tented simple face masks with rubber tubing.[1] In the modern era, oxygen has been used to treat cases of hypoxemia as well as to support patients who were thought to be at risk for hypoxemia. However, there is now clear evidence indicating the toxicity of hyperoxia; thus, oxygen supplementation should be provided only to patients with moderate to severe hypoxemia.

Hypoxia describes a state of inadequate oxygen content at the cellular level. *Hypoxemia* is a decrease in oxygen content in the blood. There can be states of cellular hypoxia in the absence of arterial hypoxemia. However, hypoxemia typically leads to tissue hypoxia. The symptoms of hypoxia can vary from mild to severe and may include serious organ dysfunction or death.

INDICATIONS FOR OXYGEN THERAPY

See ExpertConsult.com for an extended discussion; see also Chapters 10 and 44.

Current recommendations suggest oxygen supplementation in patients with hypoxemia to achieve targets such as arterial Po_2 or peripheral oxygen saturation. The British Thoracic Society guidelines for oxygen use in adults recommend a target peripheral oxygen saturation of 94–98%, corresponding to an arterial Po_2 range of 75 to 100 mm Hg.[20] However, Acute Respiratory Distress Syndrome Network trials classically target peripheral oxygen saturation ranges of 88–95% or arterial Po_2 of 55 to 80 mm Hg in acute hypoxemic respiratory failure.[21,22] In general, peripheral oxygen saturation of 90% or higher is likely sufficient for most patients requiring oxygen supplementation. The exception is in patients with obstructive lung disease at risk of hypercapnia, in whom higher oxygen targets have been associated with an increased incidence of carbon dioxide retention and death.[23,24] Thus, oxygen supplementation for patients at risk for hypercapnic respiratory failure should be titrated to a target peripheral oxygen saturation of 88–92% or an arterial Po_2 of 55 to 65 mm Hg.[20] Oxygen should be decreased once a patient recovers from an acute hypoxic illness and no longer needs supplementation.

The purpose of noninvasive oxygenation is to provide respiratory support to patients with hypoxemia who do not yet require invasive mechanical ventilation. The evidence presented in this chapter aims to guide the proper use of contemporary noninvasive oxygen therapy modalities that can suffice in many situations that would have otherwise progressed to intubation before these modalities were available.

DEVICES AND INTERFACES

Low-flow noninvasive oxygenation systems depend on a set flow rate of pure oxygen relative to the volume of ambient air inhaled during breathing to achieve a desired fractional concentration of oxygen in inspired gas. *Reservoir* systems increase the maximum effective delivery of fractional concentration of oxygen in inspired gas by increasing the fraction of pure oxygen inspired relative to ambient air. Table 137.1 contains the approximate fractional concentration of oxygen in inspired gas delivered with each device at various flow rates. *High-flow* systems aim to deliver flow rates that exceed respiratory needs to achieve accurate set delivery of fractional concentration of oxygen in inspired gas.

The goal of oxygen therapy is to avoid the negative consequences associated with tissue hypoxia. Because blood oxygen content is used as a surrogate for tissue oxygen delivery, current guidelines recommend oxygen supplementation in hypoxemic patients. Hypoxemia can be assessed by measuring the oxygen tension in an arterial blood gas test (arterial partial pressure of arterial oxygen [arterial Po_2]) or the fraction of hemoglobin saturated with oxygen either by arterial blood gas (% oxyhemoglobin, *arterial oxygen saturation*) or pulse oximetry (peripheral oxygen saturation). A normal arterial Po_2 ranges from 75 to 100 mm Hg at sea level, corresponding to concentrations of greater than 95% of oxyhemoglobin within the normal spectrum of oxygen-hemoglobin association. Hypoxemic respiratory failure is defined as an arterial Po_2 of less than 60 mm Hg. However, the arterial Po_2 can drop to as low as 30 to 40 mm Hg in a healthy person at high altitudes because of the decreasing atmospheric oxygen tension with increasing elevation.[3] Thus, values of laboratory results should be interpreted with consideration of the clinical context.

Arterial oxygen content and thereby oxygen delivery are more dependent on arterial oxygen saturation than on the absolute value of the arterial Po_2, according to the following equations:

Oxygen delivery = Cardiac output × Arterial oxygen content

Oxygen delivery = Cardiac output × [(Hemoglobin × 1.360 × % Arterial saturation) + (Arterial Po_2 × 0.0030)]

Hence, supplemental oxygen that increases saturation to acceptable levels (see later for recommended range) in a hypoxemic patient has a significant impact on oxygen delivery.

Oxygen is not without its side effects. Hyperoxia causes significant harm both at the lung tissue level and systemically, and it is associated with increased mortality in a variety of clinical settings. The mechanism of pulmonary toxicity seems to be twofold. First, high concentrations of oxygen produce free radicals that overwhelm the cellular detoxification machinery and can lead to cell injury and death. Histopathologically, hyperoxic lung injury is observed as tissue inflammation, capillary leak, cellular necrosis and apoptosis, and septal fibrosis in both animal models and human patients.[4–7] Second, oxygen washout of alveolar nitrogen can lead to *resorption atelectasis,* a process whereby the alveolar oxygen is absorbed more rapidly than replacement ventilation gas is provided and, as a result, alveoli may collapse at critically low volumes.[8,9] These detrimental effects are compounded with hyperoxia in the setting of increased alveolar pressures during positive-pressure ventilation.[10–13]

Systemically, hyperoxia produces generalized vasoconstriction, likely because of the regulatory mechanisms to reduce oxygen delivery needed to meet natural physiologic demands. In the heart, coronary vasoconstriction can lead to increased myocardial injury and decreased cardiac function.[14,15] Decreased cerebral blood flow in response to hyperoxia portends poor outcomes in patients with stroke and traumatic brain injury.[16] Hyperoxia is associated with increasing mortality in numerous clinical settings, particularly in patients with neurologic injury or after cardiac arrest.[17–19]

LOW-FLOW SYSTEMS

Nasal Cannula

Conventional nasal cannulas deliver pure source oxygen through simple nasal prongs at flow rates of 1 to 6 L/min (Fig. 137.1A). There is marginal improvement of oxygen delivery at flow rates higher than 6 L/min because of tubing resistance and increasingly turbulent air flow. Additionally, the velocity of gas felt by patients through small-bore nasal cannulas at high flow rates can be difficult to tolerate. The nasal cannula at appropriate flow rates between 1 and 6 L/min is generally well tolerated. The fractional concentration of oxygen in inspired gas delivered increases relative to the flow rate at approximately 3–4% per L/min, so that 6 L/min corresponds to a fractional concentration of oxygen in inspired gas of approximately 40–45%.[25] A caveat of this fixed low-flow delivery system is that the fractional concentration of oxygen in inspired gas fluctuates with the respiratory effort of the patient. As respiratory rate and tidal volumes increase in respiratory distress, increasing fractions of ambient air are inspired, thereby leading to lower levels of fractional concentration of oxygen in inspired gas delivered.[26,27] Additional limitations to the system include the requirement of nasal patency and unpredictable fractional concentration of oxygen in inspired gas with oral versus nasal breathing, with studies showing conflicting results. Long-term use of nasal cannulas at high flow rates can dry the nasopharyngeal mucosa, and humidification of source oxygen is advised.[20] An enhanced form of the conventional nasal cannula with three channels was initially called high-flow nasal cannula and could deliver flows up to 15 L/min, likely corresponding to an effective fractional concentration of oxygen in inspired gas of up to approximately 50–70% (Fig. 137.1B).[26,28] This nasal cannula is

Table 137.1 Estimated Effective Fractional Concentration of Oxygen in Inspired Gas of Low-Flow and Reservoir Oxygen Delivery Devices

Device	Flow (L/min)	Fio_2 (%)
Simple nasal cannula	2	28
	4	35
	6	40–45
Enhanced (Hudson) nasal cannula	10	50–60
	15	60–70
Simple face mask	5	35–40
	10	50–60
Partial rebreathing mask	10–15	50–75
Non-rebreathing mask	15	95

Fio_2, fractional concentration of oxygen in inspired gas.

(G) Nasal prong continuous positive airway pressure mask. (H) High-flow nasal cannula.

produced by Hudson RCI and is sometimes referred to as the Hudson nasal cannula. This should be not be confused with the heated *high-flow nasal cannula* (HFNC) capable of delivering flows of up to 60 L/min.

Simple Face Mask or Hudson Mask

The simple face mask provides a higher fractional concentration of oxygen in inspired gas than the traditional nasal cannula, and it is well tolerated by most patients (Fig. 137.1C). Flow rates can be adjusted from 5 to 10 L/min with a corresponding fractional concentration of oxygen in inspired gas of approximately 35–60%. However, as with nasal cannulas, the simple face mask is a fixed low-flow oxygen delivery system. As such, the effective fractional concentration of oxygen in inspired gas delivered to the patient is highly variable and depends on the patient's respiratory rate and tidal volume.[29,30] Because of a reservoir of 100 to 300 mL depending on the size of the face mask, flows of less than 5 L/min are not advisable, given the rebreathing of expired carbon dioxide, as well as increased resistance of the system during inspiration.[20,31,32] Although the simple face mask delivers higher levels of fractional concentration of oxygen in inspired gas than nasal cannulas, it has are some limitations. Patients cannot eat or drink without interruption of oxygen delivery. Additionally, long-term use can dry the oral and nasal mucosa, and humidification should be used. This mask was initially produced by Hudson RCI and is sometimes referred to as the Hudson mask.

RESERVOIR SYSTEMS

Partial-Rebreathing Mask

Partial-rebreathing masks are reservoir systems with a 600 to 1000 mL bag attached to a simple face mask. Source oxygen is delivered to the reservoir bag at a flow rate of 10 to 15 L/min but, at a minimum, at a rate to ensure inflation of the reservoir. Expired gas containing carbon dioxide and oxygen from dead-space ventilation partially fills the bag with each exhalation, and a mixture of this expired gas and fresh 100% oxygen is then rebreathed with the following inspiration. The increased fraction inhaled from the high concentration oxygen from the reservoir bag in relation to ambient air with each breath allows for higher fractional concentration of oxygen in inspired gas (50–75%, depending on the patient minute ventilation) to be delivered as compared with a simple face mask. The mask is comfortable and well tolerated by most patients, but it can be drying with long-term use and will interfere with oral intake. This mask has largely been replaced by the *non-rebreathing* (NRB) mask.

Non-rebreathing Mask

The fundamental distinction between a partial-rebreathing mask and an NRB mask is the addition of a one-way valve between the reservoir bag and face mask that prevents exhaled gases from entering the reservoir (Fig. 137.1D). To sustain inflation, the standard source oxygen flow for the NRB mask reservoir bag is 15 L/min, which can achieve an effective fractional concentration of oxygen in inspired gas of up to approximately 95%.[33,34] The NRB mask is recommended as the first-line oxygen delivery modality for patients initially presenting with severe hypoxemia (peripheral oxygen saturation < 85%).[20] As with other face masks, prolonged use can dry the mucosa. Additionally, the high fractional concentration of oxygen in inspired gas delivered can induce local pulmonary and systemic toxicity related to hyperoxia.

HIGH-FLOW SYSTEMS

Venturi Mask

The Venturi mask (Ventimask, Flexicare) is an air-entrainment mask developed by E.J. Campbell in 1967 that functions on the basis of the Venturi effect, or Bernoulli's principle (Fig. 137.1E). When a 100% source oxygen is pushed through a narrow channel, a low-pressure environment is created that entrains ambient air through apertures in close proximity to the tapered channel.[35–37] By varying the diameter of the tapered channel through which source oxygen flows and the size of the aperture through which ambient air is allowed to enter, an exceedingly accurate ratio of 100% oxygen and 21% ambient air can be delivered.[25] Current available models deliver a range of fractional concentration of oxygen in inspired gas from 24–50%. Additionally, the increased flow through the narrow source oxygen channel in combination with additional entrained air creates high total flow rates of up to 50 to 70 L/min delivered to the patients. To avoid dead-space ventilation from rebreathing expired gas in the mask, tachypneic patients may require higher than recommended source oxygen flow rates to maintain adequate flows. With sufficient flow, there is little variability of inhaled fractional concentration of oxygen in inspired gas with varying minute ventilation.[30,38,39]

A clear benefit of the Venturi mask is the fixed fractional concentration of oxygen in inspired gas delivered to the patient, a feature profoundly important in patients at high risk for complications related to excess oxygen. For quite some time, until the advent of HFNC, the Venturi mask was the only available device providing a fixed fractional concentration of oxygen in inspired gas. It is currently recommended as first-line oxygen therapy in patients at high risk for hypercarbia, such as in the case of obstructive lung diseases.[20] Although its high flows theoretically provide a small component of expiratory positive pressure, the Venturi mask is not comparable to and should not be substituted for *continuous positive airway pressure* (CPAP).[40,41]

Continuous Positive Airway Pressure

CPAP denotes a device that delivers continuous airflow at a fixed pressure throughout the respiratory cycle, typically through a full face mask (Fig. 137.1F), although nasal CPAP masks are also available (Fig. 137.1G). The full face mask covers the nose and mouth and should not be confused with the total face mask, which covers the entire face, including the eyes. Physiologically, CPAP can be provided either noninvasively through a face mask or invasively through an endotracheal tube, perhaps during a weaning trial before extubation. Although CPAP theoretically does not augment ventilation and can be thought of as purely a mechanism for the support of oxygenation by increasing the mean airway pressure, it is historically considered a mode of *noninvasive ventilation* (NIV). CPAP (and other NIV) is recommended for use in patients with respiratory failure

related to exacerbations of obstructive lung diseases and congestive heart failure.[42] Further discussion of invasive mechanical ventilation and NIV is provided elsewhere (see Chapters 135 and 136).

High-Flow Nasal Cannula

Heated HFNC delivers oxygen at rates of 40 to 60 L/min through large-bore nasal cannulas (Figs. 137.1H and 137.2). Several proprietary models are available, and all function similarly. Gas is delivered through an air-oxygen blender system to achieve a fractional concentration of oxygen in inspired gas of up to 100%. For adequate and accurate delivery of a fractional concentration of oxygen in inspired gas, the HFNC system must be set at high flow rates of 40 L/min or greater. Nasal prongs should not fully occlude the nares; instead, they should be fitted with at least a 50% gap to ensure adequate exhalation and avoid gastric distention. Humidification of gases is a standard addition to the system and is required for tolerability of the flow rates. Because maximum humidification of air, or relative humidity, is temperature dependent, HFNC units are heated to increase the humidity of delivered gases, to nearly 100% at 37°C. There are minor differences in various proprietary and locally assembled setups, but these general principles remain the same.

The most obvious benefit of HFNC is the titratable and predictable delivery of a fractional concentration of oxygen in inspired gas at high fractions. Additionally, HFNC has significant physiologic benefits in patients with hypoxemic respiratory failure. HFNC results in the application of a low level of CPAP. It has been variably estimated that each 10 L/min increase in flow generates from 0.3 to 1.0 cm H_2O CPAP.[43–46] This effect theoretically contributes to the capacity for oxygen support independent of the delivered fractional concentration of oxygen in inspired gas. As a consequence, several important physiologic benefits may accrue. In a prospective, randomized, crossover study, compared with an oxygen mask, treatment with HFNC not only caused a significant improvement in oxygenation but also decreased respiratory rate, minute ventilation, and pressure-time product, indicative of a decrease in work of breathing.[47] Tidal volume was unchanged, whereas end-expiratory lung volume increased, and the distribution of ventilation was more equitable throughout the lung. The high flow rates of HFNC also decrease physiologic dead space by reducing the fraction of rebreathed air in the upper airway, thereby providing a small fraction of ventilation support through carbon dioxide washout.[48] However, the support of ventilation is likely minimal. Thus, HFNC should not be used in place of NIV in patients needing primary ventilation support.

Another benefit of HFNC is patient comfort as compared with other high levels of oxygenation support. When compared with patients undergoing NIV, patients are generally much more tolerant of HFNC.[49] The difference is less pronounced when compared with *conventional oxygen therapy* (COT) delivery through a nasal cannula or simple face mask.[49] In a large trial comparing HFNC with COT or NIV in patients in the medical *intensive care unit* (ICU), patient comfort scores based on a visual analogue scale were best with HFNC,[50] but other studies have not shown such a significant benefit in patient comfort.[51,52]

Figure 137.2 High-flow nasal cannula in the intensive care unit. The patient is being treated with a high-flow nasal cannula for acute hypoxemic respiratory failure. This patient was successfully managed with noninvasive oxygenation for pneumonia in the setting of interstitial lung disease and mild emphysema.

INDICATIONS FOR HIGH-FLOW NASAL CANNULAS

HFNC has largely replaced many other oxygenation devices equipped to provide either high fractional concentration of oxygen in inspired gas or high airflow. Here we focus on adult patients with acute respiratory failure. In general, available evidence supports the use of HFNC in patients who have acute and acute on chronic respiratory failure with moderate to severe hypoxemia.

Indications in pediatric patients, in whom HFNC was first used, are discussed at ExpertConsult.com.

ACUTE HYPOXEMIC RESPIRATORY FAILURE

The primary indication for HFNC in adults is acute hypoxemic respiratory failure, particularly secondary to community- or hospital-acquired pneumonia. In meta-analyses of HFNC use in acute hypoxemic respiratory failure, the evidence advocates for the use of HFNC, particularly in patients with more severe hypoxemia.[63,64] Although the totality of the literature does not suggest a mortality benefit, the major benefit of HFNC is that fewer patients require escalation of therapy to intubation and mechanical ventilation, thereby reducing complications, including death, from invasive ventilation.[65]

HFNC is considered to be an aerosol-generating procedure, although the distribution of aerosolized secretions may in fact be quite modest.[66] Nevertheless, consideration should be given to its use in a negative-pressure environment in circumstances where patients with novel respiratory pathogens, such as severe acute respiratory syndrome coronavirus type 2, the agent of coronavirus disease 2019

PEDIATRIC POPULATIONS

HFNC was first used in pediatric patient populations to provide a fixed oxygen concentration through a nasal cannula while minimizing the side effects of hyperoxia in infants, such as bronchopulmonary dysplasia and retinopathy.[53] Although one study found that HFNC use in preterm neonates with respiratory distress was noninferior to nasal CPAP and NIV,[53] more recent evidence suggests that HFNC may be inferior to nasal CPAP, despite delivering a small amount of positive end-expiratory pressure and avoiding the complications associated with CPAP or NIV.[54] Given the limited evidence supporting HFNC in neonates, CPAP or NIV remains the treatment of choice for this age group.

The majority of the literature supporting the use of HFNC in the non-neonatal pediatric population is in patients with bronchiolitis, either as an initial modality for oxygen supplementation or, more importantly, as a rescue therapy when standard supplemental oxygen therapy fails. A large randomized controlled trial in infants with bronchiolitis (the PARIS study) completed through the Pediatric Research in Emergency Departments International Collaborative. compared HFNC at 2 L/kg/min with standard oxygen therapy in 1472 patients younger than 12 months.[55] Results showed that more infants randomized to standard oxygen required escalation of therapy compared with infants randomized to HFNC, although there was no increase in intubation rates, admission to the ICU, or duration of hospitalization or oxygen requirement. More notably, a majority (102 of 167; 61%) of patients in whom standard oxygen therapy failed were successfully rescued with HFNC. Similarly, a study in 202 children younger than 24 months with bronchiolitis showed higher rates of treatment failure leading to escalation of care in patients treated with standard oxygen therapy compared with HFNC, but without differences in clinical outcomes, including ICU admission and duration of therapy.[56] When compared with NIV, the superiority of HFNC is not established, particularly in children with more severe disease.[57,58]

If HFNC is used in neonates, initial flow rates should be set at 4 to 6 L/min and adjusted according to the patient's weight and clinical status.[59] In non-neonatal pediatric patients, a flow rate of 1 to 2 L/min/kg is likely sufficient.[60–62]

(COVID-19), are being treated, out of concern that aerosols generated by coughing may be augmented by HFNC use.[67]

Pneumonia

The most robust data supporting the use of HFNC are in patients admitted to medical ICUs with hypoxemic respiratory failure resulting from pneumonia. In a small open-label study comparing HFNC with Venturi mask after extubation, about one-half of the 105 randomized patients had resolving pneumonia.[68] Not surprisingly, in this population of hypoxemic individuals, the higher level of oxygen support with HFNC performed better in preventing episodes of hypoxemia, but it was also associated with fewer reintubation events. Following this, the first major clinical trial using HFNC in adults with acute respiratory failure (FLORALI) was published in 2015.[50] Frat and colleagues[50] randomized 310 patients with acute non-hypercarbic hypoxemic respiratory failure to HFNC, NIV, or an NRB mask. Most (82%) of these patients had acute hypoxemic respiratory failure resulting from pneumonia. Although the study did not reach a statistical difference in the primary outcome of need for intubation within 28 days, post hoc analysis showed a decreased rate of intubation among patients with a ratio of arterial Po_2 to fractional concentration of oxygen in inspired gas (P/F ratio) of 200 mm Hg or lower who were treated with HFNC when compared with NIV or standard oxygen through an NRB mask. Ventilator-free days, a secondary outcome, were significantly greater in the HFNC group. Additionally, even though the study was not powered to detect a mortality difference, there was a significant mortality benefit at 90 days with HFNC compared with either NIV or an NRB mask, with the majority of deaths caused by refractory shock. The mortality benefit should be interpreted with caution, however, given the aberrantly high mortality rates among all groups. These results attest to the known limitations of NIV in pneumonia,[42,69,70] and they also support a role for HFNC.

Several follow-up studies have been published, with a large proportion of study subjects having pneumonia as a cause of hypoxemic respiratory failure, although no study has specifically examined HFNC in this single diagnosis. In a large study of 604 patients, many of whom had a medical cause of respiratory failure, including pneumonia and *acute respiratory distress syndrome* (ARDS), HFNC was noninferior to NIV in post-extubation management and was associated with a shorter ICU length of stay and fewer adverse events.[71] Coudroy and colleagues[72] described the use of HFNC versus NIV in a cohort of 115 patients, one-half of whom had pneumonia, and rates of both intubation and mortality were higher in NIV. Limitations of this study include its observational design with the possibility of inherent bias as well as the immunocompromised status of the study population. In another large observational study of 1611 immunocompromised patients who mostly had pulmonary infections, HFNC was associated with lower rates of intubation and mechanical ventilation compared with NIV.[73] Most other subsequent studies were conducted in patients with acute hypoxemic respiratory failure, but often without stratification of the etiology of respiratory failure.[52,74] Taken together, current data suggest that HFNC is safe and may have benefit when compared with NIV in patients with acute hypoxemia from pneumonia. Additionally, in patients with acute hypoxemia who have absolute or relative contraindications to NIV, HFNC appears to decrease the need for invasive mechanical ventilation and perhaps mortality, and it should be used as an initial mode of oxygen therapy in patients who are not unstable enough to require immediate intubation.

Acute Respiratory Distress Syndrome

Although the diagnosis of ARDS requires a positive end-expiratory pressure of at least 5 cm H_2O delivered by either invasive or noninvasive mechanical ventilation,[75] most patients with severe hypoxemia who are treated with HFNC would otherwise meet Berlin criteria for ARDS. Furthermore, a significant portion of patients initially treated with HFNC who subsequently require NIV or mechanical ventilation remain hypoxemic (P/F ratio <300) and meet criteria for ARDS.[76]

A subgroup analysis of the FLORALI study showing benefit of HFNC in patients with a P/F ratio of 200 or lower suggests that perhaps the greatest benefit is seen in patients with more severe respiratory illness, such as in the case of early ARDS.[50] NIV may generate harmful large tidal volumes in hypoxemic respiratory failure and lead to worsened injury to the lung,[77] as suggested by the higher mortality in patients undergoing NIV in the FLORALI study and in patients with a P/F ratio lower than 150 in the LUNG-SAFE series.[78] Thus, the use of HFNC among patients with moderate to severe hypoxemic respiratory failure, especially those who appear to be progressing toward a diagnosis of ARDS, appears prudent.

Immunocompromise

Immunocompromised patients have a poor outcome in the ICU or when they receive a diagnosis of acute respiratory failure, and the requirement for intubation in this population is a predictor of increased mortality rate.[79] The initial trials using NIV in immunocompromised patients to avoid intubation and mechanical ventilation were relatively small and demonstrated a mortality benefit compared with either mechanical ventilation or COT.[80,81] Larger meta-analyses of pooled data confirmed the benefit of NIV in mortality and ICU length of stay.[82,83] However, in the most recent and largest multicenter trial of immunocompromised patients with acute respiratory failure, NIV did not perform significantly better than COT alone.[84]

Since the advent of HFNC in the adult population, NIV use has come under additional scrutiny. In a post hoc analysis of the FLORALI study, use of HFNC was associated with fewer intubations compared with either NIV or COT.[85] Furthermore, the use of NIV was an independent predictor of intubation and morality. However, in another post hoc analysis of a large randomized trial where 84% of participants had malignancies, HFNC did not perform better than NIV in subsequent need for intubation (hazard ratio, 0.42; $P = 0.2$) or 28-day mortality (hazard ratio, 0.80; $P = 0.45$).[86] A prospective cohort study also found no differences in mortality when comparing 1611 patients treated with HFNC, NIV, or standard oxygen therapy.[73] Although the study noted a statistically lower rate of intubation with HFNC, the actual clinical benefit was small.

In the single randomized trial of HFNC compared with COT in immunocompromised patients based in France

(the HIGH trial), 778 subjects were randomized to either HFNC or standard oxygen.[52] There were no statistically or clinically significant differences with respect to 28-day mortality, intubation and mechanical ventilation, and ICU or hospital length of stay. Similarly, meta-analyses of HFNC use in immunocompromised patients show mixed results.[87–90] The best guidance for clinical practice likely involves an individualized approach and a careful evaluation of the etiology of respiratory failure as opposed to a one-size-fits-all approach to immunocompromised patients.

CARDIOGENIC PULMONARY EDEMA

Although NIV clearly shows benefit in patients with cardiogenic pulmonary edema,[42] there is little evidence yet on the benefit of HFNC in patients with this disorder. To date, no randomized clinical trials have compared HFNC with NIV in hypoxemia resulting from cardiogenic pulmonary edema. Rather, many of the studies examining the utility of HFNC in patients with nonspecific hypoxemia included small proportions of patients with cardiogenic pulmonary edema.[91,92] Unfortunately, all prospective trials including patients with cardiogenic pulmonary edema patients compared HFNC with COT and did not include a comparison with NIV.[91–93] A single retrospective study comparing HFNC with NIV included patients with congestive heart failure, but this study was in immunocompromised patients, and only 8.5% of the study subjects had hypoxemia resulting from cardiogenic pulmonary edema.[72] Until further data are available, acute hypoxemic respiratory failure caused by cardiogenic pulmonary edema should be managed with NIV or intubation and mechanical ventilation, not with HFNC.

OTHER HYPOXEMIC LUNG DISEASES

With worsening hypoxemia, it is natural to escalate support through the variety of oxygenation devices available for patient care. However, in patients with acute hypoxemic respiratory failure due to interstitial lung disease, HFNC is increasingly used as an initial therapy to provide a consistent high fractional concentration of oxygen in inspired gas, a small amount of positive end-expiratory pressure to off-load respiratory effort, and the flow that comforts many patients with chronic dyspnea.[94] Of the studies evaluating HFNC in adults with acute hypoxemic respiratory failure, a small fraction of the subjects included for analysis had hypoxemia related to interstitial lung disease.[95] In small studies, patients with interstitial lung disease seem to tolerate HFNC well as an escalation therapy from COT.[96,97] Although no significant conclusions can be drawn from these studies regarding the outcome of HFNC use in interstitial lung disease, HFNC has largely replaced NIV because of improved comfort and the general lack of need for increasing ventilation in these patients who have hypoxemic respiratory failure without hypercarbia.[98,99]

As in the case of pulmonary parenchymal diseases, patients with pulmonary vascular disease with profound hypoxia and respiratory failure are often supported with HFNC, despite little data in this patient population.[91] In one small retrospective study, Li and colleagues[100] described the feasibility and efficacy of inhaled epoprostenol delivered through an HFNC in a small number of patients with pulmonary arterial hypertension or right-sided heart failure with acute worsening of hypoxia.

Other causes of acute hypoxemic respiratory failure for which HFNC has been investigated include acute pulmonary embolism. In a retrospective report, HFNC was used in 17 patients with acute pulmonary embolism with normocarbic hypoxemic respiratory failure resulting in improved clinical respiratory parameters without a need for intubation.[101] Although there are limited data on the use of HFNC in this and other specific causes of acute hypoxemic respiratory failure, it seems physiologically plausible that HFNC use would benefit most of these patients. As with all causes of acute respiratory failure and selection of noninvasive support, comorbidities and the presence of hypercarbia should be taken into account.

HYPERCARBIC HYPOXEMIC RESPIRATORY FAILURE

Although there is good evidence in support of NIV use for hypercarbic respiratory failure,[42] the rate of failure of NIV in this setting can be as high as 30–50% depending on the severity of the patient on presentation.[102] Only a few studies of HFNC in hypercarbic respiratory failure are available, and most are observational and compare HFNC with COT rather than with NIV.[103–106] There are no well-designed studies supporting the use of HFNC over NIV in hypercarbic respiratory failure, despite the theoretical benefit of carbon dioxide washout and the decrease in physiologic dead-space ventilation.[107,108] Most trials of HFNC exclude patients with hypercarbia.[50,109] Thus, HFNC should currently not be used routinely in patients with hypercarbia who require support of ventilation.

POST-EXTUBATION SUPPORT

Patients with chronic hypercarbia benefit from NIV post-extubation support in preventing reintubation.[110] HFNC has been investigated as a modality of post-extubation support for patients at either low or high risk for reintubation, with mixed results. Most extubated patients in the ICU are at low risk for respiratory failure and reintubation, but all are typically treated with supplemental oxygen.[111,112] The flow rate and oxygenation device should be selected based on the individual patient and the severity of hypoxia. When Hernández and colleagues[109] compared HFNC with COT, including a nasal cannula or an NRB mask, in 527 medical and surgical patients at lower risk for reintubation, fewer patients treated with HFNC had post-extubation respiratory failure (8.3% vs 14.4%; $P = 0.03$) and need for reintubation by 72 hours (4.9% vs 12.2%; $P = 0.004$).[109] However, in another study (the OPERA trial) of 220 non–risk-stratified, postsurgical patients randomized to either HFNC to COT by nasal cannula or face mask, no statistical differences were seen in pulmonary complications such as hypoxemia or need for reintubation.[113] These differences in trial results may stem from differences in patient populations; the study by Hernández and associates[109] included a high proportion of surgical patients, whose reintubation rate is typically lower than in medical patients. Moreover, this study

excluded patients with chronic hypercarbia, a population in whom evidence for the use of NIV is well established.

In a randomized study of 604 patients at high risk for postextubation respiratory failure, no differences were seen in the rate of reintubation or respiratory failure among those treated with HFNC when compared with NIV. However, there were significantly more adverse events, such as nasal septum and facial trauma, in patients treated with NIV (42.9% vs. 0.0%; $P < 0.001$).[71] A follow-up study excluding hypercarbic patients in a population at high risk for extubation failure was stopped early because of low recruitment and was not conclusive in evaluating the benefit of HFNC versus NIV.[74] Meta-analyses including other smaller studies of HFNC versus NIV after extubation suggest that HFNC performs better than COT, but not better than NIV, in prevention of reintubation after extubation.[114–116] These data are limited by the design and results of the included studies. Careful patient selection for an oxygenation approach after extubation is warranted given the lack of a clear benefit of HFNC in this setting.

PREOXYGENATION FOR INTUBATION

HFNC has been explored as a method of preoxygenation and of apneic oxygenation in ICU patients with acute respiratory failure before and during endotracheal intubation. Taken together, data suggest that patients with severe hypoxemia before intubation likely benefit from NIV for preoxygenation, as opposed to HFNC or COT. The evidence in support of HFNC over COT for preintubation oxygenation is mixed. In a before-after observational study of 101 patients treated either with HFNC or an NRB face mask before intubation, patients treated with HFNC had higher levels of oxygenation.[117] However, in a multicenter randomized study (PREOXYFLOW trial) of 124 patients with a P/F ratio lower than 300, there was no difference between groups treated with HFNC or face mask in oxygen saturation, adverse events related to intubation, or ventilator-free days.[118] Studies comparing HFNC with NIV have also demonstrated mixed results. In the follow-up study from the FLORALI study group (FLORALI-2), 313 patients with a P/F ratio of 300 or lower were randomized to HFNC or NIV for preoxygenation before intubation. There were no differences in outcome, other than fewer severe hypoxemic events with NIV preoxygenation in the subset of patients with a P/F ratio of 200 or lower.[119] Conversely, a smaller study (PROTRACH) of 192 patients randomized to HFNC or bag-valve-mask ventilation during rapid-sequence intubation found fewer desaturations lower than 95% (12% vs. 23%; $P = 0.045$) and peri-intubation complications (6% vs. 19%; $P = 0.007$) such as severe hypoxia, hypotension, and aspirations with HFNC.[120]

Current evidence does not support the use of HFNC for preoxygenation before intubation. At this time, HFNC for preoxygenation should only be considered for those cases of mild hypoxemia, with NIV used for more severe cases.

PERIOPERATIVE PERIOD AND DURING PROCEDURES

HFNC has been investigated in a variety of postoperative settings, particularly in patients undergoing cardiothoracic and abdominal surgical procedures. Almost all studies have failed to show clinically meaningful differences with the use of HFNC in the postoperative settings compared either with conventional oxygen by low-flow devices such as nasal cannula or face mask or with NIV. In the largest study of HFNC in surgical patients, Stéphan and colleagues[51] randomized 830 post–cardiac surgical patients who were at high risk for perioperative pulmonary complications of HFNC or bilevel positive airway pressure and found HFNC to be noninferior in prevention of respiratory failure requiring reintubation (21.0% vs. 21.9%; $P = 0.003$) and superior in causing less skin breakdown. Other studies in cardiac surgical patients show mixed results, with some suggesting less escalation of therapy with HFNC compared with nasal cannula and others showing no significant differences.[51,121,122] Similarly, no consistent decreases in intubation or pulmonary complication rates were seen with the use of HFNC compared with usual care in thoracic or abdominal surgical patients in several randomized trials.[113,123] In a meta-analysis of 14 studies of application of HFNC in postsurgical patients, pooled data suggest that HFNC significantly shortens hospital length of stay but does not reduce postoperative pulmonary complications.[124]

An intraprocedure HFNC has also been compared with NIV in high-risk patients undergoing flexible bronchoscopy, and patients in the NIV group had better oxygenation before, during, and after the procedure.[125] In summary, HFNC may be appropriate as first-line oxygen therapy for postsurgical patients, but it should not routinely be used during procedures (such as bronchoscopy).[126,127]

PATIENTS NEAR THE END OF LIFE OR NOT WISHING TO BE INTUBATED

Given the higher levels of comfort and improved general tolerability of HFNC compared with NIV, HFNC may be an appropriate choice to treat dyspnea and provide palliation for patients with severe hypoxemia who are at the end of life or do not wish to be intubated (with a do not intubate order). To date, no controlled studies in these populations have evaluated the effectiveness of HFNC. There are small cohort studies reporting improved oxygenation, fewer interruptions of oxygen therapy, and better oral intake compared with NIV in patients with hypoxemic respiratory failure and do not intubate orders.[98,128]

Key Points

- In general, a target peripheral oxygen saturation of 90% or higher (arterial partial pressure of oxygen of 60 mm Hg or higher) is likely sufficient for most patients requiring noninvasive oxygenation. In patients with obstructive lung disease at risk for hypercarbia, the target should be peripheral oxygen saturation of 88–92% (arterial partial pressure of oxygen of 55 to 65 mm Hg).
- Noninvasive oxygenation modalities include low-flow systems (conventional nasal cannula, simple face mask), reservoir systems (partial-rebreathing and non-rebreathing masks), and high-flow systems (Venturi mask, continuous positive airway pressure, and high-flow nasal cannula).

- The physiologic benefits of high-flow nasal cannula include accurate delivery of a fractional concentration of oxygen in inspired gas, an application of a small amount of end-expiratory pressure, and the theoretical but limited ventilation support through carbon dioxide washout. Since its advent, the high-flow nasal cannula has largely replaced other modalities for noninvasive oxygenation in patients with moderate to severe hypoxemic respiratory failure.
- Indications for high-flow nasal cannula include the following settings: acute hypoxemic respiratory failure resulting from pneumonia or acute respiratory distress syndrome, acute hypoxemic respiratory failure following surgery, acute on chronic hypoxemic lung diseases with escalating oxygen requirements, and end of life.
- High-flow nasal cannula *may* be considered in these settings: hypoxemic respiratory failure in immunocompromised populations, post-extubation, before intubation, and periprocedurally.
- High-flow nasal cannula should not be used in these settings: hypoxemic respiratory failure caused by cardiogenic pulmonary edema and hypercarbic hypoxemic respiratory failure.
- The major benefit of high-flow nasal cannula is that it reduces the number of patients who require intubation and mechanical ventilation.

KEY POINTS

INTRODUCTION

Extracorporeal membrane oxygenation (ECMO) is a technique of life support that diverts a fraction of the patient's blood flow through an artificial lung for gas exchange (oxygenation and CO_2 removal) and then returns it to the patient. Thanks to the improvements in technology and materials and to a deeper understanding of physiopathology, the indications, timing, and management of ECMO have changed substantially over the years. This chapter introduces the concept of ECMO and discusses its use for respiratory support in patients with acute respiratory failure.

PRINCIPLES OF EXTRACORPOREAL MEMBRANE OXYGENATION

ECMO is a generic term used to describe a number of different techniques used for prolonged cardiac and/or respiratory support. ECMO can be used for cardiac (veno-arterial bypass) or respiratory support. For respiratory support, blood can be drained either from a venous vessel (*veno-venous ECMO* [VV-ECMO]) or from an arterial vessel (arteriovenous bypass). During veno-arterial and VV-ECMO, the blood is withdrawn from the patient through a pump, whereas, during arterio-venous ECMO, the arterial pressure is the driving force. Drained *blood flow* (BF) passes through the oxygenator (*membrane lung* [ML]), where oxygen is added and CO_2 removed. Depending on the BF through the circuit, the technique may be used mainly for CO_2 removal (BF < 2 L/min) or for both CO_2 removal and oxygenation (BF up to 5 to 6 L/min). For an understanding of the different techniques available for respiratory support, it is useful to provide a brief historical perspective.

HISTORICAL PERSPECTIVE

The birth of ECMO dates to 1939 with the development of the first heart-lung machine by John Gibbon; this culminated in 1953 with the first open heart operation.[1] The first successful use of prolonged ECMO in *acute respiratory distress syndrome* (ARDS) patients was reported by Hill et al. in 1972.[2] In the following 2 years, other successful cases were reported, leading to the first multicenter randomized clinical trial of ECMO for adults with ARDS.[3] The study failed to show any survival benefit.

Contrary to its use in adults, the use of ECMO in neonatal respiratory failure showed encouraging results. After the first successful treatment in newborns reported by Bartlett et al. in 1976[4] and a few case series from different groups,[5–7] two prospective randomized controlled studies were performed.[8,9] Both studies were positive and, in a few years, ECMO became standard treatment for neonatal respiratory failure.

A landmark contribution to the use of ECMO in adults came from the pioneering work of Kolobow and Gattinoni, who addressed the reasons the National Institutes of Health ECMO trial demonstrating lack of benefit.[10] At that time, the aim of ECMO had been to provide reasonably normal blood gases.[11] For achieving normal oxygenation, a high ECMO BF rate was necessary, and the veno-arterial configuration was the standard. In 1977, recognizing that

oxygenation and carbon dioxide elimination were based on different physiologic mechanisms, Gattinoni and Kolobow realized that by removing CO_2 through the ML, ventilation of the native lung could be reduced virtually to zero.[12] They showed that nearly all the metabolic CO_2 production could be removed through an artificial lung using much lower extracorporeal BFs than those required to oxygenate the blood.[13] Based on these observations, they developed the concept of extracorporeal CO_2 removal, proposing the use of a veno-venous configuration instead of the classical veno-arterial mode and the use of low-frequency positive-pressure ventilation to rest the lung.[13] Unfortunately, the promising results of the first reports[14,15] were not confirmed by a subsequent single-center, randomized controlled trial in 40 ARDS patients.[16] In spite of this second trial finding no benefit, a few centers continued to use ECMO in adult patients; during this time, there were also important technical improvements.[17–21] In the past decade, there has been a resurgence of interest in ECMO, leading to a progressive increase in its use worldwide.

The reasons for the resurgent interest in ECMO are the following:

1. Technical developments have led to a decrease of ECMO-associated complications. Oxygenators, propelling pumps, and cannulas have all undergone substantial improvements, allowing easier, safer, and longer application of ECMO.
2. The *Extracorporeal Life Support Organization* (ELSO), founded in 1989, has gathered together most ECMO centers worldwide. ELSO maintains a registry of ECMO cases and provides annual reports on ECMO usage, survival rates, and complication rates. ELSO has also developed guidelines that represent the most important reference for ECMO users.[22]
3. The concept of *ventilator-induced lung injury* (VILI) and improvement in ARDS treatment[23] has led to the recognition that *mechanical ventilation* (MV), though necessary, can exacerbate lung damage. Ventilation with high *tidal volume* (V_T)[24–29] and high airway pressure[30–31] has been recognized as a major cause of VILI, leading to the recommendation that ARDS patients should receive "a protective ventilatory strategy." Since the concept of VILI was not recognized early in the history of ECMO, in the two aforementioned ECMO randomized trials, no attention was paid to V_T or airway pressures in either treatment group.
4. The H1N1 influenza outbreak accelerated the use of ECMO with good results. During the 2009 influenza A (H1N1) pandemic in Australia and New Zealand, 61 patients with H1N1-associated ARDS received ECMO for refractory hypoxemia, and survival was 78%.[32] Following the Australian experience, numerous case series reported survival rates ranging from 68–83%.[32–39]
5. Evidence from newer randomized trials has been viewed as positive. Two large, multicenter, randomized controlled trials published in 2009 and 2018 have compared ECMO with conventional treatment in patients with ARDS and refractory hypoxemia. The *Conventional Ventilation or ECMO for Severe Adult Respiratory Failure* (CESAR) trial[40] was conducted in the United Kingdom and published in 2009; it enrolled 180 adult ARDS patients with a Murray score of 3 or greater or uncompensated hypercapnia with a pH less than 7.20. Patients randomized to ECMO were transferred to the Leicester ECMO center, while controls remained in designated treatment centers. Survival or absence of severe disability at 6 months was 63% in the ECMO group compared with 47% of the control group. The authors concluded that referral of severely hypoxemic ARDS patients to a specialized center able to provide ECMO may increase survival. However, not all patients allocated to the ECMO group actually received ECMO, either because they died before or during transportation (5 patients) or they improved with conventional treatment after transportation to the ECMO center (17 patients). Moreover, there was no standardized protocol for MV in the control group, resulting in significantly fewer patients receiving a protective ventilatory strategy.

The second study is the ECMO to Rescue Lung Injury in Severe ARDS trial,[41] conducted more recently in France. This study included patients receiving MV for less than 7 days for refractory ARDS, defined as arterial P_{O_2}/*fractional concentration of oxygen in inspired gas* (F_{IO_2}) less than 50 mm Hg for greater than 3 hours; or alveolar P_{O_2}/F_{IO_2} less than 80 mm Hg for 6 hours; or, pH less than 7.25 with arterial P_{CO_2} 60 mm Hg or greater, despite ventilator optimization. In the first 249 patients, 60-day mortality was 35% in the ECMO group versus 46% in controls ($P = 0.09$). Because this difference did not reach statistical significance, recruitment was prematurely stopped. However, interpreting these results as "negative" is certainly too simplistic. As pointed out by Robert Bartlett in his editorial, "the 11% absolute difference in survival comparing early ECMO to conventional care with late rescue ECMO will probably be considered clinically significant by intensivists and payers for healthcare in severe ARDS."[42] Moreover, 28% of the patients in the control group required crossover to ECMO as salvage therapy, and the composite outcome of death plus crossover to ECMO was strongly in favor of ECMO treatment (relative risk, 0.62; $P < 0.001$). Finally, a post-hoc Bayesian analysis of the ECMO to Rescue Lung Injury in Severe ARDS results showed that ECMO is associated with an absolute mortality reduction of at least 2% with a 98% probability.[43]

VENO-VENOUS EXTRACORPOREAL MEMBRANE OXYGENATION

INDICATIONS

The primary indication for VV-ECMO is hypoxemic respiratory failure in patients with a high risk of mortality. According to ELSO guidelines, ECMO is indicated in patients with an arterial P_{O_2}/F_{IO_2} less than 80 mm Hg with F_{IO_2} greater than 0.90 and a Murray score of 3 to 4.[22] Several investigators have reported the association between increased mortality and more days of MV before ECMO initiation, suggesting the importance of starting ECMO early, before lung injury has become irreversible. Since 2006, several case reports have been published on the use of VV-ECMO for non-ARDS indications such as respiratory failure

due to severe trauma,[44] pulmonary embolism,[45] or severe asthma,[46] and as a bridge to lung transplant.[47]

Contraindications to ECMO include advanced age, severe disability, and incurable malignancy. Uncontrolled coagulopathy, major bleeding, and prolonged MV are considered relative contraindications, and the decision to start ECMO is discussed on a case-by-case basis.

COMPONENTS

The basic components necessary for VV-ECMO are a gas-exchange unit, a pump to propel the blood, and the cannulas and tubing for vascular access. Compared to the systems commonly adopted during cardiac surgery, ECMO systems are simpler (Fig. 138.1).

Oxygenators

Hollow-fiber oxygenators with a polymethylpentene membrane have become the standard for long-term treatment.[48–50] Compared to the original silicon membrane, hollow-fiber oxygenators have a smaller priming volume, higher gas transfer rates, and much lower resistance.[51] The use of polymethylpentene has also completely resolved the problem of plasma leakage that represented the main limitation to the use of polypropylene hollow-fiber oxygenators.[52] The gas and blood compartments are channeled, respectively, inside and outside the hollow fibers. A third compartment for heat exchange is commonly present. Each compartment has an input and an output port.

Pumps

Centrifugal pumps have almost completely replaced roller pumps for long-term applications. Modern centrifugal pumps have a hole in the center of the rotor (Mendler design)[53] and use both a magnetically suspended and a magnetically driven pump that eliminates stagnation, thrombosis, and heat production, which were common complications of earlier centrifugal pump models.

Cannulas

Vascular cannulas for ECMO have a thin wall, are commonly made of polyurethane, and are often wire-reinforced to prevent kinking or collapse. Venous cannulas have side holes close to the tip or along the last 15 to 20 cm (multistage cannulas) to facilitate drainage. Modern cannulas have heparin-coated surfaces to increase biocompatibility and reduce activation of the clotting cascade.[54] Recently, some double-lumen cannulas have become available: the most popular is the bicaval Avalon Elite.[55] With this cannula, blood is drained both from the inferior and the superior vena cava via the inflow lumen and reinfused directly into the right atrium through the return lumen aligned with the tricuspid valve.

Tubing

The tubing used for ECMO is made of polyvinylchloride, polyurethane, or silicon rubber. Appropriate connectors, with side ports for standard stopcocks, allow connection between different circuit components.

CANNULATION

The technique of choice for VV-ECMO cannulation is the percutaneous approach.[56,57] The main advantages are the reduced risk of bleeding, shorter operative time, and easier mobilization and nursing of the patient.

As a rule, the size of the cannula should not exceed two-thirds of the vessel diameter. Drainage cannulas should be big enough to ensure adequate flow with relatively

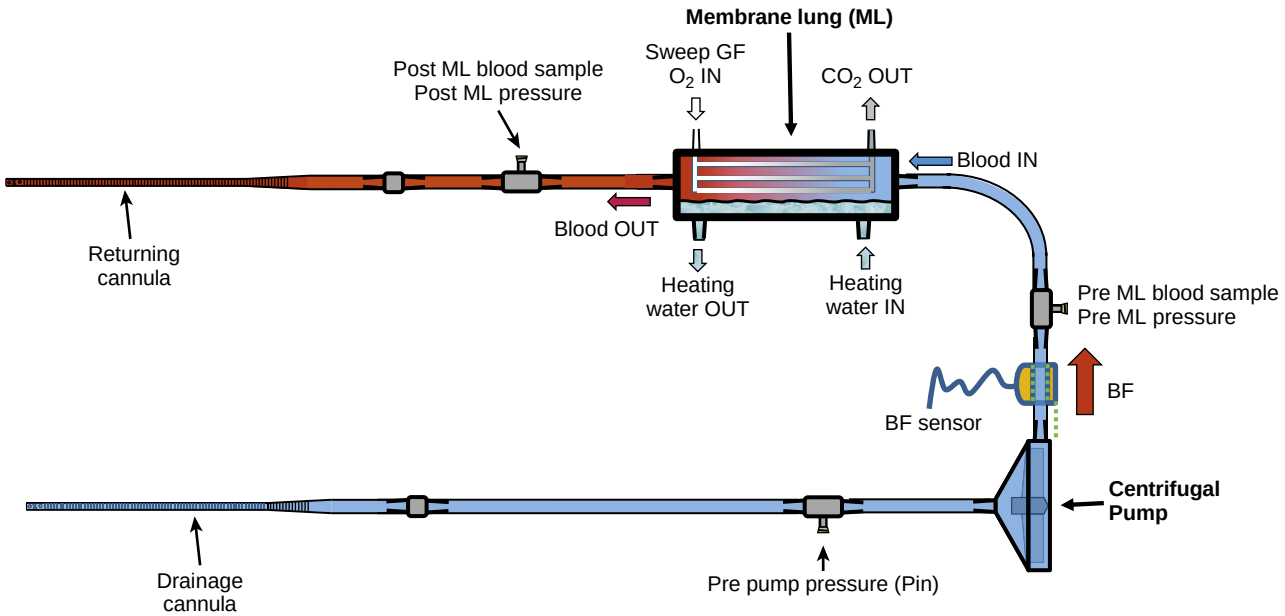

Figure 138.1 Schematic of a basic circuit for *veno-venous extracorporeal membrane oxygenation* (VV-ECMO). From the drainage to the returning cannula, a basic circuit for VV-ECMO includes a connector with stopcock for drainage pressure monitoring (pre-pump pressure or Pin); the centrifugal pump; a flow sensor for monitoring blood flow (BF); a connector with stopcock for monitoring pressure and sampling for gas analysis of the input blood (pre-membrane lung [ML] pressure); the membrane lung oxygenator (ML) (inlet and outlet port for blood, sweep gas flow (GF), and heating water are represented); and a connector with stopcock for monitoring pressure and obtaining samples for gas analysis of blood leaving the oxygenator (post-membrane [ML] lung pressure).

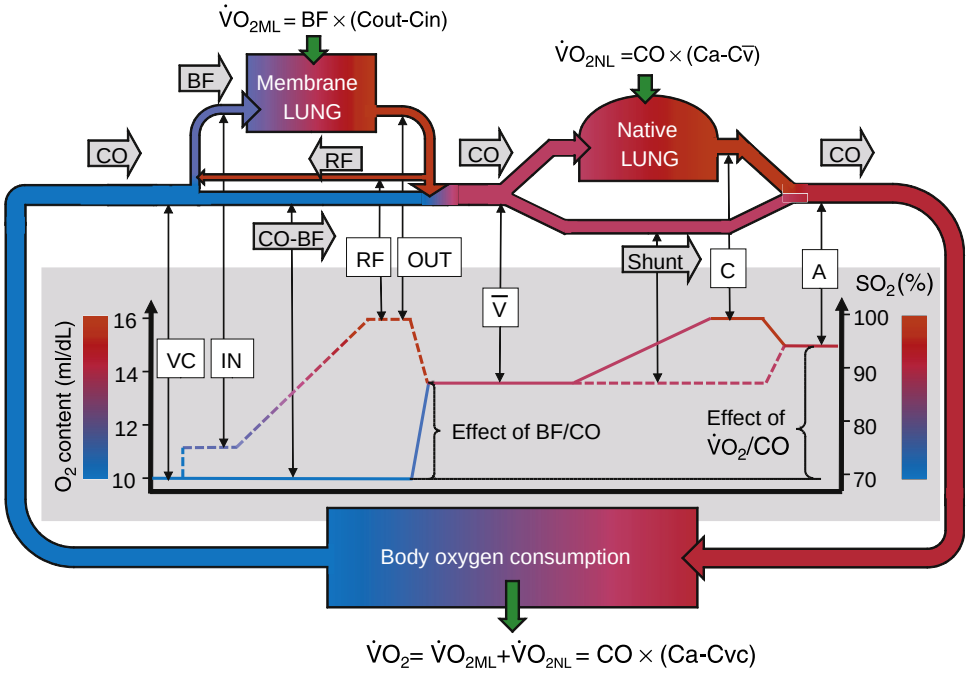

Figure 138.2 A schematic of a model of blood oxygenation during *veno-venous extracorporeal membrane oxygenation* (VV-ECMO). Blood oxygen content (mL/dL, main *y*-axis) and hemoglobin saturation (%, secondary *y*-axis) of different blood vascular districts (*left to right*: VC, vena cava; ML, membrane lung; IN, input; RF, recirculating fraction; OUT, ML output; $\bar{V}$, mixed venous; blood exiting normally functioning capillaries of the *native lung* [NL]; C; capillary; A, arterial) are represented. The oxygenation of the mixed venous blood is affected by ECMO blood flow (BF) relative to the cardiac output (CO). Arterial oxygenation is affected by the intrapulmonary shunt (Shunt). The sum of the oxygen transferred to the blood by the NL ($\dot{V}O_{2NL}$, mL/min) and the ML ($\dot{V}O_{2ML}$) equals the total patient's oxygen consumption ($\dot{V}O_2$). A more detailed description is provided in the text.

low suction pressure, and the holes and tip of the cannula should be positioned in a large, high-flow vessel.

VV-ECMO may be accomplished using three different configurations: femoral-femoral, femoral-jugular, and jugular-femoral. Factors to consider when choosing the configuration are to maximize drainage capability, allow patient mobilization, avoid complications, and minimize *recirculation* (i.e., the reentry of blood into the ML already oxygenated by the ML). The femoral-jugular access is the more frequently used; with a correctly positioned femoral cannula of 23 to 25 French, BF rates up to 6 to 7 L/min are easily obtained with minimal recirculation. The jugular-femoral approach, in which blood is drained directly from the right atrium, likely provides the best drainage, but there is a high degree of recirculation, which can effectively nullify the drainage advantage. The femoral-femoral approach offers safer access with less possibility of accidental cannula dislocation; mobilization of the patient's head is facilitated at the expense of lower limb mobilization. With this approach, however, minimization of recirculation requires careful positioning of the cannula tips, which is generally more difficult to obtain than with other approaches. To maximize the available BF, the tip of the femoral drainage cannula should be positioned in the inferior vena cava superior to the renal veins. A heparin bolus of 50 to 100 U/kg is administered immediately before insertion of the first cannula.

Double-lumen cannulas are commonly placed through the right internal jugular vein. For BF rates comparable to those commonly achieved with the traditional two-cannula configurations, insertion of cannulas up to 31 to 35 French may be necessary.

Choice of the cannulas is also based on the clinical indication. For more severely hypoxemic patients, larger cannula sizes and configurations allowing higher BFs should be selected at the start. When the patient's needs change, insertion of a second drainage cannula, an upgrade from a single to a double-cannula configuration, or a switch from VV to veno-arterial ECMO is sometimes necessary.[58]

PATIENT-MACHINE INTERACTION

The effect of VV-ECMO on arterial blood gas values is a function of the complex interplay between different factors. It is useful to discuss separately the effects on oxygenation and CO_2 removal.

EFFECT ON OXYGENATION

During VV-ECMO, the ML and the *native lung* (NL) are in series (Fig. 138.2). The physiology of VV-ECMO can be understood by following the changes in blood O_2 content from the vena cava ($Cvco_2$) to the arterial side (Cao_2). $Cvco_2$ is a function of Cao_2, *cardiac output* (CO), and the *arterial-venous O_2 difference* ($Cao_2 - Cvco_2$).

Membrane Lung

A fraction of venous return (BF/CO) is diverted through the ML. The oxygen transfer across the ML is given by $\dot{V}o_{2ML} = BF \times (Co_{2out} - Co_{2in})$, where Co_{2in} and Co_{2out} are the oxygen content of the blood respectively entering (input) and leaving (output) the ML. A fraction of output flow, the recirculation fraction, re-enters into the extracorporeal circuit, thus increasing the O_2 content of input blood and reducing the $\dot{V}o_{2ML}$. The oxygen content of the blood returning to the lung (the mixed venous blood, $C\bar{v}o_2$) is the flow-weighted average of Co_{2out} and $Cvco_2$, as follows: $C\bar{v}o_2 = [Co_{2out} \times BF + Cvco_2 \times (CO - BF)]/CO$. In practice, the effect of the ML is to increase the O_2 content of the blood returning to the lung from $Cvco_2$ to $C\bar{v}o_2$. $C\bar{v}o_2$ is then increased to the arterial concentration of oxygen by the oxygenating capacity of the patient's lung.

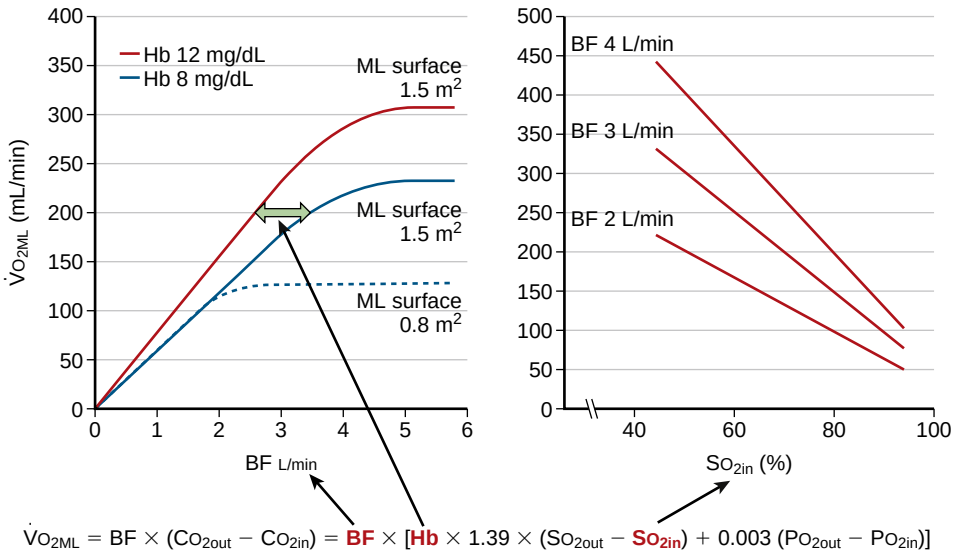

Figure 138.3 Factors determining oxygen transfer by the membrane lung. Oxygen is transferred to the blood by the membrane lung ($\dot{V}O_{2ML}$, mL/min) as a function of *extracorporeal membrane oxygenation* (ECMO) blood flow (BF, L/min, *left*) and oxygen saturation of the blood entering the *membrane lung* (ML) (So_{2in}, %, *right*). The effect of the *hemoglobin* (Hb) concentration and of the membrane lung surface area (m^2) is represented in the left panel. The formula for computation of $\dot{V}O_{2ML}$ is shown. Co_{2in}, So_{2in}, and Po_{2in} are the oxygen content (mL/dL), saturation (%), and partial pressure (mm Hg) of the blood entering the ML; Co_{2out}, So_{2out}, and Po_{2out} are the oxygen content, saturation, and partial pressure of the blood leaving the ML.

Native Lung

The oxygen transfer across the *native lung* (NL) is $\dot{V}O_{2NL} = CO \times (Cao_2 - C\bar{v}o_2)$, and the patient's total oxygen consumption is simply the sum of ML and NL oxygen transfer: $\dot{V}O_2 = \dot{V}O_{2ML} + \dot{V}O_{2NL}$.

Besides the oxygenation capability of both the ML and the NL, the main determinants of blood O_2 content are hemoglobin saturation and hemoglobin concentration. Once the hemoglobin has been saturated, the only way to increase ML O_2 transfer is by increasing the hemoglobin concentration (Fig. 138.3, left).

Under VV-ECMO, arterial oxygenation will depend on $\dot{V}O_{2ML}$, $\dot{V}O_{2NL}$, $CvcO_2$, and CO.

O_2 Transfer by the Membrane Lung. $\dot{V}O_{2ML}$ depends on three main factors (see Fig. 138.3).

1. ML. The oxygenator's oxygenation capability will depend on the membrane diffusion characteristics (thickness, material) and the membrane surface area (see Fig. 138.3, left).
2. Oxygen pressure gradient. The O_2 pressure gradient between the *gas flow* (GF) (also called the sweep gas flow) and the blood is one factor determining the transfer of oxygen. On the gas side, the O_2 partial pressure depends on the FIO_2 of the sweep gas. It is essential to understand that, similar to natural lung physiology, the transfer of O_2 through the ML is governed by ventilation-perfusion matching. And, similar to the normal lung, once a high level of partial pressure has been reached in the outlet blood, a further increase in GF will not lead to any increase in O_2 transfer. On the blood side, the higher the Co_{2in}, the lower the quantity of O_2 that can be added to the blood (see Fig. 138.3, right). An important factor that may result in a high Co_{2in} is recirculation.
3. BF. Up to a determined BF, $\dot{V}O_{2ML}$ will increase directly with the increase in flow. However, depending on the membrane surface area and the ML characteristics, there is a limit to the oxygenator flow (rated flow). Above this limit, no more O_2 can be added to the blood (see Fig. 138.3, left).

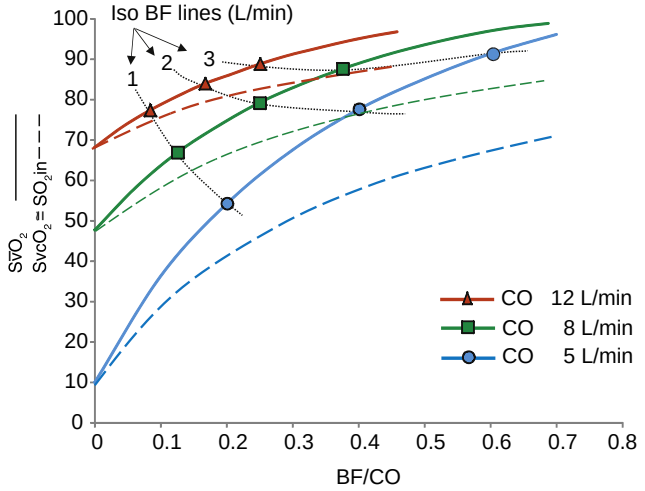

Figure 138.4 Oxygen saturation of blood entering the patient's lung ($S\bar{v}o_2$, solid lines) as a function of the blood flow (BF)/cardiac output (CO) ratio, at different CO. At constant CO and oxygen consumption, increase of BF/CO through an increase of BF results in an increase of $S\bar{v}o_2$ by two mechanisms: first, because a higher fraction of venous return is oxygenated passing through the membrane lung (ML); second, because the resulting increase in arterial O_2 saturation will lead to an increase of oxygen saturation of the blood in the vena cava ($SvcO_2$) and therefore in the input (So_{2in}) (*dashed lines*). The effect of changing BF/CO by changing CO at constant BF (iso BF lines) is also represented. Increase of CO has opposing effects on $S\bar{v}o_2$: an increasing effect resulting from the increase of $SvcO_2$ and So_{2in}, and a decreasing effect due to the lower fraction of venous return oxygenated through the ML. The former effect prevails at lower BF, while at higher BF (above 3 L/min) changes in CO have minimal effects on $S\bar{v}o_2$.

Mixed Venous Blood Oxygenation. During VV-ECMO, the main determinants of mixed venous So_2 are the oxygen saturation of the blood leaving the organs (i.e., vena cava blood saturation, $SvcO_2$) and the ratio between BF and CO (Figs. 138.2, 138.4, and 138.5). At a given BF, an increase in CO (and a decrease in BF/CO) is associated with an increase in $SvcO_2$, causing a decrease in the oxygenation contribution of the ML ($\dot{V}O_{2ML}$), thus commonly resulting in a decrease in mixed venous So_2 and ultimately a decrease in *arterial oxygenation saturation*

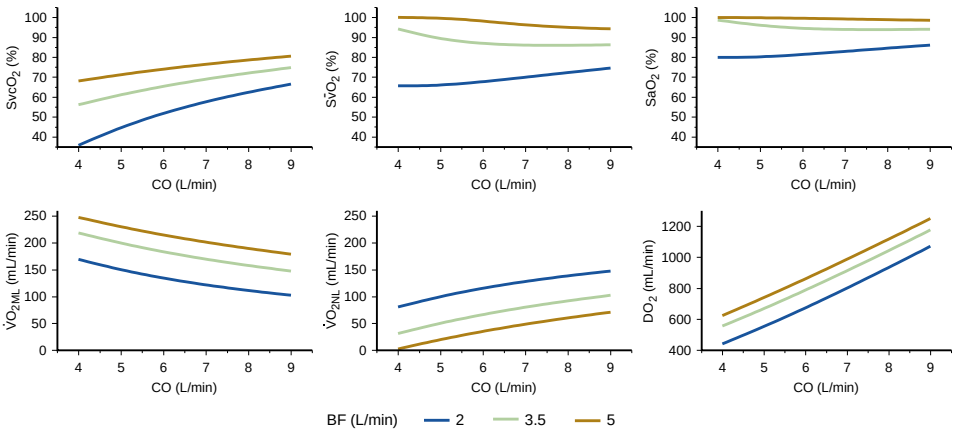

Figure 138.5 Effects of changes in cardiac output at three different *blood flows* (BFs). Oxygen saturation of the blood in the vena cava ($Svco_2$), oxygen saturation of the mixed venous blood ($S\bar{v}o_2$), oxygen saturation of arterial blood (Sao_2), oxygen transfer by the membrane lung (ML) (Vo_{2ML}), oxygen transfer by the native lung (NL) (Vo_{2NL}), and arterial oxygen delivery (Do_2) as a function of cardiac output (CO) at three different BFs in L/min.

(arterial So_2), although *oxygen delivery* ($Do_2 = Cao_2 \times CO$, the amount of oxygen delivered from the NL to the body tissues per minute) increases (see Fig. 138.5).[59] Conversely, if BF is held constant and CO is decreased (an increase in BF/CO), mixed venous So_2 and arterial So_2 will commonly increase, although $Svco_2$ and Do_2 decrease. These relationships are the basis for the manipulation of BF and CO during VV-ECMO.

Although one would hope to increase oxygenation by increasing BF/CO, there are limitations on how much the BF/CO ratio can be increased. First, a decrease in CO is associated with a parallel decrease in $Cvco_2$: below a certain threshold of BF, the expected positive effect on oxygenation of the increase in the BF/CO ratio may be offset by the decrease in $Cvco_2$ (see Fig. 138.5), resulting in a net decrease of mixed venous So_2 and arterial So_2. Second, in the presence of recirculation, either an increase in BF or a decrease in CO will increase the amount of recirculating blood, thereby blunting the expected positive effect on oxygenation. Third, an increase of BF is limited by cannula size and patient blood volume status. Fourth, oxygen delivery to peripheral organs depends on both arterial Co_2 and CO: at low oxygenation levels, a higher CO is necessary to ensure sufficient organ oxygenation.

Mixed venous blood oxygenation is also affected by the fraction of inspired oxygen of the ML (Fio_{2ML}). Increasing Fio_{2ML} increases Vo_{2ML} and thus mixed venous So_2 (eFig. 138.1).

Oxygen Uptake from the Native Lung. The NL will contribute to arterial oxygenation by adding oxygen to the mixed venous blood according to its remaining gas-exchange capacity, which depends on the severity of the lung disease (i.e., the intrapulmonary shunt fraction, $\dot{Q}s/CO$, and the *fraction of inspired oxygen of the NL* (Fio_{2NL}) (eFig. 138.2).

The main goal during VV-ECMO is to reduce and limit all the factors contributing to VILI. However, a decrease of Fio_{2NL}, *positive end-expiratory pressure* (PEEP), and/or minute ventilation may temporarily lead to worsening of gas-exchange function of the NL, increasing the reliance of patient oxygenation on the oxygenation provided by the ML. Thus, the expected level of BF and indeed the choice of ECMO equipment and cannula sizes will be strongly influenced by the oxygenation achievable by management of the NL and, most importantly, by the level of oxygenation considered clinically acceptable for delivery to the body.

EFFECT ON CO_2 REMOVAL

Removal of CO_2 during VV-ECMO is much easier to achieve than oxygenation. With any type of ML, clearance of CO_2 is always more efficient than oxygen transfer (Fig. 138.6). Whereas the amount of O_2 transfer is limited at the point at which the blood is fully saturated, there is no such limit to CO_2 removal and a substantial amount of CO_2 can be removed from venous blood. Most of the CO_2 is transported in blood in the form of bicarbonate ion. Normal venous blood carries at least 50 mL of CO_2/100 mL. This means that half a liter of venous blood contains 250 mL of CO_2, an amount equivalent to roughly the entire CO_2 production per minute by the body (approximately 250 mL/min for a 70 kg normothermic man). Thus, the entire patient CO_2 production can theoretically be removed with low BF provided that a high GF is used. At a high GF (8 to 15 L/min), the CO_2 concentration in the gas compartment remains close to 0 mm Hg, and a high CO_2 pressure gradient is maintained. The strict relationship between $\dot{V}co_{2ML}$ and GF is advantageous because it allows dissociation of CO_2 removal from oxygen transfer. In other words, the GF can be used to control CO_2 removal and BF can be used to control oxygen transfer.

This removal of a large percentage of the CO_2 production allows the clinician to decrease the minute ventilation delivered by the ventilator. If 50% of $\dot{V}co_2$ is removed by the ML, minute ventilation of the NL can roughly be halved. This is the physiologic basis for the use of ECMO to provide a more protective ventilator strategy, as discussed later.

MANAGEMENT OF THE MEMBRANE LUNG

Management of ECMO is essentially based on setting three variables:

1. BF. As we have seen, BF is the main determinant of patient oxygenation and should be set to the lowest level that provides adequate oxygenation. The required flow will be a function of the target oxygenation level and the ventilator strategy applied to the NL.
2. GF. GF is the main determinant of CO_2 removal and, consequently, it determines the minute ventilation needed from the ventilator.

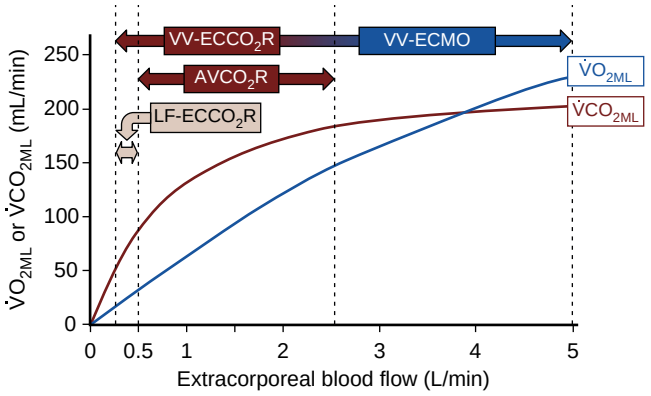

Figure 138.6 CO_2 removal and oxygen transfer as a function of *extracorporeal membrane oxygenation* (ECMO) blood flow with different available techniques. Extracorporeal carbon dioxide removal ($\dot{V}_{CO_{2ML}}$) and oxygen transfer ($\dot{V}_{O_{2ML}}$) is shown as a function of ECMO blood flow at steady state in a patient with total oxygen consumption 250 mL/min and total carbon dioxide production 200 mL/min. $AVCO_2R$, arteriovenous CO_2 removal; $LF\text{-}ECCO_2R$, low flow extracorporeal CO_2 removal; $VV\text{-}ECCO_2R$, veno-venous extracorporeal CO_2 removal; VV-ECMO, full veno-venous extracorporeal oxygenation support.

3. F_{IO_2} of the sweep gas. It is generally set to 1.0 and progressively decreased as the patient improves.

The ECMO circuit should be monitored several times daily (at least once daily by a perfusionist). Careful monitoring of the ECMO system is aimed at answering the following questions:

1. Is the oxygenator performing well? If the F_{IO_2} of sweep gas is 1, the expected P_{O_2} in the output blood should be very high (generally > 300 to 400 mm Hg). The output P_{O_2} is usually higher than 500 mm Hg at lower BFs and starts to decrease as flow approaches the rated flow for that type of oxygenator. Accounting for this effect, daily monitoring of the output P_{O_2} allows detection of any decrease in oxygenator performance, which may prompt a circuit substitution. In addition, as the oxygenator performance worsens, increasing GF rates are necessary to maintain the same arterial P_{CO_2}.
2. Is drainage from the patient effective? Efficient blood drainage is crucial. Drainage effectiveness can be assessed by monitoring the pressure proximal to the pump (Pin) (see Fig. 138.1) and the BF/revolutions per minute ratio. If drainage is insufficient, BF becomes unstable (sudden drops) and "kicking" or "swinging" of drainage lines can be noted. Pin is an essential parameter that should be monitored closely. Appropriate drainage cannula size and BF should be selected to avoid excessively negative Pin. Values of Pin above −100 mm Hg are recommended. When drainage becomes less effective, Pin and BF will decrease, and higher pump revolutions per minute must be set to maintain the same BF. The most common reason for a reduction of drainage effectiveness is a change in patient volume status and/or a decrease in venous BF proximal to the cannula tip. Volume expansion or temporary reduction of the BF is the easiest solution. It is always important to check for any change in cannula position, tube kinking, or obstruction.
3. Is there thrombosis in the circuit? The oxygenator is the main site of activation of thrombosis. Clot formation in the oxygenator may be detected by daily inspection of oxygenator surfaces, by monitoring the transmembrane pressure (difference between post (P_{postML}) and pre (P_{preML}) oxygenator pressure), and by monitoring coagulation parameters (see later).

VENTILATORY MANAGEMENT OF THE NATIVE LUNG

The main objective during VV-ECMO is to ensure adequate gas exchange while minimizing VILI.[23] As CO_2 is removed through the ML, minute ventilation can be reduced for the NL, generally by decreasing V_T (and indirectly plateau airway pressure) and/or respiratory rate. Support of oxygenation by the ML may allow a decrease in F_{IO_2} and eventually PEEP (and indirectly peak and plateau airway pressure) in the NL.

Depending on how V_T, respiratory rate, PEEP, and F_{IO_2} are set, different protective ventilatory strategies are possible. Optimal setting of the mechanical ventilator during ECMO is still a matter of debate, and strategies may vary from center to center.[60]

ELSO guidelines[22] suggest targeting ventilator management to use F_{IO_2} less than 0.4, and plateau pressure less than 25 cm H_2O while preventing lung collapse by maintaining a PEEP level of 15 cm H_2O in the first 24 hours. Notably, there are no specific recommendations about V_T setting. Peak or plateau airway pressures were the main ventilatory targets in the Conventional Ventilation or ECMO for Severe Adult Respiratory Failure[40] and the EOLIA[41] trials (see earlier).

Multicenter and single-center observational studies are the main source of information on clinical practice.[37,39–41,61–66] The largest and most recent international, multicenter, prospective cohort study on MV during ECMO is the LIFEGARDS study.[66] Data on MV settings were collected during a 1-year period in 23 medium to high case-volume ECMO centers. Within 24 hours of ECMO initiation, V_T and plateau pressure were both significantly reduced from 6.4 ± 2 to 3.7 ± 2 mL/kg predicted body weight and from 32 ± 7 to 24 ± 7 cm H_2O, respectively. On the contrary, PEEP remained unchanged or was only slightly reduced compared to pre-ECMO setting (from 12 ± 4 to 11 ± 3 cm H_2O). The results of the LIFEGARDS study largely confirmed what was reported in previous observational studies.[37,39–41,61–65]

The common trend after starting ECMO is to decrease V_T targeted to a plateau pressure below 25 to 30 cm H_2O.[29–31] Apart from isolated experienced centers that target PEEP to levels below 10 cm H_2O from the beginning,[67] most centers keep PEEP unchanged.[37,39–41,61–66] This is the dilemma between letting the lungs collapse or trying to keep them open.[68,69] Centers with greater expertise often apply different approaches in different patients or may even change the ventilatory approach in a given patient as clinical conditions change. The ventilatory strategy has a big influence on the level of BF and GF in the ML necessary to maintain adequate oxygenation. In addition, if the gas-exchange capability of the NL is poor, a higher device BF and a larger cannula size will be necessary. As soon as the lung function and the patient's clinical condition improves, the patient

may be switched from controlled to assisted MV. The current approach is to promote early mobilization. During this phase, oxygenation may not be a major problem anymore, but it is possible to manipulate GF to modulate the patient's respiratory drive and effort.

ANTICOAGULATION AND HEMATOLOGIC MONITORING

Anticoagulation during VV-ECMO is commonly achieved by continuous intravenous heparin infusion, targeted to an activated partial thromboplastin time of 45 to 60 seconds and/or to an activated clotting time of 1.5 to 2 times normal. The main advantage of activated clotting time is its prompt availability at the bedside. There has been an increasing interest in the use of thromboelastography for real-time bedside monitoring of anticoagulation. A pilot study showed that, compared to the standard of care of using activated partial thromboplastin time monitoring, use of a thromboelastography-based protocol for anticoagulation management is associated with the administration of lower heparin doses with no difference in the incidence of hemorrhagic or thrombotic complications.[70] According to ELSO guidelines, during ECMO treatment, fibrinogen and antithrombin III should be maintained within normal range.

After starting ECMO, the platelet count usually decreases. Platelet transfusions are recommended to maintain the platelet count above 50,000/μL in all patients and above 100,000/μL in the presence of active bleeding.[22]

Activation of the coagulation cascade and subsequent clot formation in the circuit are accompanied by a progressive decrease in platelet count and fibrinogen level and consumption of coagulation factors that may lead to a syndrome similar to disseminated intravascular coagulation. D-dimer levels are a reliable variable to detect circuit thrombosis. Signs of activation of the coagulation cascade along with decreased performance of the oxygenator and/or increase of transmembrane pressure should prompt replacement of ECMO circuit.

In the presence of heparin-induced thrombocytopenia, heparin infusion should be discontinued, and an alternative anticoagulant such as argatroban may be used.[71,72]

Red cell transfusion policy during ECMO is extremely variable because there is no consensus on the target hematocrit level.[73] Available guidelines recommend maintenance of hematocrit within normal limits to minimize BF requirements and maximize oxygen transfer by both the ML and the NL.

COMPLICATIONS

Bleeding complications remain the most frequent and serious complication in ECMO patients. The best sources of information on the incidence of complications are the ELSO registry reports.[74] Localized bleeding, especially from cannula insertion sites or from surgical sites, is common, seen in approximately 17% and 16% of patients, respectively. Simple compression or packing maneuvers are often sufficient to treat these complications.

Intracranial bleeding is reported in 3.9% of patients and is associated with an overall survival rate of only 17%. Pulmonary and gastrointestinal hemorrhage happens in approximately 8% and 5% of patients, respectively.

In the presence of generalized and persistent bleeding, heparin should be reduced or discontinued, and transfusion of fresh frozen plasma and platelets should be considered. To prevent bleeding, it is worthwhile to minimize procedures such as intramuscular or subcutaneous shots, thoracentesis, chest tube insertion, and substitution of nasogastric or urinary catheters.

WEANING FROM VENO-VENOUS EXTRACORPOREAL MEMBRANE OXYGENATION

Weaning from ECMO is accomplished by the progressive reduction of the ECMO contribution to oxygenation and CO_2 removal as the gas-exchange capability of the NL improves and the patient's clinical condition stabilizes (Fig. 138.7). The decision to disconnect a patient from ECMO is based on the composite assessment of several aspects of the patient's respiratory function (gas exchange function, respiratory mechanics), and hemodynamics. According to the ELSO guidelines, ECMO discontinuation can be considered when 50–80% of total gas exchange is supported by the patient's lungs.[22]

Patient readiness for weaning may easily be assessed during VV-ECMO by simply turning off the GF. At zero flow, no oxygen is added and no CO_2 is removed from the blood flowing through the ECMO circuit, and the only gas-exchange system is the patient's lung. In patients still on controlled MV, during the trial off-ECMO, respiratory rate, VT, and FIO_2 should be adjusted to values considered acceptable off-ECMO. Most commonly, ECMO is discontinued when the patient is receiving assisted spontaneous ventilation. After the GF is stopped, the patient usually has to increase respiratory effort and minute ventilation, and ventilator support should be adjusted accordingly. When the patient is considered ready, ECMO can be definitively discontinued and cannulas removed. To remove cannulas placed percutaneously, a purse-string suture, inserted around the cannulation site, is tightened immediately after decannulation and localized pressure is applied for at least 30 minutes.

LOW-FLOW CO_2 REMOVAL

Following the original concept developed by Kolobow and Gattinoni,[12,13] several devices and technical approaches have been implemented to perform extracorporeal CO_2 removal. The key is that, because these approaches use lower BFs and smaller cannulas, they are less invasive and have fewer serious side effects. The direct consequence of removing CO_2 through these devices is that it is possible to reduce the minute ventilation required through the NL, while preventing hypercapnic acidosis.

INDICATIONS

The main indications for *extracorporeal CO_2 removal* ($ECCO_2R$) are to decrease VT and RR in ARDS patients for "ultraprotective ventilation" and to decrease ventilatory needs in patients with exacerbations of COPD or severe asthma, thereby reducing dynamic hyperinflation, avoiding intubation, and facilitating weaning from MV.

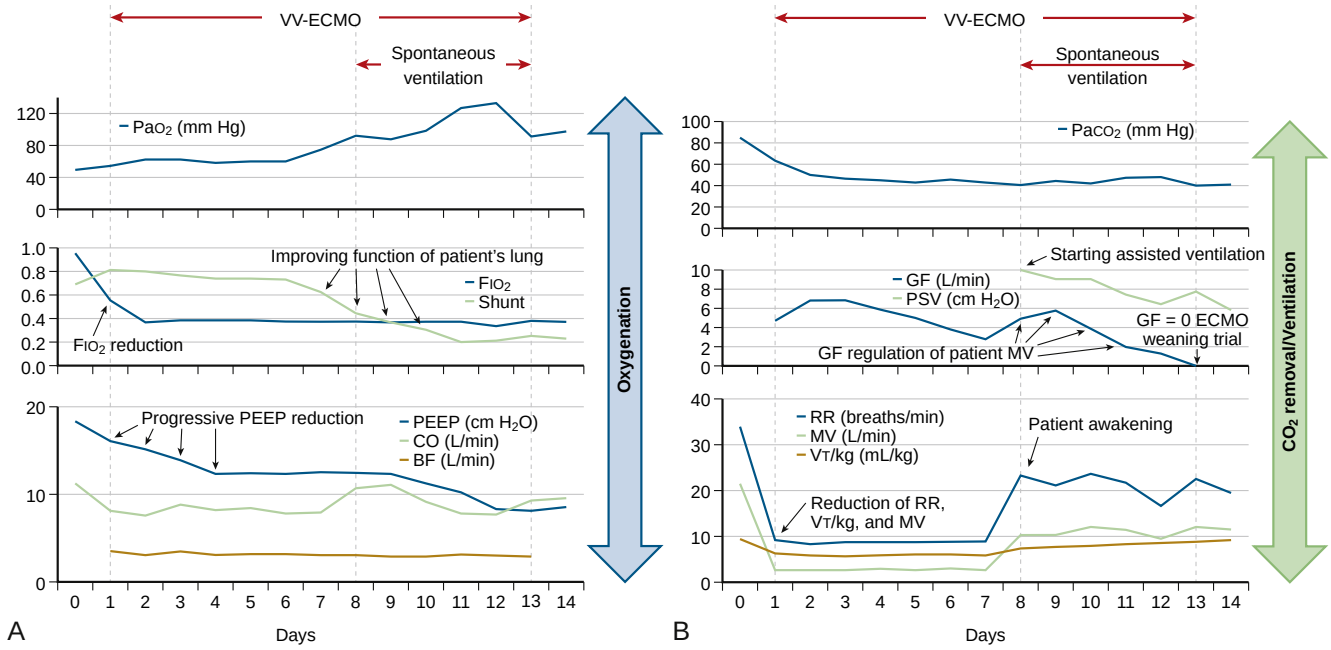

Figure 138.7 Example of ventilatory management in a patient with acute respiratory distress syndrome over 2 weeks. Oxygenation parameters (A) and ventilation parameters (B) are shown, including ventilator and *extracorporeal membrane oxygenation* (ECMO) settings, gas exchange, and hemodynamics day by day. As soon as ECMO starts, *respiratory rate* (RR), *tidal volume* (V_T/kg), and *minute ventilation* (MV) are reduced. *Positive end-expiratory pressure* (PEEP) and F_{IO_2} are reduced progressively. After the 6th day, intrapulmonary shunt (shunt) starts to decrease and Pa_{O_2} improves. On day 8, the patient is awakened. RR, V_T, and mechanical ventilation are controlled by modulating ECMO sweep *gas flow* (GF) until the patient is ready to be weaned on the day 13. Throughout the ECMO treatment, an ECMO *blood flow* (BF) of around 3 L/min is maintained while the *cardiac output* (CO) ranges between 7 and 10 L/min. PSV, pressure support ventilation.

Depending on the range of operative BFs and on the bypass configuration, the available techniques may be classified as follows:

1. *Low-flow* (LF)-$ECCO_2R$. Various devices are available that operate with very low extracorporeal BF, ranging from 250 to 500 mL/min. These systems allow removal of up to about 80 to 100 mL of CO_2/min (see Fig. 138.6). Most of these systems can be employed with small (14 to 17 French), double-lumen coaxial catheters similar to those used for continuous renal replacement. Livigni et al. were the first to describe one of these devices in 2006.[75] Since then, a number of similar devices have been described. The main limitation of these devices is the need for frequent circuit substitutions (every 24 to 48 hours). Recently, this problem has been partially solved by simplifying the circuit and using polymethylpentene oxygenators instead of the less expensive polypropylene ones. Novel systems, such as the ProLUNG, also use oxygenators with high surface areas (i.e., 1.8 m^2) to enhance CO_2 removal. A different device is the Hemolung (Alung Technologies), in which the ML and the centrifugal pump are combined and act as one unit. The rotating impeller transmits a rotational motion to the blood, thereby increasing gas-exchange efficiency.[76,77] Compared to other low-flow systems, the Hemolung shows longer duration and slightly higher CO_2 removal performance.[77]
2. *Arteriovenous CO_2 removal* ($AVCO_2R$). This arteriovenous ECMO system uses a simplified, high-technology ML (Novalung), characterized by an extremely low resistance to BF, high gas transfer efficiency, and absence of a heat exchanger. The Novalung is applied to an arteriovenous shunt obtained by connecting the femoral artery to the femoral vein using two cannulas inserted percutaneously. According to the mean systemic arterial pressure and to the size of the arterial catheter (15 or 17 French), a BF of up to 2.5 L/min can be achieved.[78,79] The main limitations of this system are the dependency on the patient's arterial blood pressure and the risk of ischemia of the leg distal to the arterial cannulation site. Close monitoring of foot temperature and pulse oximetry is recommended; if signs of ischemia are noted, prompt action is required to prevent permanent damage to the lower limb.
3. VV-$ECCO_2R$. Classical $ECCO_2R$ techniques as proposed by Gattinoni and Kolobow[12] use standard adult ECMO systems at a BF of 1.5 to 2.5 L/min. By mounting low-medium surface oxygenators such as pediatric or small adult oxygenators on small size tubes and cannulas, different ranges of flow may be achieved (from to 500 mL/min up to 2 to 2.5 L/min), allowing removal of up to 100% of the entire metabolic CO_2 production.

CO_2 REMOVAL FOR ULTRAPROTECTIVE VENTILATION IN ACUTE RESPIRATORY DISTRESS SYNDROME

The idea of ultraprotective ventilation originates from the observation that despite the use of a "protective" V_T, a substantial amount of hyperinflated lung[30] can still be present and further reduction of V_T may be beneficial. Extracorporeal CO_2 removal represents a very powerful technique to ensure protective ventilation and prevent VILI, while maintaining adequate gas exchange in patients in whom oxygenation is not a main issue. In 2006, Bein

et al. showed that use of $AVCO_2R$ allowed a reduction in ventilation to less injurious settings while oxygenation was improved.[78] $AVCO_2R$ has been employed successfully also in patients with severe influenza A. [79]

In a recent application of $AVCO_2R$, Bein et al. compared ultraprotective ventilation with VT of 3 mL/kg while on $AVCO_2R$ with a conventional protective ventilatory strategy with VT of 6 mL/kg in 79 ARDS patients. Though the study failed to show significant benefits in the 3 mL/kg group, a post hoc analysis showed a significant improvement in ventilator-free days at 60 days in the subgroup of patients with more severe hypoxemia (arterial PO_2/FIO_2 <150) at baseline.[80]

Terragni et al. were the first to use an LF-$ECCO_2R$ device in ARDS patients.[81] With this device, they were able to decrease VT from 6 to 4 mL/kg while keeping constant PCO_2 and pH levels in a group of ARDS patients. They showed a reduction of circulating inflammatory cytokines and a reduction of lung hyperinflation.

The prospective multicenter international SUPERNOVA study is the source of the most recent and largest amount of data on the use of extracorporeal CO_2 removal to enhance protective ventilation in patients with moderate ARDS.[82–84] Ninety-five patients were randomized to receive lower CO_2 extraction or higher CO_2 extraction devices (BF 300 to 500 mL/min vs. 800 to 1000 mL/min, respectively). Ultraprotective ventilation defined as VT 4 mL/kg and plateau pressure ≤25 cm H_2O or greater was achieved in 82% of patients by 24 hours from $ECCO_2R$ initiation.[82] Devices with higher CO_2 extraction capacity were able to achieve the VT target more frequently and with a lower rate of adverse events.[83] Along with higher device performance, both lower respiratory system compliance and higher alveolar dead space were associated with a greater magnitude of reduction in VT and driving pressure (ΔP, end-inspiratory plateau pressure minus positive end-expiratory pressure) from the use of $ECCO_2R$, thus suggesting that patients with these features might be most likely to benefit from $ECCO_2R$.[84]

In summary, the available literature demonstrates that the use of very low VT combined with some form of extracorporeal CO_2 removal is feasible without major side effects. However, future studies are required to demonstrate the potential survival benefits from the use of ultraprotective ventilatory strategies in ARDS patients.

CO_2 REMOVAL FOR COPD

COPD is the fourth leading cause of death in western countries and is a major cause of morbidity worldwide.[85] COPD patients experience recurrent episodes of hypercapnic respiratory failure (i.e., acute exacerbations) associated with poor prognosis and increased mortality.[86] Most patients are successfully managed with *noninvasive ventilation* (NIV), which represents the standard first-line treatment in acute exacerbations of COPD.[87] However, intubation and invasive MV are still required in 26–54% of patients.[88,89] In these patients, invasive MV is associated with a high rate of complications (e.g., ventilator-associated pneumonia, barotrauma, and failure to wean), which ultimately increases morbidity and mortality.[90–92] The main cause of NIV failure is the imbalance between the reduced capacity of the respiratory muscles to generate pressure and the respiratory load, which is increased as a result of the high ventilatory needs and expiratory flow limitation. The rationale for the use of CO_2 removal techniques is to decrease minute ventilation, and consequently airflow limitation and respiratory effort, while decreasing PCO_2 and increasing pH. $ECCO_2R$ may play a role at different stages of COPD exacerbations: to avoid intubation during the NIV phase and to reduce the duration of invasive MV and facilitate weaning.

Surprisingly, the use of $ECCO_2R$ in acute COPD patients has not been investigated until recently. The majority of the published clinical studies applied $ECCO_2R$ to prevent intubation in patients at high risk of NIV failure (pH <7.2 to 7.35, PCO_2 >45 to 95 mm Hg, or respiratory rate >27 to 40 breaths/min).[93–95] Del Sorbo et al. compared 25 patients with acute exacerbations of COPD treated with NIV and $ECCO_2R$ versus 21 historical matched controls treated only with NIV.[93] The NIV plus $ECCO_2R$ treatment showed a lower intubation rate (12% vs. 33%), and lower in-hospital mortality (8% vs. 35%); however, 52% of the treated patients showed adverse events related to the $ECCO_2R$ treatment. Kluge et al. applied an $AVCO_2R$ treatment in 21 COPD patients not responding to NIV and compared them to 21 matched controls treated with conventional invasive MV.[94] Within 24 hours of $AVCO_2R$ treatment, PCO_2 and pH significantly improved. Ninety percent of the $AVCO_2R$ patients avoided intubation, but 9 had bleeding complications. Short- and long-term survivals were similar between $AVCO_2R$ and conventional treatment. In the case-control ECLAIR study by Braune et al., VV-$ECCO_2R$ prevented intubation in 56% of the 25 treated patients.[95] Seven patients suffered from progressive hypoxemia and 9 from major bleeding. The 90-day mortality rates were 28% in both groups.

In a few cases, the use of $ECCO_2R$ to facilitate weaning from invasive MV in COPD has also been reported.[96,97] Cardenas et al. applied $ECCO_2R$ in a difficult-to-wean COPD patient: extracorporeal removal of CO_2 allowed a 30% decrease of minute ventilation with concomitant reduction in hyperinflation and improvement in gas exchange.[98] Abrams et al. successfully extubated five COPD patients within 24 hours following $ECCO_2R$ institution.[99] Garcia et al. applied VV-$ECCO_2R$ in 10 COPD patients during weaning from MV or as a bridge to lung transplant[97]; six patients were successfully weaned or underwent transplantation.

EXTRACORPOREAL MEMBRANE OXYGENATION AS BRIDGE TO TRANSPLANTATION

Lung transplantation is an important treatment option for patients with end-stage respiratory failure. The number of patients awaiting lung transplantation largely exceeds that of available organs, resulting in long waiting times. Patients developing acute exacerbation of their respiratory disease while awaiting lung transplantation have a poor prognosis, especially when invasive MV is required.[100] The mortality rate for waitlist patients with end-stage exacerbations is high.[101] In these difficult cases, bridging strategies may be necessary. The first report of ECMO as a bridging strategy dates back to 1975[102]; since then, several case series have been reported.[101–110] A recent systematic review identified 14 published studies including 441 patients from 1987 to 2013.[109] In all cases, standard veno-venous or

veno-arterial ECMO was used. The bridging time on ECMO before lung transplantation ranged from a median of 3 to 16 days. The proportion of patients successfully bridged to transplantation ranged from 50–83%, with 1-year survival rates comparable to recipients who did not receive preoperative ECMO support. In one retrospective analysis, patient outcomes were better when the patients were supported with NIV and when their bridge time until transplantation was shorter than 14 days.[110]

Clearly, proper patient selection is crucial. Absolute contraindications for ECMO bridging include the following: ineligibility for transplantation according to standard criteria, irreversible end-organ damage affecting multiple organs, sepsis and bacteremia, contraindications to systemic anticoagulation, uncontrolled metastatic disease or another terminal illness not otherwise treatable with a lung transplant, and acute intracerebral hemorrhage or stroke. Relative contraindications may vary among different centers, but usually include the following: advanced age, limitations in vascular access, obesity, frailty, and prolonged ventilatory support.[101]

Over the years, the use of ECMO to avoid tracheal intubation and MV (awake ECMO) has gained popularity, becoming the preferred first-line approach in patients awaiting lung transplantation. During ECMO support, patients are kept awake and spontaneously breathing; this helps avoid the complications associated with invasive ventilation (e.g., sedation, hemodynamic impairment, VILI, infections, diaphragmatic atrophy) but also allows active patient mobilization and facilitates respiratory physiotherapy. Moreover, the possibility of managing patients with acute respiratory failure using ECMO while avoiding intubation is also promising.

Finally, the use of low-flow extracorporeal support techniques instead of "conventional" ECMO as a bridge to lung transplantation has been described in small patient series. Fischer et al. reported on the use of $AVCO_2R$ in 12 patients with high urgency for lung transplantation experiencing severe ventilation-refractory hypercapnia and respiratory acidosis.[104] The length of extracorporeal support was 15 ± 8 days, and 10 patients were successfully bridged to lung transplantation. The only report on the use of LF-$ECCO_2R$ as a bridge to transplant is that of Ricci et al. who applied $AVCO_2R$ in 6 patients and LF-$ECCO_2R$ in another 6 patients.[107] The mean length of extracorporeal support was 13.5 ± 14.2 days with no differences between the two devices.

Key Points

- *Extracorporeal membrane oxygenation* (ECMO) refers to a technique of life support that consists of diverting part of the patient's blood to a membrane lung for gas exchange (oxygenation and CO_2 removal) and then returning it to the patient
- *Veno-venous ECMO* (VV-ECMO) is primarily indicated for hypoxemic respiratory failure in patients with a high risk of mortality or at high risk for ventilator-induced lung injury. Contraindications include advanced age, severe disability, and incurable malignancy.
- CO_2 removal is significantly more efficient than oxygenation. Depending on the *blood flow* (BF), the technique may be used mainly for CO_2 removal (BF < 2 L/min) or for both CO_2 removal and oxygenation (BF up to 5 to 6 L/min).
- ECMO BF is the main determinant of patient oxygenation. ECMO gas flow is the main determinant of CO_2 removal and, consequently, determines the minute ventilation needed from the mechanical ventilator for the native lung.
- During VV-ECMO, the native lung is ventilated in a protective way to prevent ventilator-induced lung injury. Respiratory rate, tidal volume, plateau airway pressure, and FIO_2 are generally decreased as much as possible while allowing sufficient arterial oxygenation and peripheral O_2 delivery.
- Anticoagulation during VV-ECMO is commonly achieved by continuous intravenous heparin infusion, targeted to an activated partial thromboplastin time of 45 to 60 seconds and/or to an activated clotting time of 1.5 × normal values. Bleeding remains the most frequent complication in ECMO patients. Intracranial bleeding is reported in 3.9% of patients and is associated with an overall survival rate of only 17%.
- The main indications for CO_2 removal are to permit ultraprotective ventilation of acute respiratory distress syndrome patients, to decrease the ventilatory needs of patients with exacerbations of COPD and severe asthma, to speed extubation, or to avoid intubation.

KEY POINTS

INTRODUCTION AND HISTORY

Pulmonary rehabilitation (PR) is an essential component of the comprehensive and integrated care of individuals with chronic respiratory disease. This multidisciplinary, patient-centered intervention addresses distressing symptoms, exercise limitation, and reductions in health and functional status by treating the systemic manifestations of respiratory disease, including peripheral muscle dysfunction, maladaptive coping skills, inadequate self-management skills, and nutritional depletion while recognizing the complex comorbidities typically present in these patients. Positive outcomes from PR include increased exercise tolerance, reduced dyspnea and anxiety, increased self-efficacy, and improved health-related *quality of life* (QOL).[1–3] Evidence also shows that PR reduces health care use and mortality after COPD exacerbations.[3–5]

Pulmonary rehabilitation first gained widespread attention in the mid-1990s when it was shown that, despite significant airflow obstruction, patients could exercise with sufficient intensity to achieve significant improvements in skeletal muscle function and exercise capacity.[6–9] The effectiveness of PR was further supported by studies in the early 2000s showing lower health care utilization in the year following PR.[10,11] Since that time, systematic reviews and Cochrane library analyses have demonstrated unequivocal benefits of PR for people with stable COPD and following disease exacerbation.[2,3] Moreover, it is a highly cost-effective treatment.[11–13] There is substantial and growing evidence for equivalent benefits in chronic respiratory diseases other than COPD, including asthma, bronchiectasis, cystic fibrosis, lung cancer, pulmonary hypertension, and *interstitial lung disease* (ILD).[14]

DEFINITION AND RATIONALE

The most recent American Thoracic Society/European Respiratory Society statement defines PR as "a comprehensive intervention based on a thorough patient assessment followed by patient-tailored therapies that include, but are not limited to, exercise training, education, and behavior change, designed to improve the physical and psychological condition of people with chronic respiratory disease and to promote the long-term adherence to health-enhancing behaviors."[1] Notably, this intervention is designed around the needs of individual patients and their "treatable traits."[15] As such, PR addresses a complex phenotype including pulmonary pathophysiology, comorbid conditions, adaptive (or maladaptive) behaviors, available social supports, and cultural beliefs. Program organization differs across countries and health care systems; however, it is the degree of disease complexity that dictates the type of intervention and setting for the highest likelihood of success.[16]

PR provides improvements in dyspnea, exercise tolerance, and health status exceeding those of any other therapy for COPD, despite having no direct effect on pulmonary function. This apparent paradox can be explained by understanding COPD as a systemic illness with manifestations including impaired skeletal muscle structure and function, physical deconditioning, fear of dyspnea-producing activities, and inadequate pacing and coping skills, all contributing to symptoms and disability.[17–19] PR specifically targets these comorbidities. For example, exercise training leads to improved limb muscle function, with a reduced ventilatory requirement, despite no measurable change in FEV_1.[20,21] PR also addresses other comorbidities such as nutritional depletion, poor pacing techniques, maladaptive coping skills, and fear of dyspnea-producing activities, which can result in a vicious circle of deconditioning and debilitation.

Focused interventions within PR can interrupt this cycle and improve the dyspnea associated with daily activities, improve health and functional status, and reduce health care utilization.[22–24]

INDICATIONS AND CANDIDACY

People with chronic respiratory diseases who remain symptomatic and/or who experience disability despite optimized medical therapy are candidates for PR.[1,25] Patients are referred to PR by their health care provider, usually for one or more of the following reasons:

1. Severe dyspnea and/or fatigue
2. Decreased exercise tolerance or ability, and/or low physical activity levels
3. Difficulty performing *activities of daily living* (ADLs)
4. Impaired health status
5. Decreased occupational performance or ability
6. Frequent or increased medical resource utilization
7. Difficulty coping with or managing the disease
8. Recovery from COPD exacerbation (or other acute event leading to hospitalization)
9. Preparation for or recovery from lung transplantation (or other lung surgery)
10. Nutritional depletion

Given that resources for and reimbursement of PR are limited in many countries, it is important to identify individuals who are most likely to benefit from it. Whereas a majority of people with chronic respiratory disease do benefit, responses to individual components of PR vary, and patients' gains vary across different outcomes.[26] Identification of those most likely to benefit is therefore difficult and, to date, there are no clear selection criteria to determine responders versus nonresponders to PR. The structure, staffing, and resources available in individual PR programs affect the medical complexity, number, and mix of patients that can be accommodated.[19,27] Insurance coverage also often impacts patients' ability to enroll in PR. Individuals with stable chronic respiratory disease, as well as those recently hospitalized for disease exacerbation, can benefit.[1,3]

Several studies have evaluated the impact of various clinical characteristics on patients' likelihood of achieving benefits from PR. Most of this work has, to date, focused on individuals with COPD. People with a wide range of lung function impairment benefit from PR.[1,2,25,28–30] PR is effective in improving symptoms, exercise, and quality of life, even for those with very severely impaired lung function,[1] including those preparing for lung transplantation[31] and those requiring supplemental oxygen.[32] Health care professionals often refer patients to PR when disease is severe and when they cannot identify further treatment options. Although payers may pose some limitations for PR based on lung function severity, delays in referral until disease is severe are often misguided. Indeed, people with mild-severity COPD[33,34] also achieve benefits from PR. Participation in PR earlier in disease before symptoms are severe may help to promote and establish health-enhancing behaviors (including regular exercise, physical activity, and better management of exacerbations) and can help patients cope with and manage their disease, which may favorably affect disease progression and improve outcomes.

Other characteristics, including age,[35–38] smoking status,[39] and medical comorbidities,[40–44] do not reliably differentiate between those who are or are not likely to benefit from PR. Among those with COPD, the degree to which exercise capacity is limited by muscle weakness and/or fatigue as compared to ventilatory impairment may impact gains after exercise training in PR.[45–48] For example, patients with predominance of nonventilatory exercise limitations (i.e., poor aerobic fitness) are typically able to train at higher intensities, resulting in greater training effects. However, exercise capacity improves regardless of the initial mechanism of exercise limitation; therefore, PR benefits all functionally impaired COPD patients.

Exclusions from PR may include conditions that interfere with the rehabilitation process or that would place the patient at risk during exercise training. Accordingly, there are few absolute contraindications to PR. These include:

1. Unstable angina or arrhythmia
2. Unstable bone fracture
3. Communicable infectious disease
4. Unstable psychiatric condition posing harm to self or others

Relative contraindications include severe cognitive impairment, lack of motivation, severe progressive neurologic disease, severe anemia and/or severe debilitating fatigue (e.g., due to other medical illness) that would prevent participation.

COMPONENTS

The core components of PR are shown in Table 139.1.

EXERCISE TRAINING

Exercise training is the cornerstone component of PR. Several mechanisms contribute to exercise impairment associated with chronic respiratory diseases. Ventilatory limitation is important, but skeletal muscle dysfunction and cardiovascular impairments are also key contributors limiting exercise ability.[20,49,50] For example, reductions in limb muscle mass, strength, endurance, and muscle mitochondrial density; altered resting and exercise muscle energy utilization; reduced type I (slow twitch, high oxidative capacity, fatigue-resistant) muscle fibers, fiber capillarity, and oxidative enzymes; impaired balance; and other disturbances are common among people with COPD.[49,51] Skeletal muscle dysfunction is also present among individuals with ILD,[52–54] pulmonary hypertension,[55–57] cystic fibrosis,[58] and those recovering from lung transplantation.[59–61] Skeletal muscle dysfunction results from physical inactivity and deconditioning, oxidative stress, systemic inflammation, nutritional/energy imbalance, electrolyte disturbances, aging, hypoxemia, low anabolic hormone levels, systemic corticosteroid use, and other mechanisms.[1,28,49]

Importantly, deconditioning, sarcopenia, and other aspects of skeletal muscle dysfunction can be improved with

Table 139.1 Components of Pulmonary Rehabilitation

Exercise training (lower and upper extremities) ■ Aerobic training (cycling or walking-based exercise) ■ Resistance training (free weights, exercise bands, weight machines) ■ Interval training (alternating periods of high-intensity exercise and rest/lower intensity exercise) ■ Balance training ■ Other: whole-body vibration training, neuromuscular electrical stimulation, yoga/Tai Chi
Education (see Table 139.2)
Collaborative self-management skills
Disease exacerbation, medication, and oxygen management
Psychosocial support
Nutritional support and dietary counseling
Breathing training and airway clearance techniques ■ Inspiratory muscle training ■ Pursed-lip breathing ■ Chest physical therapy (percussion/postural drainage) ■ Positive expiratory pressure vibration devices ■ Pacing and energy conservation techniques
Physical activity promotion and coaching
Emphasis on long-term health-enhancing behavior change
Advance care planning
Assessment of participants' exercise and functional capacity, symptoms, QOL/health status (and other patient-centered and health-system outcomes) before and after PR program participation (see eTable 139.1) ■ Demonstrate individual patients' progress and gains made in PR ■ Demonstrate PR program effectiveness and safety ■ Monitor program costs

PR, pulmonary rehabilitation; QOL, quality of life.

exercise training.[1,28,49,62,63] Several forms of exercise training are beneficial.[1,64] The mechanisms by which exercise capacity improves following exercise training depend on the type of respiratory disease and the type and intensity of exercise training. For example, among people with COPD, exercise training–induced fiber-type switching to a more fatigue-resistant profile and increases in mitochondrial oxidative enzyme capacity and/or fiber capillarity can result in a lower lactate production for a given workload and a delay in the anaerobic threshold.[6,7] This results in lower ventilatory demand during exercise, with improvement in breathing pattern and reduction in dynamic hyperinflation.[65] This, in turn, leads to improved exercise capacity and reduced dyspnea with daily activities.

Typically in PR, a combination of aerobic and resistance training is undertaken of the upper and lower extremities.[1,64] Continuous endurance aerobic training of the legs via cycling and/or walking-based exercise (e.g., treadmill or ground-based walking) at a set target intensity is common.[2] Endurance aerobic training improves maximal exercise capacity, endurance, dyspnea, and fatigue in COPD.[1,2,66] Exercise training also improves ADL performance, reduces systemic blood pressure, improves lipid profiles, reduces depression and anxiety, and facilitates sleep. In general, exercise training at high intensity (e.g., 60–80% of maximal workload) leads to greater gains in aerobic fitness than lower-intensity exercise (<50% of maximal workload), but low-intensity exercise still confers benefits, and the optimal training intensity is not fully understood.[67] Walking-based training improves walking endurance more than cycle training,[68] although cycle-based training is associated with less oxygen desaturation.[69] One-legged exercise (single-leg cycling) can lead to greater gains in peak oxygen uptake and/or endurance compared with conventional cycling because training a smaller muscle group enables provision of a higher-intensity training load for a longer time before reaching ventilatory limitation, poses lower ventilatory demand and, in turn, can lead to overall greater increase in aerobic capacity.[70,71] Use of rollator walkers facilitates walking exercise and reduces dyspnea for people with severe dyspnea and functional limitation.[72–74] Nordic walking with walking poles also increases exercise tolerance and physical activity levels.[75]

Bronchodilator therapy (where relevant) should be optimized prior to PR to enable exercise at higher intensities and to optimize gains in exercise tolerance.[76] Supplemental oxygen therapy is typically provided for resting and/or exercise-induced hypoxemia, to improve exercise endurance,[77] maintain safety, and allow training at higher work rates. Oxygen therapy may also enable exercise training at higher intensities for nonhypoxemic patients[78]; however, this is not a universal finding.[79,80]

Interval training, wherein periods of high-intensity exercise (e.g., 20 to 30 seconds) are alternated with periods (e.g., 30 to 40 seconds) of low-intensity exercise or rest, leads to comparable gains in exercise capacity, skeletal muscle function, QOL, and reduction in dyspnea to those made during continuous endurance training in moderate-to-severe COPD.[81–83] Those with difficulty performing continuous endurance training or who have severely impaired exercise capacity and/or severe dyspnea may benefit from interval training.[84]

Resistance training, using free weights or weight machines, can improve muscle strength and/or endurance depending on the training regimen.[85,86] Combining resistance training with aerobic training in PR leads to greater gains in muscle strength and size compared to aerobic training alone.[87–89] However, the optimal resistance training regimen for maximal gains in skeletal muscle function for individuals with chronic respiratory diseases remains unknown.

Exercise training of the upper extremities has been less studied compared to lower limb training. However, because many ADLs rely on upper extremity function, optimization is an important goal. Upper limb training (both aerobic and resistive) can increase upper limb exercise capacity,[90] improve arm strength, and improve arm endurance.[90–92] The benefits of upper limb training on dyspnea and health-related QOL are less clear,[90,91] and optimal training regimens are unknown.

The exercise prescription for individual patients in PR is based on assessment of their baseline exercise capacity. Prescription of endurance training typically involves use of low-cost field tests of exercise capacity, such as the 6-minute walk test and the incremental shuttle walk test,[93] with target intensity based on target heart rate, metabolic equivalents, or maximal exercise capacity.[93,94] Formal cardiopulmonary exercise testing is undertaken in some centers[95] but requires specialized equipment

and staff, is not universally available, and adds cost. The prescription of interval-type exercise training is typically based on cardiopulmonary exercise testing measurements. Endurance training is typically two to five times per week and is ideally prescribed three to five times weekly at 60–80% of maximal work rate for 20 to 60 minutes per session.[84] Duration and workload of exercise are progressed over the course of the program as tolerated. Interval training is typically three to four times per week at 80–100% of maximal work rate for a total of 45 to 60 minutes.[96] The resistance training prescription is typically based on baseline assessment of the maximal weight the patient can lift for each exercise (the one-repetition maximum),[49] with training intensity set at a fraction of the one-repetition maximum, depending on whether the target is improved strength[85] or endurance.[96] Resistance training is recommended 2 to 3 times per week,[1] and the workload of resistance training is progressed over the course of the program as tolerated.

Several other forms of exercise training also have demonstrated efficacy for people with COPD.[64] Balance impairments, gait disturbances, and falls are common[51,97–105]; balance worsens further after an acute COPD exacerbation.[106] Although not yet routinely included in PR, balance training incorporated into PR is well tolerated[107] and improves balance and health-related QOL.[107–109] Several tests are available to assess balance.[110] The effects of balance training on fall risk are not yet known. Whole-body vibration training, wherein the patient stands or performs squat exercises on a vibration platform, also has demonstrated benefits for several parameters of exercise tolerance and health-related QOL for people with COPD.[111–115] Though not yet used widely in PR due to need for specialized equipment, its benefits are notable, and it may be particularly helpful for individuals with difficulty participating in conventional exercise training. *Neuromuscular electrical stimulation* (NMES) is another training technique that may be considered. This involves application of an electrical stimulus to elicit muscle contraction via surface electrodes placed on the skin over the muscles targeted for training. The amplitude, frequency, and stimulation pattern impact the type of training effects achieved with NMES. It is typically well tolerated, nonpainful, and safe, although it should be avoided in those with indwelling cardiac pacemakers, defibrillators, and/or with seizure disorders. NMES can improve muscle strength, muscle mass, and exercise capacity for people with severe disease who have difficulty participating in conventional exercise training due to ventilatory limitation.[116,117] A recent meta-analysis of 16 studies of NMES, including 267 patients with COPD, showed that NMES alone confers significant improvements in quadriceps force and endurance and exercise capacity.[118] NMES is also suitable for home use,[119] but as yet is not proven to provide more benefits than conventional PR.[120] Functional electrical stimulation, in which electrical stimulation is delivered concurrently with specific exercise modalities such as cycling, is a novel approach to increasing exercise training intensity.[121] Yoga and tai chi are alternative exercise strategies that incorporate breathing training and stress reduction, confer modest benefits in 6-minute walk test, dyspnea,[122–124] or QOL,[124,125] and may be appealing to some individuals. Various adjunct interventions to optimize the benefits of exercise training have been studied, including use of heliox, noninvasive ventilation, nutritional supplements, and anabolic hormone therapy. These interventions remain largely investigational to date.[1,126]

The type of exercise training included in PR depends on locally available equipment, space, staffing, and resources.[27] The choice of exercise also depends on individual patients' abilities, comorbidities (e.g., orthopedic limitations or morbid obesity) that may require or preclude performance of selected exercise, and preferences. Incorporation of at least some form of exercise that patients find enjoyable may be more likely to encourage them to undertake exercise and physical activity in the home environment both during and after completion of the PR program. Most PR programs range in duration from 8 to 12 weeks. A Cochrane review and meta-analysis of 65 randomized controlled trials including 3822 participants with COPD demonstrated that exercise training in PR (compared to usual care) led to increased maximal exercise capacity (mean difference, 6.8 watts; 95% *confidence interval* [CI], 1.9 to 11.7; n = 779; studies =16), increased 6-minute walk distance (mean difference, 43.9 meters; 95% CI, 32.6 to 55.6; n = 1879; studies = 38), reduced dyspnea, and improved quality of life (considered further in later section on outcomes of PR).[2] Longer programs may provide more sustained benefits.[127] Recommendations for continuing exercise and physical activity are commonly provided at the completion of PR. Repeat courses of PR provide a similar degree of benefit to those of initial program participation.[128]

EDUCATION

Education is another essential component of PR. In order to sustain the benefits obtained during the formal PR program, it is imperative to provide the necessary tools and strategies to patients that promote self-efficacy, which is the foundation for health behavior change and optimized disease control. Traditionally, PR programs were established for patients with COPD and common educational topics included specific disease education, inhaler technique and medication management, benefits of exercise, how to manage symptoms, and relaxation and energy conservation techniques. Because active smoking is not an exclusion criterion for program enrollment, nor has it been shown that smokers attain fewer benefits with PR, smoking cessation education and support should be included in PR for smokers. In more recent years, other topics have been added in response to patient needs and goals, such as advance care planning, importance of physical activity, and action plans for the COPD exacerbation. However, to date, no literature has clearly demonstrated which topics are essential for inclusion or how education is best delivered. A more in-depth understanding of the learning needs of patients, especially those with chronic respiratory diseases other than COPD, is warranted, and adaptation of the education component of PR is evolving.[129] Education topics included commonly in PR programs are shown in Table 139.2.

Studies that have evaluated didactic education in addition to exercise training in PR have not shown benefits beyond those seen with exercise training alone, including improvements in health-related QOL, health care

Table 139.2 Education Topics Commonly Included in Pulmonary Rehabilitation

FOR ALL

- Anatomy and physiology of respiratory disorders (e.g., COPD, ILD, PH, asthma, CF, bronchiectasis, lung cancer)
- Benefits of exercise and physical activity
- Benefits and adverse effects of respiratory medications (disease-relevant; including proper timing and technique)
- Benefits and practical aspects of supplemental oxygen therapy
- Benefits and practical aspects of noninvasive ventilation (e.g., CPAP, BPAP where relevant)
- Anxiety management, coping skills, relaxation strategies
- Recognition and management of disease exacerbations (including triggers, symptoms, and signs)
- Pacing, energy conservation, breathing techniques, body positioning to decrease work of breathing
- Nutrition
- Advance directives/end-of-life issues and care
- Partnering with health care professionals to manage disease

FOR SELECTED GROUPS

- Smoking cessation
- Airway clearance techniques and prevention of infection spread
- Exacerbation triggers
- Preparation for or recovery from lung transplantation or other surgery
- Controlled coughing/incentive spirometry
- Ambulation and deep breathing with chest tube in place (postoperatively)

BPAP, bilevel positive airway pressure; CF, cystic fibrosis; CPAP, continuous positive airway pressure; ILD, interstitial lung disease; PH, pulmonary hypertension.

utilization, symptoms, exercise capacity, functional capacity, and anxiety and depression.[2,130,131] Despite these negative findings, patients report that the education component is important and beneficial, and studies suggest that program completion and adherence to follow-up is improved in those patients receiving education alongside exercise.[130,132] It is entirely possible that the impact of educational components may not be reflected in traditional PR outcomes but may be related to recruitment, engagement, and retention in the program, and/or to long-term adherence to health-enhancing behaviors.

The exploration of patients' learning styles and needs, as well as the urgent requirement to address waning benefits over time, has transformed how PR programs convey vital information. Significant positive impacts on health care utilization and patient-centered outcomes have been demonstrated with interventions designed to improve self-management compared with usual care in chronic respiratory conditions.[133–138] As such, educational efforts are now focused on tailored self-management interventions that support patient-centered learning. As defined by international consensus, these patient-centered interactions focus on (1) identifying need, (2) increasing health beliefs and enhancing intrinsic motivation, (3) eliciting personalized goals, (4) formulating appropriate strategies to achieve those goals and, if required, (5) readjusting goals and strategies.[139] Behavior change techniques are used to elicit patient motivation, confidence, and competence. These approaches must recognize and adapt to the individual's cognitive abilities, psychological comorbidities, social context, and cultural beliefs as well as literacy level. The development of a patient-specific, collaborative self-management plan for disease exacerbations (action plan) is an important goal of PR; this includes education about the symptoms and signs associated with exacerbations to foster early recognition followed by the implementation of an action plan, which may include contacting a health care provider and/or using filled prescriptions. A 2017 Cochrane review of 22 studies involving 3854 participants with COPD showed statistically significant improvements in QOL and a lower risk for at least one respiratory-related hospital admission in patients using COPD action plans.[140] A 2019 randomized controlled trial utilizing disease exacerbation action plans in COPD patients with comorbidities showed a shorter duration for each COPD exacerbation and a lower probability of more than one respiratory-related hospitalization during the study year compared to usual care.[141] Ongoing collaboration among patient and medical team members is key to effective self-management.[142] PR provides an ideal setting for patient learning; however, due to heterogeneity of educational and study design, no firm conclusions have been made for practice recommendations.

The rise of digital technology provides additional opportunities to explore ways to extend and enhance patient learning within PR. Online tele-video sessions and other online connections, including social media, reading content on websites, use of smart device applications, and online classrooms, can support self-management learning.[143,144] In a recent Cochrane review, compared to conventional educational approaches, use of technology to support self-management led to greater improvements in health-related QOL and physical activity for 6 months but not 12 months; there was no significant difference in hospitalizations or exacerbations at any time point.[145] Several studies have explored the use of online home-based PR and reported acceptance and feasibility; however, outcome data remain sparse.[146,147] There is promise for using technology to support learning, but caution is needed because web-based resources available to people with COPD may vary significantly with respect to quality.

Finally, it is important to note that many health care professionals involved in the delivery of PR have little formal training in delivering education and facilitating learning. This is particularly relevant with techniques such as cognitive behavioral therapy, motivational interviewing, and technology-assisted learning. Increased attention must be given to educating PR professionals on educational design, adult learning theories, and implementation.

PSYCHOSOCIAL SUPPORT

Psychosocial comorbidities such as anxiety, depression, maladaptive behaviors, poor coping skills, and decreased self-efficacy contribute to the burden of advanced respiratory disease.[148] Anxiety and depression are associated with higher severity of dyspnea during activity and impairment in QOL at the start of PR and correlate with poorer outcomes after PR. In addition, psychosocial comorbidities may impact patient acceptance and/or completion of PR.[149,150] Psychosocial and behavioral interventions vary widely among PR programs but, at a minimum, often involve educational sessions or support groups focusing on areas such as coping strategies and stress management techniques. Comprehensive PR can decrease psychosocial morbidity

in patients with severe COPD, even when no specific psychological intervention is provided.[151] Techniques such as cognitive-behavioral therapy, biofeedback, family therapy, relaxation, and hypnosis may reduce not only anxiety but also dyspnea. However, the heterogeneity of available study designs does not allow for generalizations about their efficacy or routine implementation into PR.[152] Individuals with substantial psychiatric disease should be referred for appropriate professional care.

NUTRITIONAL SUPPORT

Low body mass index is present in 20–35% of patients with stable COPD.[153] It is associated with more severe lung disease, lung hyperinflation, and lower diffusing capacity. Low body mass index is also related to decreased respiratory muscle strength, handgrip strength, exercise tolerance, and health status, and increased mortality risk as compared to normal-weight individuals with COPD.[126] Given these poor outcomes, nutritional assessment and intervention is a recommended component of comprehensive PR.

Nutritional supplementation has been shown to improve outcomes in patients with COPD. In a 1998 publication, predictors of mortality were analyzed in two different cohorts of patients with COPD. In the first cohort of 400 COPD patients who had not received nutritional supplementation, body mass index was an independent predictor of increased mortality; in the second cohort of 203 COPD patients who received nutritional supplementation, weight gain in both depleted (i.e., low body weight or low *fat free mass* [FFM]) and nondepleted patients was a significant predictor of increased survival.[154] A subsequent 2012 Cochrane review of 17 studies found moderate-quality evidence that nutritional supplementation promotes significant weight gain and FFM in patients with COPD, especially for those that are malnourished. These patients also showed significant improvements in respiratory muscle strength and overall health-related QOL.[155] During PR, optimal nutritional intervention should focus on the interaction between nutritional supplementation and exercise, specifically resistance training to build FFM, and special attention should be paid to preventing weight loss in underweight patients undergoing endurance training.

The benefits of simple nutritional supplementation to underweight patients with chronic lung disease have been underwhelming, and therefore, attention has been given to multimodality interventions combining nutrition with anabolic steroids. This combined approach has shown improved body weight, FFM, exercise tolerance, symptom scores, and survival (over a 15-month study period). However, it is difficult to separate the effects of nutritional supplementation because all patients in the treatment arms also received PR.[156,157] It is unclear whether the benefits seen in clinical trials can be applied with safety and efficacy to a more generalized population.[1]

The effects of PR are similar in obese patients when compared to normal-weight individuals.[158] It is interesting to note that the degree of static hyperinflation, prevalence of low FFM and osteoporosis, and mortality are lower in obese COPD patients compared to normal-weight patients (the obesity paradox).[159] Despite these findings, it is recommended that PR programs also provide nutritional counseling and support to those patients who are significantly overweight.

INSPIRATORY MUSCLE TRAINING, BREATHING TRAINING, AND CHEST PHYSICAL THERAPY

Modalities including inspiratory muscle training, breathing training, and chest physical therapy have been part of PR over the years, but conclusive evidence supporting their routine use is, for the most part, lacking. The respiratory muscles can become weak in people with chronic lung disease due to mechanical inefficiency of the thorax. Individuals with COPD use a significantly higher proportion of their maximal inspiratory pressure as compared to healthy subjects, which correlates to higher levels of dyspnea at any given exertion level.[160] Inspiratory muscle training significantly improves maximal inspiratory pressure; however, studies have shown variable benefits in exercise capacity, dyspnea, and functional status,[161–164] and inspiratory muscle training does not have proven added benefit when combined with conventional PR.[162] At this time, inspiratory muscle training is not routinely recommended as part of PR; however, it might benefit certain subgroups of patients with markedly reduced maximal inspiratory pressure.[165]

The goal of breathing training is to reduce air trapping by controlling respiratory rate and breathing pattern. Pursed-lip breathing, performed with patients inhaling through the nose and exhaling through the mouth over 4 to 6 seconds through pursed lips in a whistling/kissing position, facilitates the recruitment of abdominal muscles during exhalation and has a favorable effect on the breathing pattern by increasing tidal volume and reducing end-expiratory lung volumes by increasing expiratory times and stenting collapsible airways with a positive end-expiratory pressure effect.[166] Successful pursed-lip breathing can result in less hypoxemia and decreased dyspnea. In some patients, pursed-lip breathing has also been shown to reduce the oxygen cost of breathing.[167]

Other breathing training techniques include breathing while bending forward and diaphragmatic breathing. The body-forward bending position with or without arm bracing has been reported to alleviate dyspnea and increase maximal inspiratory pressure in COPD patients by improving the length-tension relationship of the diaphragm and the mechanical coupling of the rib cage. Diaphragmatic breathing is performed by breathing slowly in through the nose while allowing the abdomen to move out, then exhaling while tightening the abdominal muscles and allowing them to move inward. Diaphragmatic breathing, though widely accepted as a breathing exercise to strengthen the diaphragm, has not been shown to be beneficial and, in fact, may decrease breathing efficiency and lead to more dyspnea in some COPD patients.[167]

Chest physical therapy techniques are used to facilitate secretion removal. Techniques include postural drainage, chest percussion and vibration, and directed cough. Because cough efficacy is frequently impaired in people with COPD, cystic fibrosis, and bronchiectasis, these techniques may be useful in selected patients.[168] Chest percussion must be used with caution in patients with osteoporosis. Individuals with bronchiectasis may also benefit from training with use

of vibration positive expiratory pressure devices, such as flutter or acapella devices, to facilitate airway mucus clearance. These simple handheld devices combine the principles of high-frequency oscillation and positive expiratory pressure to loosen mucus and help to expel it from the airways.

PROMOTING PHYSICAL ACTIVITY

Physical activity is associated with important health outcomes in the general population and for people with COPD, including improved cardiovascular conditioning, bone health, mental health, cognition, quality of life, and reduced obesity, diabetes, cancer risk, and mortality.[169–176] People with COPD have low activity levels compared to age-matched healthy individuals.[177,178] Activity levels decrease further during acute disease exacerbations,[179–181] with advancing disease severity,[182] over time,[183] in the presence of comorbidities,[184] and with use of supplemental oxygen.[185,186] Among those with COPD, low physical activity levels have been associated with worse lung function,[187–189] increased systemic inflammation,[190] risk of exacerbations and hospitalizations,[191–194] and mortality.[187,191,192,195] Physical activity levels are also reduced among individuals with other chronic respiratory conditions, including ILD,[196,197] asthma,[198–200] and pulmonary hypertension, [201,202] and are also linked to worse clinical outcomes.[197,203] It is hoped that interventions to increase activity levels will improve health.

Although PR consistently leads to gains in exercise capacity, the impact of PR on participants' activity levels is variable.[1,178] Although PR can lead to gains in physical activity,[204–207] it does not universally do so,[208–212] and changes in activity are variable following PR.[213] The impact of baseline exercise tolerance on gains in physical activity after PR is also variable.[214,215] Gains in exercise capacity (what the person *can* do) do not always translate into increases in physical activity (what the person *actually* does).[216] The factors that impact peoples' performance of daily activity is the subject of intensive research. Motivation, health-enhancing behaviors, social and environmental circumstances, weather and geographic area, and sociocultural norms all influence physical activity levels.[178]

Physical activity can be assessed indirectly via questionnaires[217–220] or measured directly using activity monitors worn on the waist or arm.[178] Given the importance of physical activity for clinical outcomes, efforts are underway to adapt and refine the PR intervention to foster patients' activity levels, and physical activity is increasingly included as a routine outcome measure in PR programs.[221] However, increasing physical activity is challenging because it depends on both physical ability and behavioral motivation.[222] Motivational programs using web-based activity promoting platforms,[223,224] telerehabilitation,[225] smart phone–based activity telecoaching,[226] virtual peer group behavioral interventions,[227] and simple commercially available devices (such as pedometers and wristband devices) are under investigation and have some demonstrated success. These interventions will likely be used more routinely in PR in the future.

LONG-TERM OUTCOMES AND MAINTENANCE OF BENEFITS

Although the short-term benefits of PR across multiple outcome areas are unequivocal (Table 139.3), benefits tend to decline once the program is completed unless patients continue to exercise regularly. In a landmark trial of PR, gains in exercise performance and health status obtained after 6 to 8 weeks of therapy disappeared by 18 to 24 months.[9] Several factors are likely to affect maintenance of benefits after PR, including exacerbations of underlying disease(s), burden of continuing exercise, frailty, and depression.[228,229] Understanding these barriers may help to design strategies to promote long-term adherence.

Maintenance programs largely involve exercise training but may also include continued self-management education. The ideal design of these programs is not known. A systematic review of supervised exercise programs in COPD (primarily weekly supervised exercise) found no added benefit to symptoms, exercise capacity, or health-related QOL when compared to standard care or unsupervised exercise.[230] Subsequently, a large trial showed that patients undergoing maintenance PR after an 8-week PR program had no change in their body mass index, airflow obstruction, dyspnea, and exercise tolerance index for the first 2 years of the 3-year program; the control group instead showed an increase in body mass index, airflow obstruction, dyspnea, and exercise tolerance at 2 years.[231] The PR program involved both supervised and unsupervised exercise, hospital visits, and regular phone contact.[231] A recent meta-analysis demonstrated that supervised maintenance rehabilitation reduces the risk of COPD exacerbations (risk ratio, 0.79) and respiratory-related hospital admissions (risk ratio, 0.62).[232]

Unsupervised maintenance exercise training may be a less expensive and more accessible training modality. Unfortunately, beneficial effects have only been seen following prolonged (3 to 6 months) PR programs, whereas those following programs of 8 weeks' duration did not show maintenance of exercise capacity post-program.[233,234] The addition of strategies designed to improve adherence to exercise

has shown some promise. These additions include exercise diaries, support phone calls, follow-up assessments, pedometers, and other more complex technology.[232,235–237] Based on the available studies and the heterogeneity of interventions, it is not possible at this time to recommend one support intervention over another.

Adapting maintenance exercise programs to the needs of the individual, including alternative modes of exercise training (such as Tai Chi and water-based exercise) and complex technology (such as telerehabilitation platforms), is likely to be most successful. Incorporating the principles of PR, including exercise training, and incorporating ongoing healthy behaviors, such as physical activity, into the home setting may also lead to longer-lasting benefits. This is supported by studies of home-based programs that suggest that gains made in the home setting may be longer-lasting than those of hospital-based programs. Although regularly scheduled repeated PR sessions do not give additional prolonged benefit, "booster shots" of PR (e.g., delivered following an exacerbation) can help to return the patient to baseline functional performance.[238]

OBSTACLES TO PATIENT PARTICIPATION AND ADHERENCE

Overall uptake of PR by patients to whom it is offered remains low.[239,240] Several factors impact whether people with chronic respiratory diseases enroll in and/or complete PR. Many patients who could benefit have never been referred and are not aware of PR.[239,241–245] A recent survey of patients with chronic respiratory diseases conducted in 29 countries in Europe and the Americas illustrated that 22.4% of respondents had not been told about PR by their health care provider, 9.6% felt they did not have enough information to decide on whether to participate, and 8.9% were uncertain about the benefits it would provide.[246] Suboptimal knowledge and awareness of the process and benefits of PR among health care professionals (primary care and subspecialty providers) contributes to low patient referral rates.[239] Although training in PR for health care professionals varies across countries, formal training requirements are often minimal or lacking altogether. Among those to whom PR is offered, depression, current smoking, social isolation, transportation difficulty or travel distance, lack of perceived benefit, fear that it will be painful, poor mobility, severe dyspnea, frailty, comorbidity, and other social factors are cited barriers to PR participation.[239,246–254] Overcoming these barriers is a complex and difficult challenge. Successful approaches will likely depend on investigating and understanding the key local barriers in differing health care systems and undertaking practical solutions to foster patients' participation. This may include public awareness campaigns about PR, increased communication between health care professionals and patients about the benefits of PR, increased training for health care professionals in the discipline of PR, providing transportation and/or parking, establishment of PR programs in regions where they are currently lacking, and implementation of novel models of PR. Importantly, in many countries, PR programs are underfunded and underresourced. Limitations regarding program availability, access, insurance reimbursement, and coverage (including based on severity of disease and for repeat programs as needed) are serious obstacles to patients' participation in PR. Advocacy on the part of health care professionals, individuals with chronic respiratory diseases, and the general public is needed to improve this situation.

COMORBIDITIES

Medical comorbidities are common among individuals with chronic respiratory disease.[255–262] Multiple comorbidities typically coexist[263,264] and increase patients' morbidity and mortality risk.[18,265–268] Cardiovascular disease, peripheral vascular disease, and cognitive impairment are common among individuals referred for PR.[40,269–271] The total number or severity of comorbidities does not appear to impact PR outcomes.[40–42,44,272–274] However, individual comorbidities may impact selected outcomes for some persons.[40,42,149,150,275] PR is an important setting in which comorbidities may be newly recognized. PR providers must be aware of the spectrum of potential comorbidities, monitor patients for any concerning symptoms and signs during the program, and communicate any concerns to the referring health care professional.

Patients with complex multimorbidity may experience frequent exacerbations of symptoms, urgent care visits, hospitalizations, and/or episodes of acute-on-chronic respiratory failure. These patients have a high burden of disease-related morbidity, high health care costs, and, in many cases, an unstable condition.[19] In addition, they often face an overwhelming array of medications and testing and disease management recommendations prescribed by different providers who may not recognize the total burden for the patient. PR is an ideal setting in which to address and stabilize some of these issues (see Table 139.2). Patients with complex multimorbidity should undertake PR in a setting with a multidisciplinary health care team and a multifaceted approach that can address unique physical, functional, psychosocial, nutritional, and cognitive/behavioral needs.[16]

PROGRAM ORGANIZATION

Individuals referred to PR undergo a formal evaluation by the medical director and/or program staff to evaluate candidacy and safety for enrollment.[25] This includes a thorough medical history, physical exam, review of medical records, any testing or treatment that may be needed prior to enrollment, as well as assessment of exercise capacity, symptoms, health status, and other measures (see section on "Outcome Assessment and Measurement" later).[1] To be considered PR, programs must include, at a minimum, supervised and structured exercise training, education geared towards health-enhancing behavior change, and pre- and post-rehabilitation program outcomes measured in at least three key domains: exercise capacity, symptoms, and health status/QOL.[1,28,239,276] Assessments and outcome measures in additional areas such as physical activity, balance, anxiety/depression, health care utilization, and others are desirable but not universal.

Staffing, organization, content, and resources available in individual programs vary widely.[27,277] Staffing ranges from one or two providers to several providers in comprehensive multidisciplinary teams. PR staff typically include physiotherapists/exercise physiologists, nurses, respiratory therapists, health psychologists, and a medical director; the staff may include other disciplines such as occupational therapy, dieticians, pharmacy, social work, or others. PR program staff must demonstrate core competencies in the delivery of PR.[278–281] Staff must have familiarity with the anatomy, physiology, symptoms, comorbidities, and management of various forms of chronic respiratory disease. They should be skilled in cardiopulmonary resuscitation, and emergency resuscitative equipment should be available on site. Staff-to-patient ratios vary in different countries.[1] A program coordinator is designated in most programs. This individual develops the integrated program; organizes the program components and team members into a functioning unit; monitors the program progress, course and outcomes; and, together with the medical director, ensures that program quality metrics are met.

PR can be delivered in inpatient, outpatient, or home-based settings.[282] The severity of disease and medical comorbidities, severity of functional disability, patient preferences, available program types and locations, transportation issues, insurance coverage, and health system norms all impact the choice of PR setting. A majority of the published studies on PR have reported on outcomes of outpatient center-based or community-based programs.[1,2,66,281,283] Many outpatient programs hold sessions two to three times per week, including 1 hour of multimodality exercise training and 1 hour of education, for a total of 6 to 8 weeks, but program timing and duration vary across countries and health systems.

Inpatient PR programs are ideally suited for those with highly complex medical issues and/or needs and those who have nursing care needs or are unable to care for themselves. The criteria for admission to inpatient PR programs vary by country. In some countries such as Germany, the Netherlands, and Canada, inpatient PR centers are either the norm and/or are used widely and preferred. In contrast, in the United States, patients must have medical and/or nursing needs requiring inpatient care to qualify for inpatient PR. Typically, for inpatient programs, patients are admitted and then undertake their rehabilitation up to 5 to 6 days per week for 2 to 6 weeks.

Home-based PR often refers to programs in a nonhospital community setting or in the patient's home itself. Both of these approaches have had some demonstrated success, although largely in the context of clinical research. Presently, home-based PR is used by fewer than 5% of PR programs.[27] The structure, organization, and outcomes of home-based PR studied in the research setting are considered further under "Novel Models" later. The safety and success of home-based programs is likely dependent on the precise program structure, staffing, patient selection, and monitoring. Optimal criteria to determine which patients are most suited to undergo home-based PR are lacking to date, and insurance reimbursement and accreditation of home-based PR are not yet established or widely available. Formal accreditation of outpatient programs is available in some countries. In the United States, the American Association of Cardiovascular and Pulmonary Rehabilitation[284] accreditation requires health care professionals' participation, completion of and demonstrated knowledge in a course covering all aspects of PR, demonstration of staff competencies, formal individualized treatment plans for core components of PR (including exercise prescription), program performance measures across several outcomes, and emergency preparedness processes.[284]

OUTCOME ASSESSMENT AND MEASUREMENT

Outcome assessment for PR encompasses three areas: (1) a general audit of the effectiveness of the PR program and its components, (2) evaluation of individual patient response to the intervention, and (3) assessment of the effect of PR on society, especially with respect to its effect on health care utilization and its cost-effectiveness. Outcome assessment is also necessary to monitor patient progress, ensure patient safety, and ensure the quality of the PR program, allowing for appropriate reimbursement from payers.[1,28,285] Rehabilitation programs must demonstrate, at a minimum, outcome assessments for exercise capacity, dyspnea, and health-related QOL, key areas that have consistently shown benefit for patients. However, these outcome measures alone do not reflect the impact of PR on the complex comorbidities and systemic manifestations of chronic respiratory disease. Therefore, additional outcome areas that may be applicable in PR include anxiety, depression, disease knowledge, health literacy, self-efficacy, performance of ADLs, fatigue, adherence to medical regimens (including oxygen, smoking cessation, exacerbation rates), and health care costs. Outcome measurements commonly performed in PR can be found in the online supplement in eTable 139.1.

Dyspnea is a central and often disabling symptom in individuals with chronic respiratory disease. Dyspnea assessment should be performed both as a measurement of dyspnea during exertion and as a measurement of breathlessness over time and/or during activity using questionnaires. Exertional dyspnea is usually rated using a Borg scale or a visual analog scale. Measurement of dyspnea by questionnaire usually assesses the dyspnea associated with ADLs or the way in which exertional dyspnea limits activities. Common measurement tools include the Medical Research Council dyspnea score, Chronic Respiratory Questionnaire, Baseline Dyspnea Index/Transitional Dyspnea Index, and the University of San Diego Shortness of Breath Questionnaire.[286]

Exercise performance is a key target of the PR intervention and can be measured in the laboratory using protocols involving incremental treadmill or stationary bicycle exercise. Cardiopulmonary exercise testing comprehensively evaluates the cardiovascular, ventilatory, and musculoskeletal response to exercise and, as such, provides in-depth information on the physiologic limitations to exercise as well as on specific risks to exercise. However, field tests of exercise performance, such as the 6-minute walk test and the incremental shuttle walk test, are more commonly performed and are responsive to the PR intervention.[93,276,287–289] Both field tests are performed as per standardized protocol, and minimal clinically important

eTable 139.1 Examples of Outcome Assessment for Pulmonary Rehabilitation

Measurement	Scales/Tests
Laboratory measures of exercise performance	■ Incremental cardiopulmonary exercise testing ■ Endurance testing at constant work rate
Functional exercise capacity	■ 6-minute walk test ■ Incremental and endurance shuttle walk tests ■ Muscle strength (dynamometry) ■ Timed up-and-go testing ■ Sit-to-stand testing ■ Dowel lifting ■ Balance assessment
Exertional dyspnea	■ Borg scale or visual analogue scale during exercise testing
Dyspnea with daily activities	■ Modified Medical Research Council questionnaire ■ Baseline and transitional dyspnea indices ■ San Diego Shortness of Breath Questionnaire
Health status	■ Chronic Respiratory Disease Questionnaire ■ St. George's Respiratory Questionnaire ■ Medical Outcomes Study Short Form-36 ■ COPD Assessment Test ■ Other disease-relevant questionnaires
Functional performance	■ Pulmonary Function Status Scale ■ Pulmonary Function Status and Dyspnea Questionnaire
Physical activity	■ PROActive instrument ■ Activity monitors/accelerometers
Nutritional status/body composition	■ Body mass index ■ Body composition using bioelectrical impedance or dual-energy x-ray absorption
Psychological variables	■ Measurement of anxiety and depression (e.g., Hospital Anxiety and Depression questionnaire, Beck Depression and Anxiety Inventories)
Additional important patient-centered outcomes	■ Fatigue ■ Cognition ■ Disease exacerbations ■ Use of tobacco/vaping products ■ Patient self-efficacy, coping style, and knowledge ■ Patient satisfaction with PR program
Additional important health-system outcomes	■ Hospitalizations and urgent health care visits ■ PR program quality metrics ■ Program costs

PR, pulmonary rehabilitation.

differences have been validated for each test.[93] Additional areas of exercise assessment are increasingly undertaken in the PR setting, including muscle strength testing (using dynamometers or repetitive maximal testing), exercise ability (timed up-and-go test, sit-to-stand test), functional status,[290] ADLs,[291] and balance measurements.[107,292,293]

Clinically meaningful improvements in health-related QOL are consistently seen after PR.[2] Health status is assessed in this setting using respiratory-specific questionnaires, such as the Chronic Respiratory Disease Questionnaire or the St. George's Respiratory Questionnaire.[294,295] Effects greater than the minimal clinically important difference for each of the components of the Chronic Respiratory Disease Questionnaire (dyspnea, fatigue, emotion, mastery), and mean differences in SGRQ total score (−6.9; 95% CI, −9.3 to −4.5, $n = 1146$; studies = 19) greater than the minimal clinically important differences of 4 units, were found in the Cochrane review by McCarthy et al.[2] Some PR programs may also use a generic instrument, such as the Medical Outcomes Study Short Form-36, to complement information from the respiratory-specific questionnaires.[296]

Anxiety and depression are common in chronic respiratory disease and can influence uptake and response to PR as well as adherence to maintenance exercise and healthy behaviors. It is important to assess symptom burden on entry into PR and to measure response to this intervention. There are validated tools available, including the Hospital Anxiety and Depression Score and the Beck Depression Inventory/Beck Anxiety Inventory.[297–299]

A vitally important and rapidly growing area of interest in PR is activity promotion because physical activity levels are closely tied to important outcomes.[177] As noted previously, gains in exercise capacity made during the PR intervention do not necessarily translate into increased physical activity in daily life, and outcome measurements and interventions to promote physical activity after the PR intervention are areas of active research.[206,300]

Assessment in the areas of cognitive impairment, disease knowledge, and self-efficacy, as well as nutrition/body composition, is also possible as part of the evaluation of PR.[276,301,302] PR should be evaluated more routinely for its effect on health care utilization and its cost-effectiveness, and these outcome measures are of increasing importance to health care systems and payers. Where evaluated, PR has been shown to be one of the most cost-effective treatments with COPD, on a par with smoking cessation and bronchodilator therapy.[12,13]

It is important to note that many outcome measures performed in PR were developed in the COPD population and may not be applicable to other chronic respiratory diseases. Programs should ensure that the appropriate tools are used in these settings. In addition, routine outcome measures such as those outlined previously have not been extensively validated for individual patient assessment. Traditional one-on-one clinical assessment remains necessary for the individual patient.

NOVEL MODELS

PR remains grossly underutilized despite its recommendation by international clinical guidelines[303] (see "Policy and Access Issues" section later). Although advocacy efforts to promote traditional center-based PR are important, there is also a strong effort to develop alternative forms of program delivery. Models of home-based and community-based PR have been investigated; however, there is marked heterogeneity in the type, intensity, and frequency of both the exercise and education components. In addition, staffing and supervision vary widely. Theoretically, these alternative forms of PR might lead to improved adherence to maintenance exercise (especially for home-based programs), greater availability and accessibility to those in rural settings or with transportation issues, and cost savings.

Home-based PR has been compared with usual care without PR or with center-based programs. In both a 2010 systematic review and a 2014 meta-analysis, rehabilitation was superior to usual care with improvements in dyspnea, exercise performance, and quality of life.[304,305] Exercise training was a necessary component, but structured education was not.[304,305] The limited information also suggested noninferiority in the measured outcomes of the home-based interventions compared with center-based programs. Three equivalence trials in Canada, Australia, and England compared the effectiveness of home-based PR with center-based PR.[233,306,307] In all three trials, there was no direct supervision in the home. Completion rates favored the home-based programs, no serious adverse events were noted, and all demonstrated improvements in exercise performance and QOL over baseline. Equivalence of benefits was demonstrated in the selected outcomes tested. However, a more recent "real world" trial showed that home-based PR led to lesser improvements in exercise capacity compared with center-based PR.[308] Interactive web-based or telerehabilitation programs have shown some positive outcomes[309–312] but require further evaluation before adopting their widespread use.

Studies have also evaluated home- or community-based PR after COPD exacerbations; however, the interventions were very heterogeneous, and the results were mixed, possibly due to poor adherence in some study patients and a potentially "insufficient" dose of rehabilitation.[313–316] Video-/telerehabilitation delivered after COPD exacerbation is feasible, safe, and associated with lower hospitalization rates.[317,318] Models of PR have begun to incorporate technology-based alternatives to both supervision and delivery of educational components. These have the potential advantage of convenience to the patient and the ability to pace delivery of contents to the patient's level of mastery.[309,319,320]

Interest in delivery of PR in the home rose during the COVID-19 pandemic, wherein most PR programs necessarily suspended activities due to inability to maintain social distancing in center-based groups. Many people with chronic respiratory diseases experienced decreased functional status related to home confinement to avoid COVID-19 and to their inability to participate in PR. In addition, patients recovering from COVID-19 with muscle weakness and debility related to hospitalization and critical illness warrant rehabilitation. Although optimal strategies for rehabilitation for those recovering from COVID-19 are unknown, recommendations from an expert panel of physiotherapists have been published recently.[321] Recommendations for home-based exercise have also

been made for those on mandatory home confinement.[322] Insurance reimbursement for home-based physical therapy (including PR) during the COVID-19 pandemic has varied across countries. Unfortunately, despite general widespread increased use of telemedicine as a means of providing medical care during the pandemic, thus far in the United States, the Centers for Medicare and Medicaid Services declined to reimburse home-based PR during this period.

Studies available thus far suggest that there are no significant safety issues with PR in the home or community, but more data are needed, especially if these models include patients with advanced disease, non-COPD diagnosis, and prominent comorbidities. It is likely that these more complex patients may be better served by the resources available with center-based programs. As nontraditional models of PR are developed, additional issues must be addressed, including appropriate referrals, cost-effectiveness issues (especially if staff is required in the home),[323] and oversight as to what exactly is being delivered. This last issue is crucially important because there is a real concern about diluting a highly successful intervention and mislabeling it as PR.

PULMONARY REHABILITATION FOLLOWING COPD EXACERBATION

COPD exacerbations are associated with skeletal muscle dysfunction, decreased physical activity levels, decline in health status and lung function (which can persist for months following hospital discharge), and increased mortality.[179,323–326]

Although most research on the benefits of PR has been obtained in stable COPD, there is mounting evidence that PR is safe and beneficial following an exacerbation.[313,327] A recent Cochrane review on PR following an exacerbation reported high-quality evidence for improvements in exercise capacity and QOL, and moderate-quality evidence for decreases in health care costs.[3] Another systematic review and meta-analysis of 13 randomized controlled trials including 634 participants showed a 42% reduced risk of mortality with PR compared with usual care.[328] A recent retrospective analysis of claims data from 197,376 fee-for-service Medicare beneficiaries hospitalized for COPD in the United States in 2014 showed that participation in PR within 90 days of discharge was associated with a lower risk of death over 1 year (absolute risk difference, −6.7%; 95% CI, −7.9% to −5.6%; hazard ratio, 0.63; $P < 0.001$). Attendance at every three additional PR sessions was significantly associated with a lower risk of death (hazard ratio, 0.91; 95% CI, 0.85 to 0.98; $P = 0.01$).[329] However, uptake of PR following COPD exacerbation is low, and a better understanding of how to make post-exacerbation PR more acceptable to patients is needed.[330]

There is little available evidence evaluating PR after exacerbations in chronic respiratory diseases other than COPD. However, similar to the rationale and evidence for PR in stable non-COPD conditions, this intervention should be effective following exacerbations in other chronic respiratory diseases. In one study,[314] 15% of the study subjects had other chronic respiratory diseases, such as bronchiectasis, interstitial lung disease, and chronic asthma, with no differences in outcomes noted.

Underutilization of PR in the peri-exacerbation period is even more striking than in stable disease.[331] The optimal timing and structure of PR during the post-exacerbation period have not been well defined. This, combined with such poor uptake, raises the important issue of how to adapt a well-established successful intervention to this pivotal event in the life of an individual with chronic respiratory disease. There is an urgent need to identify barriers to participation as well as develop effective models of delivery to address this need.

PULMONARY REHABILITATION FOR DISORDERS OTHER THAN COPD

Based on the unequivocal benefits of PR in COPD, the benefits of PR for people with chronic respiratory disorders other than COPD have been investigated. The rationale for PR for non-COPD respiratory disorders is similar to that for individuals with COPD, as discussed above.[1,14] In addition to structural and functional alterations in the respiratory system, people with non-COPD respiratory disorders experience disabling symptoms, including dyspnea, fatigue, exercise impairment, anxiety, depression, and fear. They also commonly have medical comorbidities and nutritional disturbances, require complex medical regimens, may experience intermittent acute exacerbations of disease,[1,14] have difficulty coping with their disease, and may require lung transplantation. People with ILD, [332] pulmonary hypertension,[201,202] asthma,[333] cystic fibrosis,[334] non-cystic fibrosis bronchiectasis,[335] and lung cancer[336] have low physical activity levels. Skeletal muscle dysfunction has been reported for people with ILD,[53,337] pulmonary hypertension,[56] cystic fibrosis,[338,339] and those preparing for and recovering from lung transplantation.[60] Importantly, low exercise capacity is associated with worse survival for persons with ILD,[340] pulmonary hypertension,[341] and cystic fibrosis.[342] As such, PR has the potential to benefit people with these conditions. PR is recommended in disease management guidelines for idiopathic pulmonary fibrosis,[343] pulmonary hypertension,[344] and bronchiectasis.[345]

Moreover, PR is typically required prior to lung transplantation. Pretransplantation PR helps to optimize patients' conditioning and functional exercise capacity,[346] which may, in turn, improve surgical outcomes and reduce hospital length of stay.[347] It also prepares patients by providing knowledge regarding the process and potential risks versus benefits of transplantation and steps needed for recovery from it.[346]

Numerous randomized controlled trials and uncontrolled studies have confirmed benefits of PR for people with non-COPD respiratory disorders.[1,14,348] Improvements in exercise capacity, symptoms, and/or QOL have been demonstrated for individuals with ILD including idiopathic pulmonary fibrosis,[349–355] pulmonary hypertension,[356–360] cystic fibrosis and non-cystic fibrosis bronchiectasis,[58,361–364] asthma,[365–374] lung cancer,[375–379]

obesity-hypoventilation syndrome,[380] and for those recovering from lung transplantation.[381,382]

The reported magnitude of benefits varies across conditions and across different clinical outcomes, but in general, the magnitude of gain in 6-mile walk distance following PR is comparable to that seen among people with COPD.[383,384] The duration of benefits achieved in PR for non-COPD respiratory diseases also varies. For some conditions, such as ILD,[385] the duration of benefits following PR may be shorter (approximately 6 months) than the typical duration of gains (approximately 8 to 12 months) seen among those with COPD. Evidence regarding impact of disease severity on PR outcomes is limited. For people with disorders other than COPD, data regarding the impact of PR on other outcomes such as health care utilization are also, to date, largely lacking. There is little available evidence evaluating peri-exacerbation PR in chronic respiratory diseases other than COPD. However, similar to the rationale and evidence for PR in stable non-COPD conditions, this intervention should be effective following exacerbations in other chronic respiratory diseases.

The practical aspects of providing PR to individuals with non-COPD respiratory disorders have been reviewed recently.[58,348,386] Inclusion of people with varying types of respiratory disorders into PR programs that historically focused on COPD poses several logistical challenges. The exercise training regimen, education, and behavioral aspects of the program must be individualized and geared to the physiology, safety, management, and needs related to the relevant disease(s).[1,14,280,348,386] PR program staff must be trained in and familiar with the manifestations and management of the spectrum of respiratory disorders, and adequate numbers of staff members must be present so that patients are safe and their questions can be addressed. Supplemental oxygen should be available,[348,387] and specialized equipment may be needed in some circumstances (e.g., bariatric equipment for severely obese persons or telemetry for those with severe pulmonary hypertension). Education materials addressing topics relevant to a spectrum of disease states are needed.[14,386,388,389] Use of measurement tools relevant to disease outcomes is also necessary.[1,14,348,386]

Until recently, insurance coverage for PR was lacking for people with non-COPD respiratory disorders in many countries. This is changing as the evidence base supporting its use has expanded; people with non-COPD disorders are now commonly referred to and enrolled in PR programs. This will further drive the existing need for a substantive increase in access and availability of PR, which is already grossly insufficient. Further foci of research should include several key areas such as optimal candidacy, the basis of skeletal muscle dysfunction and its responsiveness to PR, optimal educational approaches and content, and outcomes such as performance of ADLs, physical activity levels, cost-effectiveness (hospitalizations, disease exacerbations), surgical outcomes, and mortality.

POLICY AND ACCESS ISSUES

Despite its well-recognized benefits and recommendation for its use in several clinical practice guidelines,[343,344,390] PR is markedly underutilized worldwide. Several factors contribute to this. Low referral rates are an important cause of PR underutilization. Currently, only 3–16% of eligible patients with COPD are referred,[391–398] and fewer than 3% receive PR after hospitalization for COPD exacerbation.[331] It is likely that referral rates are even lower for those with respiratory disorders other than COPD. Suboptimal health care professionals' knowledge and awareness of the content, process, and benefits of PR,[399–403] and suboptimal adherence to evidence-based treatment guidelines,[404] contribute to low numbers of referrals. Most health care professionals lack exposure to PR in daily practice, and detailed education regarding PR is not universally required during training, even for those specializing in respiratory disease.[239] People with chronic respiratory diseases[246] and the general public[239] also often lack knowledge about PR and, as such, they may not request referral or participate if referred.

Poor access to PR limits its delivery to and uptake by patients. In many countries, PR programs are underfunded, there are insufficient resources (space, equipment, and/or staffing) to meet patient needs,[239,405] and payers' reimbursement is insufficient for programs' sustainability.[406] Most existing PR programs accommodate fewer than 150 patients per year.[27,277] In some countries, such as the United States, there is significant geographic variability regarding access to PR; some areas, particularly rural, lack programs altogether.[407] This is also true in parts of Australia, Canada, South America, Asia, and Africa. Racial and socioeconomic disparities also affect patients' access to PR.[408]

In 2015, a joint American Thoracic Society/European Respiratory Society Task Force published an Official Policy Statement entitled *Enhancing Implementation, Use, and Delivery of Pulmonary Rehabilitation*.[239] Several recommendations and actionable items were proposed to address and improve the underutilization of PR. Progress towards implementation of these recommendations is being made gradually, but much more work in this area is needed.

Education for health care professionals,[409] provision of practical tools such as flow sheets, clinical reminders (e.g., pop-up reminders in medical records),[410] streamlining the referral process, and implementation of discharge care bundles can improve referrals to PR.[411] Increased exposure to the scientific evidence base and practical aspects of implementation and delivery of PR during the course of medical training would be desirable for health care professionals who will care for people with chronic respiratory diseases. This may require lobbying on the part of PR experts, with support of professional societies, to encourage the institutions governing health professionals' education to broaden their requirements regarding PR for trainees. Monitoring of referrals to PR as a care quality indicator would also be helpful to enhance referrals.

Public awareness campaigns, including use of social media, can increase patients' and the general public's knowledge and awareness of PR.[400,412,413] Collaborative planning between patients and their health care providers regarding treatment plans can foster patient referrals to and uptake of PR.[409,414–416] Enhanced communication between health care professionals and insurance

payers regarding the documentation of benefits and cost-effectiveness of PR, and efforts such as the US National Action Plan for COPD[417] and the United Kingdom pulmonary rehabilitation audit [283] should help foster funding and reimbursement of existing programs and support new programs in regions where they are lacking. Novel models of PR such as telerehabilitation and home-based PR are being investigated and may be suitable for some individuals, especially those who lack access to center-based programs.

We acknowledge the contributions of Dr. Richard L. Zuwallack and Dr. Bartolome R. Celli to this topic in the previous edition of this text.

Key Points

- *Pulmonary rehabilitation* (PR) is an essential multidisciplinary, patient-centered intervention in the management and integrated care of people with chronic respiratory disease, which should be offered routinely alongside other medical therapies.
- Important components of PR include exercise training, education, psychosocial support, nutritional therapy, and advance care planning.
- Despite lack of a direct effect on lung function, PR has been proven in randomized controlled trials to improve exercise performance, dyspnea, and quality of life. It also reduces health care utilization and improves emotional function and, when delivered following hospitalization for COPD exacerbation, improves survival.
- PR has also been shown to benefit people with COPD and several other disorders, including interstitial lung disease, asthma, pulmonary hypertension, cystic fibrosis, lung cancer, and those preparing for and recovering from lung transplantation.
- The magnitude of gains in exercise capacity, dyspnea, and quality of life expected from participation in PR are equal to or exceed those afforded by other medical therapies, such as bronchodilators for people with COPD.
- Exercise training is the cornerstone of PR: high- and/or low-intensity and/or interval aerobic training and resistance training of the upper and lower extremities are utilized.
- Promotion of physical activity in the home and community setting is an important goal of PR.
- PR is underutilized and under-resourced. This relates to suboptimal health care professionals', patients', caregivers', and payers' knowledge and awareness of its benefits; insufficient access to and payer support; insufficient number of programs and providers; and suboptimal uptake of and adherence by patients who could benefit from it.

THE FUTURE OF PULMONARY REHABILITATION

The field of PR and its scientific evidence base continues to grow and expand. Major challenges exist regarding availability, funding, and resourcing for PR programs, as well as uptake of and adherence to PR. Many existing health care systems are not ideally structured to accommodate the number of patients who could benefit from PR or the complexity of patients' needs. Forward-thinking health care systems would help to build the infrastructure and resources necessary to provide services to those who could benefit, as well as routinely encourage people with chronic respiratory diseases to attend PR as a standard of care, comparable to advocacy for use of preventive vaccinations and inhaled bronchodilator therapies. Widespread incorporation of PR into routine health care processes would not only reduce the morbidity and mortality of individuals but may also substantially reduce health care costs.

Further pragmatic research is needed to demonstrate the benefits and costs of PR to payers and health care systems and to learn which patients are most suitable for which types of PR interventions/components and settings. Additional areas where further information is needed include optimal strategies for education, promoting sustained health-enhancing behavior such as physical activity following PR, PR interventions for people with disorders other than COPD, and solutions to existing barriers to uptake and adherence to PR. The biologic basis of patients' varying responsiveness to exercise training and other components of PR also merits further study. Broader training of multidisciplinary health care professionals in the discipline of PR is also needed to develop experts in the field and promote referrals of patients who could benefit.

INTRODUCTION

Human lung transplantation was first attempted in 1963, but it was not until nearly 2 decades later that extended survival was achieved. Further refinements in patient selection, surgical technique, immunosuppression, and postoperative care have since facilitated the successful application of lung transplantation to a wide variety of advanced disorders of the airways, lung parenchyma, and pulmonary vasculature. The field has realized dramatic growth, with more than 64,000 procedures performed worldwide to date and approximately 4500 now performed annually.[1] Nonetheless, serious problems persist that limit the utility of this procedure. The donor pool remains insufficient to meet the demands of the many desperately ill patients awaiting transplantation. Immunosuppressive therapy is associated with a number of troubling side effects, most notably a significant risk of infection and malignancy. Despite the use of immunosuppressive agents, rejection and *chronic lung allograft dysfunction* (CLAD) develop frequently and continually threaten organ function. Though lung transplantation offers the prospect of improved functional status and quality of life, long-term survival remains an elusive goal, with only half of recipients living beyond 6 years. In order to optimize outcomes in the face of these shortcomings, judicious selection of candidates is essential and care of recipients must be rendered in a meticulous and vigilant fashion by clinicians familiar with posttransplantation management.

INDICATIONS AND CANDIDATE SELECTION

Lung transplantation is a therapeutic option for a broad spectrum of chronic debilitating pulmonary disorders of the airways, parenchyma, and vasculature. Leading indications include idiopathic pulmonary fibrosis and other idiopathic interstitial pneumonias (33% of cases), COPD (26% of cases), and *cystic fibrosis* (CF) (14% of cases).[1] Other less-common indications include emphysema caused by alpha$_1$-antitrypsin deficiency, sarcoidosis, non-CF bronchiectasis, and lymphangioleiomyomatosis. Once a common indication for transplantation, idiopathic pulmonary arterial hypertension now accounts for less than 3% of procedures, a finding reflecting major advances in the medical management of these patients. Lung transplantation in patients with lung involvement of collagen vascular disease raises concerns that extrapulmonary manifestations of the systemic disease could compromise the posttransplant course. In particular, the esophageal dysmotility and reflux that frequently characterize scleroderma could increase the risk of occult aspiration and accelerated graft loss. The demonstration that posttransplantation survival of patients with scleroderma is comparable with that of other patient populations provides reassurance that carefully selected patients can benefit from this procedure even if esophageal dysfunction is present.[2,3] Lung transplantation for locally advanced bronchioloalveolar carcinoma (now referred to as adenocarcinoma in situ) is performed only in highly selected cases because of an unacceptably high rate of cancer recurrence.[4]

Many transplant centers have abandoned an arbitrary upper age cutoff for transplant eligibility, although current selection guidelines suggest that patients older than 75 years are unlikely to be suitable candidates in most cases because of accompanying comorbidities.[5] Patients 65 years old and older represent the second largest and fastest growing cohort in the United States; they accounted for 30% of wait-list candidates in 2017.[6] However, the 5-year survival rate is considerably lower for this group compared with younger cohorts and is particularly poor for those 70 years of age and older, only 28% of whom achieve the 5-year mark.[6,7] In selecting older patients, many centers

now place an emphasis on "functional" age rather than chronologic age. This has prompted interest in using validated tools to assess frailty as part of the transplant evaluation, and emerging evidence suggests that such assessment is useful in predicting posttransplant mortality risk.[8]

Absolute contraindications to transplantation, as delineated in the most recent International Society for Heart and Lung Transplantation consensus statement, are listed in Table 140.1.[5] Several additional factors represent relative contraindications for which there is considerable variability in approach among different centers. Infection with HIV is still viewed by most centers as an absolute contraindication, but promising results with liver, kidney, and heart transplantation in HIV-positive recipients, as well as recent reports of successful lung transplantation, may soon remove this barrier.[9,10] Among candidates with CF, infection with certain species comprising the *Burkholderia cepacia* complex, in particular *Burkholderia cenocepacia* (previously known as genomovar III), is considered an absolute contraindication by many centers because of the considerable risk of posttransplantation lethal infections.[11,12] In contrast, the presence of panresistant *Pseudomonas aeruginosa* in this patient population is associated with acceptable outcomes and generally is not viewed as a contraindication.[13] Reports of recurrent *Mycobacterium abscessus* infections following transplantation have engendered reservations about listing candidates with active and poorly controlled infection preoperatively.[14,15]

The risk posed by chronic medical conditions such as diabetes mellitus, osteoporosis, gastroesophageal reflux, and coronary artery disease must be assessed individually on the basis of severity of disease, presence of end-organ damage, and ease of control with standard therapies.

Table 140.1 Absolute Contraindications to Lung Transplantation

Active or recent malignant disease
Untreatable significant extrapulmonary organ dysfunction (consider combined organ transplant procedure if feasible)
Chronic and poorly controlled infection with highly virulent and/or resistant organisms
Acute medical instability such as sepsis, myocardial infarction, or liver failure
Significant chest wall or spinal deformity expected to cause severe restriction after transplantation
Uncorrectable bleeding diathesis
Uncorrected coronary artery disease not amenable to revascularization before or at the time of transplantation
Significant obesity with a body mass index ≥35 kg/m^2
Severely limited functional status with poor rehabilitation potential
Active or recent cigarette smoking, drug abuse, or alcohol abuse
Significant psychiatric illness limiting the ability to cooperate with the medical team or adhere to the complex posttransplantation medical regimen
Repeated noncompliance with medical care
Absence of an adequate and reliable social support network

Modified from Weill D, Benden C, Corris PA, et al. A consensus document for the selection of lung transplant candidates: 2014. An update from the Pulmonary Transplantation Council of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant*. 2015;34:1–15.

Prior pleurodesis or other thoracic surgery is associated with an increased risk of intraoperative bleeding, particularly when cardiopulmonary bypass is used, but it is not a contraindication to transplantation in experienced surgical hands. Pleural thickening associated with aspergillomas similarly complicates anatomic dissection and explantation of the native lung and carries the additional risk of soiling the pleural space with fungal organisms.

Use of mechanical ventilation as a bridge to transplantation is associated with increased short-term posttransplant mortality but does not appear to affect outcomes beyond the first year.[1] Most programs are now willing to maintain some ventilator-dependent patients on the active waiting list and anticipate that the high allocation score these patients receive will expedite transplantation, but reserving the option of de-listing patients who develop intercurrent complications or progressive debility. Use of *extracorporeal membrane oxygenation* (ECMO) to bridge patients to transplantation is becoming increasingly common, with experienced centers reporting posttransplant survival rates that approximate those of nonbridged patients.[16,17] Patients undergoing ECMO who are awake, ambulatory, and liberated from conventional mechanical ventilation appear to have the best outcomes but account for a minority of patients bridged in this fashion.[18]

TIMING OF REFERRAL AND LISTING

Listing for transplantation is considered at a time when the lung disease limits basic activities of daily living and is deemed to pose a high risk of death in the short term. Disease-specific guidelines for timely referral and listing of patients, based on available predictive indices, have been published (Table 140.2).[5] The imprecise nature of these predictive indices can complicate decisions about transplant listing for all but the most severely ill patients. The patient's perception of an unacceptably poor quality of life is an important additional factor to consider but should not serve as the sole justification for listing of a patient whose disease is not deemed to be at an advanced and potentially life-threatening stage.

ALLOCATION SYSTEM

In 2005, the *Lung Allocation Score* (LAS) system was introduced in the United States, and it replaced a time-based allocation model that was perceived to bias against candidates with advanced or more rapidly progressive disease who could not tolerate prolonged waiting times.[19] The LAS system uses statistical models, incorporating more than a dozen variables, to generate predicted 1-year survival with and without transplantation for each patient.[19] Both medical urgency (1-year survival without transplantation) and "net transplant benefit" (difference between 1-year survival with and without transplantation) are factored into the calculation of the LAS. Because 1-year survival without transplantation is incorporated into both net transplant benefit and medical urgency measures, it affects the LAS more than posttransplantation survival. A raw LAS is calculated on the basis of these survival predictions and is normalized

Table 140.2 Disease-Specific Guidelines for Listing for Lung Transplantation

CHRONIC OBSTRUCTIVE PULMONARY DISEASE
■ BODE index ≥7
■ FEV_1 <15–20% predicted
■ Three or more severe exacerbations during the preceding year
■ One severe exacerbation with acute hypercapnic respiratory failure
■ Moderate to severe pulmonary hypertension
INTERSTITIAL LUNG DISEASE
■ Decline in FVC ≥10% during 6 months of follow-up
■ Decline in DL_{CO} ≥15% during 6 months of follow-up
■ Desaturation to <88% or distance <250 m on 6-min walk test or >50 m decline in 6-min walk distance over a 6-mo period
■ Pulmonary hypertension on right heart catheterization or two-dimensional echocardiography
■ Hospitalization because of respiratory decline, pneumothorax, or acute exacerbation
CYSTIC FIBROSIS
■ Chronic respiratory failure:
■ With hypoxemia alone (PaO_2 <60 mm Hg)
■ With hypercapnia ($PaCO_2$ >50 mm Hg)
■ Long-term noninvasive ventilation therapy
■ Frequent hospitalization
■ Rapid lung function decline
■ World Health Organization functional class IV (symptoms present at rest or severe with any activity)
PULMONARY VASCULAR DISEASE
■ NYHA functional class III or IV despite a trial of at least 3 months of combination therapy including prostanoids
■ Cardiac index <2 L/min/m^2
■ Mean right atrial pressure of >15 mm Hg
■ 6-min walk distance of <350 m
■ Development of significant hemoptysis, pericardial effusion, or signs of progressive right-sided heart failure (renal insufficiency, increasing bilirubin, brain natriuretic peptide, or recurrent ascites)

BODE, body mass index, airflow obstruction, dyspnea, exercise capacity; DL_{CO}, diffusing capacity for carbon monoxide; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; NYHA, New York Heart Association; PaO_2, partial pressure of oxygen; $PaCO_2$, partial pressure of carbon dioxide.

Modified from Weill D, Benden C, Corris PA, et al. A consensus document for the selection of lung transplant candidates: 2014-an update from the Pulmonary Transplantation Council of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant*. 2015;34:1–15.

to a scale of 0 to 100 for ease of use. As designed, the system preferentially allocates lungs to sicker patients while attempting to avoid situations in which outcomes are so poor that there would be no meaningful survival benefit. An initial LAS is assigned at the time of listing and is subsequently revised as needed to reflect changes in a patient's medical condition, thereby escalating the patient's priority as his or her condition worsens. Notably, patients succumbing to frank respiratory failure requiring mechanical ventilation and/or ECMO generally receive the highest priority under this system.

The introduction of the LAS system had a profound effect on the dynamics of lung transplantation in the United States.[20,21] Because there was no longer an incentive to place patients on the active waiting list simply to accrue time (many of these patients were ultimately deactivated from the list rather than undergoing transplantation), the number of actively listed patients fell to approximately one-half of the previous level. Median waiting time, which had ranged from 2 to 3 years under the time-based allocation system, decreased to less than 6 months, with one-quarter of patients waiting less than 35 days.[20] As a consequence of the shorter waiting times for sicker patients, there has been a significant and sustained reduction in the annual death rate of patients on the waiting list, one of the stated objectives of the LAS system.[21] Although there were initial fears that posttransplantation outcomes would suffer by preferential performance of lung transplantation in sicker patients, survival of patients with the highest LAS scores has steadily improved and currently falls only slightly below that of patients with lower scores.[6,22] A similar LAS system has since been adopted by several European countries and now accounts for allocation of approximately 60% of transplanted lungs worldwide.[23]

The LAS system does not address geographic disparities in organ allocation in the United States. Historically, allocation rules have dictated that lungs procured by a particular organ procurement organization were offered first to candidates at centers within that organization's region, even if there were candidates with higher LAS scores listed at centers in geographic proximity but beyond the existing boundaries of the local organ procurement organization. In response to a legal challenge, a new allocation policy was implemented that did away with this organ procurement organization–centered distribution rule and now initially offers lungs to transplant centers within 250 nautical miles of the donor hospital.

BRIDGING TO TRANSPLANTATION: ARTIFICIAL LUNG TECHNOLOGIES

As mentioned earlier, ECMO has been used to bridge critically ill patients to lung transplantation, although, historically, outcomes following transplantation have been suboptimal. Advances in artificial lung technology, including improved membranes, improved pumps, and even ambulatory support systems, make it increasingly possible to support selected patients successfully, thus permitting them to survive the wait for a suitable donor lung and, importantly, to achieve a successful posttransplant outcome[24–27] (see also Chapter 138).

Patients with isolated hypercapnic failure can be bridged with pumpless devices such as the interventional lung assist (iLA, Novalung), a low-resistance device with a meshwork of hollow fibers maximizing blood-gas diffusion; with this device, blood can be propelled by arterial pressure or a pump. Patients requiring oxygenation support can be supported with venovenous configured pump devices. Patients requiring circulatory support, as well as gas exchange support, can be managed with a conventional venoarterial configuration. It is important to understand the underlying physiology of the patient and to select the device configuration that provides the necessary support (Fig. 140.1). An application unique to patients with pulmonary arterial hypertension is the application of the pumpless iLA device from the pulmonary artery to the left atrium to off-load the right ventricle and provide "oxygenating septostomy" physiology. This strategy has effectively abolished wait-list mortality in a group of patients who traditionally had the highest mortality on the wait list.[25,28]

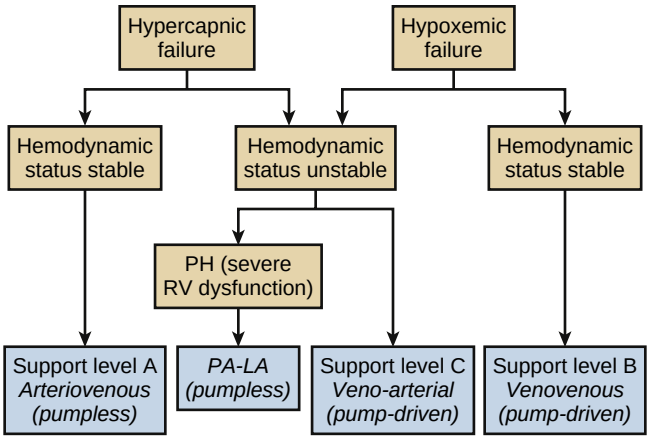

Fig. 140.1 Selection of extracorporeal lung support device and configuration. The choice of support device is largely dependent on the type of respiratory failure (hypercarbic or hypoxemic) and the hemodynamic status (stable or unstable). LA, left atrium; PA, pulmonary artery; PH, pulmonary hypertension; RV, right ventricle. (From Cypel M, Keshavjee S. Extracorporeal life support pre and post lung transplantation. In: Annich GM, Lynch WR, MacLaren G, Wilson JM, Bartlett RH, eds. *ECMO: Extracorporeal Cardiopulmonary Support in Critical Care [ELSO Red Book]*, 4th ed. Ann Arbor, MI: Extracorporeal Life Support Organization; 2011.)

Table 140.3 Standard Lung Donor Criteria

Age <55 yr
Clear chest radiograph
PaO_2 >300 mm Hg on FIO_2 1.0, PEEP 5 cm H_2O
Cigarette smoking history <20 pack-yr
Absence of significant chest trauma
No evidence of aspiration or sepsis
No prior thoracic surgery on side of harvest
Absence of organisms on sputum Gram stain
Absence of purulent secretions and gastric contents at bronchoscopy
Negative for HIV antibody, hepatitis B surface antigen, and hepatitis C antibody
No active or recent history of malignant disease (excluding localized squamous or basal cell skin cancer, localized cervical cancer, and primary brain tumors with low metastatic potential and in the absence of invasive procedures to the brain and skull)
No history of significant chronic lung disease

FIO_2, fractional concentration of oxygen in inspired gas; HIV, human immunodeficiency virus; PaO_2, arterial oxygen pressure; PEEP, positive end-expiratory pressure.

DONOR SELECTION AND MANAGEMENT

In addition to meeting defined criteria for declaration of brain death, deceased lung donors are selected on the basis of established guidelines (Table 140.3).[29] Lungs are particularly fragile organs in the brain-dead patient and are frequently compromised by volume overload, contusion, aspiration of gastric contents, ventilator-induced lung injury, or pneumonia, as well as by extensive prior smoking. As a result, most donors fail to meet standard criteria for lung donation, thus leading to a historical recovery rate of only 15–20% of lungs from deceased organ donors who are deemed able to donate other organs. Although it is reasonable to be conservative with recipient patient safety in mind, there is mounting evidence that these standard criteria may be too stringent, leading to unnecessary wastage of suitable lungs. In one study, 29 pairs of lungs that had been rejected for transplantation were assessed for the magnitude of extravascular water content, intactness of alveolar fluid clearance capacity, and presence of pneumonia or emphysema.[30] Twelve pairs (41%) were found to have minimal or no abnormalities and thus to be "potentially suitable" for transplantation. Additional evidence comes from published reports documenting that outcomes with use of "extended criteria" donors are similar to those achieved with use of donors meeting standard criteria.[31–35] Use of modified donor management protocols to optimize lung function through judicious fluid management, therapeutic bronchoscopy, and lung recruitment maneuvers has also been shown to enhance lung retrieval rates.[36,37] Additionally, a 2010 multicenter randomized trial demonstrated that use of a low–tidal volume, lung-protective ventilatory protocol (6 to 8 mL/kg; positive end-expiratory pressure of 8 to 10 cm H_2O) in brain-dead potential organ donors resulted in a doubling of lung harvest rates (54% vs. 27%) compared with a conventional ventilatory protocol (10 to 12 mL/kg; positive end-expiratory pressure of 3 to 5 cm H_2O).[38]

Despite increases in the number of organs successfully retrieved, the demand for organs continues to outstrip supply, thus prompting a search for alternatives to the brain-dead donor pool. One emerging source is the non–heart-beating or *donation after cardiac death* (DCD) donor who has experienced either an out-of-hospital (i.e., uncontrolled) cardiac arrest or a planned withdrawal of life support in the operating room. Currently, approximately 7% of lung transplants performed in the United States use DCD donors.[39] In contrast, DCD donors account for 23% of lung transplants in Australia, thus illustrating the extent to which this donor pool can be expanded with introduction of highly coordinated national protocols.[40] The 1-year and 5-year survival rates following DCD donor lung transplants are equivalent to those after procedures using conventional brain-dead donors.[41]

Once a donor has been identified, matching with potential recipients is based on size (either overall height or predicted total lung capacity) and ABO blood group compatibility. Recipients identified through standard pretransplant screening as having preformed circulating antibodies to foreign *human leukocyte antigen* (HLA) require virtual cross-matching to avoid donors with specific incompatible antigens.

LUNG PRESERVATION

The standard lung preservation technique is hypothermic flush preservation. The most commonly used solution is Perfadex (Vitrolife). Cold flush preservation at 4°C decreases the metabolic rate to 5% of normal and hence slows the dying process of the lung. Although this approach has been useful for clinical lung transplantation, cold static preservation has significant limitations: (1) a decision regarding lung use must be made quickly, with limited information

in the donor hospital; (2) once the organ is flushed, there is no second chance to reevaluate the organ before removal of the cross clamp at reperfusion; and (3) the focus is on slowing down the dying process, and it does not address or take advantage of opportunities to diagnose, treat, repair, or regenerate the donor lung.

Ex vivo lung perfusion has been developed to address these limitations. It is now possible to perfuse lungs ex vivo at normothermia for extended periods, thus creating a platform for more detailed assessment of lung function, more accurate diagnosis, and targeted treatment of donor lung injuries to improve the function of the lung after transplantation.[42–44] This creates the opportunity to engineer donor organs with gene therapy, cell therapy, and other advanced treatments to create "superorgans" that hopefully will one day afford the recipient long-term allograft function.[45,46]

Ex vivo lung perfusion has been shown to increase donor lung utilization of lungs that previously could not be used.[43,47] Short-term outcomes using lungs conditioned in this fashion have been highly favorable.[43,44] Ex vivo lung perfusion is now standard practice in the Toronto Lung Transplant Program,[44] and it is being increasingly applied worldwide.[48] The U.S. Food and Drug Administration has approved the XPS Lung Perfusion System (XVIVO Perfusion) for use in the United States.

AVAILABLE SURGICAL TECHNIQUES

Four surgical techniques have been developed: *single lung transplantation* (SLT), *bilateral lung transplantation* (BLT), heart-lung transplantation, and bilobar transplantation. Of these, BLT and SLT are the most commonly performed.

SINGLE LUNG TRANSPLANTATION

SLT is performed using a standard posterolateral thoracotomy, an anterior muscle sparing thoracotomy, or a partial "clamshell" incision (which gives access to the central mediastinum for easy cannulation for ECMO or cardiopulmonary bypass). Three anastomoses are performed: mid-mainstem, pulmonary artery, and left atrium (incorporating the two pulmonary veins). Compared with BLT, SLT permits more efficient use of the limited donor supply and tends to be better tolerated by elderly and frailer patients, but it provides less functional reserve in the setting of allograft dysfunction. It is an acceptable option for patients with pulmonary fibrosis and COPD. In the setting of severe pulmonary hypertension, SLT requires the new allograft to bear the burden of nearly the entire cardiac output because of high pulmonary vascular resistance in the native lung, thereby exaggerating the degree of permeability pulmonary edema that develops in the allograft. For this reason, the presence of significant pulmonary hypertension is considered a contraindication to SLT. Because of infectious concerns, SLT is also contraindicated in patients with suppurative lung disorders such as CF.

BILATERAL LUNG TRANSPLANTATION

BLT involves the performance of two sequential SLT procedures in succession in one operation. Surgical approaches include either a transverse thoracosternotomy (clamshell) incision, bilateral anterolateral thoracotomies (sparing the sternum), or a median sternotomy. In the absence of severe pulmonary hypertension, cardiopulmonary bypass can often be avoided by sustaining the patient on the contralateral lung during implantation of each allograft. BLT is the exclusive procedure for CF, other forms of bronchiectasis, and severe primary and secondary forms of pulmonary hypertension. BLT has supplanted SLT as the preferred procedure for patients with COPD and pulmonary fibrosis because of its superior functional outcomes and evidence, albeit conflicting, suggesting a survival advantage over SLT.[1,49–52] As a result of these practices, BLT now accounts for 80% of all procedures performed worldwide.[1]

HEART-LUNG TRANSPLANTATION

Historically the first procedure successfully introduced to allow replacement of diseased lungs, heart-lung transplantation is now infrequently performed because of the development of SLT and BLT procedures. Currently, fewer than 60 procedures are performed worldwide annually.[1] Indications are largely restricted to Eisenmenger syndrome with surgically uncorrectable cardiac lesions and to advanced lung disease with concurrent severe left ventricular dysfunction or extensive coronary artery disease not amenable to angioplasty or bypass surgery. In the past, the presence of profound right ventricular dysfunction in the setting of severe pulmonary hypertension was deemed to be an indication for heart-lung transplantation. However, subsequent experience with isolated lung transplantation has demonstrated the remarkable ability of the right ventricle to recover once pulmonary artery pressures have normalized. As a result, BLT is the preferred operation in patients with severe right ventricular failure.

BILATERAL LOBAR TRANSPLANTATION

Bilateral lobar transplantation—the use of two lobes to perform BLT in a smaller recipient—is an important procedure in the treatment armamentarium. This operation is most commonly performed to treat children or small-stature women who are running out of time to receive a suitably sized BLT. Various combinations of lobes can be used, or even a whole lung on one side with a lobe on the other. In experienced centers, the results of bilateral lobar transplants are expected to be similar to that of standard BLT.[53]

Living donor bilateral lobar transplantation was developed principally to serve the needs of candidates with far-advanced or deteriorating status that would not allow them to tolerate a protracted wait for a deceased donor in the pre-LAS era. The procedure involves transplantation of lower lobes from each of two living, blood group–compatible donors. To ensure that the lobes will adequately fill the hemithoraces, it is preferable to use donors who are taller than the recipient. Patients with CF are particularly well suited as a target population because, even as adults, they tend to be of small stature. Intermediate-term functional outcomes and survival among recipients are similar to those achieved with deceased donor lung transplantation.[54,55] Although no donor deaths have been reported, one report noted that 18% of donors experienced "serious" complications.[56] The

introduction of the LAS system to expedite lung transplantation in severely ill candidates ultimately obviated the need for this procedure in the United States, but it continues to be performed in Japan, where waiting times for deceased donors continue to exceed 2 years.[57]

ROUTINE POSTTRANSPLANTATION MANAGEMENT

Care of the lung transplant recipient requires close surveillance to ensure that the allograft is functioning properly, that immunosuppressive medications are properly administered and tolerated, and that complications are detected early and treated expeditiously. Most centers require patients to return frequently for office visits, blood tests, and chest radiographs during the initial 2 to 3 months following transplantation and to participate in an intensive pulmonary rehabilitation program during this time. Analogous to home glucose monitoring of the diabetic patient, lung transplant recipients chart their pulmonary function on a daily basis with a handheld microspirometer and are instructed to contact the transplant center for a sustained fall of greater than 10% in the *forced expiratory volume in 1 second* (FEV_1) or forced vital capacity.

Many transplant programs use frequent surveillance bronchoscopies and transbronchial lung biopsies within the first posttransplant year as a means of monitoring the allograft. Such an approach has been demonstrated to detect low-grade rejection in up to 30% of asymptomatic, clinically stable patients.[58] However, it has yet to be determined whether treatment of clinically silent disease has a beneficial impact on long-term graft function.

Immunosuppressive therapy is initiated immediately at the time of transplantation and is maintained lifelong. Approximately 75% of programs use *induction* therapy, a brief but potent effort to deplete and block activation of T cells. The predominant agent used for induction is the interleukin-2 receptor antagonist basiliximab because of its favorable safety profile.[1] Less commonly used in induction are the lymphocyte/thymocyte-depleting globulin preparations and the anti-CD52 monoclonal antibody alemtuzumab. The lack of consensus on the role of induction therapy reflects insufficient and conflicting data on the ability of these agents to reduce the incidence of acute rejection and CLAD in the lung transplant population. After the period of induction, *maintenance* therapy consists of a calcineurin inhibitor (tacrolimus or, less commonly, cyclosporine), purine synthesis inhibitor (mycophenolate or azathioprine), and prednisone. The mechanistic target of rapamycin inhibitor sirolimus is occasionally incorporated into the maintenance regimen. Use of this agent in place of a purine synthesis inhibitor does not reduce the incidence of acute rejection or CLAD and is associated with several bothersome side effects that commonly lead to discontinuation of the drug.[59] Its main role has been to facilitate dose reduction or discontinuation of calcineurin inhibitors in patients with renal insufficiency, with the goal of recovering or preserving renal function.[60,61] Sirolimus impairs wound healing and has been associated with life-threatening bronchial anastomotic dehiscence when it is used immediately following transplantation.[62] As a result, the drug should not be initiated until complete healing of the bronchial anastomosis has been documented.

Individuals providing care to transplant recipients must be familiar with the administration, side effects, and drug interactions of these immunosuppressive agents (eTable 140.1). Although serving as the cornerstone of therapy, calcineurin inhibitor administration is particularly challenging. When these agents are administered orally, their bioavailability is poor and unpredictable, thus necessitating frequent monitoring of blood levels to ensure appropriate dosing. These drugs are metabolized through the hepatic cytochrome P-450 system, and blood levels are influenced by the concurrent administration of other drugs that affect this enzymatic pathway. Adverse effects of these agents, as well as of the other drugs commonly used, are legion and contribute significantly to the morbidity associated with transplantation.

Management of medical comorbidities is an essential component of the care of the lung transplant recipient. Common medical issues that emerge in this population include osteoporosis, hypertension, renal insufficiency, coronary artery disease, diabetes mellitus, and hyperlipidemia.[63] Treatment of these conditions is similar to that in the general population. The incidence of many cancers is increased in immunosuppressed transplant recipients, and particular attention should be paid to screening in this patient population.

OUTCOMES

The impact of lung transplantation is assessed by conventional survival statistics as well as by functional and quality of life parameters.

SURVIVAL

Current median survival following lung transplantation is 6.5 years.[1] Disease-specific differences in survival are apparent but may be confounded by differences in severity of illness, comorbidities, and average age among these populations. In descending order, median survival is 9.5 years for CF, 7.0 years for $alpha_1$-antitrypsin deficiency, 6.3 years for idiopathic pulmonary arterial hypertension, 5.9 years for COPD, and 5.2 years for idiopathic pulmonary fibrosis and other idiopathic interstitial pneumonias.[1]

Mortality is highest during the first year, with primary graft dysfunction and infection representing the most common causes of early death. In contrast, most late deaths are attributable to the development of CLAD, the lethal effects of which result from both progressive respiratory failure and an increased susceptibility to infection.

In the absence of randomized trials, the question whether lung transplantation extends survival compared with the natural history of the underlying disease has been addressed using statistical modeling. In the case of idiopathic pulmonary fibrosis, a disease with an extremely poor short-term prognosis, studies have consistently suggested that lung transplantation does confer a survival advantage, but it is notable that none of these studies was conducted in patients with idiopathic pulmonary fibrosis who were receiving the

eTable 140.1 Commonly Used Immunosuppressive Medications

Medication (Class)	Dosing*	Adverse Effects	Drug Interactions
Cyclosporine and tacrolimus (calcineurin inhibitors)	*Cyclosporine:* dosed to achieve a whole blood trough level of 250–350 ng/mL (first year), then 200–300 ng/mL† *Tacrolimus:* dosed to achieve a whole blood trough level of 10–12 ng/mL (first year), then 6–8 ng/mL	▪ Nephrotoxicity ▪ Hypertension ▪ Neurotoxicity (tremor, seizures, white matter disease, headache) ▪ Hyperkalemia ▪ Hypomagnesemia ▪ Hyperuricemia/gout ▪ Hemolytic-uremic syndrome ▪ Gastroparesis ▪ Hyperglycemia ▪ Hirsutism (cyclosporine) ▪ Gingival hyperplasia (cyclosporine)	Increased blood levels: ▪ Macrolide antibiotics (except azithromycin) ▪ Azole antifungal agents ▪ Diltiazem, verapamil ▪ Grapefruit juice Decreased blood levels: ▪ Phenobarbitol ▪ Phenytoin ▪ Rifampin
Sirolimus (mTOR inhibitor)	Dosed to achieve a whole blood trough level of 6–12 ng/mL	▪ Thrombocytopenia ▪ Anemia ▪ Hyperlipidemia ▪ Peripheral edema ▪ Rash ▪ Impaired wound healing ▪ Interstitial pneumonitis	Same as calcineurin inhibitors
Azathioprine (purine synthesis inhibitor)	2 mg/kg/day	▪ Leukopenia ▪ Macrocytic anemia ▪ Thrombocytopenia ▪ Hepatotoxicity ▪ Pancreatitis ▪ Hypersensitivity reaction (fever, hypotension, rash)	Synergistic bone marrow suppression when administered with allopurinol
Mycophenolate mofetil (purine synthesis inhibitor)	1000–1500 mg bid	▪ Diarrhea ▪ Leukopenia ▪ Anemia	Concurrent use of cyclosporine may decrease serum concentrations of mycophenolate by limiting biliary secretion or enterohepatic recycling
Prednisone (corticosteroid)	0.5 mg/kg/day for 6–12 wk, then tapered to 0.15 mg/kg/day	▪ Hyperglycemia ▪ Hypertension ▪ Hyperlipidemia ▪ Weight gain ▪ Osteoporosis ▪ Avascular necrosis ▪ Myopathy ▪ Mood changes ▪ Insomnia ▪ Cataracts	No significant interactions
Polyclonal antilymphocyte or antithymocyte globulin	Dose depends on specific preparation used	▪ Leukopenia ▪ Thrombocytopenia ▪ Anaphylaxis ▪ Serum sickness ▪ "Cytokine release syndrome"—fever, hypotension	No significant interactions
Basiliximab (monoclonal IL-2 receptor antagonist)	20 mg IV on days 1 and 4	Hypersensitivity reactions (rare)	No significant interactions

*Dosing may vary among transplant centers.
†Measured by high-performance liquid chromatography assay.
bid, twice daily; IL-2, interleukin-2; IV, intravenously; mTOR, mechanistic target of rapamycin.

newer antifibrotic medications.[64–66] A survival advantage has been more difficult to demonstrate for COPD, which typically follows a protracted course even in the advanced stages, and available studies comparing wait-list and post-transplant survival have yielded conflicting results.[65,67] A more complex analysis of this issue, by using prognostic models of survival with and without transplantation, found that approximately 45% of patients with COPD would gain a survival benefit of at least 1 year by undergoing BLT, whereas only 22% would derive such a benefit if SLT were used.[68] Survival benefit was heavily influenced by pretransplant FEV_1 as well as several other functional and physiologic parameters. As an example, nearly 80% of patients with an FEV_1 less than 16% but only 11% of those with an FEV_1 greater than 25% were predicted to gain at least 1 year of life with BLT. Adults with CF also appear to derive a survival advantage from lung transplantation,[66] although one study found that this advantage was limited to patients with a predicted 5-year survival without transplantation of less than 50% and without *B. cepacia* and CF-related arthropathy.[69,70] In contrast, modeling studies have suggested that patients with CF who are younger than 18 years rarely achieve a survival benefit.[69,71] This contention has been challenged by several investigators who pointed out potential methodologic shortcomings of these studies.[72,73]Independent of underlying disease, the recipient's LAS at the time of transplantation appears to be a powerful predictor of survival benefit; patients with an LAS lower than 33 are unlikely to derive a survival benefit, while virtually all patients with an LAS greater than 40 are predicted to do so.[66]

PULMONARY FUNCTION

The peak effect of lung transplantation on pulmonary function parameters is usually not realized until 3 to 6 months following the procedure, at which time the adverse impact of such factors as postoperative pain, weakness, altered chest wall mechanics, and ischemia-reperfusion lung injury has dissipated. Complete normalization of pulmonary function is the anticipated result of BLT. Following SLT for COPD, the FEV_1 increases severalfold to a level of approximately 50–60% of the predicted normal value (Video 140.1). Similarly, SLT for pulmonary fibrosis results in marked but incomplete improvement in lung volumes, with persistence of a restrictive pattern.

Transplantation also leads to correction of gas exchange abnormalities. Oxygenation improves rapidly, permitting the majority of patients to be weaned from supplemental oxygen within the first week. Hypercapnia may take longer to resolve because of lingering abnormalities in the ventilatory response to carbon dioxide.[74]

EXERCISE CAPACITY

Exercise tolerance improves sufficiently to permit the majority of transplant recipients to achieve functional independence and resume an active lifestyle. Although free of limitations with usual activity, transplant recipients with normal allograft function demonstrate a characteristic reduction in peak exercise performance as assessed by cardiopulmonary exercise testing. Specifically, patients typically achieve a maximum oxygen consumption at peak exercise of only 40– 60% of predicted.[75,76] Suboptimal exercise performance persists in subjects tested as late as 1 to 2 years following transplantation. Despite the greater magnitude of improvement in pulmonary function experienced by bilateral transplant recipients, there is no significant difference in peak exercise performance between this group and patients who receive only one lung.[76,77]

Characteristically, breathing reserve, oxygen saturation, and heart rate reserve remain normal during exercise, whereas anaerobic threshold is reduced, a pattern most consistent with skeletal muscle dysfunction. Factors possibly contributing to this limitation include chronic deconditioning, steroid myopathy, and calcineurin inhibitor–induced impairment in muscle mitochondrial respiration.[75,78]

HEMODYNAMICS

When performed in patients with primary or secondary forms of pulmonary hypertension, lung transplantation results in normalization of pulmonary arterial pressure and enhanced cardiac output.[79] In response to a decrease in afterload, right ventricular geometry and performance gradually normalize in the majority of patients.[80,81] Even a severely dysfunctional right ventricle will recover; a threshold of right ventricular dysfunction below which recovery is not possible has yet to be defined.

QUALITY OF LIFE

After successful lung transplantation, quality of life measures improve markedly across most domains, driven largely by a reduced level of disability.[82,83] These improvements peak at 3 to 6 months after transplantation and remain higher than pretransplantation levels for up to 5 years. Nonetheless, several important limitations have been observed. Recipients are much more likely to demonstrate improvements in physical dimensions of quality of life than in mental dimensions because increased levels of depression and anxiety and poor perception of body image persist.[82–85] In addition, troubling side effects of immunosuppressive medications adversely affect quality of life.[85,86] Finally, the development of CLAD is associated with a significant deterioration in quality of life measures.[87]

COMPLICATIONS

The lung transplant recipient faces some complications related to the surgery itself, the consequences of immunosuppression, and the constant assault of immune and nonimmune insults on the allograft.

PRIMARY GRAFT DYSFUNCTION

Primary graft dysfunction (PGD) is a term applied to the development within 72 hours of transplantation of radiographic opacities in the allograft(s) associated with impaired oxygenation in the absence of identifiable insults such as volume overload, pneumonia, rejection, atelectasis, heart failure, or pulmonary venous outflow obstruction.[88] PGD is presumed to be a consequence of ischemia-reperfusion injury as well as suboptimal lung

preservation, surgical trauma, lymphatic disruption, and inflammatory events associated with donor brain death and mechanical ventilation. Supporting the concept of PGD as a form of acute, nonimmunologic lung injury, histologic examination of lung tissue from affected patients reveals a prevailing pattern of diffuse alveolar damage.[88] A widely used grading system classifies the severity of PGD based on the ratio of arterial oxygen pressure (arterial Po_2) to the fractional concentration of oxygen in inspired gas (Table 140.4).[89] In most cases, the process is mild and transient but, in approximately 10–20% of cases, injury is sufficiently severe to cause life-threatening hypoxemia (PGD grade 3) and a clinical course analogous to the acute respiratory distress syndrome.

Numerous risk factors for development of severe PGD have been identified.[90] Many of these are procedure-related factors: use of an elevated fractional concentration of oxygen in inspired gas during reperfusion, use of cardiopulmonary bypass, SLT, and administration of large-volume blood product transfusions. Recipient risk factors include a diagnosis of sarcoidosis, presence of pulmonary hypertension, and overweight or obese body habitus. A history of smoking has been identified as a donor-related risk factor. Although early studies suggested that prolonged graft ischemic time was a risk factor, more recent studies have not found this to be true.[90,91] An elevated level of interleukin-8 in *bronchoalveolar lavage* (BAL) fluid recovered from the donor has been associated with the development of severe PGD, a finding supporting the notion that inflammatory events preceding organ harvest may play a role.[92]

Treatment of severe PGD is supportive, relying on conventional mechanical ventilation using low–tidal volume strategies, as well as on ECMO for selected patients who otherwise cannot be stabilized.[93,94] The use of nitric oxide in patients with established graft injury has been associated with sustained reduction in pulmonary artery pressures and improvement in oxygenation.[95] However, the prophylactic administration of nitric oxide to all recipients at the time of reperfusion does not reduce the incidence of severe PGD.[96] Results of emergency retransplantation in this setting have been poor.[97,98]

With an associated mortality rate of 20–40%, severe PGD is a leading cause of early death among transplant recipients.[90,99,100] The risk of death remains excessive even beyond the first year, suggesting that PGD has lingering adverse consequences well after resolution of the acute event. Recovery among survivors is often protracted and incomplete, although attainment of normal lung function and exercise tolerance is possible.[101] There is an increased risk of CLAD following development of PGD, but data are conflicting on whether the increased risk spans all grades of PGD or is seen exclusively following the most severe grade.[102,103]

Table 140.4 Grading System for Primary Graft Dysfunction

Grade	Pao_2/Fio_2	Radiographic Evidence of Pulmonary Edema
0	Any	Absent
1	>300	Present
2	200–300	Present
3	<200	Present

Pao_2/Fio_2, ratio of arterial oxygen pressure to fractional concentration of oxygen in inspired gas.

AIRWAY COMPLICATIONS

During implantation of the allograft, the bronchial arterial circulation is not restored. As a consequence, the donor bronchus is precariously dependent on retrograde collateral blood flow through low-pressure pulmonary arterial and venous to bronchial vascular collateral vessels, placing the airway at risk for ischemic injury. Airway ischemia may result in bronchial anastomotic dehiscence, which, when extensive, can lead to mediastinitis, pneumothorax, hemorrhage, and death. The finding of peribronchial or mediastinal air collections on computed tomography scan is highly suggestive of bronchial dehiscence, but direct inspection using bronchoscopy is necessary to confirm the diagnosis and assess the extent. For mild cases, conservative management with reduction in corticosteroid dosing and chest tube placement for evacuation of an associated pneumothorax may be all that is necessary (Fig. 140.2). More extensive cases can be successfully managed with temporary placement of a bare metal airway stent across the dehiscence to provide a scaffolding on which granulation tissue can form.[104] Surgical intervention to buttress or revise the anastomosis is reserved for severe cases when bronchoscopic interventions fail or are not feasible, but surgical outcomes are disappointing. Pneumonectomy is a last resort in life-threatening situations in patients with an intact and functioning contralateral allograft.

Ischemic injury to the airway more commonly manifests as necrosis of the anastomotic cartilage and as areas of bronchial mucosal ulceration, dusky patches, and overlying pseudomembranes. These devitalized areas in turn place the patient at increased risk for superinfection of the airway with *Candida* and *Aspergillus* species; initiation of inhaled and/or systemic fungal prophylaxis is indicated until the airways have healed.

The most common airway complication currently encountered is bronchial anastomotic stenosis, with a reported frequency of 10–15% in contemporary series.[105,106] Narrowing can be caused by excessive granulation tissue, fibrotic stricture (Fig. 140.3), or bronchomalacia (the latter two mechanisms likely sequelae of prior ischemic injury). Occasionally, fibrotic strictures can extend beyond the anastomosis, thus leading to narrowing of the bronchus intermedius (eFig. 140.1) or lobar bronchi. Anastomotic narrowing typically develops within several weeks to months following transplantation. Clues to its presence include focal wheezing on the involved side, recurrent bouts of pneumonia or purulent bronchitis, and suboptimal pulmonary function studies demonstrating airflow obstruction and truncation of the flow-volume loop. Bronchoscopy

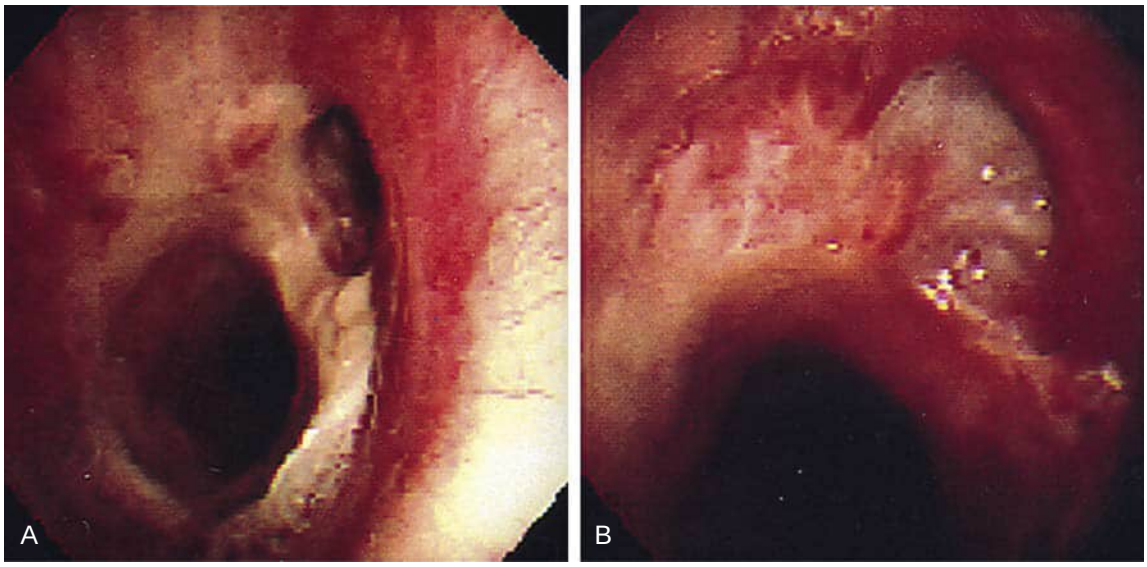

Fig. 140.2 Bronchial anastomotic dehiscence. (A) Bronchoscopic view immediately distal to the main carina demonstrates partial dehiscence of the right bronchial anastomosis at the 1 o'clock position. (B) After several weeks of expectant management, a repeat bronchoscopy demonstrates nearly complete healing of the dehiscence.

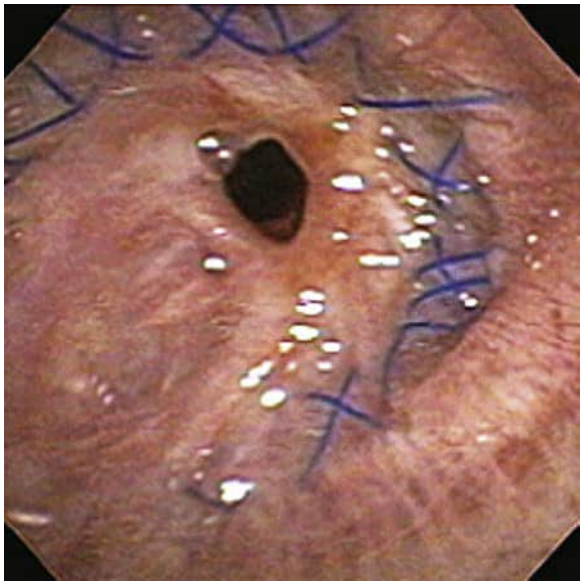

Fig. 140.3 Bronchial anastomotic stricture. Bronchoscopic view of a left mainstem bronchial anastomosis demonstrates marked narrowing of the lumen resulting from formation of a fibrous web. The true outer margin of the bronchus is outlined by the suture material.

both confirms the diagnosis and permits therapeutic interventions, including rigid bronchoscopic or balloon dilation, laser débridement, endobronchial brachytherapy, and stent placement.[107] Although these measures are often successful in the short term, recurrent stenosis is common, necessitating repeated interventions and leading to compromised functional outcomes and excess mortality.[108]

PHRENIC NERVE INJURY

Phrenic nerve injury following lung transplantation can result from intraoperative traction, use of an iced slurry to cool the allograft in the chest cavity during implantation, or transection of the nerve in the setting of extensive fibrous adhesions and difficult hilar dissection. Depending in part on whether screening is restricted to clinically suspected cases or more broadly to all recipients, the reported incidence of phrenic nerve dysfunction ranges from 3–30%.[109–112] Important albeit nonspecific clues to the presence of phrenic nerve injury include difficulty in weaning from mechanical ventilation, persistent hypercapnia, orthopnea, and radiographic evidence of persistent elevation of the diaphragm and associated basilar atelectasis. Phrenic nerve injury has been associated with increases in ventilator days, tracheostomy rates, and intensive care unit length of stay.[110] Achievement of a normal functional outcome is ultimately possible for patients with reversible injury, but recovery in some cases may be protracted or incomplete. For severely impaired patients, nocturnal noninvasive ventilatory support and diaphragmatic plication have been successful.[113,114]

NATIVE LUNG HYPERINFLATION

Acute hyperinflation of the native lung leading to respiratory and hemodynamic compromise in the immediate postoperative period has been reported in 15–30% of patients with emphysema who underwent SLT.[115,116] The combination of positive-pressure ventilation and significant allograft edema serves to magnify the compliance differential between the two lungs and may predispose to this complication. Acute hyperinflation can be rapidly addressed by use of a bronchial blocker or by initiation of independent lung ventilation, ventilating the native lung with a low respiratory rate and a long expiratory time to facilitate complete emptying.

Beyond the perioperative period, some SLT recipients with underlying emphysema demonstrate exaggerated or progressive native lung hyperinflation that more insidiously

compromises the function of the allograft. In this setting, surgical volume reduction of the native lung can result in significant functional improvement.[117]

INFECTION

Infection rates among lung transplant recipients are considerably higher than among recipients of other solid organs. The greater risk is likely related to the unique exposure of the lung allograft to microorganisms through inhalation and aspiration and to the higher level of immunosuppression maintained in these patients. A comprehensive discussion of infectious complications is beyond the scope of this chapter; only the most common pathogens are discussed.

Bacteria

Bacterial infections of the lower respiratory tract account for the majority of infectious complications and have a bimodal temporal distribution.[118,119] Bacterial pneumonia is most frequently encountered within the first month after transplantation. In addition to the immunosuppressed status of the recipient, factors that predispose to early bacterial pneumonia include the need for prolonged mechanical ventilatory support; blunted cough in response to postoperative pain, weakness, and lung denervation; disruption of lymphatics; and ischemic injury to the bronchial mucosa with resultant impairment in mucociliary clearance. Although passive transfer of occult infection with the transplanted organ is an additional concern, the presence of organisms on Gram stain of donor bronchial washings is not predictive of subsequent pneumonia in the recipient.[120] Bacterial infections, in the form of purulent bronchitis, bronchiectasis, and pneumonia, reemerge as late complications in patients who develop CLAD. Gram-negative pathogens, in particular *P. aeruginosa* (see eFig. 125.1), are most frequently isolated in association with both early and late infectious events.[118,119]

Cytomegalovirus

Cytomegalovirus (CMV) is the most common viral pathogen encountered following lung transplantation, although in the era of effective prophylaxis its incidence and impact have diminished considerably.[119] Infection can develop by transfer of virus with the allograft or transfused blood products or by reactivation of latent virus remotely acquired by the recipient. Seronegative recipients who acquire organs from seropositive donors are at greatest risk for developing infection, and these primary infections tend to be the most severe. Donor-positive–recipient-negative mismatching has also been identified as a risk factor for increased mortality at 5 years.[1,121]

In the absence of prophylaxis, CMV infection typically emerges 1 to 3 months following transplantation; antiviral prophylaxis shifts the onset to later in the course, often in the initial months after the antiviral agent is discontinued. Infection is often subclinical, evidenced only by silent viremia or shedding of virus in the respiratory tract. Clinical disease may manifest as a mononucleosis-like syndrome of fever, malaise, and leukopenia (CMV syndrome) or as organ-specific invasion of the lung, gastrointestinal tract, central nervous system, or retina. Detection of virus in peripheral blood by polymerase chain reaction techniques establishes a diagnosis of CMV infection but does not reliably predict the presence of tissue-invasive disease. Conversely, a negative peripheral blood assay result does not exclude tissue-invasive disease, particularly pneumonitis.[122] A diagnosis of CMV pneumonitis, the most common manifestation of invasive disease in the lung transplant recipient (see eFigs. 125.6 and 125.7), is unequivocally established by demonstration of characteristic viral cytopathic changes on lung biopsy or on cytologic specimens obtained by BAL, but the sensitivity of these findings is relatively low. Demonstration of CMV antigens by immunohistochemistry offers greater diagnostic sensitivity. Caution must be exercised in interpretation of a positive viral culture or polymerase chain reaction of BAL specimens because virus can be shed into the respiratory tract in the absence of tissue invasion.[122]

Standard treatment of CMV syndrome and tissue-invasive disease consists of oral valganciclovir; in severe cases, intravenous ganciclovir is preferred for initial management. Monitoring of peripheral blood viral load should be performed weekly to confirm response to therapy. Treatment should be continued until the viral load is confirmed to be below the lower limit of quantification of the assay (typically less than 200 IU/mL).[123] Some experts advocate the addition of CMV hyperimmune globulin in treatment of severe disease, but evidence supporting this practice is scant. Although treatment is effective, relapse rates of up to 40% in patients with primary infection and 24% in seropositive recipients have been reported.[124] Initiation of oral valganciclovir as secondary prophylaxis after completion of definitive treatment does not decrease the risk of relapse and is not generally recommended in consensus guidelines but is nonetheless a common practice.[123–125]

In an attempt to minimize the adverse impact of CMV infection on the posttransplantation course, emphasis has shifted to preventive strategies when either the donor or recipient is seropositive. Numerous prospective randomized trials have documented the efficacy of antiviral prophylaxis in delaying the onset and reducing the incidence and severity of CMV infection.[126] Oral valganciclovir has replaced intravenous ganciclovir as the prophylactic agent of choice because of its excellent bioavailability, ease of administration, and demonstrated efficacy.[127] Universal prophylaxis of all donor-seropositive–recipient-seronegative patients is recommended because the risk of CMV disease is high.[123] Because the risk of disease is significantly lower in seropositive recipients (independent of donor status), it has been argued that universal prophylaxis of this group leads to overtreatment, increasing costs, and unduly exposing patients to the risk of drug toxicity. In this population, preemptive strategies targeting antiviral therapy exclusively to patients demonstrating a rising viral load in peripheral blood have been advocated, but most programs still adhere to a universal prophylaxis strategy.[125,128] The duration of prophylaxis necessary to mitigate the risk of CMV was best examined in a randomized controlled trial of 136 at-risk lung transplant recipients (either donor or recipient seropositive). When patients were evaluated at month 13, there was a 4% incidence of CMV disease after a 12-month course of valganciclovir prophylaxis compared with 32% after a 3-month

course.[129] For a subset of patients followed for 4 years after completion of prophylaxis, the incidence of CMV disease remained considerably lower in the 12-month group compared with the 3-month group (12% vs. 55%).[130] Additional studies are required to determine whether 12 months is necessary or excessive and whether all at-risk subgroups require the same regimen. Consensus guidelines currently recommend a minimum of 6 to 12 months of prophylaxis for donor-positive–recipient-negative patients and 6 months for recipient-positive patients.[123]

Emergence of ganciclovir-resistant strains of CMV has been reported in 5–18% of lung transplant recipients with CMV infection.[123,131–133] Risk factors include donor-positive–recipient-negative CMV status, use of potent immunosuppressive agents such as antilymphocyte antibodies, increased number of CMV episodes, and prolonged exposure to ganciclovir.[123] High-dose ganciclovir, foscarnet, or a combination of the two is the recommended treatment regimen for ganciclovir-resistant disease.[123] Although treatment is often initially successful, the presence of ganciclovir-resistant disease is associated with decreased survival in lung transplant recipients.[131]

Aspergillus

Aspergillus species account for the majority of fungal infections following lung transplantation. Pretransplantation or posttransplantation colonization of the airways with aspergillus is most frequently cited as a risk factor for subsequent development of infection, although data remain conflicting and up to 48% of patients who develop infection have neither risk factor.[134,135]

Aspergillus infects the bronchial tree in approximately 2–5% of lung transplant recipients.[135,136] In most cases, infection is localized to the bronchial anastomosis, where devitalized cartilage and foreign suture material create a nurturing environment. Less commonly, infection may manifest as more diffuse ulcerative bronchitis with formation of pseudomembranes, typically following in the wake of a severe ischemic injury to the bronchial mucosa. Clustered within the first 3 months posttransplantation, these airway infections are often asymptomatic and detected only by surveillance bronchoscopy. Voriconazole is considered first-line therapy; nebulized amphotericin is recommended as an adjunct for airway infections.[137] Although usually responsive to treatment, airway infections have rarely progressed to invasive pneumonia or fatal erosion into the adjacent pulmonary artery.[136,138] An increased risk of subsequent bronchial stenosis or bronchomalacia has also been reported, but it is unclear whether this is a consequence of the infection or of an underlying ischemic injury to the bronchus that predisposed to infection.[139,140]

Invasive aspergillosis, a far more serious form of infection, develops in up to 7% of lung transplant recipients, most commonly within the first year.[135,136] It nearly always involves the lung but may disseminate to distant sites, particularly the brain, in a minority of patients. Symptoms are nonspecific and include fever, cough, pleuritic chest pain, and hemoptysis. Radiographically, pulmonary aspergillosis may appear as single opacity or mass (eFig. 125.2B) or nodular (see eFig. 125.2A) or cavitary opacities (Fig. 140.4 and eFig. 125.4) or as alveolar consolidation. The halo sign—a rim of ground-glass attenuation surrounding a central nodular opacity—is a suggestive but nonspecific finding on chest computed tomography scans.

Diagnosing invasive pulmonary aspergillosis can be challenging. As discussed previously, many lung transplant recipients are colonized with *Aspergillus,* thus making it difficult to interpret the significance of positive results of fungal stains and cultures derived from BAL specimens. Conversely, the sensitivity of BAL fungal stains and culture in the setting of invasive disease has been reported in the range of only 45–62% in solid organ transplant recipients.[141] Because of a similarly low sensitivity in this population, serum galactomannan (a constituent of the fungal cell wall shed during active invasion) is not recommended as a diagnostic test.[134,137] BAL galactomannan testing in this population appears to offer higher sensitivity (77–100%, with a cutoff value of 0.5) with varying specificity (40–100%) in published studies.[134] Because the prevalence of invasive disease is relatively low, however, the positive predictive value of BAL galactomannan in lung transplant recipients is as low as 24%.[142] In the context of compatible clinical and radiographic features and/or demonstration of *Aspergillus* in respiratory secretions by culture, cytology, or galactomannan assay, the clinician must exercise judgment in deciding whether to initiate an empirical trial of antifungal therapy or pursue more definitive proof by means of transthoracic needle biopsy or surgical lung biopsy.

Voriconazole is the treatment of choice for invasive aspergillosis. Addition of an echinocandin (e.g., caspofungin) is considered in cases of severe or progressive infection, although the advantage of combination therapy has not been established.

Many transplant programs use antifungal prophylaxis in an attempt to mitigate the risk of airway and invasive aspergillosis, although consensus is lacking on the best strategy and data supporting efficacy are conflicting. Voriconazole and/or inhaled amphotericin are commonly used for this purpose; the latter is typically discontinued after airway

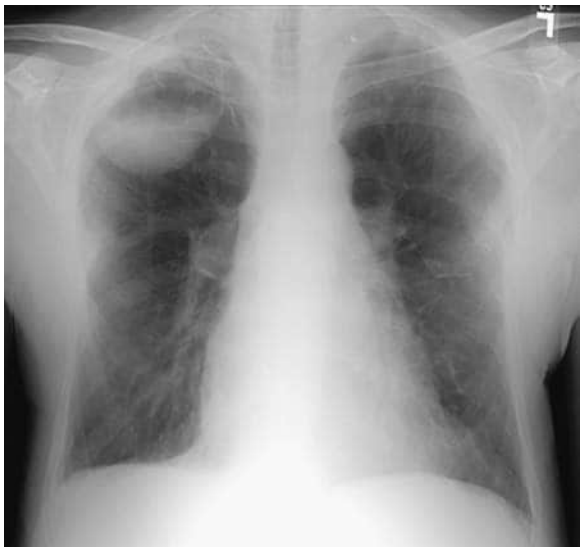

Fig. 140.4 Invasive aspergillosis. Bilateral lung transplant recipient with a large right upper lobe cavity containing an air-fluid level. Transthoracic needle biopsy demonstrated fungal elements morphologically consistent with *Aspergillus* species. The patient did not respond to antifungal therapy and required surgical resection for definitive cure.

healing has been documented. Two meta-analyses of studies involving universal antifungal prophylaxis in lung transplant recipients came to opposite conclusions on whether this resulted in reduction of posttransplantation *Aspergillus* infections.[143,144] Efficacy of an alternative strategy of targeted prophylaxis for recipients with either pretransplant or postransplant fungal colonization was demonstrated in a 2018 study from the University of Toronto group.[145]

REJECTION AND CHRONIC LUNG ALLOGRAFT DYSFUNCTION

Despite the use of potent immunosuppressive agents, allograft rejection and CLAD remain pervasive problems that constrain long-term graft and patient survival. Humoral and cellular alloimmune mechanisms have been defined to varying degrees for the more acute insults, and thus the term "rejection" is an appropriate descriptor (i.e., hyperacute rejection, acute cellular rejection, antibody-mediated rejection). However, the pathogenetic mechanisms underlying chronic forms of allograft dysfunction are less clear, and both immunologic and nonimmunologic insults have been implicated. Although still part of the transplant lexicon, the term *chronic rejection* is misleading because it oversimplifies both the mechanism and the spectrum of phenotypes that characterize long-term allograft impairment. The term CLAD has emerged as a preferred descriptor, comprising the most commonly encountered form, *bronchiolitis obliterans syndrome* (BOS), as well as the more recently described variant, *restrictive allograft syndrome* (RAS). The various forms of rejection and CLAD are described in detail in the following sections. Features of the three most commonly encountered entities—acute cellular rejection, BOS, and RAS—are summarized in Table 140.5.

Hyperacute Rejection

Hyperacute rejection is a rare but highly lethal complication mediated by preformed antibodies of recipient origin directed against HLA antigens contained in donor tissue. The pulmonary microvascular endothelium is the principal target, leading to complement-mediated and neutrophil-mediated damage and widespread deposition of platelet or fibrin thrombi.[146] Hyperacute rejection becomes clinically manifest within minutes to hours of establishing perfusion to the freshly implanted lung. The allograft appears dusky, mottled, and grossly edematous on direct inspection and densely opacified on chest radiograph. Copious amounts of pink, frothy edema fluid often are produced by the allograft and must be frequently suctioned from the endotracheal tube. Profound graft dysfunction and hemodynamic

Table 140.5 Features of Acute Cellular Rejection, Bronchiolitis Obliterans Syndrome, and Restrictive Allograft Syndrome

Feature	Acute Cellular Rejection	Bronchiolitis Obliterans Syndrome	Restrictive Allograft Syndrome
Onset after transplant	Days to months; less common beyond the first year	Beyond first year	Beyond first year
Risk factors	Uncertain	Acute rejection, lymphocytic bronchiolitis, community respiratory viruses, primary graft dysfunction, silent aspiration, CMV pneumonitis	Uncertain
Histology	Perivascular lymphocytic infiltrates	Bronchiolar submucosal inflammation and fibrosis; luminal obliteration	Intra-alveolar and subpleural fibroelastosis, diffuse alveolar damage, nonspecific interstitial pneumonia, acute fibrinoid organizing pneumonia
Signs and symptoms	Low-grade fever, dyspnea, cough, impaired oxygenation, leukocytosis	Dyspnea, chronic cough, recurrent bouts of purulent bronchitis	Dyspnea
Chest radiograph	Alveolar or interstitial opacities, pleural effusions	Clear lung fields (may show hyperinflation)	Persistent pulmonary opacities, most commonly upper lobe fibrosis and associated pleural thickening
High-resolution CT	Ground-glass or alveolar opacities, interlobular septal thickening	Tree-in-bud opacities, bronchiectasis, air trapping	Upper lobe fibrosis, pleural thickening, ground glass opacities
Pulmonary function testing	Proportional decline in FEV_1 and FVC	Disproportionate decline in FEV_1 with obstructive pattern	Decline in FEV_1 and TLC with a restrictive pattern
Yield of transbronchial biopsy	High	Low	Low
Treatment	High-dose corticosteroids	Azithromycin, retransplantation	Retransplantation; outcomes inferior to retransplant for BOS
Outcome	Favorable response to treatment	30–40% of patients demonstrate modest but often transient improvement in response to azithromycin; most patients ultimately experience progressive allograft dysfunction	Progressive allograft dysfunction

BOS, bronchiolitis obliterans syndrome; CMV, cytomegalovirus; CT, computed tomography; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; TLC, total lung capacity.

instability ensue. Most reported cases have resulted in death, but survival was reported in a patient managed with a combination of plasmapheresis, antithymocyte globulin, and cyclophosphamide.[147,148] Routine screening of all lung transplant candidates for preformed anti-HLA antibodies and avoidance of donors with the targeted antigens have proved to be highly effective in minimizing the risk of hyperacute rejection.

Acute Cellular Rejection

Acute cellular rejection is a T cell–mediated alloimmune process that principally targets the vascular component of the allograft and, to a lesser extent, the airways. Approximately one-quarter of transplant recipients experience an episode of acute cellular rejection requiring treatment within the first year after transplantation.[1] Beyond this initial period, the incidence of acute cellular rejection declines considerably. Risk factors for development of acute rejection remain poorly defined. Data are conflicting on whether the degree of HLA discordance between donor and recipient represents a risk factor.[58,149,150] Polymorphisms in toll-like receptor 4 that down-regulate recipient innate immune responsiveness are associated with a lower incidence of acute cellular rejection.[149]

Episodes of acute cellular rejection may be clinically silent in up to 40% of cases.[58] When present, clinical manifestations are nonspecific and include malaise, low-grade fever, dyspnea, cough, and leukocytosis. Radiographic opacities (eFig. 140.2), a decline in arterial oxygenation at rest or with exercise, and an abrupt fall of greater than 10% in spirometric values are important clues to the possible presence of rejection, but similar findings accompany bouts of infection.

Reliance on clinical and radiographic criteria alone runs the risk of misdiagnosis and needless augmentation of immunosuppression. Transbronchial lung biopsy represents the gold standard for diagnosis of acute cellular rejection, although its accuracy is less than ideal.[151] The procedure is safe, can be performed in serial fashion over time, and has a reasonable sensitivity and specificity. The histologic hallmark is the presence of perivascular lymphocytic infiltrates that, in more severe cases, spill over into the adjacent interstitium and alveolar air spaces. Lymphocytic bronchiolitis may accompany the parenchymal involvement or may be an independent feature. A histologic classification system has been adopted to grade the severity of acute cellular rejection (Table 140.6).[152]

Conventional treatment consists of a 3-day pulse of intravenous methylprednisolone at a daily dose of 5 to 15 mg/kg. In most cases, this results in rapid improvement in symptoms, pulmonary function, and radiographic abnormalities, but follow-up biopsies show histologic evidence of persistent rejection in 30% of patients with prior mild (A2) acute rejection and in 44% of patients with prior moderate (A3) acute rejection.[153] Asymptomatic and functionally stable patients with minimal (A1) rejection are often observed without treatment, but data demonstrating progression to a higher grade of acute rejection in one-quarter of cases and an increased risk of developing CLAD have challenged this approach.[154] Various modalities have been used for refractory or recurrent acute rejection, including antilymphocyte antibody preparations and extracorporeal photopheresis.

Acute Antibody-Mediated Rejection

There is emerging evidence in support of a second form of acute rejection, mediated by donor-specific anti-HLA alloantibodies most commonly to class II HLA but also to non-HLA epitopes. The clinical presentation is indistinguishable from that of acute cellular rejection, with dyspnea, hypoxemia, and diffuse radiographic opacities. The suggested diagnostic criteria for "definite" acute antibody-mediated rejection are as follows: (1) presence of circulating donor-specific anti-HLA antibodies, (2) clinical evidence of allograft dysfunction defined by functional (pulmonary function testing, oxygenation) and/or radiographic criteria, (3) compatible histopathologic features (e.g., neutrophilic capillaritis, diffuse alveolar damage), and (4) detection of C4d deposition along endothelial cell basement membrane.[155] Cases meeting all criteria except C4d deposition are considered "probable," but evidence suggests that the clinical presentation and outcomes are identical to those in patients with positive staining results.[156] Treatment focuses on rapid removal of the culprit antibody with plasmapheresis and inhibition of new antibody production with a combination of intravenous immunoglobulin and rituximab. Although most patients improve in response to this treatment, many go on to develop chronic allograft dysfunction. Prognosis appears more favorable for patients who successfully clear the circulating donor-specific anti-HLA antibodies.[156]

Bronchiolitis Obliterans Syndrome (See Chapter 72)

Bronchiolitis obliterans is the most common cause of CLAD and represents the major impediment to long-term graft and patient survival. Bronchiolitis obliterans is a fibroproliferative process characterized by submucosal inflammation and fibrosis of the bronchiolar walls that ultimately leads to complete obliteration of the airway lumen. The functional consequence of this process is progressive and largely irreversible airflow obstruction. Because the characteristic

Table 140.6 Histologic Grading System for Acute Cellular Rejection

Grade	Description
A0 (none)	Normal pulmonary parenchyma
A1 (minimal)	Scattered, infrequent perivascular mononuclear infiltrates
A2 (mild)	Frequent perivascular mononuclear infiltrates surrounding venules and arterioles; readily recognizable at low magnification
A3 (moderate)	Easily recognizable cuffing of venules and arterioles by dense perivascular mononuclear cell infiltrates, with extension of the inflammatory cell infiltrate into perivascular and peribronchiolar alveolar septa and air spaces
A4 (severe)	Diffuse perivascular, interstitial, and air space infiltrates of mononuclear cells with prominent alveolar pneumocyte damage and endothelialitis

From Stewart S, Fishbein MC, Snell GI, et al. Revision of the 1996 working formulation for the standardization of nomenclature in the diagnosis of lung rejection. *J Heart Lung Transplant*. 2007;26:1229–1242.

histologic features are difficult to demonstrate by transbronchial lung biopsy, FEV_1 has been adopted as a diagnostic surrogate for histology, and the term *bronchiolitis obliterans syndrome* (BOS) has been applied to this functionally defined disorder. BOS is defined as an otherwise unexplained and sustained fall in FEV_1 by at least 20% from posttransplant baseline. Approximately 50% of transplant recipients develop BOS by 5 years and 75% by 10 years.[157]

Acute cellular rejection and lymphocytic bronchiolitis have been consistently identified as major risk factors for development of BOS, findings supporting the view that BOS is a consequence of alloimmune injury.[158,159] Whereas the risk of BOS appears to correlate with the severity and frequency of these immunologic insults, even minimal (A1) acute rejection is associated with an increased risk.[154,160] Other possible immune-mediated risk factors include the presence of anti-HLA antibodies (particularly de novo donor-specific anti-HLA antibodies) and the development of anti–type V collagen antibodies.[161,162] Nonimmune factors may also be important in initiating or perpetuating injury, thus suggesting that BOS may represent the end result of a wide array of insults to the airway epithelium. These factors include CMV pneumonitis, community respiratory viral infections, airway colonization with *Aspergillus* or *Pseudomonas,* PGD, and gastroesophageal reflux with occult aspiration.[102,159,163–167]

Although often viewed as a late complication, BOS manifests within the first 2 years after transplantation in one-third to one-half of cases (early-onset BOS).[168,169] The decline in FEV_1 that heralds the onset of BOS may be either insidious or abrupt. Dyspnea, weight loss, cough, and recurrent bouts of purulent tracheobronchitis, with recovery of *P. aeruginosa* from sputum cultures, are characteristic clinical features. Although chest radiographs are usually unremarkable, high-resolution computed tomography commonly reveals air trapping (Fig. 140.5, eFig. 140.3, and Videos 140.2 and 140.3), tree-in-bud opacities, and/or bronchiectasis. The natural history of BOS is highly variable; patients with early or abrupt onset generally experience more rapid decline in lung function and higher mortality.[168,169] Median survival from diagnosis is 1.5 years and 2.5 years for those with early-onset and late-onset BOS, respectively.[168]

In the past, BOS was treated by augmenting immunosuppression, but this approach has not proved to be effective.[170] Use of azithromycin subsequently garnered interest based on its anti-inflammatory properties and its demonstrated benefit in treating other airway disorders. Several retrospective studies and one small prospective, randomized placebo-controlled trial documented short-term improvement in the FEV_1 in approximately 30–40% of patients with BOS who were treated with this agent.[171–174]Although still controversial, performance of surgical gastric fundoplication to control gastroesophageal reflux has been associated with improvement in lung function in some patients with BOS.[170,175] At this time, the only definitive treatment for advanced BOS is retransplantation.

The development of strategies to prevent BOS is an area of intense research, but to date there has been little substantive progress. In recognition of the established link between acute rejection and BOS, most transplant centers routinely perform surveillance lung biopsies to detect and treat clinically silent acute rejection, but the impact of this strategy on risk of BOS remains uncertain.[176] Early identification of recipients with gastroesophageal reflux and aggressive correction with fundoplication may delay or prevent onset of BOS, but this remains a controversial strategy.[177] A small, single-center, randomized placebo-controlled trial demonstrated that the prophylactic administration of azithromycin after transplantation improved BOS-free survival, but larger multicenter studies will be required to corroborate these findings.[178] Finally, some centers have used a strategy to screen for donor-specific anti-HLA antibodies and, if detected, treat with intravenous immunoglobulin and rituximab in the hope of reducing the subsequent risk of developing BOS.[179]

Restrictive Allograft Syndrome

Approximately one-third of recipients develop a form of CLAD referred to as *restricted allograft syndrome* (RAS).[180–182] In contrast to BOS, RAS is characterized by restrictive physiology and is defined by a concomitant fall in FEV_1 of more than 20% and a decrease in total lung capacity greater than 10% compared with baseline values. Another distinguishing feature is the presence of persistent radiographic opacities that most characteristically appear as predominantly upper lobe fibrotic changes, often with associated pleural thickening (Fig. 140.6). The histologic

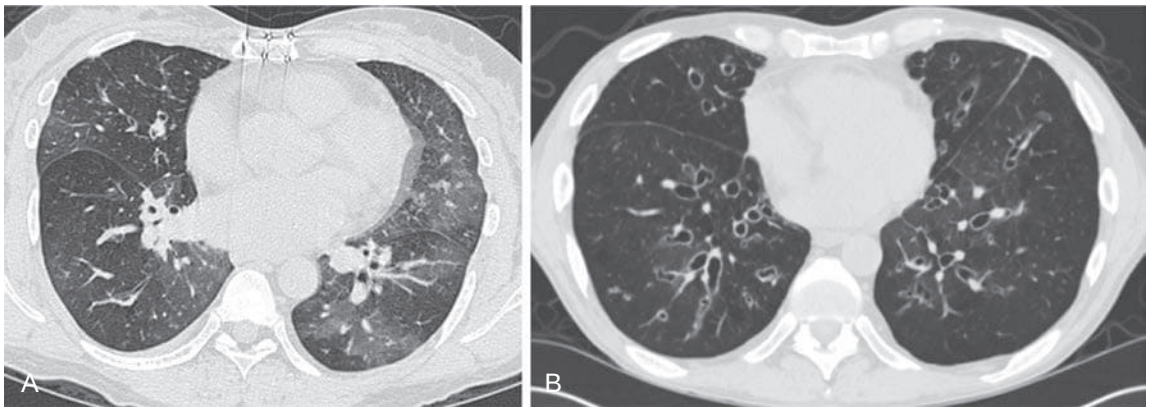

Fig. 140.5 Bronchiolitis obliterans syndrome. (A) High-resolution computed tomography image obtained during expiration demonstrates a mosaic attenuation pattern consistent with air trapping. (B) Image obtained from another patient with bronchiolitis obliterans syndrome demonstrates extensive bronchiectasis.

findings vary among published reports and include intra-alveolar and subpleural fibroelastosis, diffuse alveolar damage, nonspecific interstitial pneumonia, and acute fibrinoid organizing pneumonia. Survival is considerably worse than that associated with the more commonly encountered entity of BOS.[180]

POSTTRANSPLANTATION LYMPHOPROLIFERATIVE DISORDER

Posttransplant lymphoproliferative disorder (PTLD) describes a spectrum of abnormal proliferative responses involving B cells in the majority of cases and ranging from benign polyclonal hyperplasia to malignant lymphomas. In the majority of cases, *Epstein-Barr virus* (EBV) is the stimulus for B cell proliferation, which proceeds in an unchecked fashion because of the muted cytotoxic T cell response in the immunosuppressed host. EBV-naive recipients who acquire primary infection at the time of organ transplantation are at greatest risk of developing PTLD.[183]

The prevalence of PTLD in contemporary series is approximately 4–5% in adult lung transplant recipients.[184,185] The risk of developing PTLD is greatest within the first posttransplantation year, although up to one-half of all cases are seen beyond this point. Most early-onset cases involve the allograft and typically manifest as one or more pulmonary nodules that may be accompanied by mediastinal adenopathy (Fig. 140.7).[184,186] In contrast, beyond the first year, intra-abdominal and disseminated forms of disease predominate.

The diagnosis of PTLD is most firmly established by tissue biopsy. Care must be exercised when interpreting transbronchial lung biopsies because the aggregates of lymphocytes associated with acute cellular rejection can resemble foci of PTLD on these small tissue specimens. Diagnosis is aided by demonstration of the presence of EBV-infected cells by in situ hybridization or immunohistochemical staining. Determination of EBV-associated nuclear antigen viral load in the peripheral blood by using DNA amplification techniques has been touted as an ancillary diagnostic tool. One study of adult lung transplant recipients reported a sensitivity of 77% and specificity of 100% for a plasma EBV-associated nuclear antigen polymerase chain reaction assay.[187] However, additional studies using standardized assay techniques and threshold values for positive results are required before conclusions can be drawn about the diagnostic utility of viral load testing.

The initial therapeutic approach to PTLD involves reduction in the magnitude of immunosuppression to permit partial restoration of host cellular immunity against EBV. This may be sufficient to cause regression of tumor in mild cases, but patients with more advanced or rapidly progressive disease should be treated with rituximab (after confirmation that the tumor is CD20 positive). This agent is generally well tolerated and is associated with a complete response rate of 50–60%.[188,189] Patients with disease refractory to rituximab are treated with standard chemotherapy (cyclophosphamide, doxorubicin hydrochloride, vincristine sulfate, and prednisone regimen), although this is associated with considerable treatment-related morbidity and mortality.[188,190] There is no proven role for antiviral therapy in the setting of established PTLD.

LUNG CANCER

Lung cancers following lung transplantation arise predominantly in the native lung of SLT recipients with underlying COPD or pulmonary fibrosis, most of whom have had significant prior smoking histories.[191–195] The reported frequency of lung cancer following SLT is as high as 6.9%.[193] Data are conflicting on whether transplantation confers an increased likelihood of developing de novo lung cancer or whether the incidence is comparable with that of the general population with similar risk factors.[195] Less commonly, a previously unsuspected cancer may be incidentally detected in the explanted lung removed at the time of transplantation and may then recur in the allograft or in distant sites. Finally, there are rare reports of lung cancer of donor origin transmitted to the recipient.[196]

Lung cancer in the transplant recipient often progresses at a rapid pace, potentially leading to initial confusion with

Fig. 140.6 Restrictive allograft syndrome. Chest radiograph demonstrating upper lobe fibrosis and associated pleural thickening characteristic of restrictive allograft syndrome.

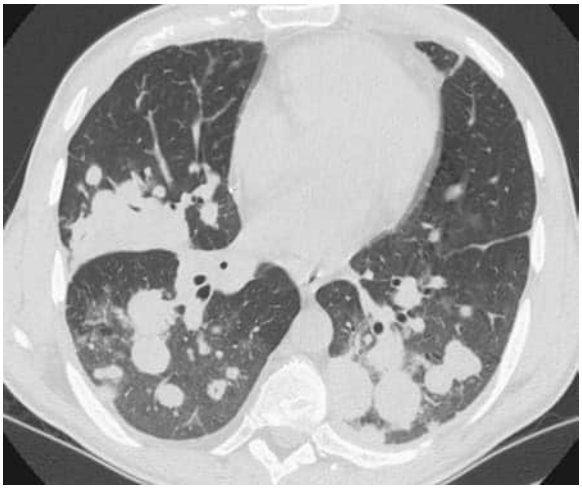

Fig. 140.7 Posttransplantation lymphoproliferative disorder. Computed tomography scan demonstrates multiple nodules and masses, proven on biopsy to represent high-grade B cell lymphoma. In situ hybridization studies revealed the presence of Epstein-Barr virus RNA.

an infectious process (eFig. 140.4).[191] This aggressive behavior may reflect loss of antitumor immune surveillance in the immunosuppressed host or may be caused by a more specific effect of calcineurin inhibitors in promoting tumor growth.[197] Overall prognosis is poor but should not preclude attempts at curative resection in the rare instances in which early-stage disease is encountered.

RECURRENCE OF PRIMARY DISEASE

Care reports and small case series describe recurrence of several primary disorders in the lung allograft.[198] Although accurate figures are not available, sarcoidosis appears to have the greatest propensity to do so. Recurrence of sarcoidosis is typically asymptomatic and marked by incidental recovery of noncaseating granulomas on transbronchial biopsy and occasionally by the presence of micronodular opacities in the upper lobes on computed tomography scan. Cases of recurrent lymphangioleiomyomatosis have also been reported. The abnormal smooth muscle cells found in the allograft are of recipient origin, a finding suggesting that the mechanism of recurrence involves migration or metastasis from an extrapulmonary site.[199] Other diseases for which recurrence has been reported include Langerhans cell histiocytosis, desquamative interstitial pneumonia, and hereditary pulmonary alveolar proteinosis. Recurrence of emphysema following transplantation for alpha$_1$-antitrypsin deficiency has been reported in the context of resumption of smoking.[200]

RETRANSPLANTATION

Outcomes following early retransplantation (within the first year) are poor.[98,201,202] This is particularly true for emergency retransplantation for primary graft dysfunction, and this practice is discouraged. In contrast, retransplantation in carefully selected patients with chronic graft failure caused by BOS results in acceptable survival rates, albeit inferior to those achieved with primary transplantation.[202,203] For unclear reasons, patients with restrictive CLAD appear to have poorer outcomes following retransplantation than do patients with BOS.[204]

The LAS system affords retransplantation candidates the same high priority as patients with idiopathic pulmonary fibrosis. This has led to shortened waiting times and to a doubling in the number of retransplantation procedures performed annually.[98]

For a discussion of the future directions in the field of lung transplantation, see ExpertConsult.com.

Key Points

- Lung transplantation is a therapeutic option for a broad spectrum of advanced disorders of the airways, lung parenchyma, and pulmonary vasculature. The most common indications are idiopathic pulmonary fibrosis, COPD, and cystic fibrosis.
- The lung allocation system now used in the United States takes into account both medical urgency (predicted 1-year survival without transplantation) and "net transplant benefit" (difference between predicted 1-year survival with versus without transplantation).
- The introduction of ex vivo lung perfusion has facilitated more precise assessment and reconditioning of marginal lungs before transplantation and successful use of organs that would previously have been discarded.
- Although there has been significant improvement in perioperative mortality, long-term outcomes have only modestly improved. Median survival following transplantation is 6.5 years.
- Common early complications include primary graft dysfunction, bronchial anastomotic dehiscence and stenosis, and bacterial pneumonia.
- Infection rates among lung transplant recipients are severalfold higher than among recipients of other solid organs, presumably because of exposure of the allograft to microorganisms by inhalation and aspiration and the higher level of immunosuppression used.
- Acute cellular rejection, characterized by perivascular lymphocytic infiltration, is commonly encountered in the first year. It usually responds to high-dose corticosteroid therapy but is a major risk factor for subsequent development of chronic lung allograft dysfunction.
- The major limitation to long-term allograft function and patient survival is chronic lung allograft dysfunction, caused in most cases by bronchiolitis obliterans syndrome and less commonly by restrictive allograft syndrome. Current therapeutic approaches to preventing and treating chronic lung allograft dysfunction are inadequate, leaving retransplantation in selected patients as the only effective means of addressing this complication.

FUTURE DIRECTIONS

Since its introduction in 1963, lung transplantation has evolved from a heroic surgical therapy to a standard lifesaving therapeutic option for selected patients with advanced lung disease. Nonetheless, major hurdles must yet be overcome to facilitate wider applicability of lung transplantation and more enduring results. The donor organ supply must be expanded to meet demand. More effective and less toxic immunosuppressive strategies must be developed to prevent graft loss from chronic immunologic injury. An improved understanding of CLAD and its various subtypes is required to develop strategies to treat injuries of the transplanted lung in a targeted fashion.

Increased use of ex vivo lung perfusion for assessment and treatment has offered a partial solution to enhancing the number, quality, and durability of lung allografts. The ultimate solution to many of the current impediments will likely come with advances in gene therapy, stem cell therapy, and tissue engineering. Advances in immunologic manipulation of the recipient and immunologic modulation of the organs to look more like "self" will ultimately one day bring us closer to a state of immune tolerance (i.e., permanent graft acceptance in the absence of chronically administered immunosuppressive agents). It is only through these basic research initiatives that lung transplantation will truly fulfill its potential as a safe, effective, and durable treatment option.

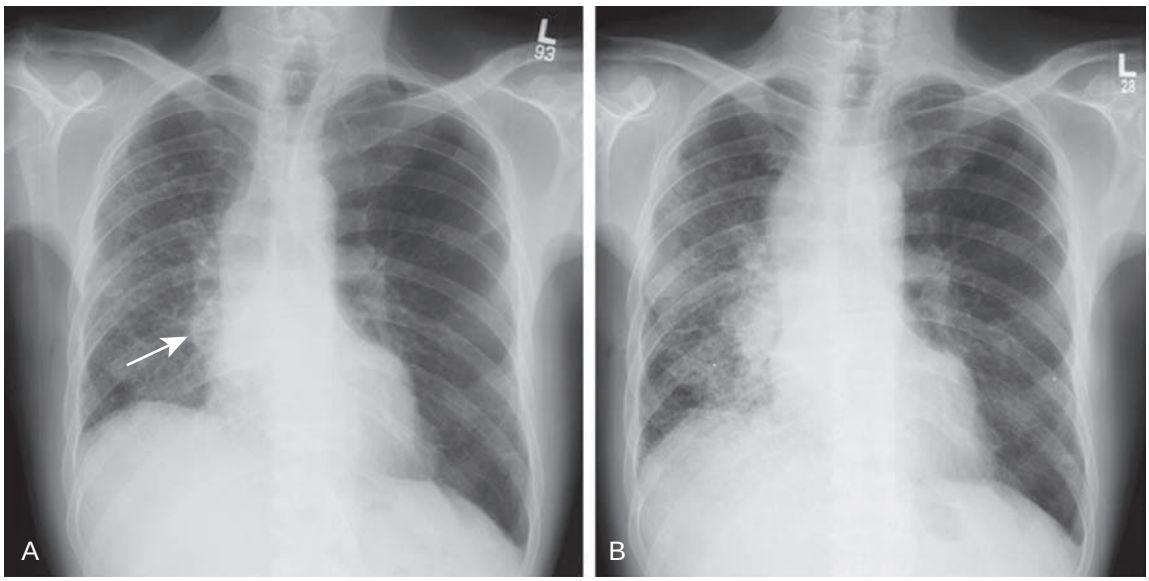
eFigure 140.3 Bronchiolitis obliterans syndrome: high-resolution computed tomography findings in a bilateral lung transplant recipient. (A–C and Video 140.2) Axial inspiratory high-resolution computed tomography shows minimal findings, with only slightly inhomogeneous lung opacity best seen in the bases (C). (D–F and Video 140.3) Axial dynamic expiratory high-resolution computed tomography (performed during a forced vital capacity maneuver) shows interval development of extensive, bilateral inhomogeneous lung opacity—the lighter regions reflect normal, collapsing lung at expiratory imaging, whereas the darker areas (*arrowheads*) represent air trapping resulting from small airway obstruction, reflecting bronchiolitis obliterans. (Courtesy Michael B. Gotway, MD.)



eFigure 140.4 Bronchogenic carcinoma arising in the native lung. The patient had undergone a left single lung transplant for idiopathic pulmonary fibrosis. (A) Chest radiograph demonstrates slight fullness in the infrahilar region of the native right lung (*arrow*). (B) Repeat chest radiograph only 2 months later demonstrates marked enlargement of the right infrahilar mass, as well as an increase in adjacent interstitial opacities. This proved to be a right lower lobe squamous cell lung cancer with associated lymphangitic spread.

Why Symptoms may be Poorly Managed
Management of Pain
Management of Anxiety
Management of Delirium
Management of Dyspnea
Management of Nausea and Vomiting
Management of Hunger and Thirst
WITHHOLDING AND WITHDRAWAL OF LIFE-SUSTAINING THERAPY
What Therapies are Withheld and Withdrawn
Withholding and Withdrawal of Intubation and Mechanical Ventilation
KEY POINTS

INTRODUCTION

Patients with acute, chronic, and acute-on-chronic respiratory failure often have a high expected mortality and suffer from symptoms such as pain and dyspnea as their disease progresses and they approach the end of their life. These patients may receive aggressive life-extending treatments when they, their families, and their physicians believe that doing so is reasonable and consistent with the patient's treatment preferences. Alternatively, patients and their families (or surrogate decision makers) may elect to forgo life-sustaining therapies, such as mechanical ventilation, when the application of these therapies will not help the patient reach his or her goals of care. Similarly, therapies can also be withdrawn when a trial of intensive treatment fails to achieve their medical goals. When clinically appropriate, the withholding and withdrawal of life-sustaining therapy is supported by ethical and legal principles. These principles, along with the process of medical decision making and the desirable components of end-of-life care, are discussed in detail in this chapter.

PREDICTING THE OUTCOME OF RESPIRATORY FAILURE

The high prevalence of diseases that lead to respiratory failure, coupled with the morbidity and mortality they cause, has prompted clinicians and investigators alike to seek prognostic information about patients with these disorders. Prognostication is especially important when discussing end-of-life care with patients and their loved ones, but unfortunately remains imprecise.

For patients who are critically ill, there are well-known scoring systems that prognosticate mortality during the current hospital admission. Two examples of these scores are the *Acute Physiology and Chronic Health Evaluation* (APACHE) score, which has gone through four iterations,[1–4] and the *Simplified Acute Physiology Score* (SAPS), which has undergone two iterations.[5,6] Both of these scores include a host of physiologic and chronic illness variables, and perform well with areas under the receiver operating curve greater than 0.80. However, although both APACHE and SAPS are widely used in critical care research, their clinical use is less widespread.

In diseases leading to chronic respiratory failure, as in acute respiratory failure, scoring systems are also not commonly used for prognostication in a clinical context. In particular, COPD has a variable and unpredictable trajectory. Although multivariable disease severity scores, such as the *Global Initiative for Chronic Obstructive Lung Disease* (GOLD)[7] and BODE (*body mass index* [BMI], airflow obstruction, dyspnea, and exercise capacity),[8] improve mortality prediction, they do not predict mortality well in individual patients.[9–11] Two large systematic reviews from 2013[12] and 2017[11] investigated factors associated with mortality in patients with COPD. The first review included 189,772 patients hospitalized with an acute exacerbation of COPD and found that 12 factors were associated with death within 90 days (increasing age, male sex, low BMI, heart failure, chronic kidney disease, altered mental status, use of long-term oxygen therapy, lower extremity edema, GOLD stage 4, right heart failure, acidemia, and elevated plasma troponin). Another 9 factors, compared between survivors and nonsurvivors, were associated with increased death

within 2 years (increasing age, low BMI, heart failure, presence of diabetes, ischemic heart disease, malignancy, decreasing *forced expiratory volume in 1 second* (FEV_1), long-term oxygen therapy, and lower arterial Po_2 at the time of hospital admission).[12] The second systematic review aimed to identify indices and variables that predicted risk of death within 12 months in patients with COPD in the community (i.e., not after hospitalization).[11] Although some individual factors across indices predicted mortality (including FEV_1, BMI, patient-reported dyspnea, 6-minute walk distance, and history of prior severe exacerbations), this study concluded that "the quality of evidence remains low, such that no single variable or multivariable score can currently be recommended" for mortality prediction. See Chapter 63 for more information about prognosis in COPD.

As another example, *idiopathic pulmonary fibrosis* (IPF), also has an unpredictable course, with patients experiencing long periods of stability punctuated by occasional or repeated exacerbations with decompensation and even death.[13] Median survival in patients with IPF remains at 3 to 4 years after diagnosis; however, new antifibrotic therapies have been shown to delay progression of the disease. Although not yet clear, pooled data suggest that these agents may improve survival.[14,15] Many studies over the past decades have found that specific baseline and follow-up variables are associated with increased mortality in IPF, including sex, age, forced vital capacity, diffusing capacity for carbon monoxide, a decline in forced vital capacity greater than 10%, initiation of long-term oxygen, and acute exacerbation.[16–20] In addition, multivariable indices have been developed, including the Composite Physiologic Index,[21] Du Bois Prognostic Index,[17] and the GAP (Gender, Age, and Physiology) Index.[16] Similar to critical illness and COPD, these indices do not predict mortality well in individual patients, with one study finding that these scoring systems did not outperform diffusing capacity alone.[20] See Chapter 89 for more information about IPF prognosis.

Overall, prognostic scoring systems have contributed greatly to our understanding of the general outcomes of patients with respiratory failure and other conditions. Furthermore, the calibration and discriminatory power of the scoring indices may improve as more studies are performed and more patients are entered into scoring system databases. Yet, at present, the systems are imperfect in predicting outcome in an individual patient and, due to variability in disease course, these scores may never be able to predict mortality well in individuals. For the foreseeable future, therefore, the use of prognostic scoring systems should continue to be used as an aid alongside medical decision making to help in counseling patients and surrogates about the outcomes experienced by patients with similar severity of illness. However, scoring systems should not be used by themselves to decide who is destined to die despite intensive care or as the sole factor to determine whether to offer treatment or to declare a particular treatment inappropriate.

TREATMENT GOALS AT THE END OF LIFE

The limitations of prognostication are unfortunate because patients' and their families' predictions of prognosis largely determine their treatment preferences, just as physicians often base their recommendations to patients and families on their own prognostic estimates. Many patients with acute respiratory failure due to potentially reversible causes, as well as their families, generally prefer goals focused on rescue and life prolongation until death appears highly likely.[22] In contrast, patients with end-stage chronic lung diseases, such as COPD and lung cancer, often prefer care focused on maintaining comfort rather than on extending their lives.[23] These preferences appear to be related to patients' perceptions of how advanced their underlying conditions are. For example, hospitalized patients with lung cancer who thought they were going to live at least 6 months were more likely to favor life-sustaining treatment over comfort care than patients who thought they had at least a 10% chance of dying within the next 6 months.[24] Of course, the treatment goals of life prolongation and maintenance of comfort need not be mutually exclusive. Life support and symptom relief are often sought simultaneously.

The term *end-of-life care* is meant to encompass two processes. One, the withholding and withdrawal of life support, represents the tapering of life-sustaining interventions, such as pulmonary rehabilitation in the outpatient setting and mechanical ventilation in the *intensive care unit* (ICU).[25–28] The other, the administration of palliative treatment, applies to improving patient comfort by treating symptoms such as pain with analgesics, dyspnea with opiates, and anxiety with anxiolytics. Combining these two processes signifies that end-of-life care involves more than removing something—in this case, life-saving treatments—from patients. It also means giving something to patients—excellent ongoing care in the form of proper medical decision making; thoughtful communication; an appreciation of their needs and those of their families, physicians, and other caregivers; the use of an appropriate setting for death; and the management of pain, dyspnea, and other symptoms. This comprehensive and compassionate approach is what is meant by the expression "intensive caring at the end of life."[29]

WHERE AND HOW PATIENTS DIE

In less developed countries, most patients with respiratory failure who die do so at home, largely because they have limited access to hospitals and other institutional settings. In the United States and other developed nations, however, patients most often die outside the home, although the proportion of people dying at home has increased over the past 2 decades. For example, of the large cohort of hospitalized patients in the landmark 1995 *Study to Understand Prognosis and Preferences for Outcomes and Risks of Treatment* (SUPPORT), 47% died within 6 months of study enrollment, and 55% of these died during the enrollment hospitalization.[30] Of the patients who survived the enrollment hospitalization, 46% died during another hospitalization later that year, and only a minority died in a nursing home or hospice, let alone at home.[31] Similarly, in one investigation of all the deaths recorded in six states during 1999, 38% of patients died in hospitals, and 22% died after ICU admission.[32] Ten years later, a 2009 study concluded that 540,000—fully one-fifth—of all patients who die in the United States do so in ICUs each year.[33] More recently, a

subsequent study analyzed trends in U.S. deaths over 15 years and concluded that, in 2015, compared with 2000, the proportion of deaths happening in hospital decreased from 32.6–19.8%, and deaths at home increased from 30.7–40.1%.[34] However, even though more people seem to be dying at home, this same study found that use of the ICU in the last 30 days of life among decedents increased from 24.3% in 2000 to 29.0% in 2015.

Many factors account for the high prevalence of in-hospital and in-ICU deaths in the United States and, presumably, other developed countries. Among them are the availability of these facilities and the fact that, compared with other countries, fewer elderly persons still reside with their families. In addition, in the United States, patients must be determined to have less than 6 months to live to qualify for hospice care. This requirement, in light of the difficulty of predicting life expectancy, may help explain why hospice has been underutilized.[35]

When ICUs were first developed during the 1950s and 1960s in the United States and Europe, patients who died in them did so despite full support, including attempted *cardiopulmonary resuscitation* (CPR). The wishes of patients and their surrogates regarding such support rarely were solicited, and do-not-resuscitate orders were seldom written for the patients because most hospitals felt obligated to perform CPR on everyone. Indeed, a host of potentially restorative treatments were automatically provided with little concern about their effectiveness or desirability. This approach was based on the belief, then held by both health professionals and the public, that technologies should be used to preserve life whenever possible regardless of the human and economic costs.[36]

In subsequent decades, however, this technologic imperative (providers using advanced technologies to do everything possible to extend life) seems to be giving way to a more patient-centered approach in which the appropriateness of certain treatments is based on an individualized assessment of the likely burdens and benefits. In the 1980s and 1990s, it became clear that many patients do not prefer attempted restorative therapy in all instances, and courts in the United States declared that these patients have a right to refuse them.[37] The ethical, legal, and economic consensus resulting from these developments was subsequently reflected in a series of statements from professional societies[38–43] on the appropriateness of forgoing life-sustaining therapies at the end of life. As a result, although hospitalized patients once died despite attempted restorative treatment, for the past 20 to 30 years, they are more likely to die upon withholding and withdrawal of life support and the administration of palliative care, especially in the ICU.[27,28,44]

ETHICAL AND LEGAL JUSTIFICATION FOR END-OF-LIFE CARE

JUSTIFICATION FOR WITHHOLDING AND WITHDRAWING LIFE-SUSTAINING THERAPY: A HISTORY

The withholding and withdrawal of life support is justified by four ethical principles[45] (Table 141.1). The first principle is *beneficence*: the physicians' obligation to do good for patients. Relieving pain and suffering, rather than sustaining life at all costs, may be beneficent in certain situations. The second principle is *nonmaleficence*: the physicians' obligation to avoid harm. Life-sustaining interventions may be painful and unlikely to sustain life in a way judged meaningful by the patient, and forgoing such interventions may reduce harm. The third principle is *autonomy*: respect for the patients' right of self-determination. Patient autonomy is reinforced when patients are allowed to refuse unwanted life-sustaining therapies. The fourth principle is *justice*: the fair allocation of medical resources. Justice may be served if life support is withdrawn from one patient with a very poor prognosis to help another patient with a much better prognosis, such as during a mass casualty event or a pandemic.[46]

Table 141.1 Ethical (Worldwide) and Legal (United States) Principles for Withholding and Withdrawing Life-Sustaining Therapy

ETHICAL PRINCIPLES
Beneficence
Nonmaleficence
Autonomy
Justice
LEGAL PRINCIPLES: RIGHT OF INFORMED CONSENT AND REFUSAL
Exercised by patients with decision-making capacity
Exercised by family members for incapacitated patients
■ As authorized under proxy directives
■ Using a substituted-judgment standard (facilitated by instructional directives)
■ Using a best-interests standard
Exercised by a court-appointed conservator
■ Using a substituted-judgment standard (facilitated by instructional directives)
■ Using a best-interests standard
Exercised by physicians, often after ethics committee review
■ Using a substituted-judgment standard (facilitated by instructional directives) (legal justification in a few states)
■ Using a best-interests standard (no legal justification)

From Beauchamp TL, Childress JF, eds. *Principles of Biomedical Ethics*. 4th ed. Oxford, UK: Oxford University Press; 1994; and Luce JM, Alpers A. End-of-life care: what do the American courts say? *Crit Care Med*. 2001;29:N40–N45.

In the United States, the withholding and withdrawal of life-sustaining therapies is justified legally by the principles of informed consent and refusal, which have strong roots in common law.[47] The right of adults with decision-making capacity either to consent to or refuse treatment, the legal right of surrogates to act for incapacitated adult patients, and the standards of substituted judgment (through which surrogates make inferences about what treatment decisions patients *would* make if they were able to make decisions for themselves) and best interests (surrogates also may consider the patients' best interests) have been upheld in U.S. court cases for more than a century. Selected landmark cases and their rulings are summarized in Table 141.2, and their principles are now considered standard in end-of-life care.

Respect for patient autonomy was supported by the U.S. Congress with the passing of the Patient Self-Determination Act in 1990. This statute mandates that patients admitted to medical facilities be asked whether they have advance

Table 141.2 Selected United States Court Cases Establishing Right of Refusal, Right of Surrogate Decision Making, and Standards of Substituted Judgment

Principle	Case	Year	Ruling
Right of adults with capacity to consent to or refuse	*Schloendorff v. Society of New York Hospitals*[151]	1914	"Every being of adult years and sound mind has the right to determine what should be done with his own body; and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages, except in cases of emergency when the patient is unconscious or when it is necessary to operate before consent can be obtained."
	Bartling v. Superior Court[76]	1984	Allowed a man with advanced COPD to have a mechanical ventilator removed against the wishes of both his physicians and the hospital.
	Bouvia v. Superior Court[77]	1986	Ordered a hospital to stop force-feeding a quadriplegic woman against her will even though she might die in the process.
Legal right of surrogates to act for incapacitated adult patients	*In re Quinlan*[78]	1976	Allowed the parents of a vegetative patient to refuse mechanical ventilation through the mechanism of surrogate decision making.
	Barber v. Superior Court[152]	1983	Allowed that not only mechanical ventilation but also nutrition and hydration—indeed, any therapy that was not clearly benefiting the patient—could be forgone.
	Cruzan v. Director, Missouri Department of Health[153]	1990	Allowed states to require "clear and convincing evidence" of patients' prior wishes before care was forgone, but did not require states to do so. Accepted the argument that the right of adult patients with decision-making capacity to refuse any and all therapies was protected under the Constitution.
Standards of substituted judgment and best interests	*In re Conroy*[154]	1983	A nephew asked that a feeding tube be withdrawn from his elderly aunt, who had not declared her wishes before becoming demented, on the grounds that forgoing nutrition and hydration was in her best interest. The court allowed the best-interests standard in this case because the burdens of continuing the patient's life outweighed the benefits and because the recurring, unavoidable pain of life with treatment was such that administering therapies such as nutrition and hydration was inhumane.
	Wendland v. Wendland[155]	2001	California Supreme Court deliberated on the issue of whether a conservator could withhold or withdraw life support from a patient who was conscious but incapable of articulating his/her current wishes. The Court ultimately ruled that life support could be discontinued only if there was clear and convincing evidence that "the patient wished to refuse life-sustaining treatment or that to withhold such treatment would have been in his best interest." The decision in this case suggests that the courts are unlikely to allow surrogates to limit treatment in patients who are neither terminally ill nor permanently unconscious unless the patients have specified what they would want done in such a situation.

directives and, if directives are not already in place, that patients be assisted in creating them.[48] Advance directives are of two types: instructional directives stating what patients want done in a given situation (e.g., living wills) and proxy directives that appoint surrogates to make decisions for them in these situations (e.g., the durable power of attorney for health care). Even though these documents can potentially extend patient autonomy beyond the point of incapacity, they are fraught with well-documented shortcomings, including (1) lack of detailed directions due to nonspecific language of the documents, (2) misalignment with patient wishes over time if the wishes change, (3) potential to be "overridden" by surrogate decision makers who face very difficult decisions when their loved ones become incapacitated, and (4) lack of access by first responders so that wishes can be appropriately communicated and followed during an emergency.[49–52] Furthermore, the paradigm of advance directives has shifted away from the mere completion of the document to the process of advance care planning, which involves conversations between patients, their surrogates, and their physicians about goals of care, which often are revisited over time as the patient's condition changes.[53] To address some of the problems associated with advance directives, many states have authorized use of a *physician/provider order for life-sustaining therapy* (POLST) form (eFig. 141.1), sometimes called a MOLST (medical) or COLST (clinician) form. These orders are enacted after conversations between patients (and their loved ones) and clinicians and generally include sections pertaining to preferences for CPR in the event of cardiac or respiratory arrest; therapies applied during events short of arrest but when life support might be needed (e.g., mechanical ventilation during a severe COPD exacerbation); and additional treatments, such as transportation to a hospital, artificial nutrition, or antibiotic therapy. Once signed, the POLST form is kept on file by the signing clinician and nearby hospitals, and a copy is placed on the patient's refrigerator in the home so

first responders can immediately understand preferences for life support. One particular advantage of a POLST form over an advance directive is that the POLST is an order from a licensed medical provider and therefore can be used by emergency personnel, whereas an advance directive may not be sufficient to avoid invasive treatment by first responders called to a home.

Legal guidelines are less clear when incapacitated patients lack family members or other surrogates, and controversy exists over how to make medical treatment decisions for these patients, who are often termed "unrepresented."[54,55] Such patients may have an advance directive, but because advance directives are not a medical order, decisions still need to be made and carried out by someone. Some states allow physicians to make decisions for such patients on the basis of wishes expressed to the physicians when the patients had decision-making capacity. However, no state explicitly allows physicians to make decisions on the basis of a best-interests standard. Be that as it may, as shown in a study from seven U.S. medical centers, some physicians do make decisions to withhold or withdraw life-sustaining therapy from incapacitated patients on the basis of best interests, usually after consultation with their colleagues or with a hospital ethics committee.[56] Other physicians ask the probate court to appoint conservators or other advocates for the patients, presumably to ensure a fair, transparent, and deliberate process of decision making for these vulnerable patients. Fortunately, a 2020 joint statement from the *American Thoracic Society* (ATS) and American Geriatrics Society specifically addresses medical decision making in unrepresented patients and provides guidance for institutions on (1) offering advance care planning to prevent a patient from becoming unrepresented; (2) implementing strategies, such as capacity assessment and exhaustive searches for surrogates, to determine if patients thought to be unrepresented may actually not be; (3) using a formal diverse interprofessional committee to manage decision making for unrepresented patients; (4) using the full gamut of available information on the patient's values and preferences to guide decisions; (5) managing decisions for unrepresented patients using a fair process; and (6) using this fair process even when state law allows less oversight.[57]

REQUESTS FOR NONBENEFICIAL TREATMENTS

A prominent ethical challenge, especially in critical care but also in pulmonary medicine, is how to respond appropriately to requests from patients and surrogates for life-prolonging interventions that the clinician believes are nonbeneficial. Some treatments are physiologically futile in that they cannot accomplish the intended physiologic goal, for example, restoration of sentient life in a patient who is found apneic and pulseless with rigor mortis. More commonly, though, these cases are not so absolute.

Literature suggests that conflicts in these cases are not uncommon, including data that 25% of physicians in European ICUs reported providing treatments that they felt were nonbeneficial, and that 20% of patients in U.S. ICUs were felt by physicians to have received nonbeneficial therapies.[58,59] In past decades the term *futility* was used to describe these conflicts, and several publications in the 1990s from investigators and professional societies attempted to provide recommendations on how to define futility and manage such disputes.[39,42,43,60] However, these guidelines were often discordant, which led to confusion, and included arguments for futility that concealed the value-laden assumptions and underlying issue of rationing inherent in these disputes.[61] There is now general consensus that, rather than revolving around true physiologic futility (where physiologic goals cannot be achieved, such as the case of the patient with rigor mortis), these conflicts commonly involve value-laden judgments about the appropriateness of particular therapies in the setting of the patient's illness.[62]

A landmark 2015 joint multisociety statement from the ATS, American Association of Critical Care Nurses, American College of Chest Physicians, European Society of Intensive Care Medicine, and *Society of Critical Care Medicine* (SCCM) specifically addressed this issue by providing clear recommendations for preventing intractable conflicts and managing requests for potentially inappropriate treatments (Fig. 141.1).[63] These recommendations include (1) implementation of preventative strategies to avoid unresolvable treatment conflicts, including early proactive communication; (2) use of the term "potentially inappropriate" rather than "futile," except in rare cases when the requested intervention is impossible to accomplish; (3) management of intractable conflicts (despite intensive communication and negotiation) by a fair conflict resolution process that includes hospital review, attempts to find an accepting provider at another institution, and external review of decisions; (4) procedural oversight when time pressures make each step of the recommendations infeasible; (5) public advocacy for policies and legislation about life-prolonging therapies.

JUSTIFICATION FOR ADMINISTERING PALLIATIVE CARE

Administering Medications for Symptom Relief During the Dying Process

The ethical and legal permissibility of providing medications for symptom management throughout the dying process has been outlined by two separate 1997 U.S. Supreme Court cases and is now the standard of care. The cases of *Washington v. Glucksberg*[64] and *Vacco v. Quill*[65] dealt with the constitutionality of laws prohibiting physician-assisted dying (see later for more information on this topic) in Washington and New York. Although the Court ruled that both states could prohibit assisted dying, the justices reasoned that this prohibition was justified because these states had no barriers preventing patients from receiving medications to relieve pain and suffering. Through this and other statements, a majority of the justices suggested that being free of pain while dying was a liberty interest protected under the Constitution.[66]

The Supreme Court distinguished assisted dying from palliative care in *Glucksberg* and *Vacco* by accepting the ethical principle of double effect. Under this rule, acts such as giving sedatives and analgesics that lead to morally good effects, such as the relief of suffering, are permissible even if they produce morally bad effects, such as the hastening of death, provided that only the good effect is intended. The morally bad effect may be foreseen

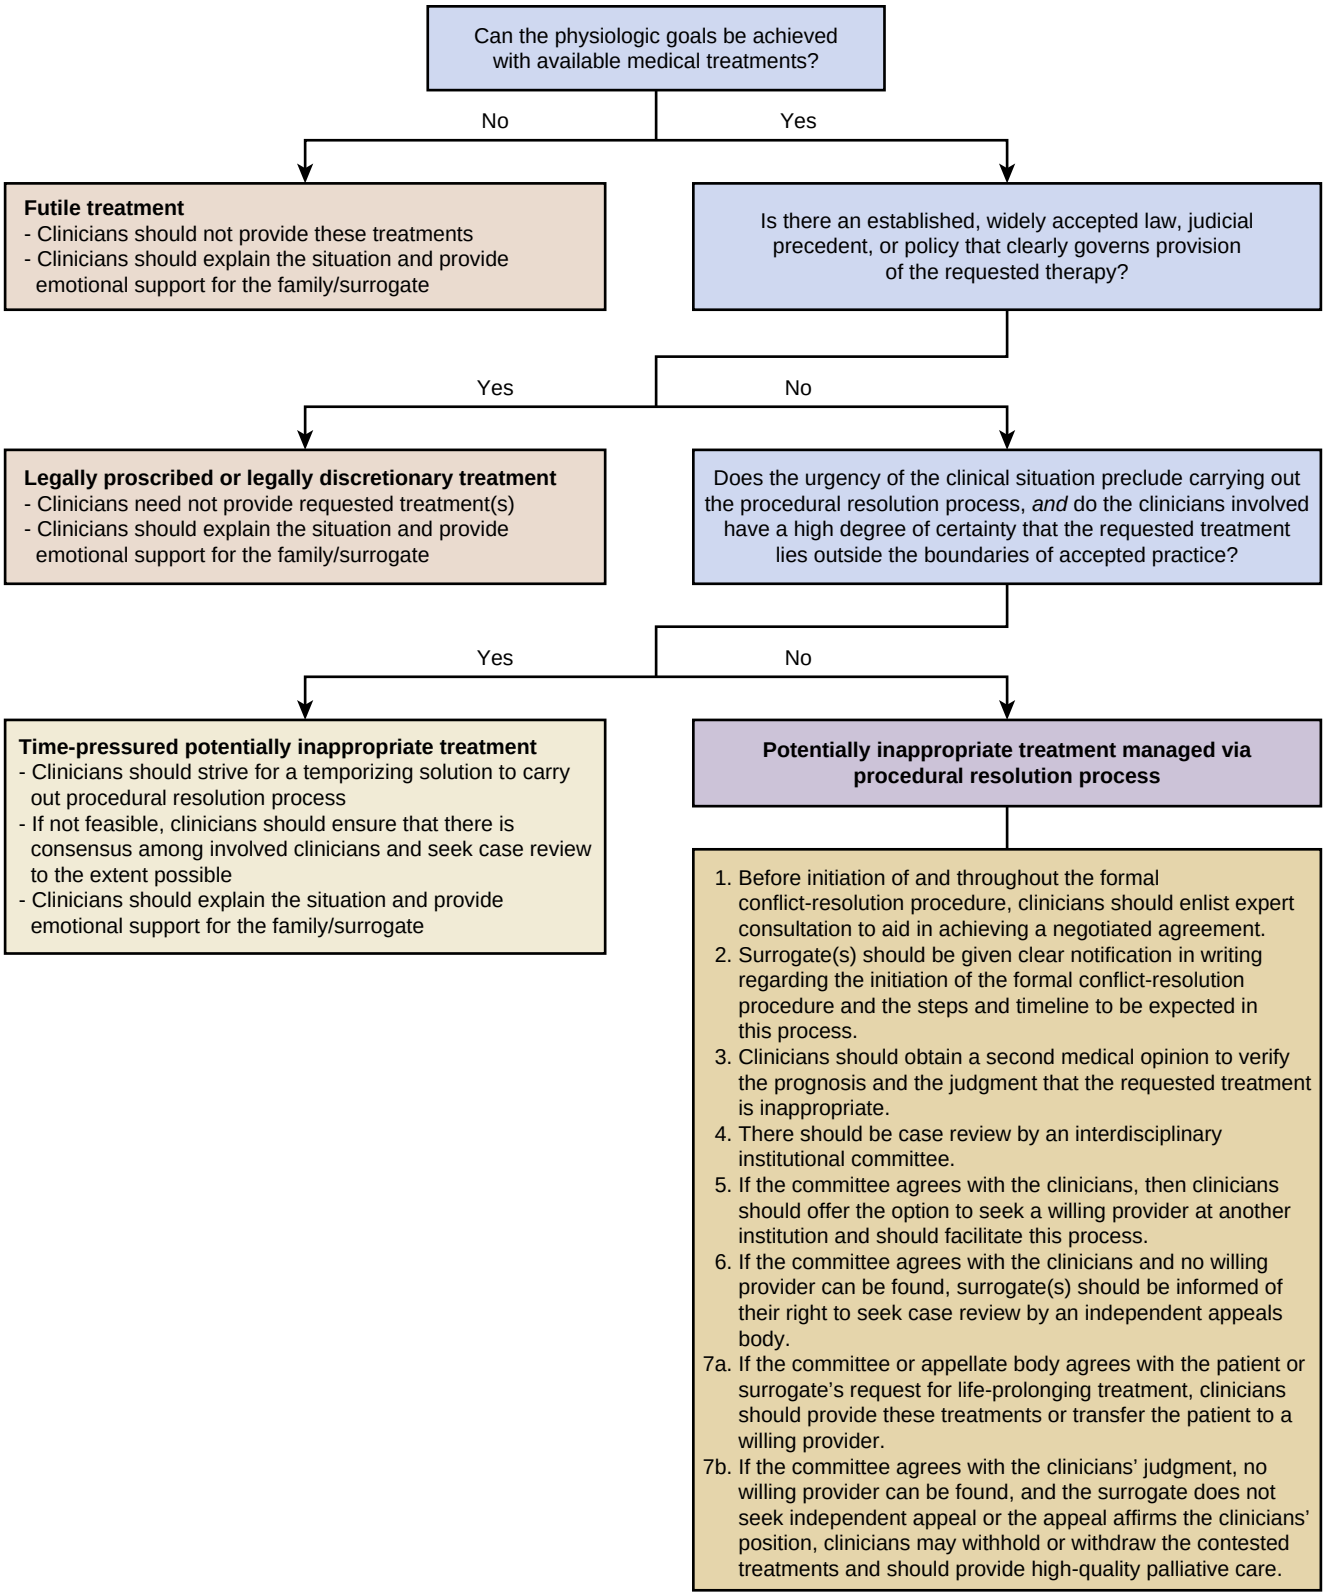

Figure 141.1 Recommended approach to managing requests for potentially inappropriate treatment. First, the clinician needs to determine if the desired physiologic goals can be achieved with available medical therapy. If yes, then the question arises whether the requested potentially inappropriate therapy is governed by a widely accepted law or precedent. The two kinds of relevant laws are (1) substantive laws that explicitly make it legal for clinicians to refuse to provide life-sustaining treatment (e.g., clinicians may refuse treatments in most U.S. states when a patient has been correctly determined to be brain dead because such patients are legally dead) and (2) procedural laws that, for example, grant clinicians authority to act as the surrogate rather than the family (e.g., in France the attending physician is the authorized decision maker for incapacitated patients). If governing laws or policies do not apply, then a series of steps to resolve the conflict over the disputed therapy (*bottom right*) should be taken. (From Bosslet GT, Pope TM, Rubenfeld GD, et al. An official ATS/AACN/ACCP/ESICM/ SCCM policy statement: responding to requests for potentially inappropriate treatments in intensive care units. *Am J Respir Crit Care Med.* 2015;191[11]:1318–1330.)

in that physicians are aware of its possibility and even its likelihood, but they may not wish it. The bad effect also may not be a means to the good effect, and the good effect must outweigh the bad one; that is, risking death is reasonable in palliating a terminally ill patient only if there are no less risky ways of relieving suffering.[67] The Supreme Court's approval of palliative care included sanctioning the practice of terminal sedation, in which patients are rendered unconscious while life-sustaining therapies, including nutrition and hydration, are withdrawn. Under *Vacco*, a state may allow terminal sedation if it is "based on informed consent and the double effect."[65]

Physician-Assisted Dying

Physician-assisted dying (PAD) refers to the practice by which heath care providers prescribe medication(s) to a patient knowing that they will be used to hasten death. PAD is currently legal in several countries including Canada, Belgium, Switzerland, the Netherlands, Luxembourg, Colombia, and Victoria, Australia. In the United States, the Supreme Court has addressed PAD in three cases. In the first two of these mentioned previously, *Washington v. Glucksberg*[64] and *Vacco v. Quill*[65] in 1997, the Court upheld the rights of states to prohibit PAD and stated that individuals do not have a constitutional right to PAD. The third case was prompted when PAD was legalized in Oregon in 1997 under that state's Death with Dignity Act. In 2006, the U.S. Supreme Court upheld a lower court decision preserving the legality of PAD in Oregon.[68]

PAD is now legal in a growing number of additional U.S. states (including Washington, Vermont, Montana, California, Colorado, Hawaii, New Jersey, and Maine) and Washington, DC. The initial Oregon statute included the following safeguards, with other states generally adopting the same principles: (1) The patient should be an adult 18 years or older; (2) the illness should be terminal with life expectancy of less than 6 months; (3) the patient should have decisional capacity; (4) the patient should undergo a mental health evaluation if impaired judgment is suspected; (5) the patient should make two oral requests with a waiting period between; (6) the patient should prepare a written request; (7) the medication should be administered by the patient; (8) the physician should provide information about other options, such as hospice and palliative care; (9) the physician should file a report with the state; and (10) there should be immunity from civil or criminal liability unless negligence or misconduct is identified. Some states also require certification by two physicians. eFigure 141.2 provides an example of the Physician Reporting Form that must be completed in Vermont.

Several publications have provided insight into how PAD is being used in the United States and throughout the world.[69–72] Few patients request lethal medications, and PAD-associated deaths represent a very small fraction of total deaths. Many patients who request PAD are also receiving hospice and/or palliative care. The most common underlying terminal illness is cancer, and patients report that their rationale for requesting PAD is concern about pain and loss of autonomy and control of bodily functions.[69-72]

MEDICAL DECISION MAKING AT THE END OF LIFE

THREE MODELS OF THE PHYSICIAN-PATIENT RELATIONSHIP

Medical decisions about value-laden choices may be made by physicians, patients, their families, or other surrogates alone or in combination. How decisions are actually made depends in large part on the preferences of patients and surrogates for their decision-making roles, which can range from independently making choices based on facts to ceding decision-making authority to clinicians.[73] There are three general models of decision-making: paternalistic, informed choice, and shared.[74]

Perhaps the oldest model is *paternalistic;* this model has also been called parental or priestly. According to it, physicians act as guardians in defining what their patients' interests are and then serving these interests as they see fit, with little or no input from the patients themselves.[75] The paternalistic model overlooks the strong social norm of respect for patient autonomy and the reality that, in pluralistic societies, it is unlikely that physicians can reliably discern what treatments best advance the interests of their diverse patients. However, some patients and surrogates prefer this model. The paternalistic model once dominated medical decision making at the end of life in the United States. In fact, the early cases such as *Bartling,*[76] *Bouvia,*[77] and *Quinlan*[78] (see Table 141.2) were brought because physicians and hospitals were unwilling to let patients or surrogates refuse therapy. It is ironic—and perhaps a cautionary tale about the limits of medical paternalism—that some physicians today demand that patients and families forgo treatment that other physicians once insisted they accept.

In the second model, *informed choice*, health care providers supply information about options to patients and their loved ones, who then independently use this information to arrive at decisions and choices about therapies.[79] Limitations of this model of decision making include that some patients and surrogates may not be able to comprehend the array of data necessary to make an informed choice, and they may feel particularly burdened by the process of making decisions in this manner.[80]

In the third model, *shared decision making* (SDM), physicians and patients/surrogates collaborate to help patients define their health-related values, discuss treatment options, and decide which alternative is best. This process is more than the mere passing of information: It is a moral deliberation, based on a mutual understanding of the medical facts and the patient's values.[81] The shared model of medical decision making is best suited for situations in which physicians, patients, and families have adequate time to deliberate, when reasonable treatment options exist, and when the best course of action may vary according to patients' values and preferences. Evidence from audio recordings of ICU family conferences suggests that the process of shared decision making about life support for incapacitated, critically ill patients is often suboptimal.[82] For example, clinicians frequently failed to explain principles of surrogate decision making, elicit patients' values and preferences, and discuss reasonable treatment options, including a purely palliative approach to care.[83–86]

There is general consensus among clinicians and policy makers that SDM should be the default approach to making treatment decisions with patients and surrogates, but confusion has surrounded its definition, use, and implementation. To provide clarification, guidance, and recommendations for SDM, the ATS and SCCM jointly published a statement in 2016 emphasizing the importance of patients and family engagement in ICUs.[73] This statement presented several recommendations about the use of SDM: (1) SDM is a collaboration between patients, surrogates, and clinicians to make health care decisions using not only the best available evidence but also the patient's values and goals; (2) SDM should be used when defining goals of care and when making major treatment decisions; (3) shared decisions should rely on three main elements: information exchange, deliberation, and making a treatment decision; (4) decision making approaches vary widely (from patient- or surrogate-directed to clinician-directed models), and providers should adapt the SDM process according to patient or surrogate preferences; and (5) providers should receive specific training in communication skills.

IMPORTANCE OF PHYSICIAN, PATIENT, AND FAMILY COMMUNICATION

Of course, American families would not need to be so involved in medical decision making in the ICU setting if physicians facilitated such decision making when the patients' diseases were less advanced and the patients could speak for themselves.[87] Yet, SUPPORT[88] and other subsequent studies[89,90] have shown that physicians and patients rarely discuss end-of-life issues in advance of the patients' deterioration, even when patients reside in nursing homes. A study of patients with severe COPD enrolled in pulmonary rehabilitation revealed that almost all had health concerns, including about being intubated, but only a minority had completed an advance directive describing their choices.[91] Furthermore, although the patients generally wanted discussions with their physicians, only 19% had such discussions, only 15% had discussed life support, and only 14% thought that their physicians understood their end-of-life wishes. In another study of advanced cancer patients, 63% of those who had an end-of-life discussion before death had that discussion as an inpatient.[90] And, in a study of patients with end-stage renal disease receiving dialysis, less than 10% reported having had an end-of-life care discussion with their nephrologist in the past year.[89]

The reasons that patients with chronic and terminal diseases do not discuss end-of-life care with their physicians have been studied since the 1990s. In the COPD pulmonary rehabilitation study noted earlier, patients who had not had discussions reported their own procrastination and their physicians not initiating the topic as the most important reasons for lack of conversations.[91] When these patients participated in an end-of-life educational intervention as part of their rehabilitation, they were more likely to pursue such discussions with their physicians and to complete durable powers of attorney for health care. In another study of patients with advanced acquired immunodeficiency syndrome, barriers to communication about end-of-life care included the patients noting that they did not "like talking about getting very sick" and "would rather concentrate on staying alive than talking about death."[92] Physicians who did not initiate discussions most often agreed that, "There is too little time during our appointments to discuss everything we should" and "I worry that discussing end-of-life with [patient name] will take away his or her hope." Many physicians in this study acknowledged that they felt uncomfortable discussing end-of-life issues, suggesting that their own discomfort was as important as the lack of time in inhibiting communication.

Limited communication between physicians and patients was also reported in SUPPORT.[88] Furthermore, SUPPORT revealed that communication was frequently inadequate between physicians and the families of critically ill patients. This finding was corroborated by a study from an ICU in France in which half the families of critically ill patients reported the same inadequacy.[93] The 2018 Royal College of Physicians report "Talking about dying: how to begin honest conversations about what lies ahead," further examined physicians discussing death and found prominent barriers in three categories: culture, confidence, and practicalities. Some physicians continue to believe that, within the culture of medicine, discussions about dying could be perceived by patients as failure. With regard to confidence, they felt that initiating these conversations was uncomfortable, that diagnostic uncertainty enhanced this discomfort, and that their training in communication skills had been inadequate. Finally, practical issues also impacted their willingness to discuss dying, and these included lack of time, cultural or religious differences, confusion over their role (for example, versus a primary care provider), and lack of privacy.[94]

Although many studies, including those discussed earlier, have demonstrated that communication about end-of-life issues is often inadequate, many other investigations have also reported that it is crucial for patient and family well-being. Families believe that timely and compassionate communication with a focus on a patient's values and goals is of key importance in patient care[95] and rate communication skills of their loved ones' clinicians as at least as important as clinical skills.[96] Improvement in family satisfaction with their relatives' care is associated with increased time spent by clinicians giving information,[97] more time by clinicians spent listening rather than speaking during conversations,[98] and specific content of these conversations, including assurances of non-abandonment and comfort, as well as support for family's decisions about end-of-life care.[99]

In a study where families were interviewed about their experiences in the ICU and about the decision-making process for withholding or withdrawing life support,[100] a high incidence of conflicts was reported, the vast majority of which were between themselves and physicians. The conflicts most often involved problems in communication or perceived unprofessional behavior, such as disregarding the primary caregiver in treatment decisions. These families identified pastoral care and prior discussion of treatment preferences as sources of psychological support. They appreciated lenient visiting hours and the availability of family conference rooms. Most of the families singled out attending physicians as the preferred source of information and reassurance.

IMPROVING COMMUNICATION AND THE QUALITY OF CARE AT THE END OF LIFE

Results from studies of various interventions to improve communication and quality of care at the end of life have been mixed, especially in those studies focusing on critical illness. Some interventions have been demonstrated to improve surrogates' satisfaction and psychological symptoms, as well as patient outcomes. These include (1) a family information leaflet that improved family understanding of how ICUs function and increased family satisfaction with ICU care[101]; (2) intensive communication achieved through proactive, frequent family meetings led by attending physicians that increased family satisfaction and decreased ICU length of stay among patients who died[102]; and (3) a brief communication intervention in French ICUs for families of patients judged certain to die that improved bereavement outcomes.[103] In a 2016 *randomized controlled trial* (RCT), communication facilitators assigned to families of critically ill patients reduced symptoms of depression among family members at 3 months, decreased ICU costs, and had no effect on ICU mortality.[104] In addition, although a 2018 cluster RCT of a multifaceted interprofessional ICU intervention, including advanced communication training for nurses, intensive support and communication for families, and implementation/quality improvement specialists to enhance incorporation of family support into clinician workflow, found no improvement in surrogates' psychological symptoms at 6 months after study enrollment, the intervention improved surrogates' perceptions of the patient-centeredness of care, and led to decreased ICU length of stay among both survivors and nonsurvivors.[105]

However, other studies have not found such improvements. Another RCT of family meetings with loved ones of chronically critically ill patients led by either palliative care specialists or intensivists did not improve the burden of anxiety or depression symptoms among surrogates.[106] Neither did another intervention consisting of a decision aid about prolonged mechanical ventilation.[107] Moreover, in an RCT comparing specific simulation-based training in communication skills for internal medicine and nurse practitioner trainees to usual education, there was no increase in the quality of communication about end-of-life care or in the quality of end-of-life care itself, and the simulation training was associated with increased symptoms of depression in patients.[108] In aggregate, the current literature suggests that purely informational interventions may not be effective at improving communication about and quality of end-of-life care, whereas interventions that incorporate longitudinal communication and emotional support may be more promising.

UNDERSTANDING WHAT PATIENTS, FAMILIES, AND CLINICIANS NEED AT THE END OF LIFE

End-of-life care could be optimized if the needs of the parties involved in the dying process were better understood.

Table 141.3 Factors Important to Patients and Family at End of Life

PHYSICAL NEEDS
Maintaining hygiene
Release from breathing difficulties
Remaining conscious and clearheaded to the end
Physical independence to the end
EMOTIONAL NEEDS
Regular update on medical condition
Opportunity to discuss fears and anxieties
Telling the absolute truth to patients
Involving patients in care policy and decisions
SPIRITUAL NEEDS
Being at one with God
Praying
Conversation with clergy about meaning of death
SOCIAL NEEDS
Capacity to help others

Modified from Natan MB, Garfinkel D, Shachar I. End-of-life needs as perceived by terminally ill older adult patients, family and staff. *Eur J Oncol Nurs*. 2010;14:299–303.

In this regard, a survey of seriously ill patients, recently bereaved families, physicians, and other caregivers revealed the needs important to all four groups, namely making decisions about treatment preferences, knowing what to expect about one's physical condition, and preparing for death.[109] Other important needs were sharing time with family and friends; being kept clean; being free of pain, anxiety, and dyspnea; and being treated as a "whole person." Patients also rated as important being mentally aware, coming to peace with God, not being a burden to their families, being able to help others, praying, having funeral arrangements planned, and gaining a sense of completion in life (Table 141.3).

The needs of families have also been assessed in several studies and were summarized in an overview[110] and emphasized in 2017 guidelines.[111] Overall, family needs include being with the dying patient, being helpful to the patient, being informed of the dying patient's changing condition, understanding what is being done to the patient and why, being assured of the patient's comfort, being comforted, having an opportunity to express emotions, being assured that the family's decisions were right, finding meaning in the patient's death, and having personal needs attended to during the dying process.

Unfortunately, the practical needs of clinicians who care for dying patients have not been well studied. Nevertheless, at a minimum, all caregivers probably need to feel comfortable during the dying process, to gain experience from it, and to feel supported by their colleagues and by their institutions. Nurses, respiratory therapists, social workers, and clergy who work alongside physicians want to know that the physicians respect them, provide them with adequate information, take their opinions into account, and engage in proper decision-making practices at the end of life.[112]

PROVIDING APPROPRIATE SETTINGS FOR DYING PATIENTS

Under the SDM model of the physician-patient relationship, physicians are obligated to help patients understand their conditions, explore their therapeutic options, and decide what is best for them. Essential to this relationship is preparing patients for death when appropriate. Such preparation should include consideration of whether the patients' interests are best served by hospital and ICU admission when death is imminent, assuming that impending death can be identified. Many patients, especially those with COPD and other chronic diseases that allow time for advance planning as death approaches, decide to die in a hospice or at home if given the opportunity.

Terminally ill patients may choose a trial of attempted restorative treatment in the hospital or undergo it because their wishes are not known. If the trial fails, such patients should be allowed to die in an environment comfortable for them and their families. A private room with enough space to accommodate visitors might be such an environment. Visiting hours should be relaxed, if necessary, to allow families and friends to spend as much time as they wish with dying patients. Some hospitals have separate palliative care units for this purpose. Others offer palliative care teams or services that consult throughout the hospital. Families of loved ones who are dying are also often offered private food and beverage carts.[112,113]

EMOTIONAL AND SPIRITUAL SUPPORT

Reviews of end-of-life care in and outside the ICU have emphasized the importance of providing emotional and spiritual support to dying patients and their families.[111,113] Physicians contribute to this support, of course, and their regular communications and presence at the bedside are deeply valued. Nurses, respiratory therapists, social workers, clergy, and other members of the health care team deliver most of the support, however. On occasion, patients or their families request that friends, caregivers, and religious persons from outside a particular institution provide consultations or participate in bedside rituals or observances. These should be allowed, if not encouraged, unless they interfere with patient care.

End-of-life care may extend after death, in that physicians, nurses, and others who have helped the patients' families when the patients were alive have much to offer thereafter. Advising on the disposition of bodies, reporting the results of autopsy studies, coordinating burials and funeral services, and attending funerals are among the professional responsibilities of caregivers greatly appreciated by families. These responsibilities can be assumed by independent bereavement follow-up services.[114] Alternatively, caregivers who have established personal relationships with families in the ICU and other settings may maintain them after the patients' death.

Physicians, nurses, and other caregivers have their own emotional and spiritual needs, as mentioned earlier, and caring for dying patients and their families exacts an appreciable toll on them. Although there is increasing attention to moral distress among clinicians, especially those working in ICUs, there have been no major breakthroughs in diagnosis, prevention, or treatment. Caregivers themselves should have opportunities to grieve. Conferences scheduled after patients die provide both an opportunity for bereavement and a mechanism for evaluating the processes of withholding and withdrawal of life support and of administering palliative care.[115,116] Such evaluation may lead to improvements in these processes for future patients.

SYMPTOM MANAGEMENT

WHY SYMPTOMS MAY BE POORLY MANAGED

Management of pain and other symptoms is a traditional role and responsibility of the medical profession. Nevertheless, patients too frequently die with pain and other distressing symptoms. Nearly 50% of SUPPORT patients or their surrogates interviewed after study enrollment reported that the patients experienced pain during hospitalization.[117] Nearly 15% reported extremely or moderately severe pain at least half the time, and many of those patients with pain were dissatisfied with its control. Uncontrolled pain was most common among patients with more dependence on others in activities of daily living and who had more comorbid conditions, more anxiety, more depression, and a poorer quality of life.[117] The prevalence of dyspnea, confusion, and mental health symptoms such as anxiety and depression is also high at the end of life.[118–120]

The poor management of pain and other symptoms in some patients is probably due in large part to the strong emphasis placed on the diagnosis and treatment of diseases rather than on the relief of symptoms. Palliative care reverses this emphasis and, when properly applied, should help increase patient comfort at the end of life. Nevertheless, the transition from restorative to palliative care is far from seamless for many patients. In this regard, it is difficult for patients and their families to know when to stop requesting treatment, just as it is for physicians and other caregivers to stop recommending life-sustaining therapies.

Pain and other symptoms may also be poorly managed because they are subjective experiences not easily assessed by objective methods. Pain and sedation scales have been developed to quantify the levels of pain and anxiety among patients who can communicate. Nevertheless, some patients cannot adequately communicate these sensations, either because they cannot find the words or because they are intubated and sedated. To detect pain in these patients, physicians and other caregivers must attend to patient grimacing and other admittedly nonspecific manifestations of pain, including tachycardia and hypertension. Although bispectral analysis of the electroencephalogram has been used to assess the level of sedation in ICU patients, the correlation of this technique with sedation scales and, most important, with the subjective experiences of patients is unclear.[121]

Another reason that symptoms are poorly managed at the end of life is that patients differ in their desire for symptom relief. Some patients value symptom relief highly and would prefer to be rendered unconscious rather than to experience pain, anxiety, or dyspnea, especially at the end of life. Others, however, would be willing to tolerate these

symptoms or have them mitigated only slightly to stay awake. Dying patients may find it difficult to titrate sedatives and analgesics to their desired level of consciousness, although they should be encouraged to do so. Physicians and caregivers may find it even more difficult to achieve the ideal level of sedation and analgesia for patients who cannot communicate or administer drugs to themselves.

Finally, symptoms may be inadequately managed because physicians and other caregivers feel uncomfortable about giving high doses of sedatives, analgesics, and other mood-altering agents. In some instances, this discomfort stems from a reluctance to cause drug addiction in dying patients, a concern irrelevant to the patients' condition. Other discomfort results from awareness that the agents may hasten death by depressing not only consciousness but also respiratory and cardiovascular function. That the U.S. Supreme Court has justified the administration of sedatives and analgesics under the principle of the double effect should help put caregivers at ease (see earlier for discussion of double effect).[67]

MANAGEMENT OF PAIN

Indirect approaches to pain control include nonpharmacologic means. For example, placing patients in a quiet environment where friends and family can visit may diminish the sense of pain, as may the proper treatment of anxiety and depression. Although respiratory depression due to drugs or underlying disease is usually undesirable in patients with COPD, the encephalopathy that results from the hypercapnia and hypoxia may be tolerated, if not favored, in terminally ill patients because it attenuates pain. Similarly, patients who forgo nutrition and hydration at the end of life may develop a euphoria that has been attributed to the release of endogenous opioids or the analgesic effects of ketosis.

Direct approaches to pain control generally center on the use of opioids, most commonly morphine. In addition to causing analgesia, morphine induces some degree of sedation, respiratory depression, constipation, urinary retention, nausea, and euphoria. It also produces vasodilation, which may cause hypotension, in part through the release of histamine. Fentanyl, a synthetic opioid approximately 100 times more potent than morphine, which has recently become a common and dangerous drug of abuse, does not release histamine and therefore causes less hypotension. Hydromorphone, a semisynthetic morphine derivative, is more sedating than morphine and produces little euphoria.[122–124]

Morphine, fentanyl, and hydromorphone can be administered orally, transcutaneously, subcutaneously, rectally, or intravenously. Opioids are usually given by the intravenous route to ICU patients, including those who are dying. These agents may be administered to inpatients and outpatients alike through the technique of patient-controlled analgesia. Long-acting oral preparations of morphine and hydromorphone are available for outpatients. Fentanyl can be administered orally in the form of a lollipop. It can also be given by the transcutaneous route (i.e., a patch), which makes this agent particularly suitable for patients who have difficulty with oral medications.

Opioids ideally should be administered in anticipation of pain and not afterwards. The optimal doses of these drugs given for pain relief are unknown and certainly vary among patients. Nevertheless, opioids generally should be started in relatively low doses, if respiratory depression and other side effects are to be avoided, and titrated upward until their analgesic effect is realized. In reports of critically ill patients undergoing the withholding and withdrawal of life support in both adult and pediatric ICUs, opioids were used in doses sufficient to achieve pain relief that caregivers considered adequate.[125,126] In dying patients, the use of opioids should not be limited by some arbitrary amount but by the balance between analgesia and any undesirable side effects.

MANAGEMENT OF ANXIETY

As in the case of pain, anxiety and its physical manifestation of agitation can be managed nonpharmacologically. If drugs are required, benzodiazepines and propofol are preferred. Benzodiazepines cause anterograde amnesia in addition to anxiolysis, and they exert a synergistic sedating effect with opioids. Benzodiazepines also cause hypotension and cardiac depression, especially when administered quickly and in high doses. Lorazepam, an intermediate-acting agent, can be given by the oral, intramuscular, or intravenous route; when given intravenously, it can be administered by bolus or by constant infusion. Midazolam, which is short-acting, is usually administered intravenously by constant infusion, although boluses may be required when therapy is initiated.[123,124,127]

Propofol is an intravenous general anesthetic agent with sedating, amnestic, and anxiolytic properties when administered in subanesthetic doses. In such doses, propofol is similar to midazolam in that it is usually given by constant infusion after bolus injection. The drugs are also comparable in the sedation they produce, although propofol has a greater propensity to cause hypotension.[123,124,127] Neither propofol nor midazolam is appropriate for the management of anxiety for outpatients and, in hospitals, their continuous use is usually restricted to the ICU.

MANAGEMENT OF DELIRIUM

Delirium may be mistaken for anxiety because it can also cause agitation. The distinction is clinically important both because the conditions are treated pharmacologically with different drugs and because the drugs used to treat anxiety can exacerbate delirium.[124] Delirious patients should be helped to obtain regular sleep, should be oriented regularly to their environment, and should avoid benzodiazepines, which cloud consciousness. Published guidelines for delirium management in critically ill patients recommend against the routine use of medications, except in patients experiencing significant distress from these symptoms.[124] Haloperidol was widely used in the past to treat delirium in critically ill patients, but it has undesirable side effects, including QT prolongation, rigidity, restlessness, and other dyskinesias. Due to these undesirable side effects, alternative agents such as risperidone, olanzapine, and quetiapine are more commonly used today but should be avoided if possible. These three medications are atypical antipsychotics, and side effects include somnolence, dizziness, movement problems, the rare neuroleptic malignant syndrome, and tardive dyskinesia. Olanzapine and quetiapine can also cause orthostatic hypotension.

MANAGEMENT OF DYSPNEA

Especially in the early stages of disease, dyspnea should be understood and managed according to its underlying pathophysiology. In patients with far-advanced lung disease, attention to pathophysiologic mechanisms is less important, and treatment is more palliative than restorative. Bronchodilators may not reduce breathlessness in such patients, corticosteroids may cause more unwanted side effects than symptom relief, and other therapies may likewise be ineffective. Patients with COPD who are dying, at home or in hospice, do not benefit from exercise training and may be too breathless to attend pulmonary rehabilitation programs; these patients should be encouraged to use wheelchairs and to rest.[128,129]

Patients with chronic respiratory failure of whatever cause should receive supplemental oxygen, which has been shown both to increase survival and to decrease breathlessness.[130,131] In the United States, Medicare reimbursement for long-term oxygen therapy is based on physiologic criteria (e.g., arterial $Po_2 < 55$ mm Hg or $Spo_2 \leq 88\%$ while breathing room air), not symptomatology. Despite this fact, many patients use oxygen primarily to relieve dyspnea, and hospice patients do not have to meet physiologic criteria to receive reimbursement. Supplemental oxygen is usually started in low doses (e.g., 1–3 L/min) and titrated to effect. The results of titration are difficult to predict inasmuch as neither the flow rate nor the route of administration of oxygen determines its impact on breathlessness.[127] Some studies have also shown that oxygen delivered to patients with advanced lung disease and refractory dyspnea does not provide any symptomatic benefit over compressed room air delivered by nasal cannula.[132,133] In addition, breathless patients are frequently relieved by exposure to fresh air in the outdoors or during automobile rides with the windows down. Those who are bedridden may benefit from using fans to blow air over their faces.[134]

For patients who have refractory dyspnea after standard medical therapy and nonpharmacologic treatments (e.g., fan, pursed-lip breathing), opioids should be considered for symptom relief.[128] Opioids may be particularly useful in patients who have pain in addition to breathlessness, such as those with lung cancer.

Benzodiazepines such as alprazolam have been shown to reduce dyspnea in some patients with COPD.[135] Yet, these agents may also cause drowsiness, discoordination, and dysphoria, and they should not be used routinely, except in selected patients whose dyspnea is refractory to other therapies.[128,134]

MANAGEMENT OF NAUSEA AND VOMITING

Nausea and vomiting may result from systemic illnesses, such as diabetes, renal failure, hypercalcemia, adrenal insufficiency, and viral infections. These symptoms may also be caused by central nervous system disorders, including cerebral metastases and other conditions that increase intracranial pressure; primary gastrointestinal diseases, such as gastric outlet obstruction; and a variety of drugs, including theophylline, phenytoin, opioids, antibiotics, and chemotherapeutic agents. Nausea and vomiting may remit with treatment of the disorder or with discontinuation of offending drugs. Because eating can increase nausea, patients may benefit by being placed on a nothing-by-mouth status or undergoing gastric decompression. Clear liquid diets may be administered to patients as tolerated. Supplemental oxygen has been shown to reduce the incidence of postoperative nausea and vomiting.[136]

Patients with nausea and vomiting who do not respond to more conservative measures may be candidates for prophylactic or therapeutic antiemetic therapy, which can be given orally, intramuscularly, intravenously, or in suppository form. Among the older antiemetics are chlorpromazine, promethazine, prochlorperazine, and other phenothiazines and muscarinic receptor antagonists, such as scopolamine, which is particularly helpful in patients with vestibular symptoms. Evidence for the use of specific agents for treating nausea and vomiting at the end of life is sparse, and there are no data suggesting that any one medication should be used preferentially.[137]

MANAGEMENT OF HUNGER AND THIRST

Evidence suggests that most patients with advanced disease who are at the end of their life do not experience hunger and thirst in the same way as healthy individuals.[138] Patients may desire food and fluids until they die; alternatively, they may choose not to eat or drink. Some patients with advanced illness also choose to stop eating and drinking as a method of hastening their own death, a practice that is ethically and legally justified.[139–141] For the few patients who are symptomatic, hunger, thirst, and dry mouth usually can be alleviated with small amounts of food and fluids or by the application of ice chips or lubrication to the lips. Similar measures can be used in other settings, including the ICU.

WITHHOLDING AND WITHDRAWAL OF LIFE-SUSTAINING THERAPY

WHAT THERAPIES ARE WITHHELD AND WITHDRAWN

Although most research on withholding and withdrawing life-sustaining therapies has taken place in ICU settings, these processes are carried out in many settings and contexts. These studies reveal that variation exists across institutions and countries in the type, number, and sequence of interventions that are withheld or withdrawn.[26,27,142–144] CPR, vasopressors, intubation/mechanical ventilation, and dialysis are generally the first interventions to be withdrawn or withheld, although notable variation across studies and patients exists, followed by other interventions, including transfusions, intravenous fluids, parenteral nutrition, antibiotics, and tube feedings. Decisions regarding withholding therapy are often reached sooner than decisions about withdrawing therapy, in part because of the psychological difficulty families (and perhaps clinicians) experience when death quickly ensues after withdrawing a life-extending treatment. In addition, whereas decisions not to intubate patients tend to be made early for patients not yet receiving mechanical ventilation, once patients are on ventilators, decisions to withdraw ventilatory support are sometimes made late, even after several other interventions are forgone.

WITHHOLDING AND WITHDRAWAL OF INTUBATION AND MECHANICAL VENTILATION

Withholding or withdrawal of intubation and mechanical ventilation is an action that commonly leads to death among patients with acute, chronic, or acute-on-chronic respiratory failure. Although patients with chronic respiratory failure often decide against these therapies if they should decompensate, some patients either request life-sustaining measures or are intubated in an emergency setting where their wishes may not be known. Similarly, patients with acute respiratory failure are frequently intubated because there is no window of opportunity to discuss goals and values and/or their conditions are assumed to be reversible. Subsequently, after days or weeks of mechanical ventilation without improvement, consideration of withdrawing intubation and mechanical ventilation often emerges. Death in the ICU most commonly results from withholding or withdrawing mechanical ventilation.[28,145]

Several published guidelines for withholding and withdrawing mechanical ventilation provide specific recommendations and procedures on how to facilitate this process.[40,41,146] After the decision for withdrawal of mechanical ventilation has been made through high-quality communication with a patient and surrogates, they should be informed about the dying process and changes in physiology that they will observe. They should also be allowed to spend time with their loved one and with clergy or other persons who provide emotional support.

Practical aspects of the withdrawal process will often need to be tailored to patient preferences. For example, a patient who wishes to remain conscious for as long as possible, even if this means enduring more suffering, would require a different approach than a patient who prefers to prioritize comfort over consciousness.[147,148] Before commencing with actual withdrawal procedures, it is important to ensure that do-not-resuscitate and do-not-intubate orders are written and that adequate analgesic and sedative medications are readily available. Interventions that do not provide comfort, such as laboratory tests, some medications, dialysis, and neuromuscular blocking agents, can then be stopped.

There are two general approaches to withdrawal of mechanical ventilation: terminal weaning and immediate extubation. High-quality evidence comparing these two approaches is lacking, so it is unknown which method is best. With terminal weaning, first described in 1983,[149] mechanical ventilation support is rapidly titrated off, usually over 10 to 20 minutes, with concomitant titration of opiates to maintain comfort. Most patients who are terminally weaned are able to breathe room air with the endotracheal tube in place. With anticipation of the need for further doses of sedatives and opiates if the airway becomes obstructed, the patient can then be extubated. With immediate extubation, ventilatory support is not gradually decreased; instead, the patient is administered preemptive opiates, often in high doses, and extubation is rapid. In one study, immediate extubation was associated with more airway obstruction and gasping, but not with increased psychological distress among surrogates; however, this study was small and observational, so it is difficult to draw inferences from it.[150] This approach requires very careful assessment of and attention to the need for anticipatory opiates because the risk for respiratory distress may be greater.

When intubation and mechanical ventilation are withdrawn, most patients with respiratory failure die of their underlying diseases. Nevertheless, some survive, and their survival should not be prevented by drugs that hasten death. At the same time, even patients who are too sick to survive should not receive drugs that interfere with observing tachypnea and other signs that may signal the need for symptom relief. For these reasons, although sedatives and analgesics may be given to relieve suffering, neuromuscular blocking agents should generally not be used in patients for whom intubation and mechanical ventilation will be withdrawn.

Key Points

- End-of-life care is a combination of palliative treatment and withholding and withdrawal of life-sustaining therapy provided to patients who are terminally ill, including those with acute, chronic, and acute-on-chronic respiratory failure.
- End-of-life care is justified by the ethical principles of beneficence, nonmaleficence, autonomy, and justice and by the legal right of informed patients to consent to or refuse any or all therapy, including that which sustains life.
- The legal right of consent or refusal may be exercised by patients themselves or by their family members and legally appointed surrogates through substituted-judgment and best-interests standards.
- End-of-life care is enhanced by a shared model of medical decision making and by intensive communication among patients, family members, and caregivers. Such care should attend to the needs of patients, families, and caregivers alike.
- When patients or their surrogates request treatments that clinicians believe are potentially inappropriate, clinicians should generally pursue a stepwise approach to dispute resolution, including intensive communication with the patient/surrogate, involvement of expert consultants (e.g., ethics consultants), review by a hospital committee, and an offer of transfer to another facility.
- Some interventions aimed at improving communication with patients and families, especially those that incorporate longitudinal communication and emotional support, seem to increase satisfaction and reduce the burden of mental health symptoms, but other interventions, especially those that are purely informational, have not shown these improvements.
- The components of end-of-life care include providing appropriate settings for dying patients; supplying emotional and spiritual support; managing such symptoms as pain, anxiety, delirium, dyspnea, nausea, vomiting, hunger and thirst; and removing unwanted therapies.
- After shared decision making with patients and surrogates, mechanical ventilation and other life-sustaining therapies can be withheld or withdrawn by following guidelines and focusing on provision of comfort measures to prevent pain and other suffering.

HIPAA PERMITS DISCLOSURE OF POLST ORDERS TO HEALTH CARE PROVIDERS AS NECESSARY FOR TREATMENT
SEND FORM WITH PATIENT WHENEVER TRANSFERRED OR DISCHARGED

Medical Record # (Optional)

National POLST Form: A Portable Medical Order

Health care providers should complete this form only after a conversation with their patient or the patient's representative. The POLST decision-making process is for patients who are at risk for a life-threatening clinical event because they have a serious life-limiting medical condition, which may include advanced frailty (www.polst.org/guidance-appropriate-patients-pdf).

Patient Information. **Having a POLST form is always voluntary.**

This is a medical order, not an advance directive. For information about POLST and to understand this document, visit: www.polst.org/form

Patient First Name: _____

Middle Name/Initial: _____ Preferred name: _____

Last Name: _____ Suffix (Jr, Sr, etc): _____

DOB (mm/dd/yyyy): ____/____/_____ State where form was completed:_____

Gender: ☐ M ☐ F ☐ X Social Security Number's last 4 digits (optional): xxx-xx-___ ___ ___ ___

A. Cardiopulmonary Resuscitation Orders. Follow these orders if patient has no pulse and is not breathing.

Pick 1

☐ **YES CPR: Attempt Resuscitation, including mechanical ventilation, defibrillation and cardioversion.** (Requires choosing Full Treatments in Section B)

☐ **NO CPR: Do Not Attempt Resuscitation.** (May choose any option in Section B)

B. Initial Treatment Orders. Follow these orders if patient has a pulse and/or is breathing.

Reassess and discuss interventions with patient or patient representative regularly to ensure treatments are meeting patient's care goals. Consider a time-trial of interventions based on goals and specific outcomes.

Pick 1

☐ **Full Treatments (required if choose CPR in Section A).** Goal: Attempt to sustain life by all medically effective means. Provide appropriate medical and surgical treatments as indicated to attempt to prolong life, including intensive care.

☐ **Selective Treatments.** Goal: Attempt to restore function while avoiding intensive care and resuscitation efforts (ventilator, defibrillation and cardioversion). May use non-invasive positive airway pressure, antibiotics and IV fluids as indicated. Avoid intensive care. Transfer to hospital if treatment needs cannot be met in current location.

☐ **Comfort-focused Treatments.** Goal: Maximize comfort through symptom management; allow natural death. Use oxygen, suction and manual treatment of airway obstruction as needed for comfort. Avoid treatments listed in full or select treatments unless consistent with comfort goal. Transfer to hospital **only** if comfort cannot be achieved in current setting.

C. Additional Orders or Instructions. These orders are in addition to those above (e.g., blood products, dialysis).
[EMS protocols may limit emergency responder ability to act on orders in this section.]

D. Medically Assisted Nutrition (Offer food by mouth if desired by patient, safe and tolerated)

Pick 1

☐ Provide feeding through new or existing surgically-placed tubes ☐ No artificial means of nutrition desired

☐ Trial period for artificial nutrition but no surgically-placed tubes ☐ Not discussed or no decision made (provide standard of care)

E. SIGNATURE: Patient or Patient Representative (eSigned documents are valid)

I understand this form is voluntary. I have discussed my treatment options and goals of care with my provider. If signing as the patient's representative, the treatments are consistent with the patient's known wishes and in their best interest.

✖ (required)

The most recently completed valid POLST form supersedes all previously completed POLST forms.

If other than patient, print full name: | **Authority:**

F. SIGNATURE: Health Care Provider (eSigned documents are valid) Verbal orders are acceptable with follow up signature.

I have discussed this order with the patient or his/her representative. The orders reflect the patient's known wishes, to the best of my knowledge. [Note: Only licensed health care providers authorized by law to sign POLST form in state where completed may sign this order]

✖ (required) | **Date** (mm/dd/yyyy): Required / / | **Phone # :** ( )

Printed Full Name: | **License/Cert. #:**

Supervising physician signature: ☐ N/A | **License #:**

A copied, faxed or electronic version of this form is a legal and valid medical order. This form does not expire. 2019

National POLST Form – Page 2 *******ATTACH TO PAGE 1********

Patient Full Name:

Contact Information (Optional but helpful)

Patient's Emergency Contact. (Note: Listing a person here does **not** grant them authority to be a legal representative. Only an advance directive or state law can grant that authority.)

Full Name:	☐ Legal Representative ☐ Other emergency contact	Phone #: Day: ( ) Night: ( )
Primary Care Provider Name:		Phone: ( )
☐ Patient is enrolled in hospice	Name of Agency: Agency Phone: ( )	

Form Completion Information (Optional but helpful)

Reviewed patient's advance directive to confirm no conflict with POLST orders: (A POLST form does not replace an advance directive or living will)	☐ Yes; date of the document reviewed:_____ ☐ Conflict exists, notified patient (if patient lacks capacity, noted in chart) ☐ Advance directive not available ☐ No advance directive exists

Check everyone who participated in discussion: ☐ Patient with decision-making capacity ☐ Court Appointed Guardian ☐ Parent of Minor ☐ Legal Surrogate / Health Care Agent ☐ Other: _____

Professional Assisting Health Care Provider w/ Form Completion (if applicable): Full Name:	Date (mm/dd/yyyy): / /	Phone #: ( )

This individual is the patient's: ☐ Social Worker ☐ Nurse ☐ Clergy ☐ Other:

Form Information & Instructions

- **Completing a POLST form**:
  - Provider should document basis for this form in the patient's medical record notes.
  - Patient representative is determined by applicable state law and, in accordance with state law, may be able execute or void this POLST form only if the patient lacks decision-making capacity.
  - Only licensed health care providers authorized to sign POLST forms in their state or D.C. can sign this form. See www.polst.org/state-signature-requirements-pdf for who is authorized in each state and D.C.
  - Original (if available) is given to patient; provider keeps a copy in medical record.
  - Last 4 digits of SSN are optional but can help identify / match a patient to their form.
  - If a translated POLST form is used during conversation, attach the translation to the signed English form.
- **Using a POLST form:**
  - Any incomplete section of POLST creates no presumption about patient's preferences for treatment. Provide standard of care.
  - No defibrillator (including automated external defibrillators) or chest compressions should be used if "No CPR" is chosen.
  - For all options, use medication by any appropriate route, positioning, wound care and other measures to relieve pain and suffering.
- **Reviewing a POLST form:** This form does not expire but should be reviewed whenever the patient:
  (1) is transferred from one care setting or level to another;
  (2) has a substantial change in health status;
  (3) changes primary provider; or
  (4) changes his/her treatment preferences or goals of care.
- **Modifying a POLST form:** This form cannot be modified. If changes are needed, void form and complete a new POLST form.
- **Voiding a POLST form:**
  - **If a patient or patient representative (for patients lacking capacity) wants to void the form**: destroy paper form and contact patient's health care provider to void orders in patient's medical record (and POLST registry, if applicable). State law may limit patient representative authority to void.
  - **For health care providers**: destroy patient copy (if possible), note in patient record form is voided and notify registries (if applicable).
- **Additional Forms.** Can be obtained by going to www.polst.org/form
- As permitted by law, this form may be added to a secure electronic registry so health care providers can find it.

State Specific Info	For Barcodes / ID Sticker

For more information, visit www.polst.org or email info@polst.org Copied, faxed or electronic versions of this form are legal and valid. 2019

eFigure 141.1 Example of a *physician/provider/portable order for life-sustaining therapy* (POLST) form. A POLST is a medical order signed by a provider that communicates the patient's wishes in the case of a life-threatening event. This order can be placed not only in the patient's chart with the provider and local hospitals but also in the home so that first responders readily understand his or her wishes in the event of an emergency. Patient Choice At End Of Life — Physician Reporting Form

(continued)

4. PHYSICIAN DETERMINATIONS

Indicate compliance by checking the boxes. (Both the attending and consulting physicians must make these determinations.)

1. Determined that the patient:
   - ☐ a) is suffering with a terminal condition;*
   - ☐ b) is capable;**
   - ☐ c) is making an informed decision;
   - ☐ d) has made a voluntary request for medication to hasten his or her death;
   - ☐ e) is at least 18 years old and a Vermont state resident.***
2. Informed the patient in person, both verbally and in writing, of all the following:
   - ☐ a) the patient's medical diagnosis;
   - ☐ b) the patient's prognosis, including an acknowledgement that the physician's prediction of the patient's life expectancy is an estimate based on the physician's best medical judgment;
   - ☐ c) the range of treatment options appropriate for the patient and the patient's diagnosis;
   - ☐ d) if the patient was not enrolled in hospice care, all feasible end-of-life services, including palliative care, comfort care, hospice care, and pain control;
   - ☐ e) the range of possible results, including potential risks associated with taking the medication to be prescribed; and
   - ☐ f) the probable result of taking the medication to be prescribed.
3. ☐ Referred the patient to a second physician for medical confirmation.
4. ☐ Verified that the patient did not have impaired judgment based on my evaluation or as the result of a referral of the patient to a psychiatric or psychological clinician.

D MEDICATION PRESCRIBED AND INFORMATION PROVIDED TO PATIENT

To be prescribed no sooner than **48 hours after the last** of the following:

1. Patient's written request was signed;	DATE
2. The patients second oral request;	DATE
3. Offering the patient the opportunity to rescind the request.	DATE

To the best of my knowledge, all of the requirements under the Patient Choice at End of Life Act have been met.

X	PHYSICIAN'S SIGNATURE	DATE

If comments in any section exceed the space provided, please use an attached page. Supplemental comments should be identified using the appropriate alphanumeric notation (e.g., C3).

* "Terminal condition" means an incurable and irreversible disease that would, within reasonable medical judgment, result in death within six months.

** "Capable" means that a patient has the ability to make and communicate health care decisions to a physician, including communication through persons familiar with the patient's manner of communicating if those persons are available.

*** Factors demonstrating residency include, but are not limited to: 1) Possession of a Vermont driver's license; 2) Registration to vote in Vermont; 3) Evidence that a person leases/owns property in Vermont; or 4) Filing of an Vermont tax return for the most recent tax year. Only the attending physician is required to affirm Vermont residency.

This form is revised periodically. To assure that you are using the most current version, please refer to: http://healthvermont.gov

APPENDIX GLOSSARY OF TERMS AND STANDARD SYMBOLS

I. PRIMARY AND QUALIFYING SYMBOLS

GENERAL

P	Pressure (Includes also *partial* pressure of a gas in a mixture of gases or in blood.)
L	Lung
W	Chest wall
RS	Respiratory system
Pl	Pleura

VENTILATION

V	Volume of gas
$\dot{V}$	Flow of gas
I	Inspired
E	Expired
A	Alveolar
T	Tidal
ET	End-tidal
D	Dead space
STPD	*Standard Conditions: s*tandard *t*emperature (0° C), barometric *p*ressure (760 mm Hg), and *d*ry.
BTPS	*Body Conditions: bo*dy *t*emperature and ambient *p*ressure, *s*aturated with water vapor at these conditions.
ATPS	*Ambient Conditions: a*mbient *t*emperature and *p*ressure, *s*aturated with water vapor at these conditions.

GAS EXCHANGE–BLOOD FLOW

Q	Volume of blood
$\dot{Q}$	Flow of blood
F	Fractional concentration of gas
C	Concentration in blood
S	Saturation in blood
b	Blood, in general
a	Arterial blood
v	Venous blood
$\bar{v}$	Mixed venous blood
c	Capillary blood
c′	Pulmonary end-capillary blood

II. VENTILATION AND LUNG MECHANICS

STATIC LUNG VOLUMES

VC	*Vital Capacity:* The maximum volume of gas that can be exhaled after fully inflating the lungs.
FRC	*Functional Residual Capacity:* The volume of gas remaining in the lungs at the end of quiet expiration.
TLC	*Total Lung Capacity:* The volume of gas in the lungs after a maximum inspiration.
RV	*Residual Volume:* The volume of gas remaining in the lungs after a maximum exhalation.
IC	*Inspiratory Capacity:* The volume of gas that can be inhaled from resting end-expiration (FRC) to full inflation (TLC).
ERV	*Expiratory Reserve Volume:* The volume of gas that can be exhaled from resting end-expiration (FRC) to full exhalation (RV).
IRV	*Inspiratory Reserve Volume:* The volume of gas that can be inhaled from resting end-inspiration to full inflation (TLC).

DESCRIPTORS OF FORCED BREATHING MANEUVERS

FVC	*Forced Vital Capacity:* The volume of gas that can be forcibly exhaled after fully inflating the lungs.
FEV_t	*Timed Forced Expiratory Volume:* The volume of gas exhaled at a specified time after beginning the forced vital capacity maneuver. For example, FEV_1 = forced expiratory volume in 1 second.
FEV_t/FVC	*Ratio of Timed Expiratory Volume to Forced Vital Capacity:* For example, FEV_1/FVC, usually expressed as a percentage.

FEF_x *Specified Forced Expiratory Flow:* The forced expiratory flow rate during a specified portion of the forced vital capacity. For example, $FEF_{200–1200\,mL}$ = forced expiratory flow rate between 200 and 1200 mL of the forced vital capacity; $FEF_{25\%–75\%}$ = forced expiratory flow rate between 25% and 75% of the forced vital capacity.

$\dot{V}max_{x\%}$ *Specified Maximum Expiratory Flow:* The instantaneous expiratory flow rate when *x* percent of the forced vital capacity has been exhaled. For example, $\dot{V}max_{50\%}$ = maximum expiratory flow rate at 50% of the forced vital capacity.

MVV *Maximum Voluntary Ventilation:* Volume of gas exhaled while making maximum breathing efforts during a certain time interval (often 12 seconds).

VR *Ventilatory Reserve:* The difference between ventilatory capacity during maximum exercise (estimated as MVV or calculated from FEV_1) and minute ventilation at peak exercise; VR, which is also known as *breathing reserve,* represents the potential for further increase in ventilation during maximum (or peak) exercise.

$P_{I_{max}}$ *Maximum Inspiratory Pressure:* The maximum pressure generated by the respiratory muscles during an attempted inspiration.

$P_{E_{max}}$ *Maximum Expiratory Pressure:* The maximum pressure generated by the respiratory muscles during an attempted exhalation.

DESCRIPTORS OF VENTILATION

f *Respiratory Frequency:* The number of breaths during 1 minute.

V_T *Tidal Volume:* The volume of gas inspired or expired during each breath.

$\dot{V}_E$ *Expired Ventilation:* The volume of gas (BTPS), usually measured at the mouth, exhaled during 1 minute.

$\dot{V}_I$ *Inspired Ventilation:* The volume of gas (BTPS), measured or calculated, inhaled during 1 minute.

$\dot{V}_A$ *Alveolar Ventilation:* The volume of gas (BTPS), exhaled from the lungs during 1 minute, that contributed to gas exchange; calculated as expired ventilation minus dead space ventilation.

$\dot{V}_D$ *Dead Space Ventilation:* The volume of gas (BTPS), exhaled from the lungs during 1 minute, that did not contribute to gas exchange; also known as *wasted ventilation.* Calculated from the equation

$$\dot{V}_D = \dot{V}_E \frac{Pa_{CO_2} - P_{E_{CO_2}}}{Pa_{CO_2} - P_{I_{CO_2}}}$$

where Pa_{CO_2}, $P_{E_{CO_2}}$, and $P_{I_{CO_2}}$ are the partial pressures of CO_2 in arterial blood, mixed expired gas, and inspired gas, respectively.

V_D *Dead Space Volume:* The volume of the physiologic dead space; calculated as $\dot{V}_D/f$.

V_D/V_T *Ratio of Dead Space to Tidal Volume:* The proportion, usually expressed as a percentage, of each breath that does not contribute to CO_2 removal (i.e., the proportion of each breath that is wasted).

VE *Ventilatory Equivalent:* The minute ventilation required for each liter of gas exchanged, either O_2 or CO_2; used as a measure of the efficiency of the lungs as a gas exchanger. For O_2:

$$VE_{O_2} = \frac{\dot{V}_E\,(BTPS)}{\dot{V}_{O_2}\,(STPD)}$$

VOLUME-PRESSURE RELATIONSHIPS

C *Compliance:* General symbol for compliance, or the ratio of volume change of the structure per unit change in applied pressure across the structure.

C_L *Lung Compliance:* The volume change of the lung divided by the difference between alveolar pressure (Palv) and pleural pressure (Ppl), which is also known as the transpulmonary pressure (P_L).

C_W *Chest Wall Compliance:* The volume change of the chest wall divided by the difference between pleural pressure (Ppl) and body surface pressure (Pbs), which is also known as the transthoracic pressure (P_W).

Crs *Respiratory System Compliance:* The volume change of the lung and chest wall divided by the difference between alveolar pressure (Palv) and body surface pressure (Pbs), or transpulmonary pressure (P_L) plus transthoracic pressure (P_W).

Cdyn *Dynamic Compliance:* Value for compliance based on measurements made during uninterrupted breathing.

Cst	*Static Compliance:* Value for compliance based on measurements made during periods of no airflow.
C/V_L	*Specific Compliance:* Value for compliance divided by the lung volume at which it was measured, usually functional residual capacity.

FLOW-PRESSURE RELATIONSHIPS

R	*Resistance:* General symbol for frictional resistance, or the pressure difference divided by flow.
R_{AW}	*Airway Resistance:* Resistance calculated from pressure difference between airway opening (Pao) and alveoli (Palv) divided by the airflow.
R_L	*Total Pulmonary Resistance:* Resistance calculated by dividing flow-dependent transpulmonary pressure by airflow at the mouth.
G_{AW}	*Airway Conductance:* The reciprocal of R_{AW}.
G_{AW}/V_L	*Specific Conductance:* Value for airway conductance divided by the lung volume at which it was measured.

III. GAS EXCHANGE

BLOOD

Examples shown are for O_2; other gases (e.g., CO_2, N_2, CO) or other sites (e.g., $\bar{v}$, c') can be substituted when appropriate.

P_{O_2}	*Partial Pressure of O_2:* General designation (expressed in mm Hg); source usually specified (e.g., arterial P_{O_2} or Pa_{O_2}).
S_{O_2}	*Blood Saturation:* General designation (expressed as a percentage); source usually specified (e.g., arterial S_{O_2} or Sa_{O_2}).
C_{O_2}	*Oxygen Content:* General designation (expressed in mL/dL); source usually specified (e.g., arterial C_{O_2}).
$\dot{V}_{O_2}$	*Oxygen Consumption:* The volume of O_2 (STPD) utilized by the body during 1 minute; usually calculated as the amount of O_2 extracted from inspired gas.
$\dot{V}_{O_{2max}}$	*Maximum Oxygen Consumption:* The maximal volume of O_2 (STPD) that can be utilized by the body during 1 minute of maximally attainable exercise.
$\dot{V}_{CO_2}$	*Carbon Dioxide Output:* The volume of CO_2 (STPD) produced by the body during 1 minute; usually calculated as the amount of CO_2 added to exhaled gas.
RQ	*Respiratory Quotient:* The ratio of $\dot{V}_{CO_2}$ to $\dot{V}_{O_2}$ during steady-state metabolic activity.
RER	*Respiratory Exchange Ratio:* The ratio of $\dot{V}_{CO_2}$ to $\dot{V}_{O_2}$, as in RQ, but also including the influence of transient changes in body stores of respiratory gases.

GAS TO BLOOD

$(A–a)P_{O_2}$	*Alveolar-Arterial P_{O_2} Difference:* The difference in P_{O_2} between mean alveolar gas and arterial blood (expressed in mm Hg).
D_L	*Diffusing Capacity of the Lung:* Expressed as the volume of gas transferred per minute per unit of alveolar-capillary pressure difference for the gas used, which is usually specified (e.g., $D_{L_{CO}}$ or $D_{L_{O2}}$).
D_M	*Diffusing Capacity of the Alveolocapillary Membrane.*
$1/D_L$	*Total Resistance to Diffusion:* The sum of the resistance to diffusion of the test gas across the alveolocapillary membrane ($1/D_M$) and the resistance to diffusion within the red blood cells attributable to the chemical reaction between the test gas and hemoglobin ($1/\theta V_C$). These relationships are expressed by the Roughton-Forster equation: $$\frac{1}{D_L} = \frac{1}{D_M} + \frac{1}{\theta V_C}$$
D_L/V_A	*Diffusion per Unit of Alveolar Volume:* The value of D_L (STPD) divided by V_A (BTPS), both measured in the same breathing maneuver.

IV. HEMODYNAMIC DESCRIPTORS

$\dot{Q}_T$	*Cardiac Output:* The total output of the left ventricle during one minute.
$\dot{Q}_S$	*Pulmonary Shunt Flow:* The total amount of blood per minute perfusing completely nonventilated gas-exchange units; hence, blood that does not come in contact with inspired gas and does not contribute to oxygen uptake. Often called the *right-to-left shunt,* but this term also includes intracardiac shunts.

$\dot{Q}S/\dot{Q}T$ — *Pulmonary Shunt Fraction:* The total pulmonary shunt ($\dot{Q}S$), or venous admixture, expressed as a percentage of total cardiac output ($\dot{Q}T$) according to the equation:

$$\frac{\dot{Q}S}{\dot{Q}T} = \frac{Cc'O_2 - CaO_2}{Cc'O_2 - C\bar{v}O_2} \times 100$$

where $Cc'O_2$ is the O_2 content of end-capillary blood; CaO_2 is the O_2 content of arterial blood; and $C\bar{v}O_2$ is the O_2 content of mixed venous blood. While breathing 100% O_2 (and sampling systemic arterial blood, not end-capillary blood), $\dot{Q}S/\dot{Q}T$ is a measure of right-to-left shunting of blood.

PPA — *Pulmonary Artery Pressure:* The pressure—systolic, diastolic, or mean—measured in the pulmonary artery.

PLA — *Left Atrial Pressure:* The pressure, usually mean, measured in the left atrium.

Pcap — *Pulmonary Capillary Pressure:* The mean pressure in the pulmonary capillaries, sometimes abbreviated Pc, which cannot be measured directly in humans but is frequently estimated by the equation:

$$Pcap = PLA + 0.4\,(PPA - PLA)$$

PPW — *Pulmonary Wedge Pressure:* The mean pressure measured by the pulmonary artery occlusion technique, which provides an estimate of the postcapillary, or pulmonary venous, pressure.

PVR — *Pulmonary Vascular Resistance:* The resistance to blood flow through the lungs; a calculated value from the equation:

$$PVR = \frac{PPA - PLA}{\dot{Q}T}$$

in which PPW is often used to approximate PLA.

V. OTHER USEFUL TERMS

PEEP — *Positive End-Expiratory Pressure:* The condition in which the pressure in the lungs at the end of expiration is positive (i.e., higher than atmospheric). Usually applied externally by ventilator adjustments; when PEEP results from failure to exhale fully at the end of expiration, it is called *intrinsic* (PEEPi).

$P_{0.1}$ — *Mouth Occlusion Pressure:* The pressure measured in the mouth during the first 0.1 second of attempted inspiration after the airway is temporarily occluded while the subject is breathing. An estimate of the central drive to breathe.

TI/TT — *Duty Cycle:* The ratio of the duration of inspiration (TI) to the duration of inspiration and expiration (TT), a reflection of respiratory timing.

VI. USEFUL EQUATIONS

Alveolar Gas Equation — Often used to calculate mean alveolar P_{O_2} (P_{AO_2}):

$$P_{AO_2} = P_{IO_2} - \frac{P_{ACO_2}}{R}$$

where P_{IO_2} is the P_{O_2} of inspired gas; P_{ACO_2} is the alveolar P_{CO_2} (usually assumed to equal arterial P_{CO_2}); and R is the respiratory exchange ratio. Because of some assumptions, this equation is an approximation. For calculating the exact P_{AO_2}, an additional term is needed, where F_{IO_2} is the fractional concentration of O_2 in inspired gas.

$$P_{AO_2} = P_{IO_2} - \frac{P_{ACO_2}}{R} + \left[P_{ACO_2} \times F_{IO_2} \times \frac{(1-R)}{R} \right]$$

Henderson-Hasselbalch Equation — Useful for calculating any one of three variables, pH, HCO_3^-, or H_2CO_3, when two of them are known:

$$pH = pK + \log\left[\frac{[HCO_3^-]}{[H_2CO_3]}\right]$$

where pK, the dissociation constant, is 6.10 for plasma at 37° C; $[HCO_3^-]$ is the concentration of bicarbonate in plasma; and $[H_2CO_3]$ is the concentration of carbonic acid in plasma (both in mol/L). The equation can be rearranged by using P_{CO_2} (in mm Hg) and its solubility in plasma so that

$$pH = pK + \log\frac{[HCO_3^-]}{[P_{CO_2} \times 0.0301]}$$

Starling Equation — Net fluid exchange (Jv) across the microvascular barrier in the lungs:

$$Jv = LpS\,[(Pc - Pi) - \sigma d\,(\pi c - \pi i)]$$

where Lp is the hydraulic conductivity ("permeability"); S is the surface area; Pc is the microvascular hydrostatic pressure; Pi is the perimicrovascular hydrostatic pressure; σd is the osmotic reflection coefficient; πc is the microvascular colloid osmotic pressure; and πi is the perimicrovascular colloid osmotic pressure.
